Neurology: A Queen Square Textbook Edited by Charles Clarke, Robin Howard, Martin Rossor and Simon Shorvon
ISBN: 978-1-405-13443-9

Whilst every effort has been made in the preparation of this book to ensure that the details given are correct, it is possible that errors have been overlooked (for instance in pharmaceutical or pharmacokinetic data). The reader is advised to refer to published information from the pharmaceutical companies and other reference works to check accuracy.

For figures, tables and other previously published data, every effort has also been made to contact relevant copyright holders but if any have been inadvertently overlooked, the publishers will be pleased to make the necessary arrangements at the earliest opportunity.

Beginnings

A conversation with Professor Ian McDonald

Ian McDonald[1] kindly agreed to write the foreword for this book. Sadly, he died shortly before it was completed. We had met in Queen Square in 2004 to discuss what I had in mind, an integrated, practical textbook from the National Hospital and the Institute of Neurology.

'That is quite splendid', Ian had replied when I explained the nature of our project. 'Of course', he continued: 'a book like this has never been produced previously, and I think no one has been able to draw together the different personalities here – and that will not be at all easy . . .'.

Ian went on: 'Charlie Symonds[2] once told me that he had suggested a similar project to the National Hospital Medical Committee in the late 1930s'. Dr Charles Symonds' proposal had received an immediate veto from his senior colleague Dr Samuel Kinnier Wilson[3]: 'Dr Symonds there is no place for *that*. I have already written the definitive book, there is no need for another', Kinnier Wilson is said to have responded, acidly.

True, this present book came to fruition slowly. The authors are busy people, distinguished in specialist fields, but they have come together to produce this volume. The editors are most grateful to them all.

During the last five decades, neurology has progressed immeasurably and Queen Square has become a truly international centre. The editors have tried to integrate this international dimension, drawing on clinical experience and perspectives from Australia, Canada, China, Europe, India and USA. We thank our international editors for their comments and guidance.

We hope *Neurology: A Queen Square Textbook* achieves its object – to reflect the clinical practice of neurology as we know it and to illustrate the approach we teach and follow at the National Hospital for Neurology & Neurosurgery and the Institute of Neurology, Queen Square.

We all have valued Ian McDonald's encouragement and hope that if he were still with us, he would feel the finished product was worthy of the institutions and teachers that have guided our thoughts and practice over the years.

Charles Clarke
Queen Square
London WC1

1. Professor Ian McDonald (1933–2006) was Professor of Neurology from 1978 to 1998. One of his great legacies remains his research into multiple sclerosis; his humanity, warmth and civility provide enduring memories for his students, colleagues and friends throughout the world.
2. Sir Charles Symonds, KBE, CB (1890–1978) was appointed physician to *The National* in 1926. A selection of his many papers entitled *Studies in Neurology* was published in 1970.
3. Dr Samuel Kinnier Wilson (1878–1937) was appointed physician to *The National* in 1912. He had written the seminal paper on Progressive Hepato-Lenticular Degeneration shortly before this. *Neurology*, his famous textbook, was published posthumously in 1940.

Foreword

Queen Square in Bloomsbury, London, is known the world over as a centre for neurology and clinical neuroscience. Like many institutions, *The National*, initially The National Hospital for the Relief and Cure of the Paralysed and Epileptic, was founded through the hard work and generosity of people with a broad sense of charitable intent, especially the Chandler family – Johanna Chandler, her sister Louisa and their brother Edward. The doors of the original building opened in Queen Square in 1860. Dr Jabez Spence Ramskill was the first physician appointed, followed shortly by Dr Charles Brown-Séquard. Since 1860 there has been an unbroken record of progress across the clinical neurosciences. The names of all those who contributed in those early years are too numerous to mention, but amongst those who stand out today in an historical perspective are Dr Charles Brown-Séquard, Dr John Hughlings Jackson, Sir William Gowers, Sir David Ferrier, Sir Victor Horsley, Sir Gordon Holmes, Dr Samuel Kinnier Wilson, Sir Francis Walshe, Sir Charles Symonds and Dr Macdonald Critchley.

The National Hospital has undergone many changes and revolutionised its approach, for example towards neurological rehabilitation and brain injury, and has developed close and inseparable links with the Institute of Neurology, which has helped to promote research at Queen Square in both basic and clinical sciences. Both Hospital and Institute are now involved in advancing an extensive range of developments in translational medicine that are transforming the treatment of neurological diseases. These developments are reflected in this book.

The Institute of Neurology

The Institute of Neurology was established in 1950 and has been part of University College London since 1997. The Institute provides research and teaching of the highest quality in neurosciences, and professional training for clinical careers in neurology, neurosurgery, neuropsychiatry, neuroradiology, neuropathology and clinical neurophysiology. With its concentration of clinical and applied scientific activity, the Institute provides a unique national resource for both postgraduate training and research in the basic neurosciences and its associated clinical disciplines. The Institute currently holds active grants for research into the causes and treatment of a wide range of neurological diseases, including movement disorders, multiple sclerosis, epilepsy, brain cancer, stroke and brain injury, muscle and nerve disorders, cognitive dysfunction and dementia; the work of the Institute's clinical academic staff remains closely integrated with the Hospital.

The National Hospital for Neurology & Neurosurgery today

The National, now part of University College London Hospitals NHS Foundation Trust, is a thriving hospital, largely refurbished behind the 1890 façade. The hospital receives over 1000 new outpatient referrals each month and has over 200 beds, a dedicated ITU, extensive rehabilitation services and all ancillary departments in the most substantial specialist neurological hospital within the UK. The hospital provides the surrounding district general hospitals with specialist services. Many of the consultant staff continue to hold appointments that are linked to both general hospitals, the Institute of Neurology and *The National* itself. This maintains unique contact between the disciplines of research and clinical practice.

Neurology: A Queen Square Textbook

This book, the first of its kind to come from these two institutions, has a distinctly clinical flavour. It has been written very largely by clinicians, each in the forefront of their field, and focuses on the practical aspects of diagnosis, treatment and patient care. The book also provides an introduction to the basic sciences of neurology, of increasing importance in medical practice. It has been a pleasure to be one of the contributing authors.

Professor Roger Lemon PhD FMedSci
Sobell Chair of Neurophysiology & Director, Institute of Neurology (2002–2008)

Preface

All Editors, Authors and Specialist Advisory Editors of *Neurology: A Queen Square Textbook* hold or recently held consultant or equivalent posts at the National Hospital for Neurology & Neurosurgery and/or the Institute of Neurology, Queen Square.

The National Hospital is part of University College London Hospitals NHS Foundation Trust, and the Institute of Neurology part of University College London.

The twenty Co-ordinating Authors organised individual chapters, encouraged and liaised with over 70 contributors and with them wrote this book.

The Specialist Advisory Editors gave invaluable advice and guidance in their respective fields. To ensure a worldwide perspective, the six International Regional Editors, all of whom have had close connections with Queen Square, provided advice and comment.

This book is an attempt to provide a fresh and up-to-date approach to the fascinating subject of neurology. We encouraged each author to relate their own clinical experience but, in order to achieve a degree of consistency, we took a robust overview of the important specialities within neurology and their relevance. Each chapter has been coordinated by an expert in the field, to give the reader an overall grasp of each major subject, indicating where developments within neurosciences fit into a broader picture.

The limited size of this book means that it has not been possible to provide references for all material. With the growth of information technology, a wealth of detailed sources are readily available.

We are most grateful to all those who have helped in this joint venture.

Charles Clarke
Robin Howard
Martin Rossor
Simon Shorvon
Queen Square
London WC1

Acknowledgements

We know that the skills of clinical practice are handed down, both by teachers and role models. The editors wish to thank all those who have taught, advised and inspired them – in many aspects of neurology and its related disciplines, in neuroscience and in research. When we came to list these many individuals, we soon realised we would be unable to mention each by name. Instead, we trust that those who read this book will understand how much the editors and authors owe to others. We hope we can pass on some of that knowledge and experience.

We thank our publishers, Wiley-Blackwell, and especially Helen Harvey (Project Manager), Rob Blundell (Development Editor), Martin Sugden (Publisher), who, having accepted that the project was viable, have waited for and worked on the draft manuscripts with unstinting patience. David Gardner, in Cyprus and Best-set, Hong Kong have transformed the draft illustrations into a coherent sequence, to make the finished product one that has truly crossed national boundaries. The authors have worked hard, for no personal reward and, despite numerous requests for text, diagrams and amendments, have remained firmly behind this project.

Secretarial help has also been invaluable, and amongst those who have contributed over and above their normal duties, we thank especially Claire Bloomfield, Wyn Jagger and Mary Wright.

The Rockefeller Library has provided its valuable resources, both historical and current. The Audio Visual Services Unit has been most helpful with the sourcing of some of the figures and photographs.

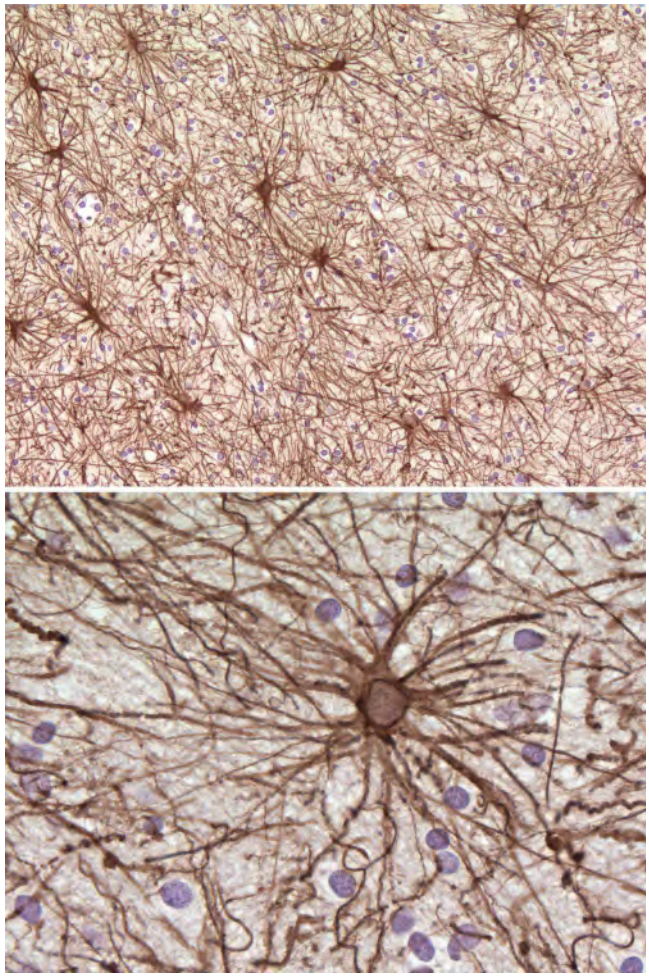

Plate 2.1 Astrocytes.

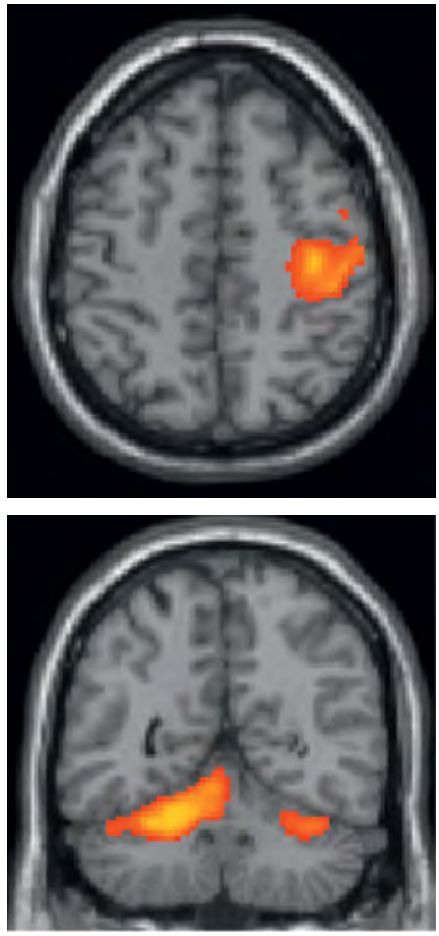

Plate 2.2 Cortical and cerebellar fMRI with voluntary activity of left hand (button press). Task-related activation can be seen in the contralateral hand region of primary sensorimotor cortex on the axial image and in the ipsilateral contralteral lobule VI of the cerebellum on the coronal image (Courtesy Dr Alex Leff, Wellcome Trust Centre for Neuroimaging, Institute of Neurology).

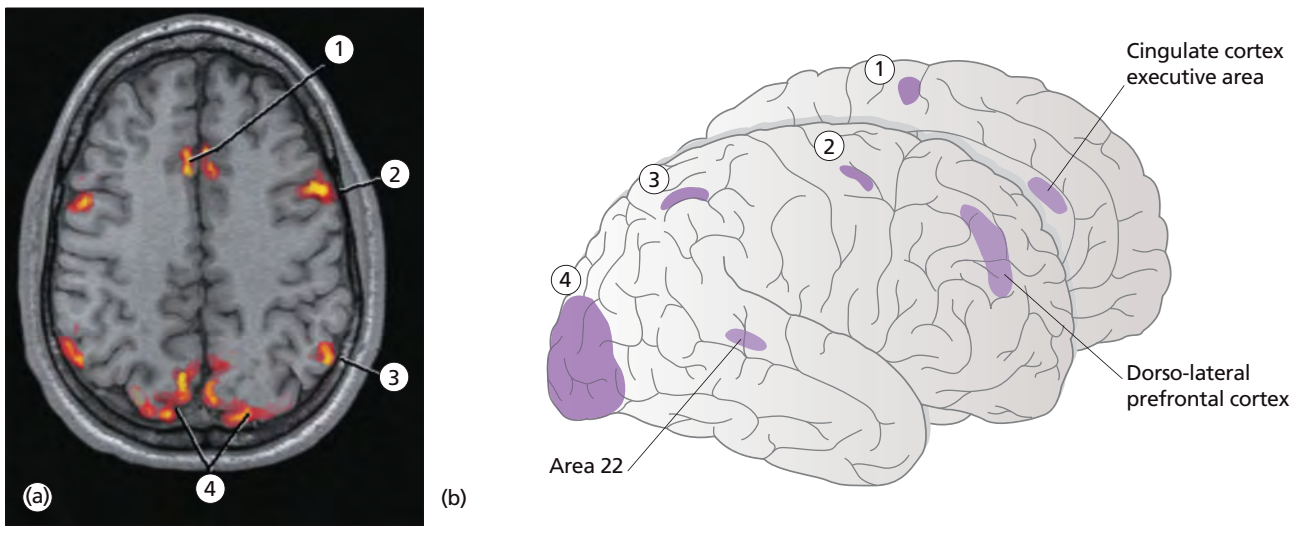

Plate 2.3 Functional MRI (a) and diagram (b) indicating cortical eye fields. 1. Supplementary eye field. 2. Frontal eye field. 3. Parietal eye field. 4. Occipital cortex.

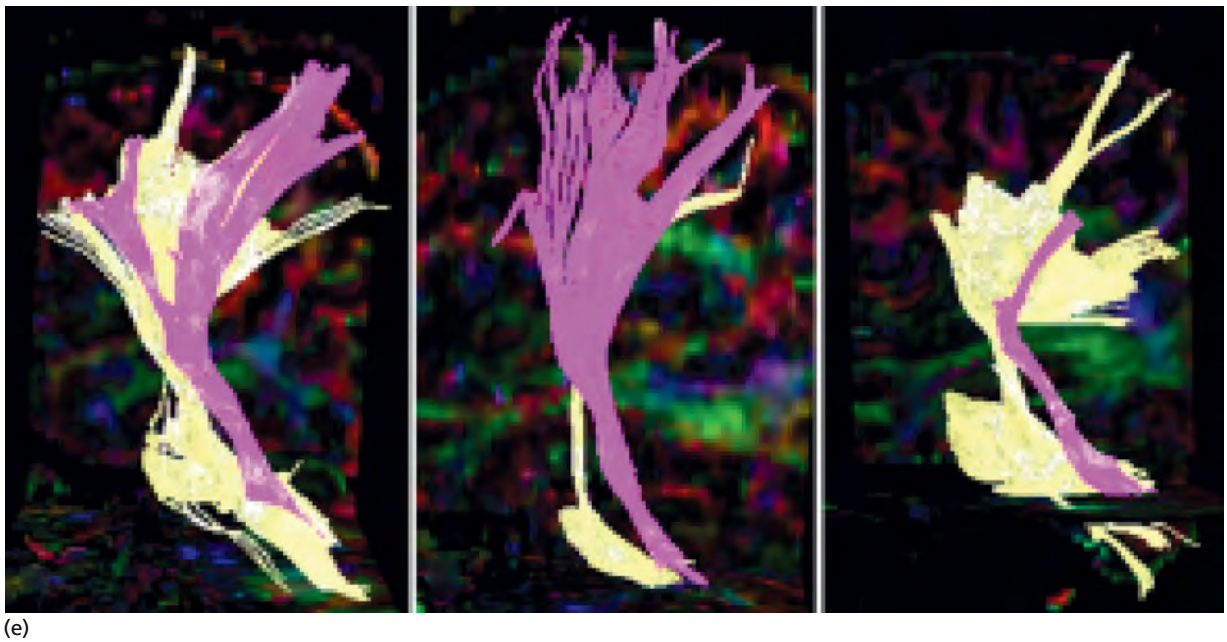
(d)



(e)

Plate 5.1 MRI findings in Parkinson's disease (PD), multiple system atrophy (MSA) and progressive supranuclear palsy (PSP). (a) Putaminal atrophy, hyperintense rim (arrow) and putaminal hypointensity (relative to globus pallidus) on T2-weighted images (1.5 T) in a patient with MSA. (b) T2-weighted images (0.5 T) showing 'hot cross bun' sign (inset shows a real hot cross bun) in a patient with MSA. (c) Infratentorial atrophy and signal change in pons, middle cerebellar peduncles (arrow) and cerebellum on T2-weighted images (0.5 T) in a patient with MSA. (d) Sagittal images in patients with (left to right) PD, MSA and PSP, showing atrophy of pons and cerebellum (arrows) in MSA and atrophy of midbrain (arrow – the 'hummingbird sign'). (e) Tractography (3 T) of the middle cerebellar peduncle (MCP, yellow) and superior cerebellar peduncle (SCP, purple) in patients with (left to right) PD, MSA and PSP, showing selective atrophy of MCP in MSA and of SCP in PSP. (Figure 5.1(a–c) from Schrag *et al.* 1998 and (d,e) from Nilsson *et al.* 2007 with permission.)

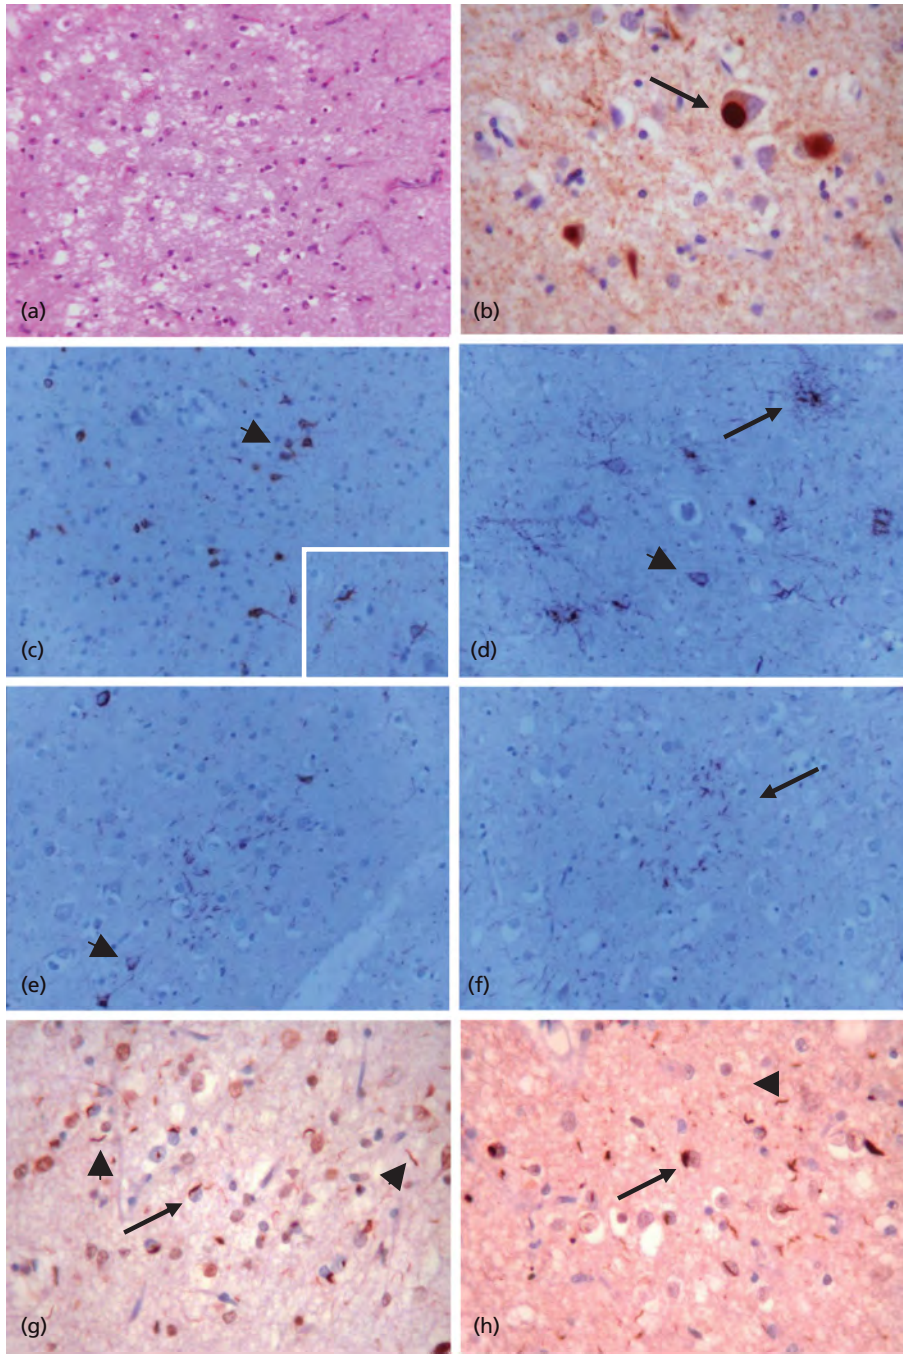


Plate 7.1 (a) Neuropil spongiosis occurring in superficial cortical laminae is seen in FLTD (Haematoxylin and eosin preparation, frontal cortex). (b) Tau-positive Pick body is a characteristic feature of Pick's disease (AT8 immunohistochemistry, temporal cortex). (c) A combination of tau-positive neuronal (arrowhead) and glial pathology is found in FLTD due to intronic mutations located close to the alternatively spliced exon 10 (this case: exon 10 +16 mutation). Insert showing tau-positive oligodendroglial coiled bodies (AT8 immunohistochemistry, temporal cortex). Tau-positive neurofibrillary tangles and pretangles (arrowhead) occur both in progressive supranuclear palsy and corticobasal degeneration (d and e arrowhead). However, tufted astrocytes are the characteristic glial pathology in progressive supranuclear palsy (d arrow) and the so called astrocytic plaques are found in corticobasal degeneration (f arrow) (AT8 immunohistochemistry, frontal cortex). Neuronal intracytoplasmic inclusions (arrow) and neurites (arrowhead) are ubiquitin-positive (g) and are immunoreactive for TDP-43 (h) in FTLD-U (g: ubiquitin immunohistochemistry; h: TDP-43 immunohistochemistry, temporal cortex). Figures courtesy of Professor Tamas Revesz, Queen Square Brain Bank, Department of Molecular Neuroscience, UCL Institute of Neurology.

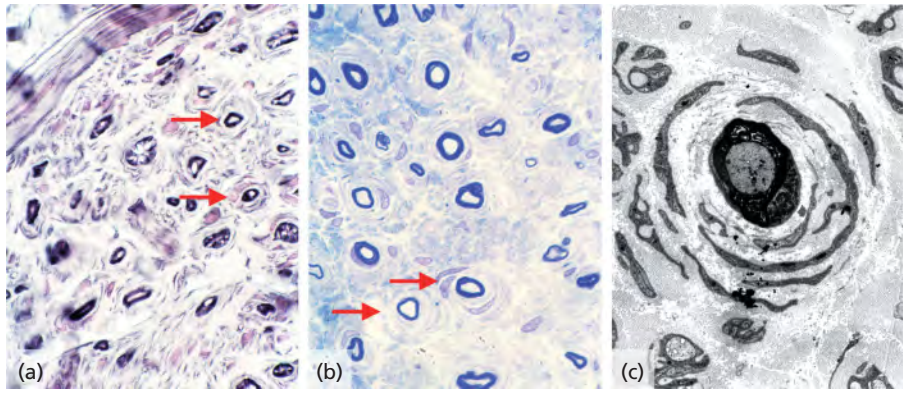

Plate 9.1 Charcot–Marie–Tooth type 1a with formation of onion bulbs. (a) Paraffin section (transverse) shows concentric formations (arrows) with a reduction of fibre density. The interstitial space is widened, indicating oedema with a mucoid component. (b) Semi-thin resin section (toluidine blue) confirms the abundant presence of onion bulbs (arrows). (c) Electron microscopy of the same nerve with concentric arrangement of Schwann cells around myelinated axons. The Schwann cells appear as plump, elongated and rounded stacks, separated by longitudinally oriented collagen fibres (light grey).

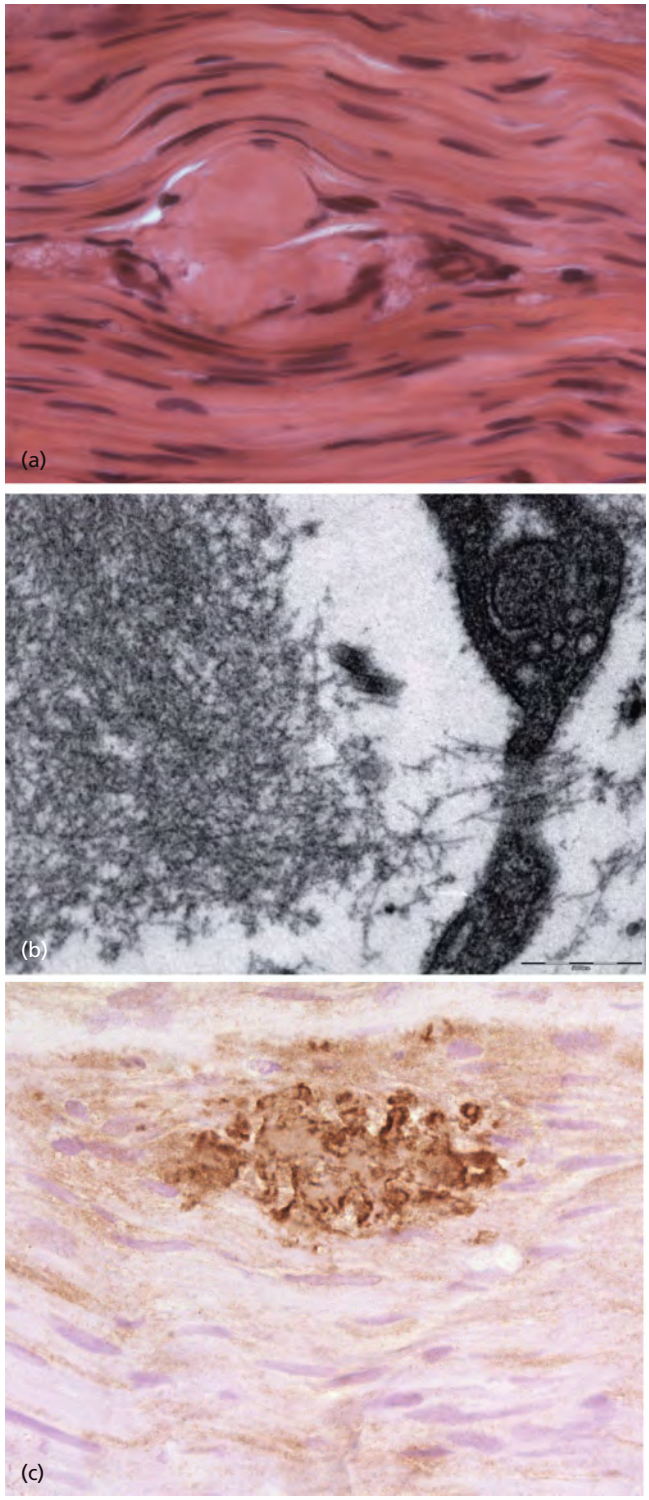

Plate 9.2 Amyloid neuropathy. (a) Haematoxylin and eosin stained paraffin section with a large amyloid deposition in the endoneurium, displacing normal structures. The nerve is severely depleted of large myelinated axons. (b) Electron microscopy of the same nerve, visualizing amyloid fibrils. (c) The amyloid is composed of transthyretin (determined by immunohistochemistry).

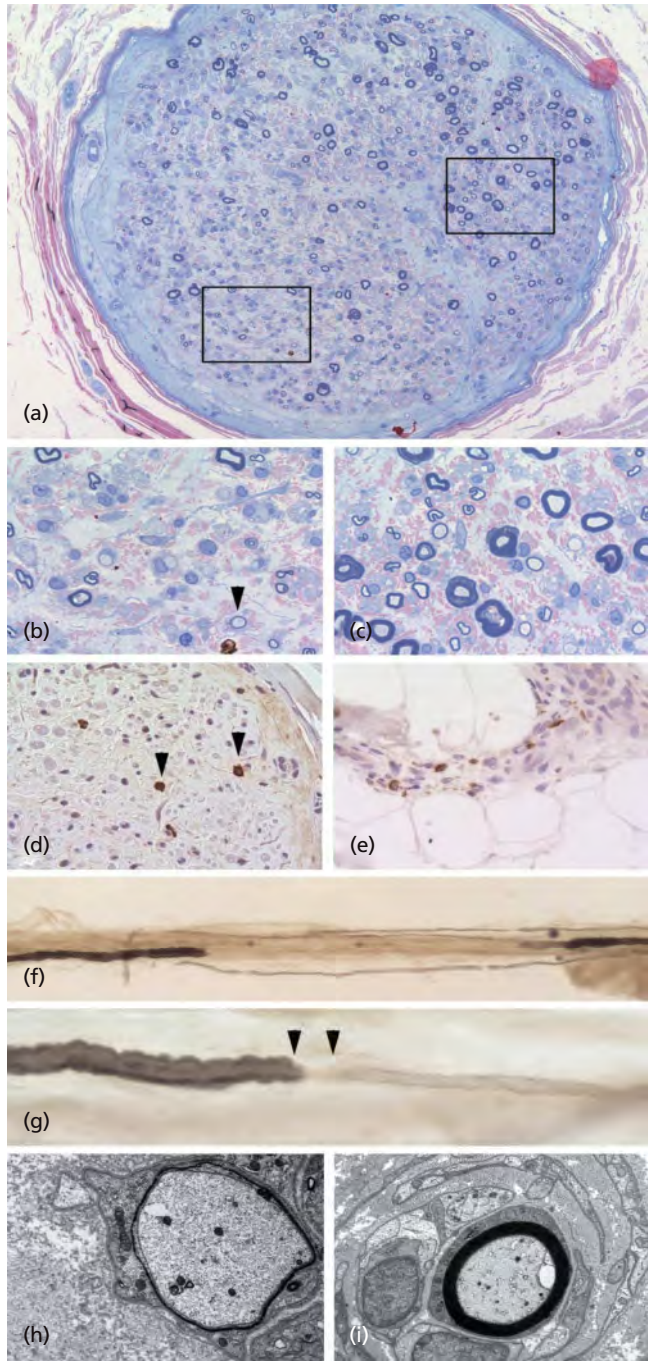

Plate 9.3 Chronic inflammatory demyelinating polyradiculoneuropathy. (a) Patchy loss of myelinated fibres in a fascicle of the sural nerve (semi-thin resin section, toluidine blue). The left lower rectangle is shown in higher magnification in (b). (b) Close-up of the area with a significant loss of large myelinated fibres (arrowhead indicates a thinly myelinated fibre). There are several other thinly myelinated and entirely demyelinated fibres. (c) More densely populated area corresponding to the right upper rectangle in (a). (d) Endoneurial T cells (CD8 immunohistochemical staining). (e) Most CIDPs are also characterized by a variable peri-vascular infiltrate as shown here (CD8 immunohistochemistry). (f) Teased fibre preparation which shows a segmental demyelination. To unequivocally identify segmental demyelination, myelinated fibres have to be identified on either end of the demyelinated stretch. (g) Close-up of demyelination, which shows a myelinated segment on the left, the end of which is indicated by the left arrowhead. This is followed by an expanded internode length, the end of which is indicated by the right arrowhead. The subsequent stretch of the axon is very thinly myelinated. (h) Electron microscopy of a demyelinated and thinly remyelinated axon. (i) Axon with almost regular myelin thickness, surrounded by concentric formations of Schwann cell laminae, also designated onion bulbs.

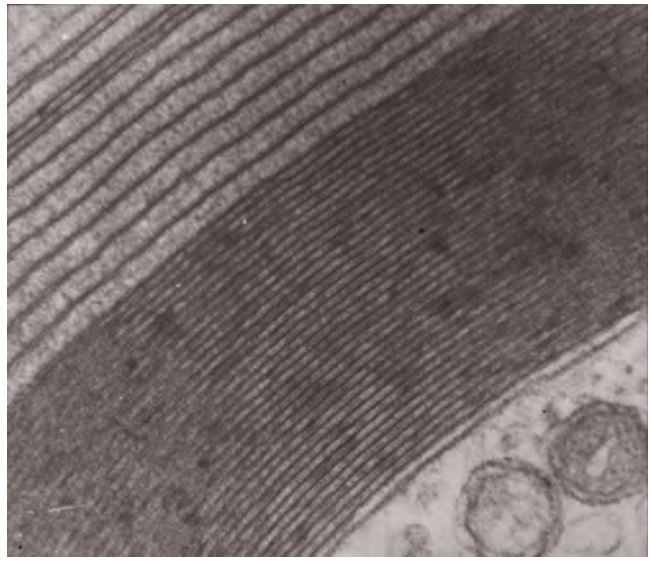

Plate 9.4 Widely spaced myelin. The normal myelin lamellae are tightly compacted and have a periodicity in electron microscope preparations of 12–15 nm. In the demyelinating neuropathy associated with immunoglobulin M (IgM) paraprotein that has activity against MAG (anti-Mag PDPN) the intraperiod line becomes split giving an overall periodicity of 30–40 nm. There is a suggestion of material within the widened spaces, possibly IgM.

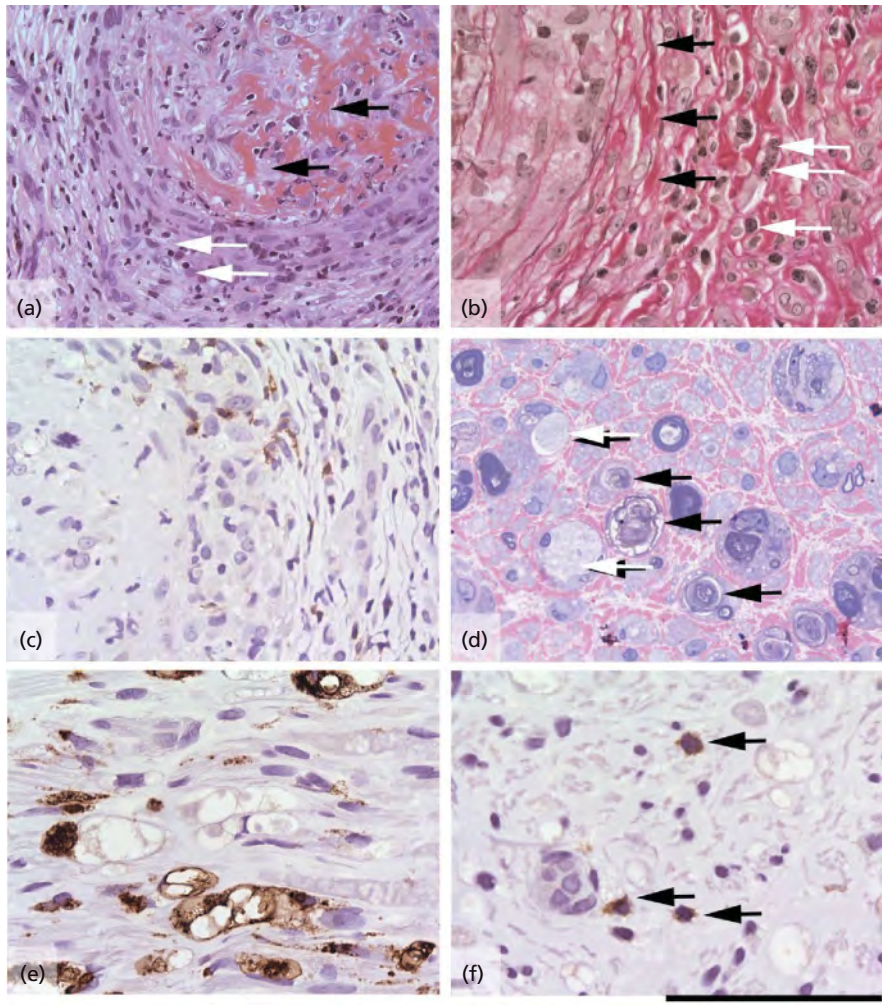

Plate 9.5 Vasculitis and severe axonal neuropathy in a peripheral nerve. (a) Fibrinoid necrosis (black arrow) of a medium-sized vessel. The vessel wall is densely infiltrated by inflammatory cells (white arrows). (b) Van Gieson elastica staining to visualize the distended and infiltrated vessel walls (red, black arrows) and interdispersed lymphocytes (white arrows). (c) CD8 immunohistochemical staining to visualize T cells in the vessel walls. (d) Semi-thin resin sections on a transverse section of the adjacent nerve. Black arrows show acutely degenerating axons. White arrows indicate macrophages with the characteristic fine granular bright cytoplasm and peripheral small dark nucleus. (e) CD68 immunohistochemical staining to visualize digestion chambers and macrophage in the acutely degenerating nerve. (f) Accompanying occasional T-cell infiltrates in the affected nerve. This is regarded as a bystander effect to the overall inflammatory disease and should not be regarded as primary inflammation.

Plate 9.6 Charcot joint in a foot secondary to recurrent severe vasculitic neuropathy. The second phalanx has been amputated and a new vasculitic ulcer is present on the sole of the foot.

Plate 9.7 Typical clinical appearance of a patient with myotonic dystrophy. Note ptosis, frontal balding, typical facies and distal wasting.

Plate 9.8 Typical facial, hand and foot appearances in Anderson–Tawil syndrome. Note hypertension, micrognathism, low-set ears, down-turned mouth, short digits, clinodactyly of the fifth digits and syndactyly of the toes.

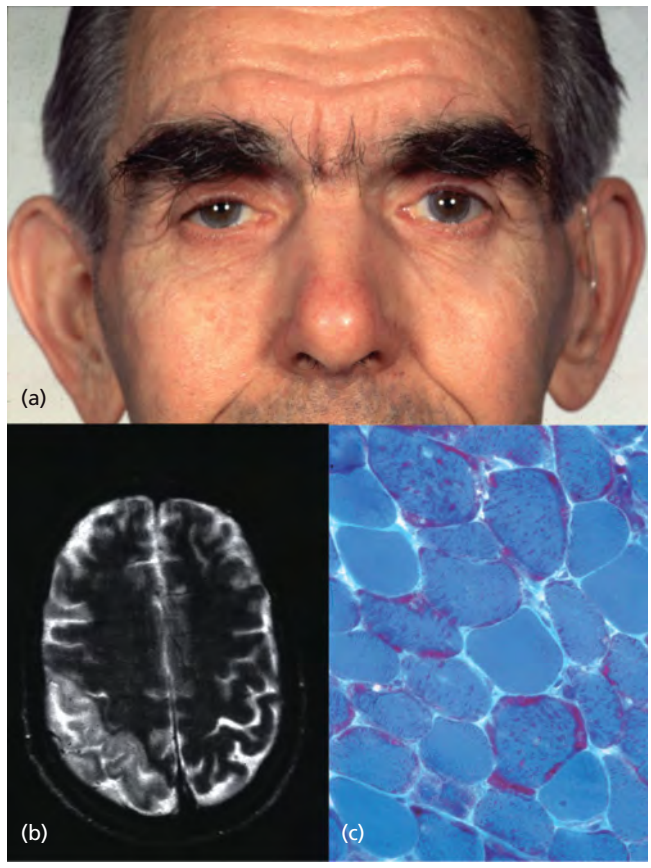

Plate 9.9 (a) Mitochondrial myopathy. Note not only the ptosis but hearing aid indicating deafness. (b) MRI T2W showing occipito-parietal, not respecting usual anotomical vascular territories, following a stroke-like episode in a case of mitochondrial disease. (c) Ragged red fibres stained with Gomori Trichrome stain – muscle fibres with peripheral accumulations of abnormal mitochondria.

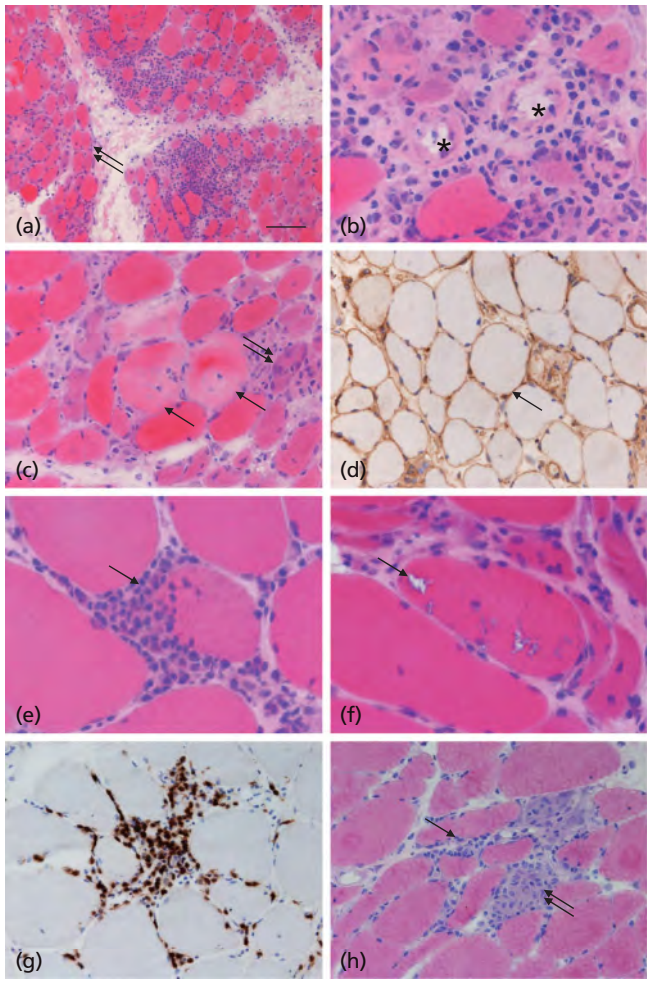

Plate 9.10 In dermatomyositis, atrophic fibres often display a peri-fascicular arrangement (a, double arrow). Lymphocytic infiltrates are frequently peri-vascular (b, * indicate small arterioles) and peri-mysial but may extend into the endomysium. There is fibre necrosis (c, arrows) and regeneration (c, double arrow). MHC Class I is expressed at the sarcolemma (d, arrow). The features of inclusion body myositis include endomysial lymphocytic infiltration with infiltration into intact muscle fibres (e, arrow) and rimmed vacuoles that occur in fibres without lymphocytic infiltration (f, arrow). The inflammatory infiltrate is composed predominantly of CD8-positive T lymphocytes (g). In polymyositis, the inflammation is largely endomysial in location (h, arrow). In this example, necrotic fibres infiltrated by macrophages are prominent (h, double arrow). a–c, e, f, h, haematoxylin and eosin; d, immunohistochemical staining for MHC Class I; g, immunohistochemical staining for CD8.

Plate 9.11 Inclusion body myositis may present with focal weakness of the quadriceps muscles, identified easily in this case by the focal thigh wasting – when compared to the lower leg muscle compartments.

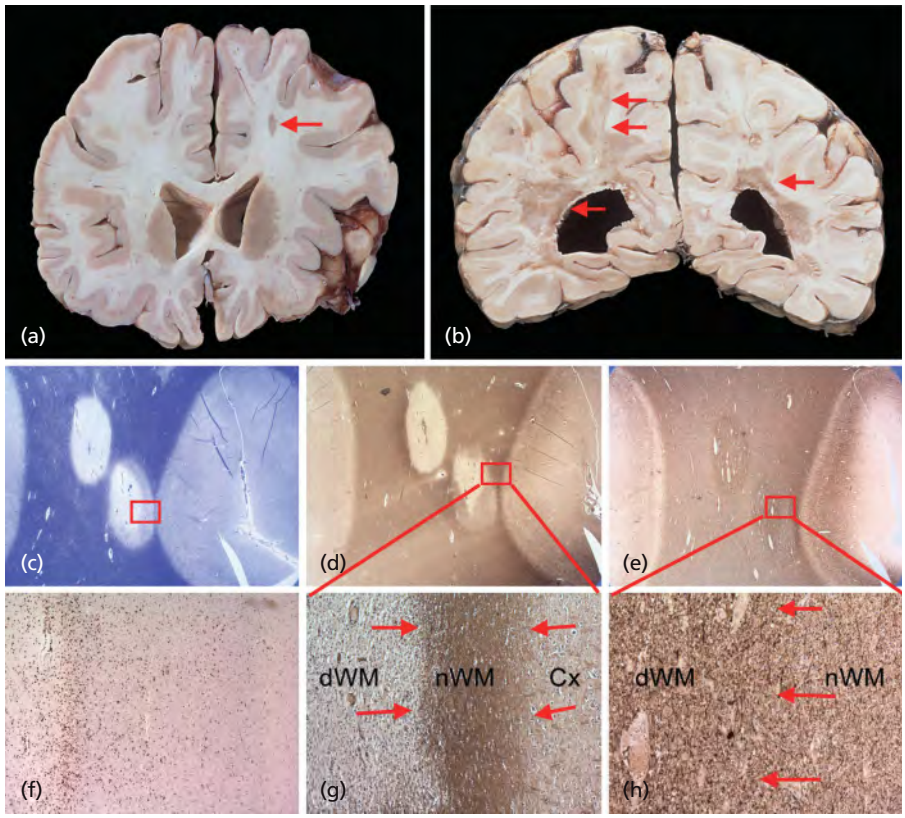

Plate 10.1 Macroscopic and microscopic findings in multiple sclerosis. (a,b) Macroscopic pathology of demyelination (coronal sections of formalin fixed brains). (a) Arrow pointing at a small circumscribed demyelination in the frontal white matter. Loss of myelin appears grey, similar to cerebral cortex. (b) Coronal section of the occipital lobe with extensive multi-focal and confluent demyelinations (arrowhead). (c–e) Two foci of demyelination, one with partial remyelination (red box) stained for myelin or axons. (c) Luxol fast blue stains myelinated structures dark blue and the punched-out well-demarkated defects indicates loss of myelin. (d) Myelin basic product (MBP) immunohistochemistry labels myelinated fibres, and shows the same punched-out demyelination with a smaller rim of remyelination fibres in the lowest lesion. (e) Immunohistochemical staining of phosphorylated neurofilament demonstrates the prescence of axons within the demyelinating lesions, which appear of slightly increased density than the surrounding intact white matter. (f) CD68 immunohistochemistry labels microglia and macrophage activity. The area corresponds to the red rectangle in (c–e), it clearly shows a demarcation between demyelinated and remyelinated regions. (g) High power magnification of the boxed area in (d) (MBP) on the left with loss of the myelin (demyelinated white matter [dWM]), a myelinated area in the centre (WM) and normal cortex (Cx) with myelinated on the right, all indicated by arrows. (h) High magnification of the labelled area in (e) shows the axons in the lesion on the left (dWM) and outside the lesion (nWM), the border is indicated by arrows. (Images and macroscopic specimens courtesy of Sebastian Brandner; histological specimens courtesy of Klaus Schierer, UCL Institute of Neurology.)

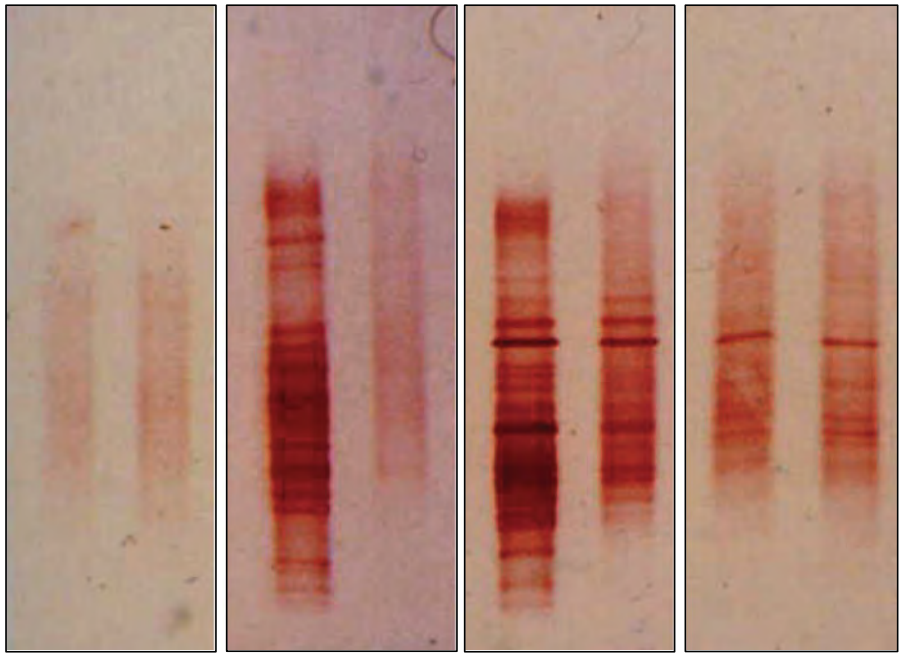

(a) **CSF−/Serum−** (b) **CSF+/Serum−** (c) **CSF++>Serum+** (d) **CSF+/Serum+**

Plate 10.2 Isoelectric focusing of paired cerebrospinal fluid (CSF) and serum. (a) CSF–/serum–. (b) CSF+/serum–. (c) CSF++/serum+. (d) CSF+/serum+. The oligoclonal band patterns in (b) and (c) indicate intrathecal antibody synthesis.

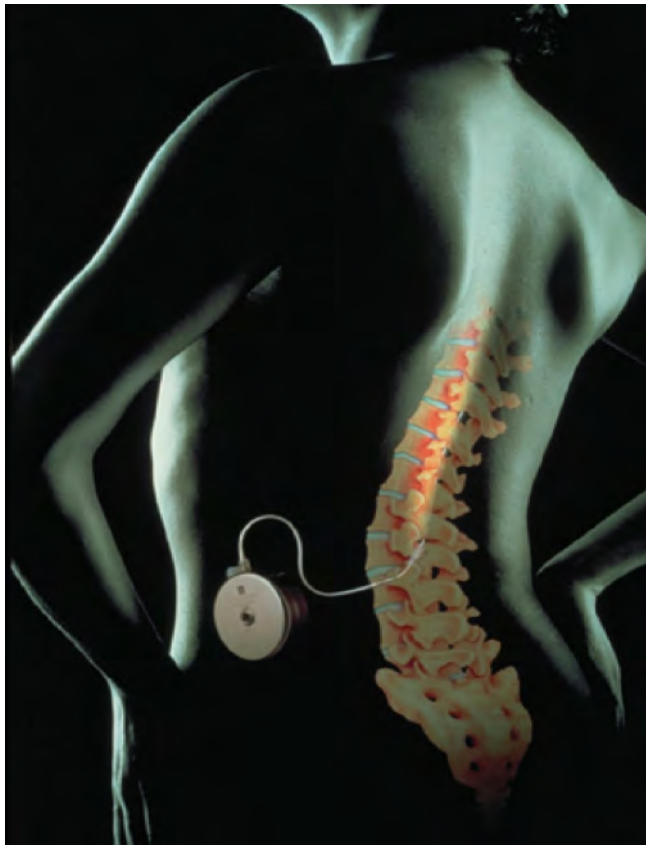

Plate 10.3 Abdominally placed baclofen pump and intrathecal catheter. Medtronic™.

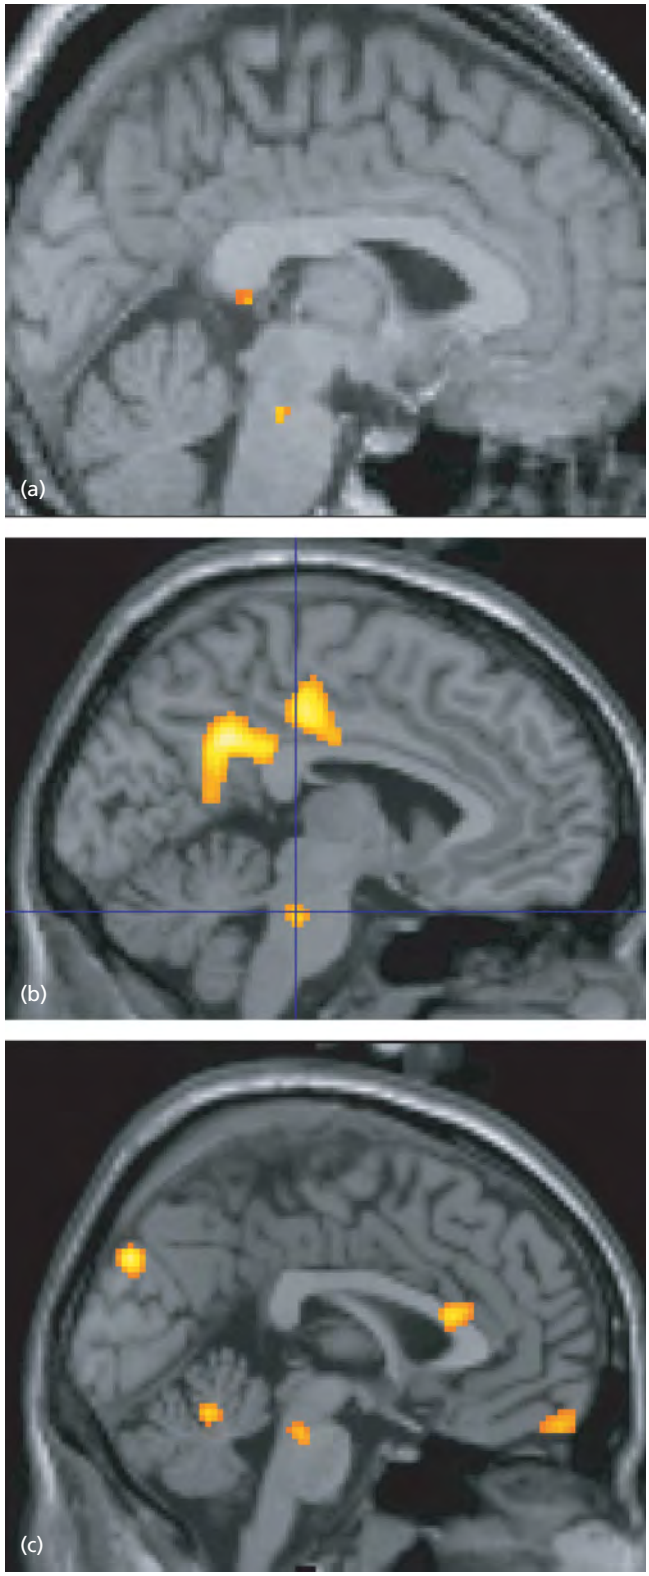

Plate 11.1 Activation on positron emission tomography (PET) in a patient with cluster headache and migraine (a) who experienced a migraine without aura during the scan after nitrate triggering, and demonstrated activation in the rostral ventral pons. Similarly activation in the same region with spontaneous attacks of episodic migraine (b) and in chronic migraine (c).

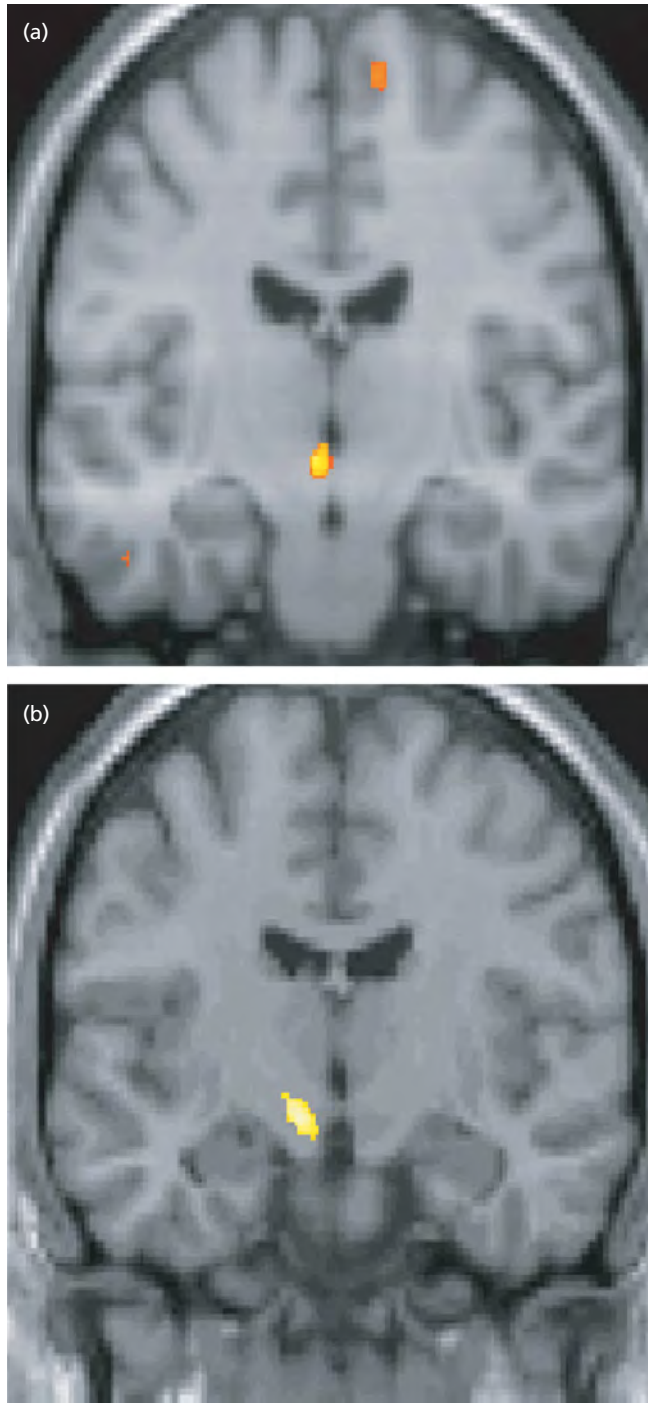

Plate 11.2 Activation on positron emission tomography (PET) in the posterior hypothalamic grey matter in patients with acute cluster headache (a). The activation demonstrated is lateralized to the side of the pain (May *et al.* 1998). When comparing the brains of patients with cluster headache with a control population using an automatic anatomical technique known as voxel-based morphometry (VBM) that employs high-resolution T1-weighted MRI, a similar region is shown (b) with increased grey matter signal activation (May *et al.* 1999).

Plate 13.1 Mild optic disc swelling in acute demyelinating optic neuritis. The absence of haemorrhages or exudates is characteristic.

Plate 13.4 Branch retinal artery occlusion. Note the cloudy retinal swelling superiorly.

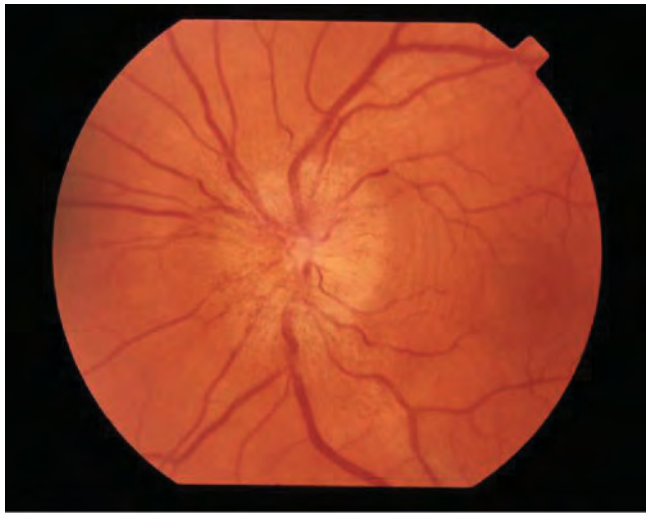

Plate 13.2 Optic neuritis in secondary syphilis. Typically, slit lamp examination shows vitreous cells.

Plate 13.5 Central retinal artery occlusion with cherry red spot.

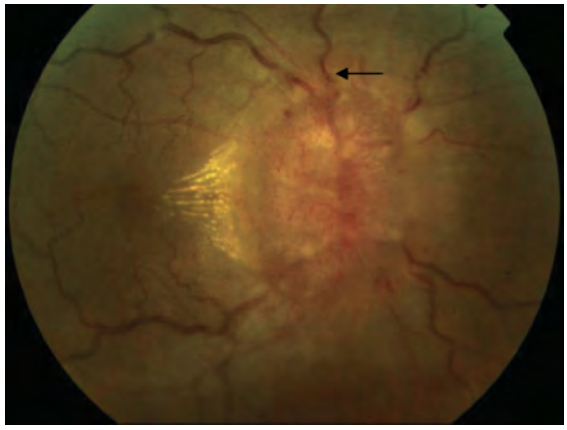

Plate 13.3 Acute neuroretinitis. Note the hard exudates, swollen disc and perivenous infiltrates (arrow).

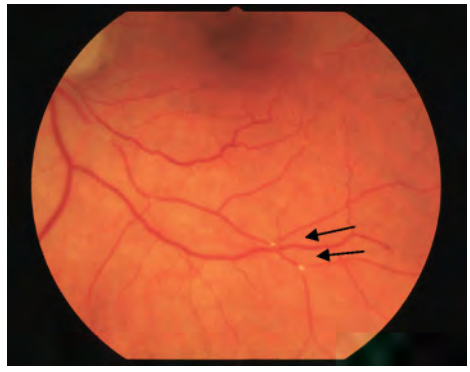

Plate 13.6 Cholesterol emboli (arrows).

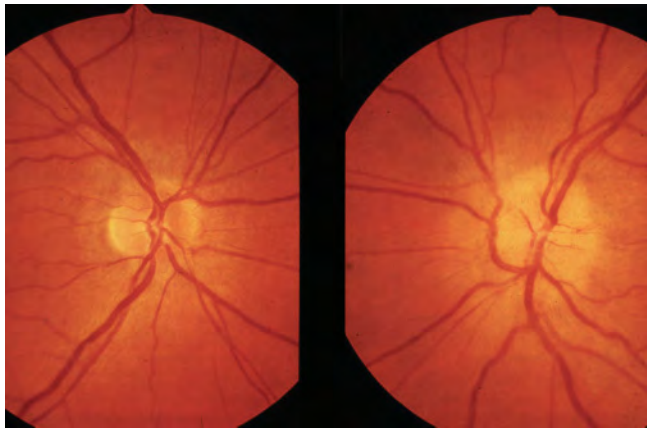

Plate 13.7 Left optic disc swelling and crowded right disc with absent physiological cup in non-arteritic ischaemic optic neuropathy.

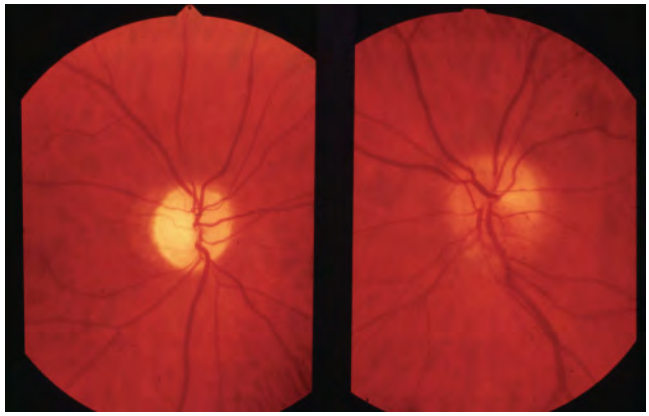

Plate 13.8 Pseudo-Foster Kennedy syndrome. Left optic disc swelling caused by non-arteritic AION; right optic disc atrophy resulting from previous episode.

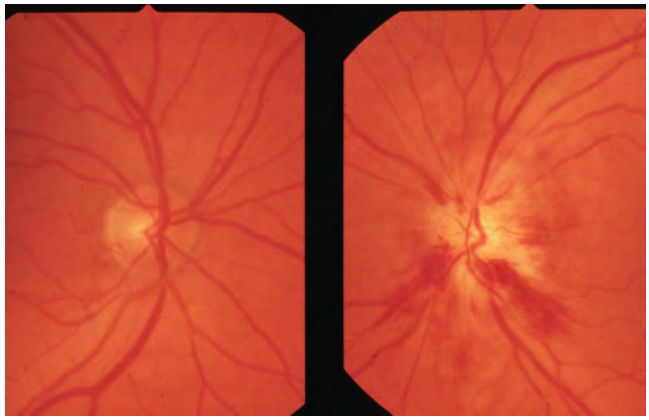

Plate 13.9 Vasculitic anterior ischaemic optic neuropathy (AION) – note left disc swelling with pallor and flame-shaped haemorrhages.

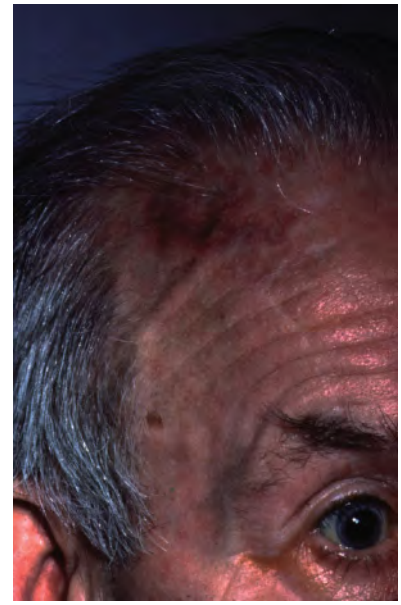

Plate 13.10 Temporal arteritis with superficial scalp necrosis.

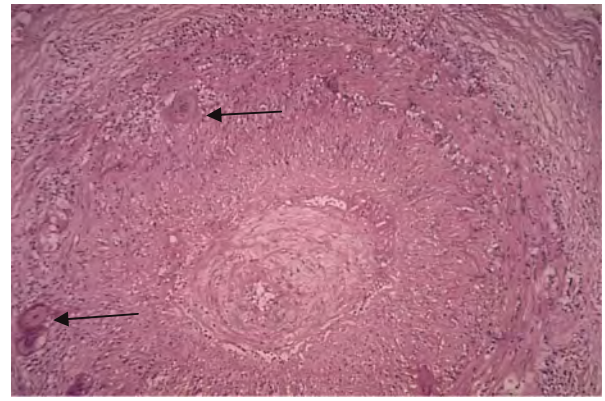

Plate 13.11 Temporal arteritis histology. Note massive intimal thickening to obliterate vascular lumen and multinucleate giant cells (arrows).

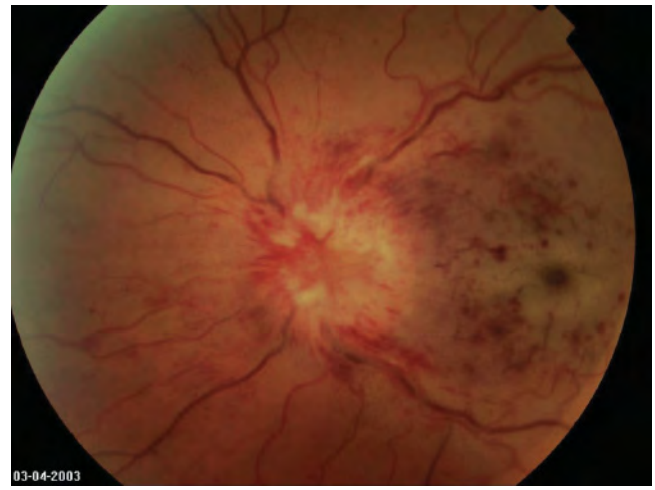

Plate 13.12 Optic disc swelling plus cherry red spot in neoplastic infiltration.

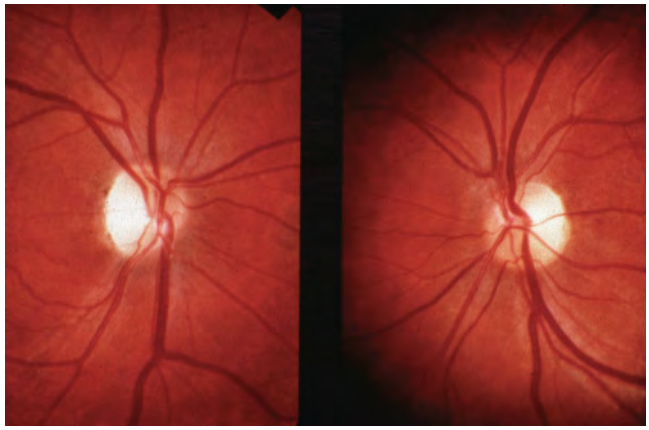

Plate 13.13 Bilateral optic atrophy caused by dominant optic atrophy.

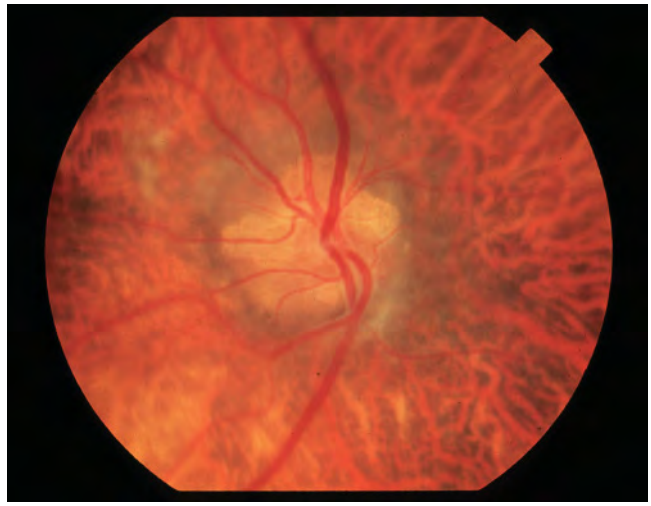

Plate 13.16 Disc drusen. Note anomalous vessel branching and absent physiological cup.

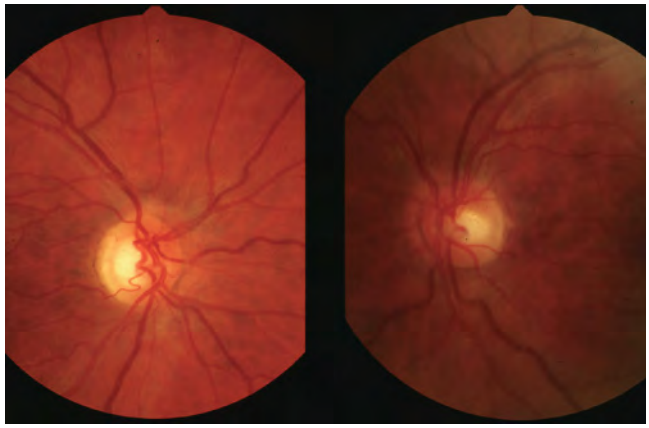

Plate 13.14 Temporal optic disc pallor in established Leber's hereditary optic neuropathy.

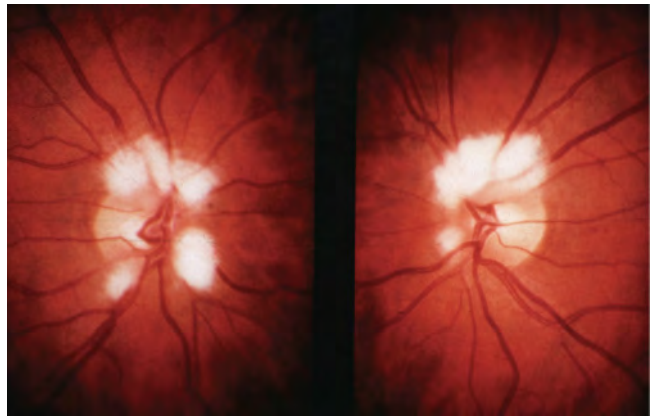

Plate 13.17 Myelinated retinal nerve fibres.

Plate 13.15 Traumatic optic neuropathy.

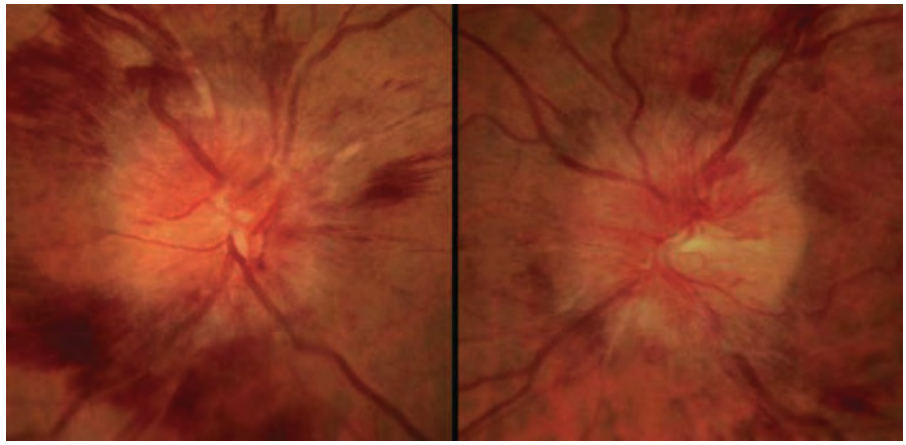

Plate 13.18 Acute haemorrhagic papilloedema.

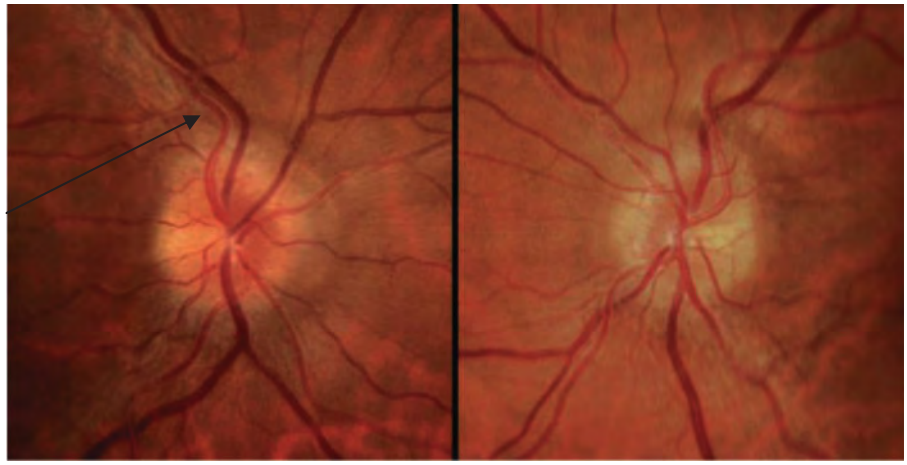

Plate 13.19 Early papilloedema. Note nerve fibre layer swelling starting to obscure right supero-temporal branch retinal artery (arrow).

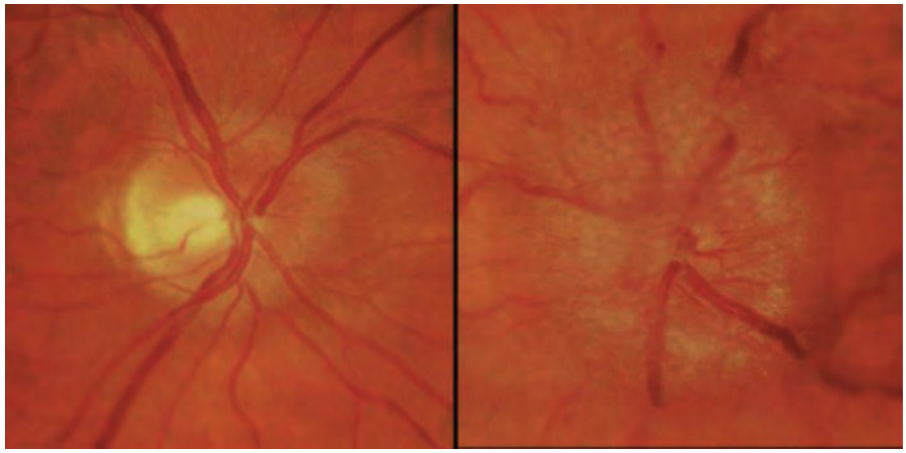

Plate 13.20 Asymmetrical bilateral papilloedema.

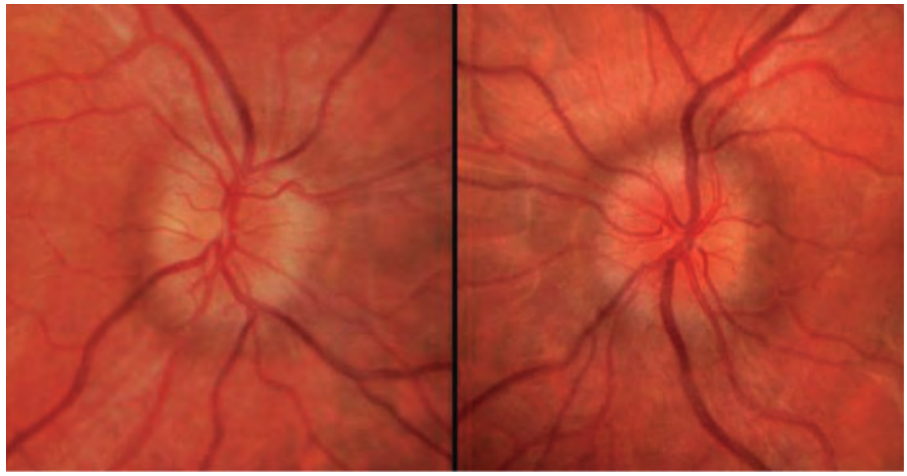

Plate 13.21 Chronic compensated papilloedema.

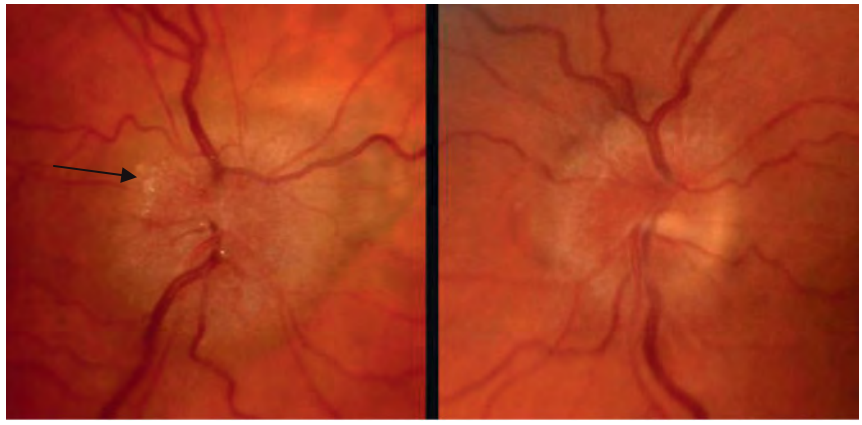

Plate 13.22 Vintage papilloedema with corpora amylacea (arrowed).

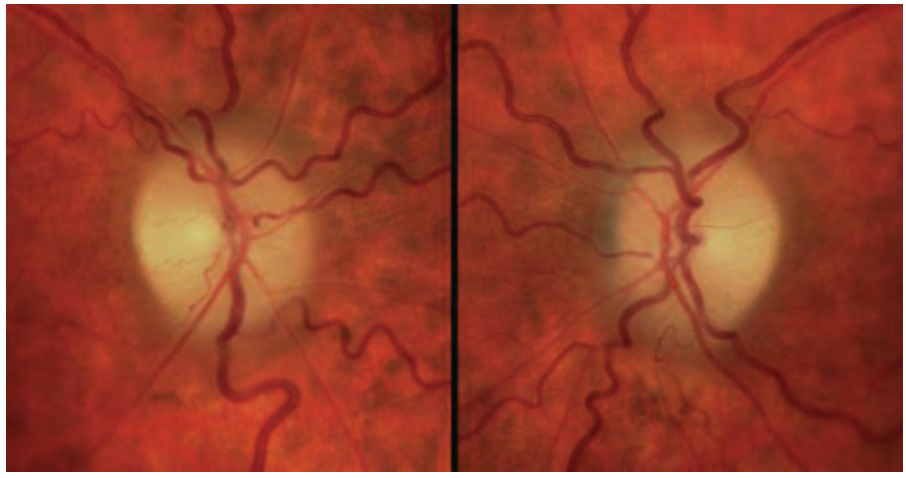

Plate 13.23 Atrophic papilloedema.

Plate 13.24 Subtle right proptosis due to orbital mass is best observed from above.

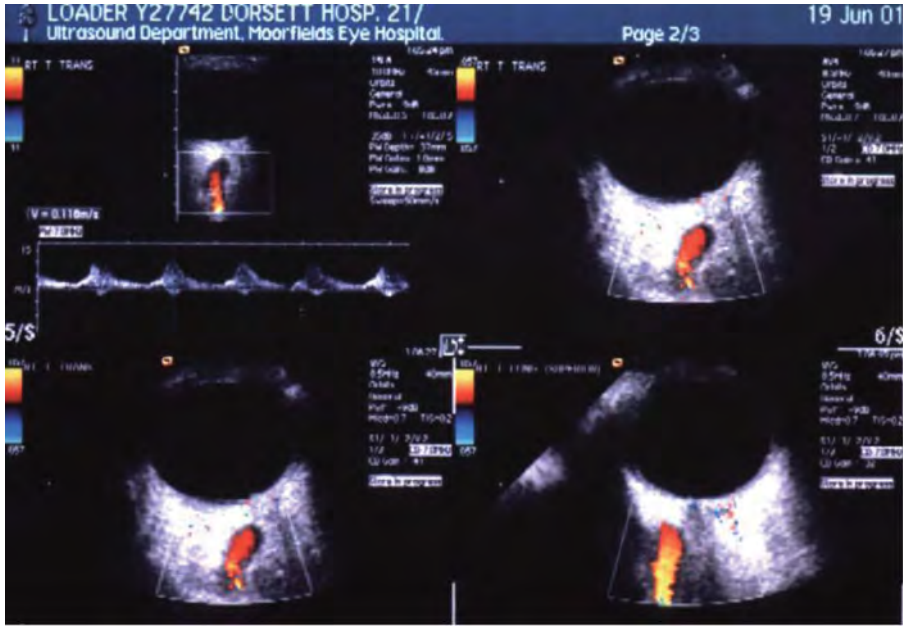

Plate 13.25 Colour Doppler flow mapping showing flow reversal (red) in superior ophthalmic vein due to carotid-cavernous fistula.

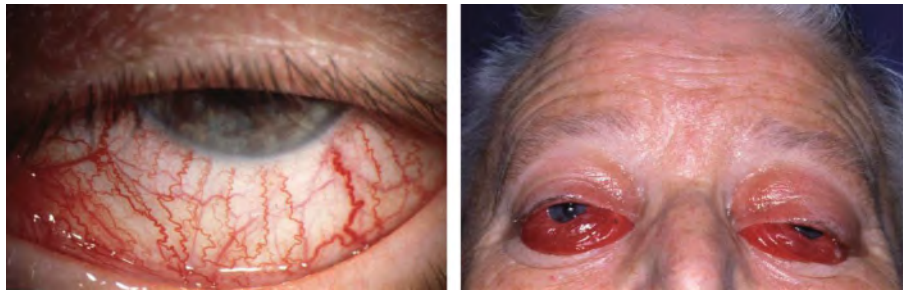

(a) (b)

Plate 13.26 (a) Arterialized conjunctival vessels in carotid-cavernous fistula. (b) Bilateral chemosis in carotid-cavernous fistula.

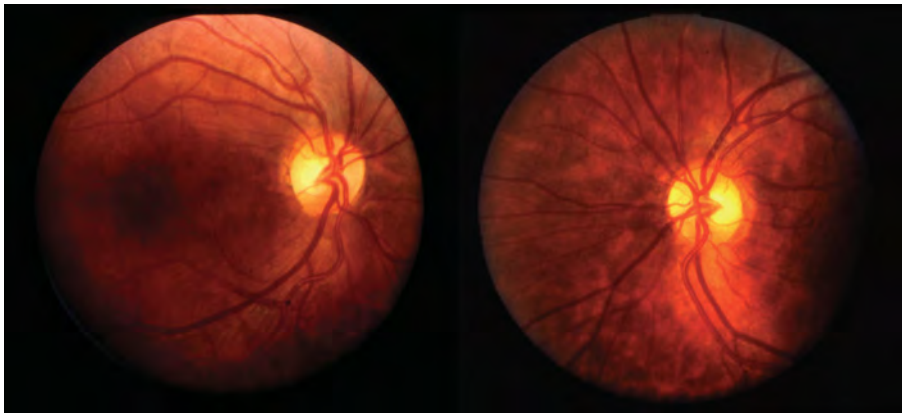

Plate 13.27 Band atrophy in bitemporal hemianopia due to chiasmal transection.

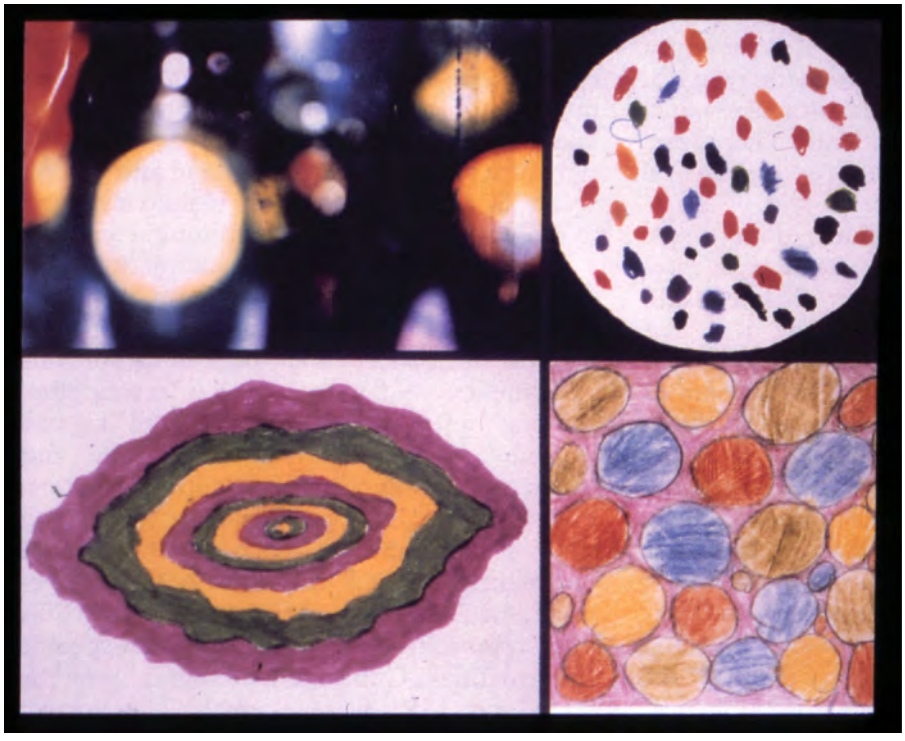

Plate 13.28 Visual phenomena recorded by four patients with occipital epilepsy. (Reproduced from Panyiotopoulos, 1999 with permission.)

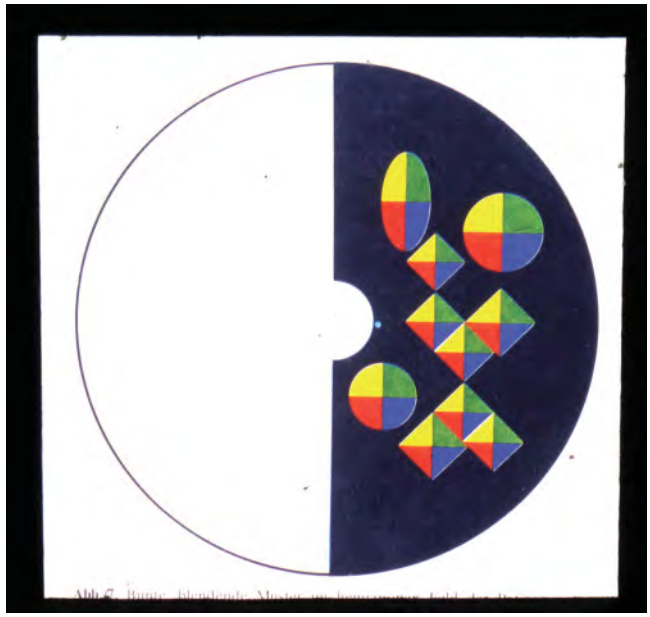

Plate 13.29 Geometric hallucinations within a hemianopic field defect recorded by the patient. (Reproduced from Kölmel, 1985 with permission.)

Plate 13.30 Metamorphopsia recorded by a patient following occipital lobe surgery. (From Mooney *et al.* 1965, with permission.)

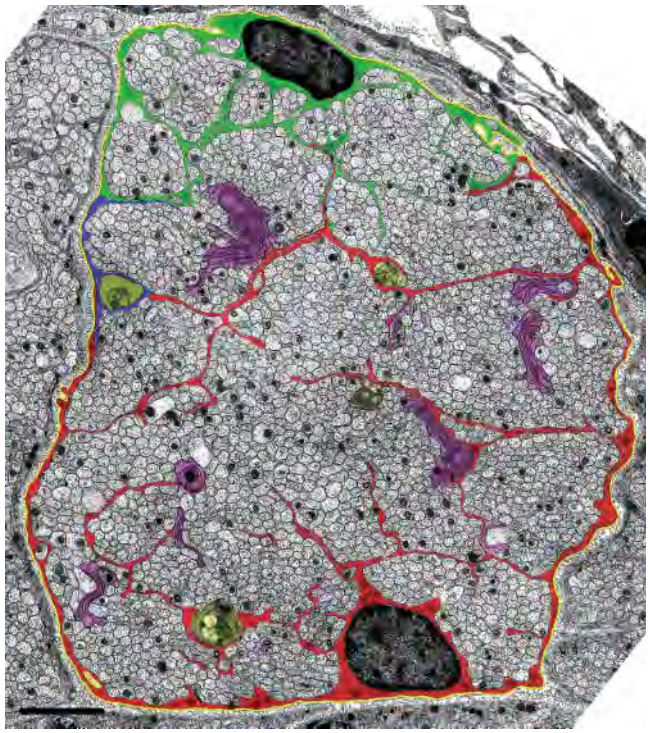

Plate 15.1 Electronmicrograph of olfactory ensheathing cells (OECs). Each colour represents the cytoplasm of a different OEC.

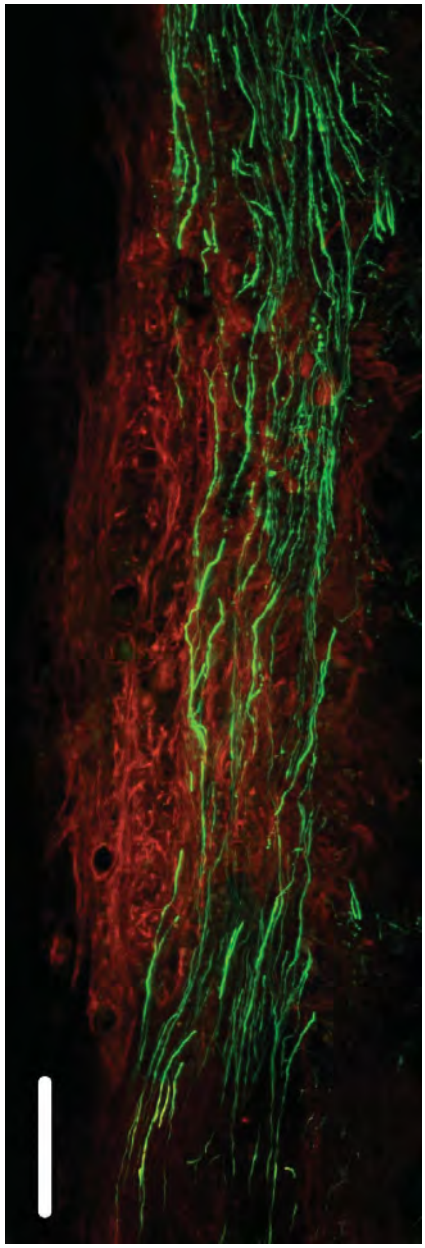

Plate 15.2 Photomicrograph of longitudinal section of rat spinal cord showing regeneration of neurones (green) through an area of transplanted olfactory ensheathing cells (OECs; red).

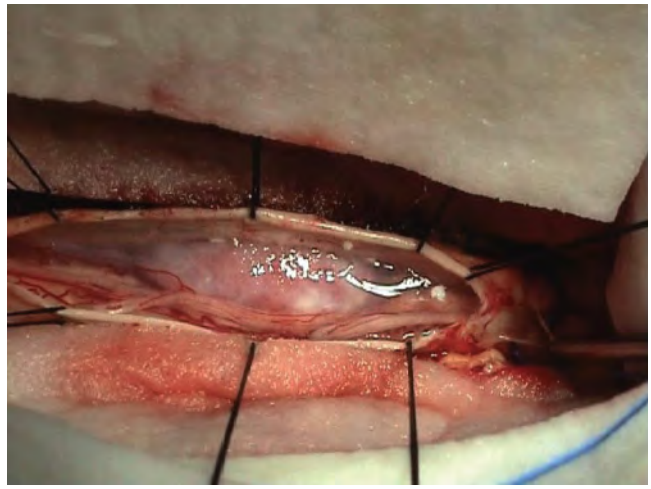

Plate 15.3 Operative photograph of intradural microscopic exploration of spinal meningioma with overlying arachnoid intact. Stay sutures hold dura opening, tumour arises from anterolateral dura mater.

Plate 20.7 (a) Coronal functional magnetic resonance imaging (fMRI) during opening and closing of hand in a patient with right superior frontal gyrus low-grade tumour. (b) Sagittal fMRI during picture naming task in a patient with a peri-insular tumour showing activity in Broca's area and in the visual cortex remote from the tumour.

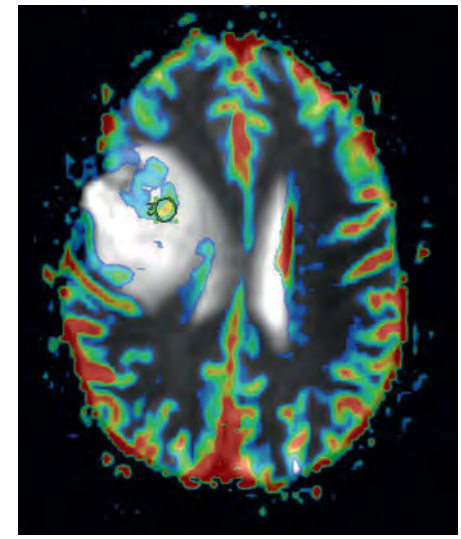

Plate 20.8 Relative cerebral blood flow (rCBV) colour overlay map in a low-grade oligodendroglioma showing area of increased rCBV in the anterior part of the tumour.

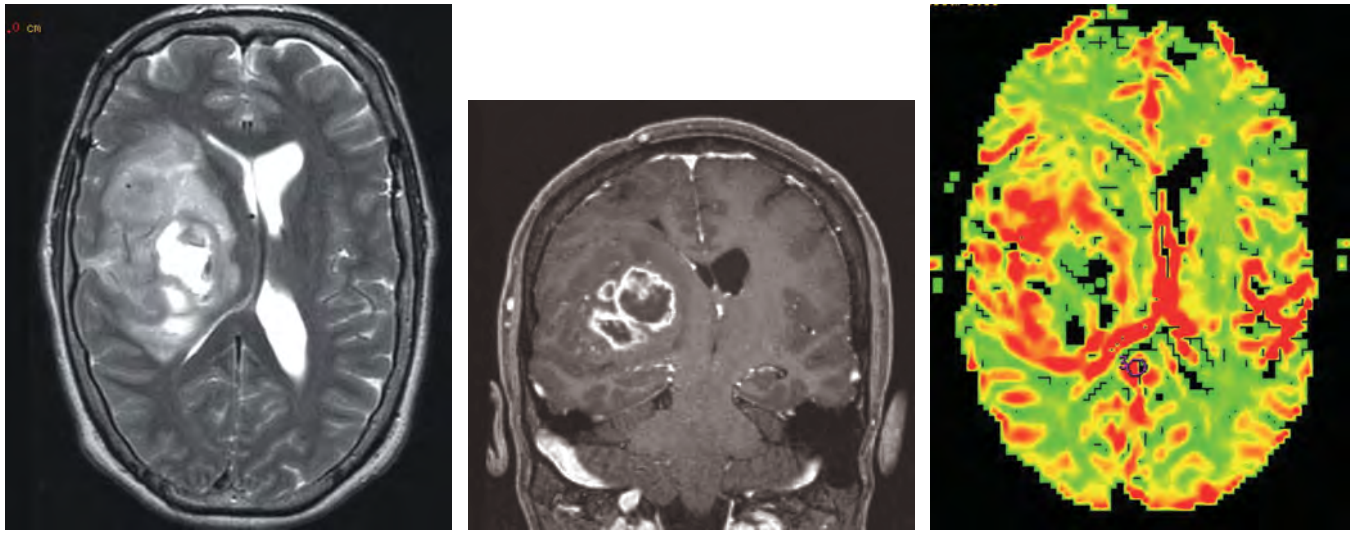
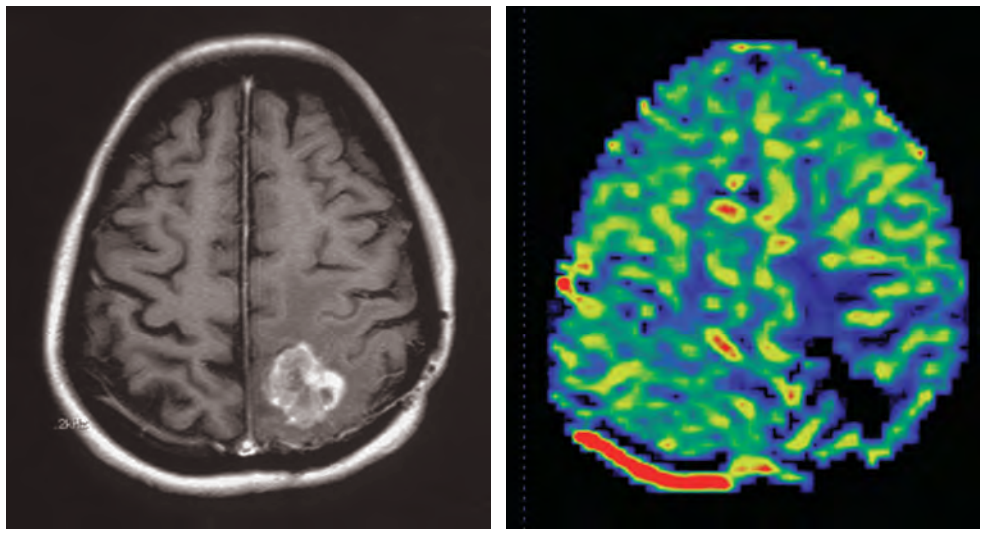


(a) (b) (c)

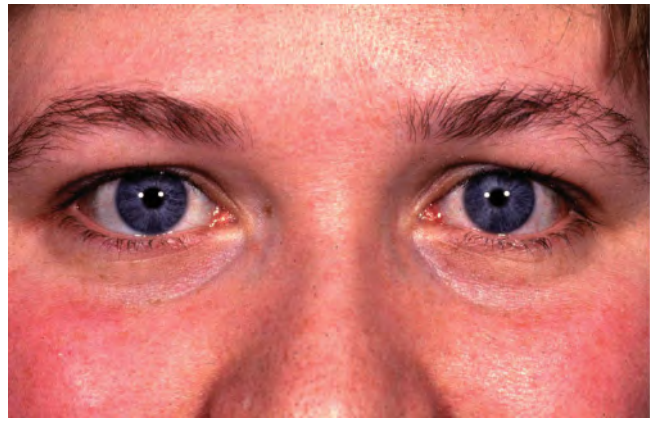
Plate 20.9 (a) T2 images of a high-grade oligodendroglioma showing a heterogeneous mass with a necrotic centre. (b) The contrast-enhanced T1 image demonstrates irregular ring enhancement within the mass. (c) On rCBV map large intra-tumoural areas of increased blood volume (in red) indicate areas of neovascularity.



(a) (b)

Plate 20.10 (a) Radiation necrosis following radiotherapy for a high-grade glioma. Contrast-enhanced T1 images show a brightly enhancing left parietal mass, indistinguishable from recurrent glioma. (b) rCBV shows mass has a decreased blood volume compared to normal white matter and appears dark, in keeping with radiation necrosis. A recurrent glioma is likely to have shown an elevated rCBV.

Plate 23.1 Segmental hyperhidrosis as a presenting feature in a patient in whom there were large areas without sweating. He had the Holmes–Adie syndrome with Ross's variant. (From Mathias 1998, with permission.)



Plates 23.2 (*left*) and **Plate 23.3** (*right*) Pupillary dilatation in Holmes–Adie syndrome and its response to pilocarpine. In Plate 23.2, the left pupil is clearly the larger – there is a diminished response to light. In Plate 23.3, the pupillary response to dilute pilocarpine (constriction) is greater on the left than in the normal right eye. (From Mathias 1998, with permission.)

1 Neurology Worldwide: the Burden of Neurological Disease

Simon Shorvon

Neurological disease casts a heavy shadow on the lives of the patient, their family and friends and on society. The aim of all neurological services should be to alleviate the suffering associated with the disease, and to realize this aim the rational planning of such health services requires knowledge in four broad areas. First, information is required about the epidemiology of the condition – its frequency and distribution within a population, its causation, mortality and co-morbidity. Second, it is important to know the broad impact of the disease (the 'burden of illness') on individuals, families and on health services and societies and also its financial cost. Third, data are needed on the effectiveness (and cost-effectiveness) of diagnostic, investigatory and treatment interventions. Finally, knowledge is required of the existing health care resources and their distribution and priorities. The last two areas are outside the scope of this chapter, and here a necessarily extremely brief overview of selected issues related to the epidemiology and burden of illness is given, where possible using figures derived from studies from the National Hospital in London. These set the scene for the more detailed consideration of neurological disease contained in the rest of the volume.

Epidemiology of neurological disease

It is self-evident that knowledge of epidemiology will be important to underpin any decision about the provision of health care resources. It is also clear that epidemiological data (on frequency, distribution, mortality, etc.) are of little value unless related to an intervention or therapeutic advance. Epidemiclogical data is particularly valuable for resource provision. Sadly, however, in practice, even where reliable data exist, these are used only inconsistently in planning health care. It is for this reason that in many, indeed perhaps most, health care settings, the provision of facilities for neurological care is often surprisingly fragmented and inappropriately targeted.

Neurology: A Queen Square Textbook Edited by Charles Clarke, Robin Howard, Martin Rossor and Simon Shorvon
ISBN: 978-1-405-13443-9

Frequency and distribution of neurological disease

Incidence and prevalence are the most common measures of frequency used in medicine.

Incidence is defined as the rate at which new cases occur in a specified population during a specified period. The incidence rate is usually calculated as the number of new cases occurring per 100,000 of the general population per year.

Prevalence is defined as proportion of a population that are cases at a point in time. The prevalence rate is usually calculated as the number of existing cases per 1000 of the general population. Point prevalence is calculated as the number on a particular day (prevalence day) and period prevalence is calculated as the number in a population over a specified period of time. Lifetime prevalence is defined as the risk of acquiring the condition at any time during life and is another important figure.

For many neurological diseases, information on even these basic measures is incomplete. Furthermore, the frequency of many neurological disorders varies markedly in different geographical regions, differs in urban when compared with rural settings, may differ with ethnicity, and is of often linked to lifestyle and socio-economic factors.

In most neurological illnesses there are also striking differences in frequency at different ages, and so the age distribution of the population will affect the frequency, and some diseases have marked gender differences. For these reasons, age-specific or sex-specific rates, or frequency estimates in restricted age ranges, are generally more informative than crude rates. For instance, the annual incidence of stroke in a population is about 190/100,000/year, but in the population over 65 years the rate is 1100/100,000/year. Similarly, the incidence and prevalence of Parkinson's disease in the general population is 20/100,000/year and 2/1000, and in those over 65 years is 160/100,000/year and 10/1000.

Changes in age structure in populations will impact heavily on the number of patients with diseases that have age-specificity. In most developing countries, the population has a far greater proportion of children and young adults than in developed countries (Figure 1.1 shows age structures in a typical developed [Sweden]

and developing country [Costa Rica]). It is also important to recognize that although worldwide human populations are growing in an exponential fashion, growth rates vary widely among different countries and regions and the concept of 'doubling time' is a useful way of quantifying this. Doubling time – the time it is predicted to take for a population to double in size – depends not only on population size and mortality rates, but also on the number of children per woman (Table 1.1) and various other social and health parameters.

The approximate non-standardized figures for the prevalence and incidence of neurological disorders in a developed country are shown in Table 1.2. This table illustrates one other important point – that for chronic diseases, as for many neurological diseases, the incidence rates may be low but prevalence rates are high. This is important for health service planning, as the facilities required for incident cases are very different from prevalent cases. The former require provision for investigation and acute therapy and the latter largely for follow-up, social care, long-term therapy and rehabilitation.

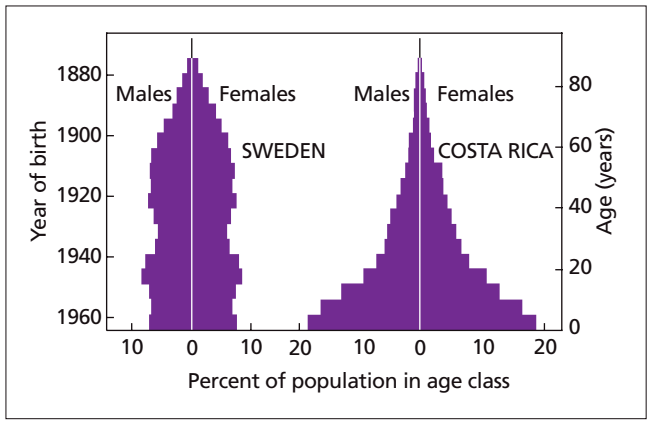


Figure 1.1 Age structure in developed (Sweden) and developing (Costa Rica) countries. (From Worldwatch Database (1996), with permission.)

The results of age-adjusted incidence and prevalence figures in a population of 100,230 persons in a selection of general practices served by the National Hospital for Neurology and Neurosurgery in London from a research project published in 2000 are shown in Tables 1.3–1.5. Here, the rates are adjusted for age to reflect the general UK population and are given alongside comparative results from other studies. Overall, the onset of 625 neurological disorders was observed per 100,000 population during the year of observation. Six per cent of the population in whom lifetime prevalence was surveyed had had a neurological disorder. In the UK, diseases of the nervous system accounted for 7.6% of all GP consultations between 1981 and 1982. The frequency of disability in private households amongst those over 16 years of age in the UK in 1971 was comprehensively delineated in the Harris Report. Disabilities relevant to neurology – CNS disorders, muscular dystrophies, congenital malformations of the spine and hydrocephalus, cerebral birth injury, senility as a cause of cognitive disability – occurred with a prevalence of 78/1000. The UK Office for Population Censuses and Surveys (OPCS) survey of disability 16 years later graded disability according to severity as well as overall frequency. The prevalence of complaints relevant to neurology was 13% for 'CNS disorders', 2% each for dementia and mental retardation, and 6% for back complaints. In a later study, 'CNS complaints' accounted for 7% of disability overall but for 16% of conditions with a high severity score. Roughly similar figures are found elsewhere. Population-based estimates from the USA, for instance, report point prevalence rates of neurological conditions (excluding headache, back pain and discs, mental retardation, psychosis, non-neurological visual and hearing loss and nervous system trauma) of 3.6/100.

It is therefore clear that neurological diseases are common and cause significant degrees of disability. Furthermore, the existing figures are probably underestimates, as there are many difficulties associated with the collection of statistics in neurology, leading mainly to under-ascertainment. Such issues apply to epidemiological studies in all areas, but in addition to the varied general issues there is one particular problem for neurology that requires

Table 1.1 Population size in selected developing and developed countries – doubling time.

Country	Approximate population size (millions)	Fertility (mean number of children per woman)	Doubling time* (years)
Germany	81	1.40	–654
Japan	125	1.50	217
USA	258	2.00	92
China	1178	1.90	60
Mexico	90	3.40	30
Philippines	65	4.10	28
Iran	63	6.60	20
Nigeria	95	6.60	23

* Doubling time is the predicted time it will take for the population to double in size. The doubling time depends on population size, age structure, number of children per women and mortality rates. These figures were taken from the WorldWatch database, and predate improvements in child health, reductions in mortality rates amongst children and young adults and the HIV epidemic. A negative number implies a shrinking population.

Table 1.2 Annual incidence and point prevalence figures of common neurological disorders (1984). Data derived from Kurtzke 1982; Hopkins 1993; Hughes 2002; Zakrzewska & Hamlyn 1999; Hirtz *et al*. 2007 and other sources. The table includes only those conditions with an incidence above 1/100,000/year; whole populations considered, without age standardization, and excludes shingles.

Disorder	Incidence (per 100,000 persons/year)	Point prevalence (per 100,000 persons)
Migraine	370	12,100
Acute stroke	190	900
Epilepsy	50	710
Febrile convulsions	50	
Dementia	50	250
Chronic polyneuropathy (all types)	40	24
Transient ischaemic attacks	30	
Bell's palsy	25	
Parkinson's disease	20	200
Meningitis	15	
Subarachnoid haemorrhage	15	
Metastatic brain tumour	15	
Primary brain tumour	5	6
Trigeminal neuralgia	4	1
Multiple sclerosis	4	90
Motor neurone disease	2	4
Acute post infectious polyneuropathy	2	1
All muscular dystrophies	1	6

Table 1.3 The National Hospital for Neurology and Neurosurgery (NHNN) record linkage study: age- and sex-adjusted incidence rates for neurological conditions, compared with previously reported rates.

Conditions	NHNN linkage age- and sex-adjusted rate (95% CI)/100,000/year	Previously reported incidence rates/100,000/year
Stroke		
First cerebrovascular episode	205 (183–230)	200
Second cerebrovascular episode	42 (33–55)	28–35
Intracranial haemorrhage	10 (5–17)	5% of stroke, i.e. 10
Seizure disorders		
Epilepsy	46 (36–60)	24–53
Single seizures	11 (7–18)	20
Tumours		
Primary CNS tumours (benign and malignant)	10 (5–18)	7; 15
Parkinson's disease	19 (12–27)	12–18
Compressive mononeuropathies – all except carpal tunnel syndrome (CTS)	49 (39–61)	40
Arm – all excluding CTS	24 (17–33)	
Leg – all	20 (14–29)	
Polyneuropathies		
Diabetic polyneuropathy	54 (33–83)	40
All excluding diabetic and alcoholic	15 (9–23)	11
Shingles	140 (104–184)	71; 131; 400; 480
Post herpetic neuralgia	11 (6, 17)	13; 34; 9% of shingles
Bacterial CNS infection (overall)	7 (4–13)	10; 11
Essential tremor	8 (4–14)	24

Continued on p. 4

Table 1.3 *Continued*

Conditions	NHNN linkage age- and sex-adjusted rate (95% CI)/100,000/year	Previously reported incidence rates/100,000/year
Trigeminal neuralgia	8 (4–13)	2; 4
Benign CNS tumour	7 (3–13)	10
Multiple sclerosis	7 (4–11)	2–8
Severe head injury	7 (3–12)	4–6
Subarachnoid haemorrhage	7 (3–12)	10–15
Subdural haematoma	6 (3–12)	
Cluster headache	6 (3–10)	10 (6–14)
Cranial nerve disorder (excluding II, III, IV, VI, Bell's palsy or trigeminal neuralgia)	6 (2, 12)	
Disorders of II, III, IV, VI, including pupillary abnormalities but not optic neuritis	6 (3–11)	
Aseptic meningitis	5 (2–9)	1; 11 (10–12)
Metastatic CNS tumour	4 (1–9)	14 (12, 16); 15
Presenile dementia	4 (2–9)	
Cerebral palsy	3 (1–8)	1.5; 2.7; 9
Neonatal encephalopathy or stroke	3 (1–8)	
Other congenital CNS abnormalities	3 (1–8)	7
Brachial neuritis	3 (1–7)	2
Guillain–Barré syndrome	3 (1–6)	1–2
Myasthenia gravis	3 (0.8–7)	0.25–0.8; 1
Primary malignant CNS tumour	3 (0.7–7)	5 (F) 6 (M); 5
Transient global amnesia	3 (0.5–7)	
Spinal cord injury	3 (0.9–7)	1.3–4; 5
Acute cervical myelopathy related to disc	2 (0.2–6)	
Cranial nerve injury	2 (0.5–5)	
Demyelination disorders not limited to optic nerve and not fulfilling criteria for MS	2 (0.4–5)	1.2
HIV encephalopathy	2 (0.8–5)	
Idiopathic myelopathy	2 (0.4–6)	
Motor neurone disease	2 (0.3–5)	1–2
Spondylitic myelopathy (chronic)	2 (0.5–6)	
Truncal mononeuropathy	2 (0.6–6)	
Diabetic amyotrophy	1 (0.1–4)	
Focal dystonia	1 (0.1–4)	2.2
Non-cervical disc-related cord or cauda equine damage (i.e. other disc or anatomical anomalies)	1 (0.1–3)	1.6; 3
Optic neuritis	1 (0.2–3)	
Spinal malformation	1 (0.1–2)	3.3

A small number of cases of the following diseases were also found in this study: cerebellar degeneration, dementia of uncertain cause, frontal dementia with anterior horn cell disease, neurosarcoid with cord involvement, neurofibromatosis, tuberous sclerosis, communicating hydrocephalus, aqueduct stenosis, cerebral cyst, tonsillar herniation with Chiari malformation, syringomyelia, myotonic dystrophy, myositis, idiopathic neurogenic bladder, tubercular meningitis, meningococcal meningitis, syphilis, streptococcal meningitis, *Streptococcus pneumoniae* brain abscess, *Listeria* meningitis, cryptococcal meningitis, and an unidentified ventriculitis in a man dying of a reticulosis).

Table 1.4 The National Hospital for Neurology and Neurosurgery record linkage study: lifetime prevalence of neurological conditions, and previously reported rates.

Conditions	Lifetime prevalence/1000 population (95% CI)	Previously reported point prevalence (PP) rates or estimated lifetime prevalence/1000
Stroke	9 (8–11)	5

mention. This is the difficulty of 'case definition' (and thus case ascertainment). Many neurological disorders are defined on clinical criteria, with the inevitable subjectivity this entails. Thus, boundaries exist in which symptoms are occurring without formal diagnosis – for instance, the boundaries between ageing and Alzheimer's disease and between chronic headache and migraine. Similarly, in epilepsy, the inclusion of febrile seizures, single seizures and acute symptomatic seizures within a definition of epilepsy will more than double frequency figures. In some neurological disorders, only 'the tip of the iceberg' cases are known to health care professionals, a common effect in conditions that are only mildly symptomatic in their early stages, such as migraine, some neuropathies, some dementing illnesses and Parkinson's disease. Severity also varies markedly, and the inclusion of mild cases will greatly inflate frequency figures but with relative reduction in burden of illness. Studies of epilepsy from the National Hospital provide examples of this – with over 60% of patients with epilepsy entering long-term remission and incurring only a minor impact on health services (see below). Case finding methods also need to be tailored to the disease's spectrum of severity and frequency, and any method using hospital statistics will greatly underestimate the true number of cases as many

minor or static neurological conditions are cared for outside the hospital setting.

Ethnic differences in disease were shown by the study of Stewart *et al*. from a multi-ethnic region of London in stroke. A stroke register was used with 12 sources of case ascertainment. The population size was 234,533 with 72% Caucasian, 21% Black (11% Afro-Caribbean, 7.5% West African and 2.5% mixed) and 3% South Asian. Incidence rates were standardized for age and sex. The crude annual incidence rate of stroke was 130 (120–141/100,000/year and the age-adjusted rate figure (to a standard European population) is 125 (115–135). The rate in the Black population was significantly higher with an incidence rate of 221 (177–276 per 100,000). The rate, not surprisingly, increased with age. The study also looked at social class and found higher rates in those less than 64 years in lower social classes. This sort of study generates hypotheses about causation (as yet not explained) and provides data for rational health care planning (partially implemented).

Similar considerations apply when considering rarer conditions, especially those requiring complex medical care where a sound estimate of frequency is important. A study of the prevalence and causation of dementia in those under 65 years, carried out by Harvey *et al*. in West London, is one example. In this population of 567,500 people, the prevalence of dementia in those aged 30–64 years was 0.54/1000 (0.45–0.64). For those aged 45–64 years, the prevalence was 0.98/1000 (0.81–1.18). From the age of 35 onwards, the prevalence of dementia was found to approximately double with each 5 year increase in age. On the basis of these figures, it was estimated that in 2003, there were 18,319 (15,296–21,758) people with dementia under the age of 65 in the UK. Using diagnostic algorithms, 34% had Alzheimer's disease, 18% vascular dementia, 12% fronto-temporal dementia, 7% dementia with Lewy bodies and 19% had other causes which included Huntington's disease, multiple sclerosis, corticobasal dementia, prion disease, Down's syndrome (probably underestimated), Parkinson's disease and others.

From the perspective of health services, figures of prevalence and incidence of the cases receiving treatment are important, as it is these cases that consume resources, not untreated (usually mild) or cases before diagnosis. In 1998, a large study of epilepsy was published by the author and colleagues amongst a population of 2,052,922 in England and Wales of persons with epilepsy receiving anti-epileptic drug treatment (Wallace, Shorvon & Tallis 1998). This provided accurate age-specific rates (Figure 1.2) and both the period prevalence and incidence of treated epilepsy was lower in children and higher in the elderly.

Neurology is also distinguished from other areas of medicine by the large number of uncommon conditions within its purview (neurology has the highest number of conditions listed in the International Classification of Diseases), and therefore large populations must be studied to obtain accurate population-based data with appropriate statistical reliability. Sampling error increases with rarer events and for many diseases there are few reliable data.

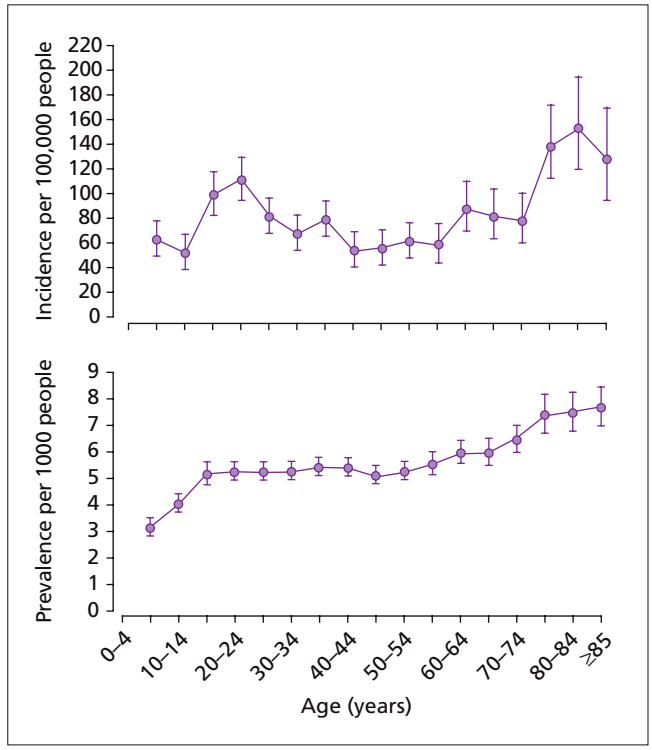

Figure 1.2 Standardized prevalence and incidence rates of treated epilepsy in a population of 2,052,922 persons in England and Wales in 1995. (Bars indicate 95% CI.) Prevalence of treated epilepsy: overall 5.15/1000 people (95% confidence interval [CI] 5.05–5.25); age 5–9 years 3.16 [2.86–3.48]; 10–14 years 4.05 [3.70–4.42], 65–69 years 6.01 [5.50–6.57]; 70–74 years 6.53 [5.97–7.14]; 75–79 years 7.39 [6.73–8.11]; 80–84 years 7.54 [6.78–8.39]; 85 years and older 7.73 [6.98–8.66]). Incidence of treated epilepsy: overall 80.8/100,000 people (76.9–84.7); 5–9 years 63.2 [50.5–79.1]; 10–14 years 53.8 [42.4–68.3]),` 65–69 years 85.9 [68.5–107.3]; 70–74 years 82.8 [65.0–105.2]; 75–79 years 114.5 [116.9–179.2]; 80–84 years 159 [125.2–202.6]; 85 years and older 135.4 [100.4–178.7]). (From Wallace, Shorvon & Tallis (1998), with permission.)

Causation

The attribution of causation to neurological disease is not always a simple matter. Most neurological diseases are multifactorial in nature, being the result of complex interactions between genetic and environmental influences. The balance between the two varies. The genetic influences can be very strong – for instance, in single gene disorders with high penetrance (e.g. Huntington's disease). In others the genetic influence is the result of more complex interactions between presumed susceptibility genes of which there may be many (e.g. epilepsy), and in other diseases identifiable Mendelian genetic influences do exist but are seen in some families cases only (Alzheimer's disease for instance is familial in about 10% of cases). The environmental influences are predominant in many diseases, for instance head injury or cerebrovascular disease. An interaction between genetic and environmental factors occurs in other diseases, for instance the interaction of smoking and genetic susceptibility in Parkinson's disease, or geographic location and genetic susceptibility in multiple

sclerosis. The latter is an interesting example as there are often unexplained geographical variations which may reflect either environmental or genetic influences or both. In most neurological diseases, even the common diseases, the primary causes are not clearly understood (see Chapter 10).

In multifactorial disease, it is often helpful to define 'risk factors'. The study of the epidemiology of a disease, in particular using case–control methodologies, can give important clues as to relative importance of different risk factors. The use of risk factor, hazard ratio and odds ratio calculations allows meaningful comparative statistics to be drawn up. This is demonstrated by the example of epilepsy resulting from cerebrovascular disease. In one study, a history of stroke has been found to be associated with an increased lifetime occurrence of epilepsy (OR 3.3; 95% CI 1.3–8.5). Among the other vascular determinants, only a history of hypertension was associated with the occurrence of unprovoked seizures (OR 1.6; 95% CI 1.0–2.4). The risk of unprovoked seizures rises to 4.1 (95% CI 1.5–11.0) in subjects having a history of both stroke and hypertension. Haemorrhagic stroke (subarachnoid haemorrhage and, to a lesser extent, primary intracerebral haemorrhage) are followed by a higher risk of seizures. The cumulative probability of developing seizures after a first stroke is about 6% after 1 year and rises to 11% at 5 years, with significant differences across stroke subtypes (cerebral infarction 4 and 10%; primary cerebral haemorrhage 20 and 26%; subarachnoid haemorrhage 22 and 34%). The risk of epilepsy among survivors of subarachnoid haemorrhage caused by ruptured cerebral aneurysm is highest in patients with acute symptomatic seizures (RR 7.0; 95% CI 2.3–21.6) and those with severe neurological sequelae (RR 2.5; 95% CI 0.9–6.3). Another study by Wallace and colleagues compared the frequency of stroke after the development of late-onset seizures in 4709 individuals who had seizures beginning at or after the age of 60 years, with 4709 randomly selected, matched controls with no history of seizures. Log-rank testing, adjusted for matching, showed a highly significant difference in stroke-free survival between the two groups ($P < 0.0001$) and the relative hazard of stroke at any point for people with seizures compared with the control group was 2.89 (95% CI 2.45–3.41).

Mortality

The mortality rate of any condition is defined as the number of persons with that condition dying during a specified period divided by the number of persons in the same population. This information is of limited value, particularly in chronic neurological disease, without a knowledge of the underlying rate of death in patients without the condition or of age distribution. Therefore, mortality is often expressed as the ratio between the observed and expected numbers of death – this measure is known as the standardized mortality ratio (SMR). Expected deaths are calculated by measuring the death rates of a reference population with an age distribution that is similar to the study population. When there is no difference in mortality between the study and reference population the SMR is 1. The 95% CI provides an estimate of the significance of the calculated SMR. Another useful measure is the proportional mortality ratio which is the percentage of deaths that are due to any one cause. Life expectancy, defined as the median survival, is linked to age and is often lowered in neurological disease when compared with a healthy population, but statistics are complex to derive and there are few studies of this in neurological disease.

Taking epilepsy as an example, in a UK cohort study we followed a cohort of 564 newly diagnosed cases of epilepsy for 11–14 years and found an overall SMR of 2.1 (95% CI 1.8–2.4). Patients with acute symptomatic epilepsy (SMR 3.0; 95% CI 2.0–4.3), remote symptomatic epilepsy (SMR 3.7; 95% CI 2.9–4.6) and epilepsy due to congenital neurological deficits (SMR 25; 95% CI 5.1, 73.1) had significantly increased long-term mortality rates. In idiopathic epilepsy the SMR was 1.3 (0.9–1.9) – in other words not significantly different from the national population. The study also calculated the hazard ratio (HR), or risk of mortality in a particular group with a particular risk factor compared to another group without that particular risk factor. For epilepsy overall , it was 6.2 (95% CI 1.4–27.7; $P = 0.049$). Rates varied with the cause of epilepsy: cerebrovascular disease (HR 2.4; 95% CI 1.7–3.4; $P < 0.0001$), CNS tumour (HR 12.0; 95% CI 7.9–18.2; $P < 0.0001$), alcohol (HR 2.9; 95% CI 1.5–5.7; $P = 0.004$) and congenital neurological deficits (HR 10.9; 95% CI 3.2–36.1; $P = 0.003$). An older age at the time of diagnosis was also associated with significantly increased mortality rates (HR 1.9; 95% CI 1.7–2.0; $P < 0.0001$). Life expectancy has also been calculated in the same population based on the Weibull distribution. This depends on age at time of diagnosis and aetiological group, and of course reductions in life expectancy diminish over time. In our study of epilepsy, overall reduction in life expectancy, at the time of diagnosis, was found to be up to 2 years for people with a diagnosis of idiopathic or cryptogenic epilepsy, and up to 10 years in people with symptomatic epilepsy.

Mortality rates can be a useful way of quantifying treatment, but it is equally important in some neurological conditions to consider quality of life. This was well shown in a study of survival after radiotherapy in malignant glioma by Clarke and colleagues in 1996. Radiotherapy is known to prolong life (in one trial to 38 weeks after radiotherapy compared to 14 weeks with steroids alone). However, the side effects of radiotherapy can be severe, and the trade off between survival and quality of life is important to consider. It was found that the clinical status before radiotherapy was a good indicator of the duration of disability-free life after radiotherapy. The authors concluded that for those already disabled by the tumour, radiotherapy offered little physical gain and even if not severely disabled the treatment could cause severe adverse effects.

Other measures and rates

Other epidemiological measures and rates can be derived, for instance related to childbirth or co-morbidity, and are of importance in certain health care areas:

• *Birth rate* is usually defined as the number of live births per mid-year population;
• *Fertility rate* is usually defined as the number of live births per number of women aged 15–44 years;
• *Infant mortality rate* is defined as the number of infant (<1 year) deaths per number of live births;
• *Stillbirth rate* is defined as the number of intrauterine deaths after 28 weeks per total births;
• *Perinatal mortality rate* is the number of stillbirths + deaths in first week of life per total number of births.
Such epidemiological data can be used to investigate causation and assist prevention, but the issues are often complex.

This is well illustrated in a study of fertility in epilepsy amongst a general population of 2,052,922 persons in England and Wales. Age-specific fertility rates were defined as the number of live births per 1000 women-years at risk, in each age category. Fertility was about 30% lower among women with treated epilepsy, with an overall rate of 47.1 live births per 1000 women aged 15–44 per year (42.3–52.2), compared with a national rate of 62.6 in the same age group. The standardized fertility ratios were significantly lower between the ages of 25 and 39 years in women with epilepsy ($P < 0.001$; Figure 1.3). The reasons for these lower rates are complicated. There are undoubtedly social effects: women with epilepsy have low rates of marriage, marry later, experience social isolation and stigmatization. Some avoid having children because of the risk of epilepsy in the offspring, and some because of the teratogenic potential of anti-epileptic drugs. Other patients have impaired personality or cognitive development. However, there are other biological factors that could lead to reduced fecundity. These include genetic factors and adverse anti-epileptic drug effects. The lowering of fertility is a worrying finding which is another and important source of disadvantage for women with epilepsy. If there are potentially preventable causes, these should be sought.

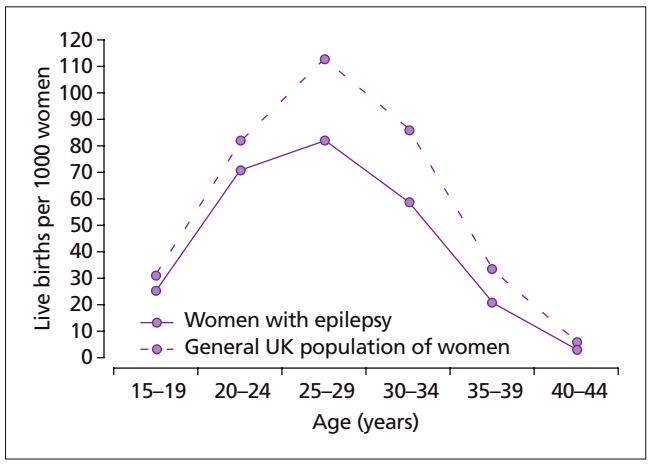

Figure 1.3 Comparison of age-specific fertility rates in women with treated epilepsy and general UK population of women in 1993 (study of a population of 2,052,922 persons). (From Wallace, Shorvon & Tallis (1998), with permission.)

Many neurological conditions have chronic courses, so long-term follow-up is important to our understanding of their prognosis and resource implications. Epidemiologically based prospective cohort studies are the optimal method of study to assess the full impact of the disease.

Burden of illness

Although the study of the epidemiology of disease provides figures on incidence, prevalence, risk factors and distribution within a population, such information is of little practical value unless linked to a treatment (or prevention) programme and resource utilization. A problem that lies at the heart of care provision is the need to focus interventions where needed.

Definitions

The term 'burden of illness' in its widest sense incorporates all negative impacts of illness, although is often used to denote the financial costs of illness where costs are understood to encompass the full social costs, both subjective hard to quantify elements as well as objective more easy to quantify measures. These cost of illness studies have the advantage of attempting to quantify a range of negative effects in monetary terms and thus allow comparisons to be drawn. Their disadvantages are obvious – notably the inherent inaccuracies and absurdities of trying to define quality of life issues in terms of monetary loss. Utility measures (e.g. quality-adjusted life years [QALYs] and disability-adjusted life years [DALYs]) have also been derived to try to quantify burden more widely, and a particularly important project has been 'The Global Burden of Disease' project sponsored by the WHO and World Bank. The burden of illness on individuals and on carers are not comprehensively accounted for in such studies which focus on broad categories biased towards societal and economic considerations.

Cost of illness studies

The principal concern of physicians is to provide individual care, but as health care costs are rising so fast, and even the richest economies are seeking to limit expenditure, clinicians are necessarily now involved in factoring in economic considerations when making therapeutic decisions. This has led to cost of illness studies, which although important are bedevilled with methodological problems that limit their usefulness.

The perspective taken in the analysis is of primary importance in any study of cost of illness. The cost (and burden) for individuals has quite different parameters to the burden for families, for health services or for society in general. Most cost of illness studies are carried out from the point of view of society, with social costs estimated in terms of lost employment, lost productivity and premature death.

Costs are usually divided into two types: direct and indirect. In outline, the direct costs are defined as any resource utilization required in the care of the illness. These include medical costs such as primary care, hospital out-patient, hospital in-patient,

investigation, drugs and non-medical costs such as residential care, community care, training and rehabilitation. Indirect costs are defined as the costs resulting from lost economic production and include premature mortality, dependency, unemployment and underemployment. There are various categories of cost, and any comprehensive analysis should include opportunity costs and transfer payments. Estimation of indirect costs may use the 'human capital' approach which ascribes a monetary value to a person in terms of their potential productivity. In health economic analysis the willingness to pay approach has become popular, which defines costs in terms of how much a person would be willing to spend. This has the advantage of accounting for intangible as well as tangible effects. Both methods are difficult to carry out and both are open to a wide variety of biases and criticisms. With all neurological disorders, the indirect costs are greatly in excess of the direct costs. In one study of epilepsy in 1994, for instance, indirect costs accounted for only 13% of all costs in spite of relatively narrow definition of cost.

There are four common methodologies for carrying out economic appraisal and comparative studies: cost-minimization analysis, which compares interventions where the outcomes are the same; cost-effectiveness analysis, where outcomes are compared using a single natural measure (e.g. in epilepsy, cost per 50% reduction in seizure frequency); cost–utility analysis, which are particularly useful for comparing costs between diseases, in which different outcomes can be accounted for and costs are compared in terms of their effects on a utility measure (e.g. the effect on QALYs); and finally cost–benefit analysis which measures outcome in terms of economic benefit – accounting for both direct and indirect costs. The latter analysis is the most comprehensive, but in neurology there have been few examples of cost–benefit studies. With the increasing availability of expensive therapies and investigations, however, there is a pressing need for good economic appraisal.

WHO burden of illness studies

In recent years, the WHO and World Bank have evolved a more comprehensive series of measures of the impact of disease. The best known are the QALY or the DALY. The DALY uses a methodology that focuses on disability whereas the QALY focuses on quality of life. These were formidable efforts, involving the WHO in 40 person-years of effort and the collection of data on 483 separate sequelae in 107 diseases and 14 million death certificates. It has to be said, as will be quite obvious to all, that reducing the impact of illness into a one-dimensional measure presents difficulties that are as intractable as those of quantifying illness in monetary terms. The Global Burden of Disease study provides comparative statistics on the impact of disease from 107 countries. To what extent this effort is worthwhile, finally, in helping set priorities has been seriously questioned.

The DALY is an indicator that is most useful in making comparisons between diseases and between regions, and in Table 1.6 some comparative figures are shown for neurological and psychiatric disease. On the basis of this analysis, neuropsychiatric disease accounted for about 15% of the global burden of disease (and 34% of the global burden of disability). Cerebrovascular disease accounts for instance for about 10% of the global burden of neuropsychiatric disease, dementia 2% and epilepsy 1%.

The personal burden of neurological disease – stigma

The burden of illness of any neurological disease includes aspects that are less directly related to economic factors. Psychological, social, educational, employment and legislative aspects can have a major impact. Some of these are proportionate and rational (e.g. driving restrictions in epilepsy or stroke) but others are not, and a particular issue for patients with neurological disease is the stigma attached to the disease.

Table 1.6 Disability-adjusted life year (DALY; in thousands) calculations for year 2000 for neurological and psychiatric conditions. Disability-adjusted life year is an indicator of the time lived with a disability and the time lost due to premature mortality. Reproduced with permission from the World Health Organization 1996b.

Condition	DALYs			
	Developed countries*	India	Sub-Saharan Africa	World
Neurological and pychiatric conditions (all)†	24,682	23,949	15,788	165,082
Cerebrovascular disease	5,166	5,223	5,487	45,770
Unipolar depression	6,721	10,064	6,193	60,166
Bipolar disease	1,673	2,867	1,785	16,722
Schizophrenia	2,151	2,041	611	14,614
Epilepsy	427	848	526	4,712
Alcoholism	4,611	1,113	2,387	18,973
Dementia	3,286	1,192	453	10,135
Parkinson's disease	523	167	63	1,278
Multiple sclerosis	222	253	140	1,569

* Defined as 'established market economies'.

† This category excludes cerebrovascular disease.

Stigma deserves special mention, for it is important in many neurological disorders and yet its consequences are overlooked in burden of illness studies. It is often divided into three categories: enacted (actual experience of discrimination), felt (the fear of discrimination) and self (for instance, devaluation or shame or withdrawal as a personal response to perceived discrimination). There are complex interactions and society will often construct a 'stigma theory' about a disease – to explain the dangers the person represents and which imputes a wide range of imperfections on the basis of the disease. The impact of stigma in neurological disease and epilepsy provides an example. The fact of 'being epileptic' is often more devastating than the simple occurrence of occasional epileptic seizures. In 1989, in Britain, felt stigma was found to be nine times less common than enacted stigma. For the patient, epilepsy results in a continuing uncertainty of being interrupted by recurrent attacks which are unpredictable, often dramatic, frighten, horrify or anger onlookers and which are imbued in primitive beliefs about possession and disgust. There results in society a belief that sufferers are retarded, weak, slow, antisocial, physically unattractive or aggressive. Such beliefs are most prevalent in developing societies, but even in the USA in a number of states, up until 1956, people with epilepsy were prohibited from marrying and could be sterilized, and until the 1970s were excluded from restaurants and theatres. In a large study published in 1999 and 2000, amongst more than 5000 persons with epilepsy in Europe, 51% reported feeling stigmatized and 18% highly stigmatized.

The impact of even non-serious illness can be significant. A study from Dunedin of tension headache and migraine showed significantly poorer social, mental, physical and emotional functioning than matched non-headache controls. Although equal numbers of those with and without migraine were in employment, 80% of women with migraine were earning ≤$30,000 or less compared to 67% of controls. Nearly half of those with migraine reported that their headaches impaired their social activities. The burden of disease resulting from migraine was considered equal to that of asthma.

Relative costs – developing countries

Ill health has an economic burden that can impose high and regressive cost burdens on the patient and family in all countries. However, in poorer countries the proportion of family income spent on health may be particularly high, not least as ill health results also in unemployment and underemployment. In Sri Lanka, for instance, where health services are free at the point of delivery, it has nevertheless been estimated that the total cost of all illness amounts to 10% of household incomes, and it is likely that neurological illnesses, because of their generally chronic and disabling nature, are particularly onerous. Tuberculosis (TB) is a serious chronic illness which has been well studied from the health economic point of view. In Thailand, it has been reported that TB results in 15% of poor households having to sell material property and 10% taking out loans. In India, amongst patients with TB, 67% of rural patients and 75% of urban patients incurred TB-related debts. Eleven per cent of school children with parents with TB had to discontinue their studies and another 8% had to take up employment. What applies to TB will no doubt also apply to chronic neurological diseases. The impact of diseases depends primarily on the economic position of the family (the lower the economic status, the greater the impact) and the social or family networks and community support available.

Treatment gap

It is also largely economic factors that lie at the heart of failure of treatment. Taking the example of epilepsy again, in 1989, Shorvon and colleagues coined the phrase 'epilepsy treatment gap' to provide a numerical measure of the extent of failure of therapy. The treatment gap was defined as the percentage of patients with active epilepsy in a population who do not receive anti-epileptic drugs. It is a simple estimate based on prevalence and drug supply figures for that country, and assumes standard low dose monotherapy. Surprising and disturbing results were obtained – in Pakistan, the Philippines and Ecuador treatment gaps of 94%, 94% and 80%, respectively, were ascertained. Although estimates, we considered these to be underestimates if anything (resulting from low estimates of prevalence and assumptions of low drug dosages). Since then, prospective population-based studies have largely confirmed these findings, with 62% treatment gap ascertained, for instance, in China and 73–78% in India. Another study has shown that 41% of people with epilepsy in China have never received anti-epileptic drugs. There are various reasons for these deficiencies of treatment including cost, availability (not least the availability of drugs in pharmacies), cultural factors, lack of medical facilities, and lack of understanding of the potential and role of therapy. Closing the 'treatment gap' has become a priority for health services in many countries, and these findings were a primary stimulus for the highly successful joint WHO and the International League Against Epilepsy (ILAE) campaign to improve epilepsy care – *The Global Campaign Against Epilepsy.* The campaign is one example of how epidemiological data can be translated into societal action, and the results of the campaign interventions using improving treatment gap statistics are currently under evaluation.

Certain topics of interest have had to be omitted from this necessarily brief survey of 'The burden of neurological illness worldwide'. Amongst these, prevention is not mentioned, although the prevention of neurological disease has not been well studied generally. In most countries of the world, even basic epidemiological data on many, particularly uncommon, neurological disorders has not been calculated. Ethical issues are also important in this area but are not covered here, especially in relation to resource utilization. For instance, as doctors, our primary responsibility is to the individual patient and not society. Therapies which are not 'cost' effective' from the epidemiological or societal point of view, may be nevertheless beneficial in an individual – and here the societal and clinical perspectives may clash (although cultures that purport to put society before the individual usually apply hypocritically different standards to the

rulers and the ruled). The impact of social policy, for instance in relation to financial benefits and social support, on the burden of illness has also not been touched upon, although it can greatly influence the individual burden.

2 Nervous System Structure and Function

Charles Clarke, Roger Lemon

BASIC NEUROSCIENCE

Introduction

The complexity of the nervous system posed daunting challenges for clinical neurology as the discipline emerged from the late 19th century into the early 20th. However, despite the truly remarkable description of the intricacies of axonal and dendritic networks by Cajal in the 1890s, using the light microscope (Figures 2.1 and 2.2), the cortical mapping by Brodmann and later the fine detail of neuro-anatomical pathways by Brodal and many others in the 1940s, it remained entirely evident that a distinctly rudimentary knowledge of neuro-anatomy – and little of physiology – was all that was necessary to provide a robust basis for most day-to-day neurological practice. It is also something of an enigma that neurologists training in the 21st century continue to use basic clinical tools from over 100 years ago; many neurologists in the past have had a relatively sketchy knowledge of pathways, physiology and mechanisms – although this is an indication of the reliability of simple observation of symptoms and signs in day-to-day practice.

But times are changing fast. Advances in imaging, neurogenetics, neurochemistry, neurotransmitter technology, immunology and molecular biology have added entirely new dimensions to clinical practice, to the relevance of neuronal and glial ultrastructure and function and complexities of neuro-anatomy. We now begin by looking at ultrastructure, functional imaging, genetics, chemistry and neuronal activity to understand conditions as diverse as Alzheimer's disease, Parkinson's disease, myasthenia gravis, polyneuropathies and recurrent headache – itself the most common neurological complaint the world over and of major economic importance. This chapter provides a brief overview of how the nervous system is organized and, where appropriate, how abnormalities found on examination are explained, both anatomically and neurochemically.

Neurology: A Queen Square Textbook Edited by Charles Clarke, Robin Howard, Martin Rossor and Simon Shorvon
ISBN: 978-1-405-13443-9

The functional unit: the neurone

The neurone (>100 billion within the human brain) is the functional unit of the nervous system. Neuronal specificity, size and cell type vary greatly. One α-motor neurone of the lumbar cord has an axon over 1 m in length and innervates between several hundred and 2000 muscle fibres – to form a motor unit. By comparison, some spinal or intracerebral interneurones have axons under 100 μm long which terminate on a single neuronal cell body. A summary of neuronal ultrastructure follows.

The neurone is constituted by its nucleus, cytoplasm, neuronal membrane and cytoskeleton (Figure 2.3). Neurotransmission and intrinsic modification of the neurone itself are its functions – to facilitate transfer of information, to adapt to and record change. The combination of axonal electrical activity and synaptic neurotransmitter release provides the basis for most interneuronal transmission, with an important role also for the release of neuromodulators. The integrity of intraneuronal and glial structure and function is also essential; glia are now known to play a part in synaptic transmission, re-uptake of neurotransmitters and the general control of the extracellular environment in which the neurones are located. Neuronal plasticity indicates the ability of neurones to adapt, to change, singly, in sequence and/or in groups and is a particularly well-developed aspect of the mammalian nervous system. Plasticity has a pivotal role in both learning and recovery from injury, and can involve changes in all or any part of the neurone.

From the neurone cell body (soma, perikaryon) extend neurites, i.e. axons (up to 1 m long) and dendrites (rarely longer than a few millimetres). Most axons branch repeatedly to establish synaptic connections with other neuronal cell bodies. In this way neurones are able to make divergent connections with many other neurones within the CNS.

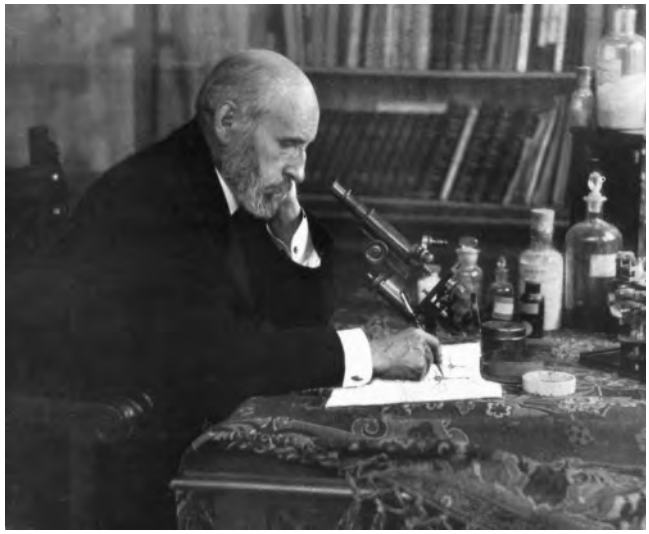

Figure 2.1 Santiago Ramón y Cajal (1852–1934) with his light microscope in 1915. (*With kind permission of the Instituto Cajal*, Madrid.)

The dendritic and soma membrane represents the main region through which the neurone receives its synaptic input. Some neurones receive many thousands or even hundreds of thousands of such inputs. The neuronal membrane is the 5 nm thick barrier enclosing cytoplasm, excluding substances bathing the neurone. This membrane bilayer of phospholipid has typically a polar hydrophilic head and an insoluble non-polar hydrophobic tail. Neuronal membrane proteins are responsible for the interaction between the neurone and its environment. These proteins are:

- Ion channels, usually either ligand-gated or transmitter-gated;
- Receptors; and
- Cell adhesion molecules.

The cytoskeleton consists of microtubules, neurofilaments and microfilaments. Microtubules are some 20 nm diameter, hollow-walled strands of α and β tubulin – polymers of globular microtubule associated proteins (MAPs). Tau is an axonal MAP. Dynein and kinesin are motor proteins (aka molecular motor or motor molecules) that convert chemical energy in ATP into mechanical energy (movement).

Neurofilaments are 10 nm thick (intermediate filaments of all other cells), braided, tight, physically strong protein strands. They form a peri-nuclear network and provide structural integrity. Microfilaments are 5 nm thick, braided duplexes of actin (42–44 kDa). They are critically involved in neurone shape, where they have a role analogous to those in muscle.

Neuronal replication is the exception, although neurogenesis has been clearly shown to take place in the olfactory neuroepithelium, hippocampus and hypothalamus. Neuronal dynamics imply that intraneuronal contents are continually being reformed and degraded. The cofactor ubiquitin molecule interacts with degraded proteins via hydrophobic residues – complexes of more than five ubiquitin molecules are broken down by an ATP-dependent multi-enzyme system, the 26S proteasome. Failure to remove degraded proteins is of signal importance in many neurodegenerative diseases (e.g. Alzheimer's disease; Chapter 7), and myopathies such as inclusion body myopathy (Chapter 9).

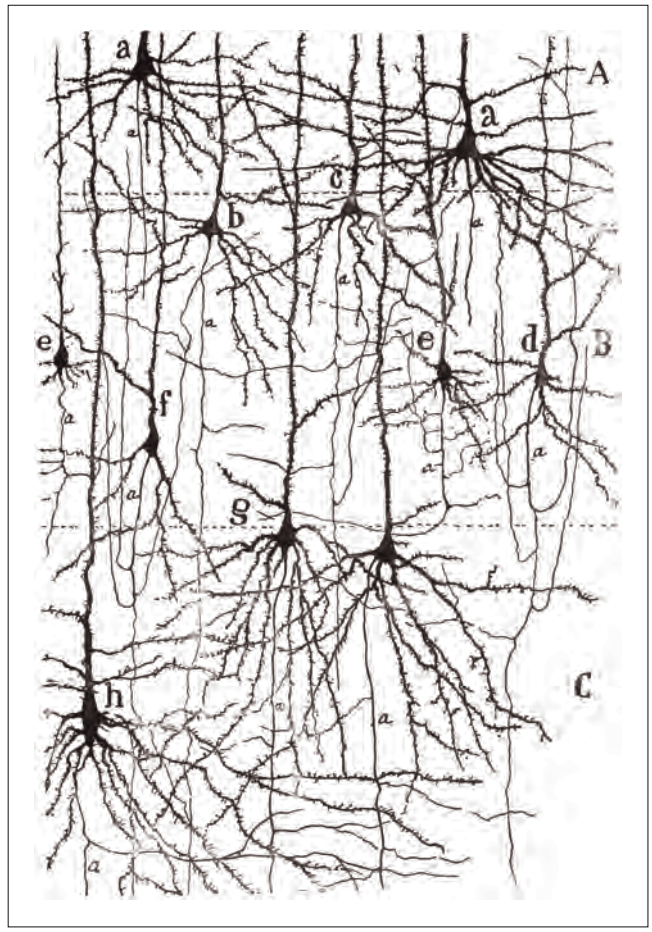

Figure 2.2 Fine detail of cortical neuronal networks (Cajal). First, second and third layers of precentral gyrus of the cerebrum. A, B, C, small pyramidal cells; D, E, medium pyramidal cells; F, G, H, bitufted cells and dendritic shafts. (*With kind permission of the Instituto Cajal*, Madrid.)

Amyloid and tau in degenerative brain diseases

Any detailed account of normal and pathological neurochemistry is far outside the scope of this chapter. However, it is relevant to include here a synopsis of some neurochemical findings in common degenerative neuronal diseases, especially Alzheimer's (Chapter 7).

In Alzheimer's disease, neurofibrillary tangles develop – filamentous inclusions within the soma and dendrites adjacent to it. Paired helical and 15 nm straight insoluble protein filaments become visible. These are isoforms of tau, the microtubule binding protein that in health is soluble. This structural change in the cytoskeleton is likely to impair axonal transport, neurotransmission and eventually viability of the neurone.

In the second pathological hallmark of Alzheimer's, the extracellular senile plaque, deposits of amyloid are surrounded by dystrophic neuronal elements. Amyloid is the name given to

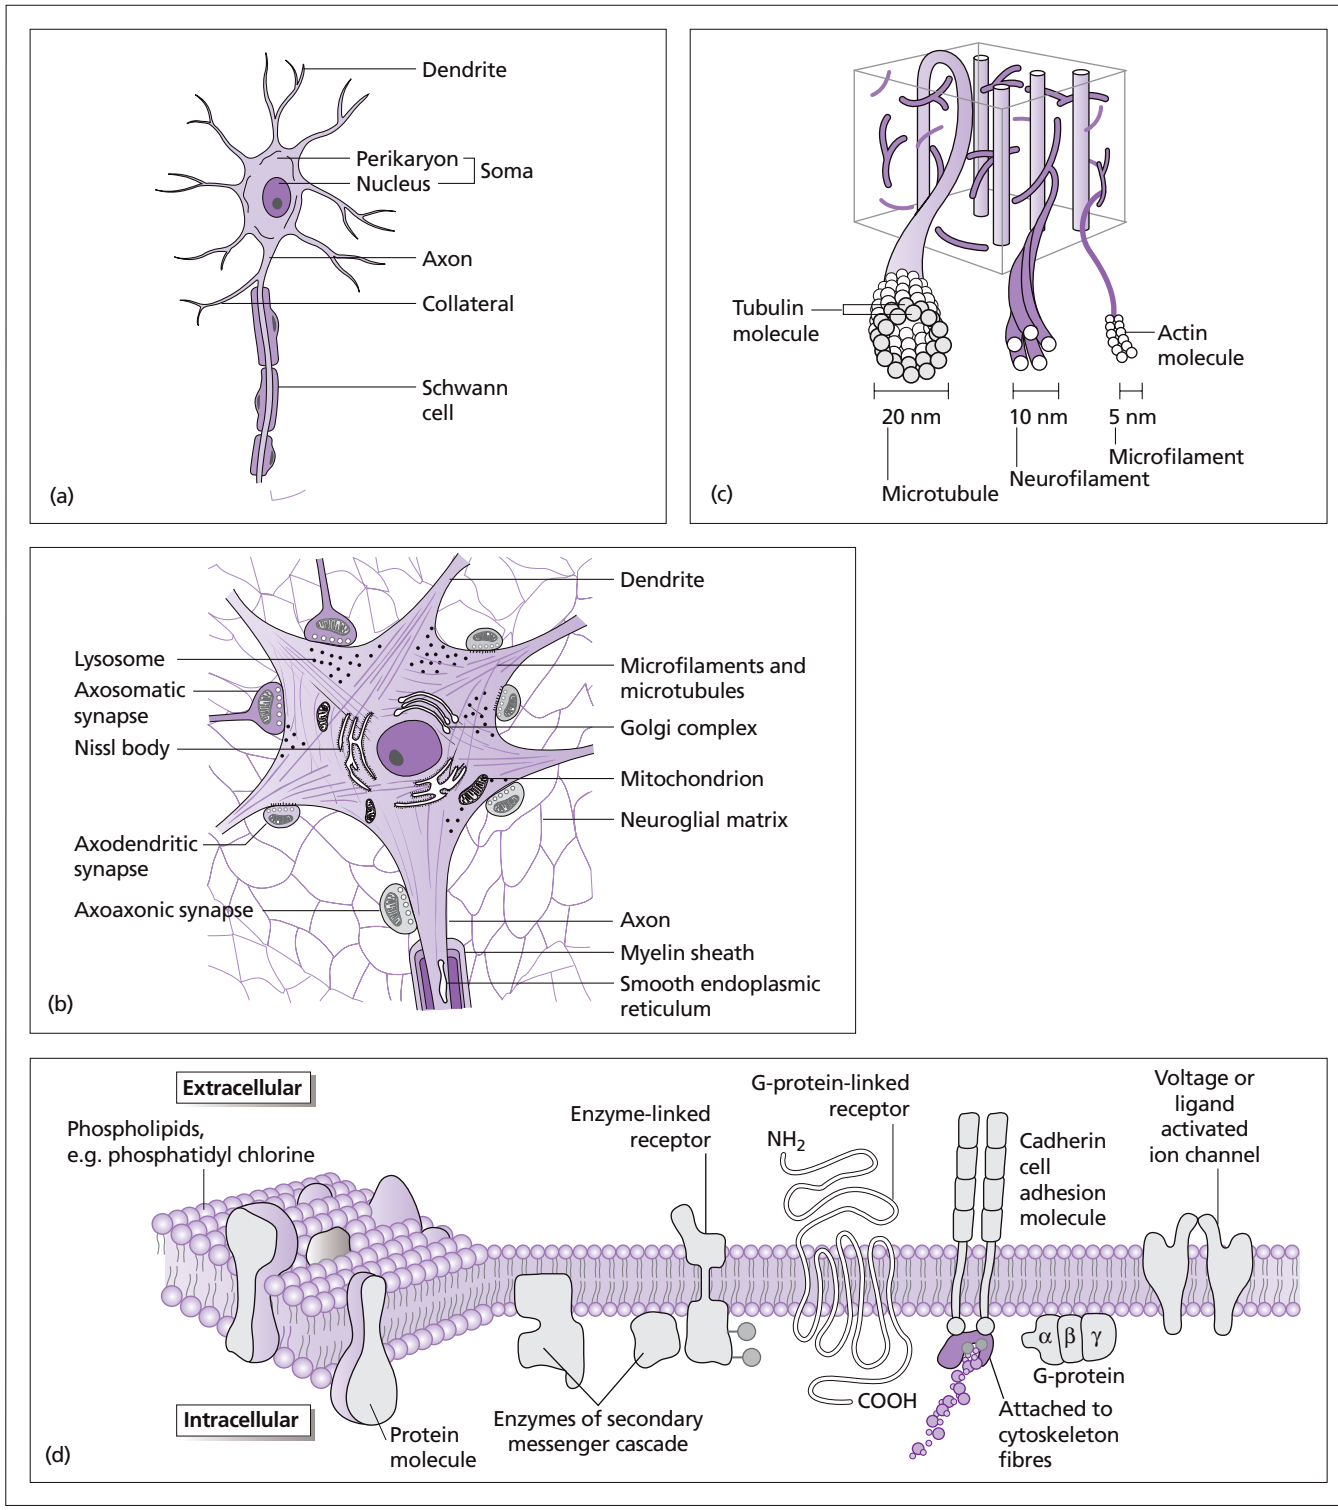

Figure 2.3 Motor neurone. (a) Soma, axon and Schwann cell; (b) ultrastructure; (c) cytoskeleton; (d) neuronal membrane.

β-pleated sheets of aggregates of fibrillar peptides that stain with Congo red and are doubly refractive in polarized light. Aβ amyloid, a 4 kDa peptide cleaved from amyloid precursor protein (APP) is the main constituent of histological amyloid.

APP is one member of a larger family of amyloid precursor-like proteins, APLP1 and APLP2. APP is encoded by a gene in the long arm of chromosome 21; it exists in three main isoforms of 695–770 aminoacids. Neuronal APP is the source of most

extracellular Aβ amyloid in Alzheimer's disease. APP synthesis takes place in the rough endoplasmic reticulum. It is glycosylated in the Golgi apparatus and offered to the surface of the neurone as an integrated membrane protein. A fraction of APP within the plasmalemma remains within the neurone from which are generated various forms of Aβ ($A\beta_{1–40}$, $A\beta_{1–42}$, truncated $A\beta_{17–40}$ peptides). Putative mechanisms of neurotoxicity of Aβ fragments and the genetics of Alzheimer–APP gene mutations (chromosome 21), presenilin 1 and 2 (chromosomes 14 and 1), and allelic forms of ApoE (chromosome 19) are discussed in Chapter 7.

Neurotransmission

Electrical synapses

Between mammalian neurones, electrical synapses, found, for example, in the giant squid, have largely been replaced by chemical transmission systems. Evolutionarily distant electrical synapses still occur at gap junctions, where the synaptic cleft is some 3 nm wide. Connexin protein complexes (see Myelin below) span these narrow gaps, coupling adjacent cells electrotonically with pores some 2 nm in diameter. These pores are large enough for the passage of all major cellular ions and many organic molecules. Electrical transmission is bi-directional, and slow. Gap junctions are seen in mammalian glial cells, epithelial cells, smooth and cardiac muscle cells, and in some nuclei in the brain, e.g. the inferior olivary nucleus. There is evidence that during brain development, transmission via gap junctions between neighbouring neurones coordinates growth and maturation.

Chemical synapses

In a chemical synapse, the synaptic cleft is some 20–50 nm wide and filled with an adherent matrix, ensuring its stability. The presynaptic element, usually an axon terminal, houses mitochondria, synaptic vesicles and larger secretory granules – the dense-core vesicles seen on electron microscopy (EM). Either side of the synaptic cleft specialized areas of accumulated protein comprise membrane differentiations, with an active zone on the presynaptic side opposite the post-synaptic density. The post-synaptic density houses receptors. Receptors make possible intracellular events, a change in membrane potential or secondary chemical events. Receptors are specially sensitive to interaction with neurotransmitters and neuromodulatory agents released by the presynaptic neurone.

Types of CNS synapse

CNS synapses are classified as axodendritic (axon → dendrite), axosomatic (axon → cell body), axo-axonic and dendrodendritic. The terms Gray's Type I and II synapses are also used (Figure 2.4):

- *Gray's Type I*: asymmetrical, post-synaptic membrane differentiation thicker and more complex than presynaptic, usually excitatory;

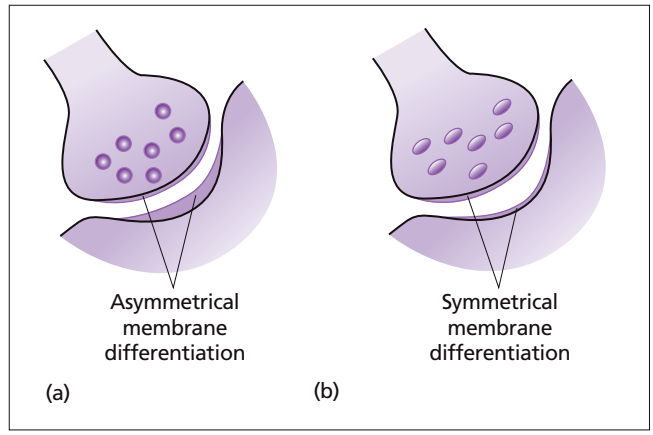

Figure 2.4 Types of synapse. (a) Gray's Type I: asymmetrical, typically excitatory; (b) Gray's Type II: symmetrical, typically inhibitory.

- *Gray's Type II*: symmetrical membrane differentiation, similar thickness, usually inhibitory.

Peripheral nervous system synapses

Synaptic transmission is involved in communication throughout the peripheral nervous system (PNS), including transmission from motor nerves to striated skeletal muscle fibres and from autonomic fibres to smooth and cardiac muscle. The skeletal neuromuscular junction is a specialized cholinergic synapse facilitating fast reliable neuromuscular transmission. Its peripheral site and accessible micro-anatomy has made possible a detailed study of its function in health and disease.

Neuromuscular junction

At the motor end-plate presynaptic active zones are closely aligned to the post-synaptic membrane densely packed with acetylcholine receptor sites (Figure 2.5). Acetylcholine, liberated by an action potential leads to acetylcholine release from synaptic vesicles into the synaptic cleft. Depolarization of the motor end-plate follows.

Neurotransmitters

Effective chemically mediated synaptic transmission requires transmitters to be synthesized, transported, liberated appropriately and metabolized or recycled. Neurotransmitters fall into one of four categories (Table 2.1).

Neurotransmitters are synthesized in several ways. Glutamate and glycine are ubiquitous amino acids, abundant in all cells including neurones. GABA and amine neurotransmitters are made only by neurones that release them, via specific enzymes and precursors. Synthesizing enzymes for both amino acid and amine neurotransmitters are transported to the axon terminal where they direct transmitter synthesis, locally and promptly.

Table 2.1 Principal neurotransmitters.

Amino acids	Amines	Peptides (many others)	Gases
γ-Amino-butyric acid (GABA)	Acetylcholine (ACh)	Cholecystikinin (CCK)	Nitric oxide (NO)
Glutamate (Glu)	Dopamine (DA)	Dynorphin	Carbon monoxide [?] (CO)
Glycine (Gly)	Adrenaline (epinephrine)	Enkephalins (Enk)	
	Noradrenaline (norepinephrine)	*N*-acetyl-aspartyl-glutamate (NAAG)	
	Histamine	Neuropeptide Y	
	Serotonin (5-HT)	Somatostatin	
		Substance P	
		Thyrotropin-releasing hormone (TRH)	
		Vasoactive intestinal peptide (VIP)	

Purines, ATP and adenosine are also neurotransmitters.

Once synthesized, transporter proteins concentrate amino acid and amine transmitters within synaptic vesicles.

Peptide neurotransmitters are strung together by ribosomes within the rough endoplasmic reticulum (ER) and cleaved to form active molecules in the Golgi apparatus (GA). Secretory granules bud off the GA and are carried to the axon terminal by axoplasmic transport.

Amine and amino acid transmitters are stored in and released from synaptic vesicles. Peptide neurotransmitters are stored in and released from secretory granules. These may coexist in the same neurone, to be released under different conditions.

Transmitter release

Neurotransmitter release into the synaptic cleft is triggered by the arrival of an action potential at the axon terminal, where depolarization of the terminal membrane causes voltage-gated calcium channels to open. Vesicles release transmitters by exocytosis at an active zone into the synaptic cleft; the vesicle membrane is recovered by endocytosis.

Secretory granules (dense core vesicles) also release neurotransmitters by exocytosis, but typically not at active zones. Peptide neurotransmitters are not released by every action potential, but typically by high frequency trains of action potentials. Peptide release is typically slow (50 ms), while amino acid and amine release is rapid.

Transmitter-gated ion channels and G-protein-coupled receptors

Neurotransmitter–receptor binding – a key–lock analogy is simple but valuable – alters the shape of receptor protein and hence its function. There are two distinct types of receptor. Transmitter-gated ion channels consist of protein subunits that open an ion pore, and change shape in response to neurotransmitter. For example, the ACh-gated ion channel at the neuromuscular junction, permeable to both Na^+ and K^+, is triggered to produce an excitatory post-synaptic potential (EPSP) in response to ACh. Both ACh and glutamate-gated channels trigger EPSPs when activated, i.e. are excitatory. Glycine-gated and GABA-gated channels, permeable to Cl^- ions and tending to hyperpolarize the resting membrane potential, are inhibitory, triggering inhibitory post-synaptic potentials (IPSPs). Amino-acid and amine neurotransmitters deliver fast synaptic transmission via transmitter-gated ion channels.

G-protein-coupled receptors are involved in a more diverse, slower and longer lasting mechanism of chemical synaptic transmission in response to amino-acid, amine and peptide neurotransmitters. Receptor proteins activate G-proteins that travel along the intracellular face of the post-synaptic membrane. These in turn activate effector proteins – membrane-located G-protein-gated ion channels or enzymes that synthesize second messengers.

Glia

Within the CNS, four types of glial cells support neuronal activity: astrocytes, oligodendrocytes, microglia and ependymal cells. Schwann cells are the neuroglia of the PNS, investing certain peripheral axons with myelin. Neurones are biologically dependent upon glia.

Astrocytes

These are microscopically star-shaped shaggy cells from which protrude several dozen, fine astroglial processes that make intimate contact with neurones (Plate 2.1). Intermediate filaments within astrocyte cytoplasm lend tensile strength to the brain and cord. Glycogen granules within astrocyte cytoplasm provide intermediate energy (glucose) to surrounding neurones. Astrocytes are engaged in recycling glutamate and GABA and scavenging K^+ ions following neurotransmission; they have an essential role in controlling the composition of the extracellular fluid. Glial limiting membranes – from astrocytic processes – cover the pial surface of the brain and with ependyma line the ventricles. Vascular processes of astrocytes are in intimate contact with CNS capillaries. Astrocytes retain a capacity to multiply throughout life, and do so following neuronal injury to form glial scars (gliosis). Neoplastic proliferation leads to astrocytomas (Chapter 20).

Oligodendrocytes (oligodendroglia)

One oligodendrocyte lays the myelin sheaths of 30–40 CNS axons, the inner and outer surfaces forming the spiral sheaths seen as minor and major dense lines on microscopy. The axon is exposed between oligodendroglial segments at each node of Ranvier. Paranodal pockets – collections of cytoplasm – are visible at each end of each myelin lamination (see Schwann cells below).

CNS myelination commences *in utero* and continues for some 20 years in humans. The effect of the ensheathing myelin lamellar spiral is to facilitate both saltatory conduction and axonal integrity. The nature of CNS demyelination, i.e. the breakdown of normal rapid axonal saltatory conduction, seen typically in multiple sclerosis, is discussed in Chapter 10. Neoplastic proliferation leads to oligodendrogliomas (Chapter 20). Within grey matter, modified oligodendroglia are seen as satellite cells – involved in interneuronal ion transfer. Many CNS axons remain unmyelinated – typically small <0.2 μm diameter fibres.

Microglia

Some cells of neuro-epithelial lineage develop into phagocytes, known as microglia. When stimulated by neuronal injury, demyelination or vascular CNS damage, microglia increase in size to become motile scavengers.

Ependyma

Ependyma are ciliated cells that line the cerebral ventricles and central cavity of the cord, together with astrocytic glial limiting membrane. Their function is to define the integrity of the parenchyma–CSF interface. Ependymal cilia are involved in CSF propulsion. Neoplastic proliferation produces ependymomas (Chapter 20).

Schwann cells

A sequence of Schwann cells ensheaths each myelinated axon of a peripheral neurone. Like CNS oligodendroglial sheaths, ultrastructural major and minor dense lines are seen, and paranodal sockets of cytoplasm at the end of each Schwann cell, recognized by Ranvier in the 1880s. The mesaxon is the mesenteric membrane, displaced centrifugally as the spiral layering of the Schwann cell develops (Figure 2.6). One main function of the Schwann cell is to make possible saltatory conduction. Modified Schwann cells, known as satellite cells, are found within posterior root ganglia and those known as teloglia at enclosed peripheral sensory nerve endings.

Myelination is an active lifelong process. Remyelination is the response to peripheral nerve injury. The effects and mechanisms of peripheral nerve demyelination are discussed further in Chapter 9.

Peripheral nerve fibre types

The complex classification (Table 2.2) of fibre types, assembled largely from mammalian data, is seldom used in clinical practice, but it is of distinct value when a particular fibre type is studied. In the cat conduction velocity up to 15 m/s is achieved in unmyelinated fibres and up to about 120 m/s in myelinated fibres; there is much variation between species. Afferent fibres are classified on a numerical system I–IV, while the A–C classification includes mixed nerves. Peripheral nerve ultrastructure is outlined in Figure 2.6; pathological features are discussed in Chapter 9.

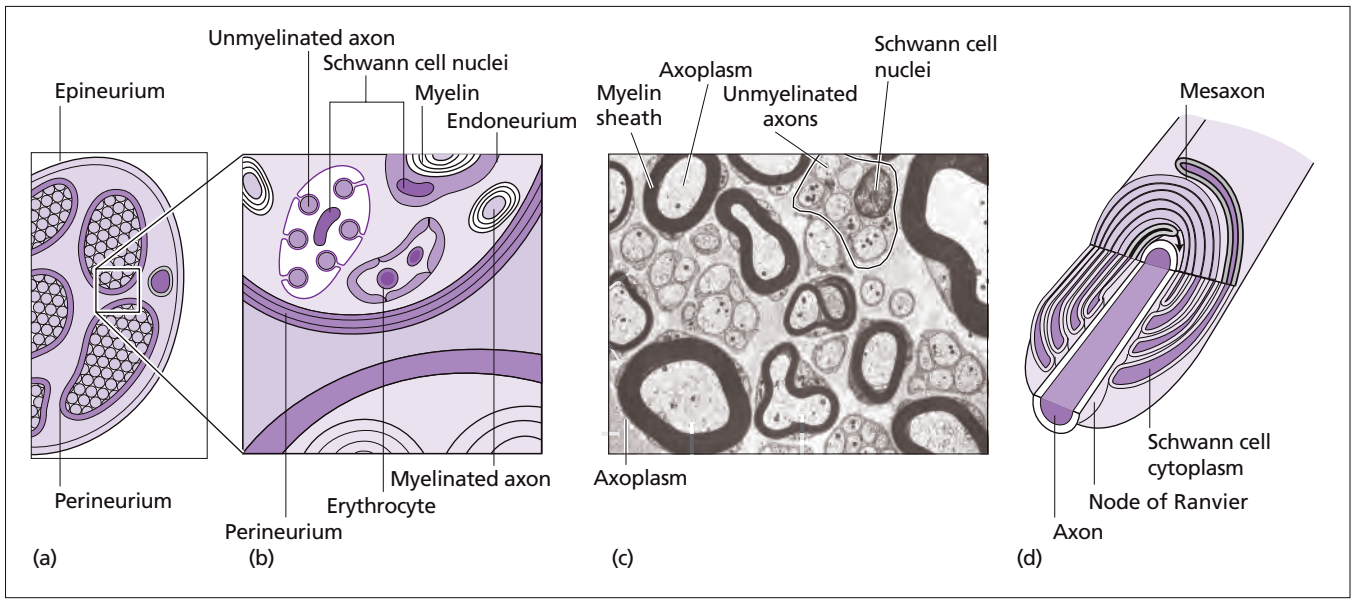

Figure 2.6 Peripheral nerve and Schwann cells. (a) Nerve trunk (transverse section). (b) Detail of (a). (c) Electron micrograph of Schwann cells and axons (courtesy of Professor Sebastian Brandner, Istitute of Neurology). (d) Spiral myelin sheath of Schwann cell.

Table 2.2 Fibre types within peripheral nerves from various mammalian data.

Fibre type	Diameter (μm)	Conduction velocity m/sec	Function
Aα (mixed)	13–22	17–120	α-motor neurones, muscle spindle primary endings, Golgi tendon organs, touch
Aβ (mixed)	8–13	40–70	Touch, muscle spindle secondary endings, joint position
Aγ (mixed)	4–8	15–40	Touch, pressure, γ-motor neurones
Aδ (mixed)	1–4	5–15	Pain, crude touch, pressure, temperature
B (mixed)	1–3	3–14	Preganglionic autonomic
C (mixed)	0.1–1	0.2–3	Pain, touch, pressure, temperature, postganglionic autonomic
Ia (afferent)	12–20	70–120	Muscle spindle primary endings
Ib (afferent)	11–19	66–120	Golgi tendon organs
II (afferent)	5–12	2–50	Touch, muscle spindle secondary endings
III (afferent)	1–5	4–20	Pain, pressure, temperature, crude touch
IV (afferent)	0.1–2	0.2–3	Pain, touch, pressure, temperature

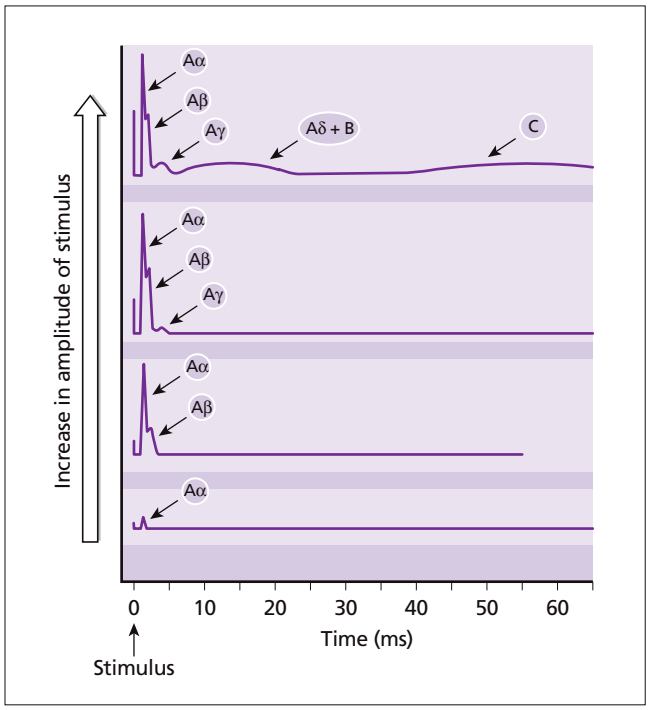

Figure 2.7 Recruitment of nerve fibre types with increasing stimuli. Responses from a typical mixed (motor and sensory) nerve, e.g. sciatic.

Myelin and saltatory conduction

The degree of myelination and fibre diameter are the principal factors determining conduction velocity. The contribution of each nerve fibre type to a compound action potential is outlined above (Figure 2.7). In disease, it will be appreciated that mechanisms that alter nerve function are divided broadly into axonal, i.e. those that affect the axon itself, and demyelinating, where the intregrity of myelin is compromised.

Myelin was a word coined by Virchow, simply for a fatty substance obtained from various tissues; it was adopted by Schwann to describe the 'white substance' of peripheral nerves. CNS myelin provides similar conduction properties, but there are specific neurochemical characteristics that differentiate it from peripheral nerve myelin. Some functional and structural features of peripheral nerve myelin are outlined here:

- Rapid conduction along both peripheral nerves and within the CNS is achieved by saltatory conduction.
- In the myelinated nerve fibre the axonal membrane is adapted at regular sites. Of note, at each node of Ranvier voltage-gated sodium channels are concentrated; these are involved in action potential propagation. Fast and slow potassium channels are involved in membrane repolarisation.
- Depolarization of the axonal membrane at each node of Ranvier is induced by an initial influx of Na^+ ions, leading to a voltage-dependent massive influx of more Na^+ ions, and a new wave of depolarization to be propagated in saltatory fashion (i.e. jumping) to the next node of Ranvier.

Table 2.3 Myelin protein characteristics.

Glycoproteins	Approx %*	Mass (kDa)	Chromosome†
P0	65	28	1
PMP22	4	22	17

Basic proteins			
MBP	10	14–21.5	18
P2	5	14.8	8
Other proteins			
CNP	<0.5	46/48	17
PLP/DM20	<0.5	30/25	X
Cx32	<0.5	32	X

* Of myelin proteins.
† In humans.

- Depolarization is also achieved in unmyelinated fibres, but by sodium channels distributed along the whole length of the axon.

Myelin saves space and conserves energy – to achieve a given mean conduction velocity an unmyelinated axon would require a diameter some 40 times greater than a myelinated one and it would consume 5000 times more energy.

Composition of the myelin sheath

Peripheral myelin is the differentiated plasma membrane of a Schwann cell. It is a lipid-rich, tightly packed spiral surrounding the axon (Figure 2.6) penetrated by cytoplasmic channels (Schmidt–Lanterman incisures).

Gene cloning of the principal myelin proteins and their association with specific neuropathies has thrown light on their role in myelin formation and maintenance. Some basic features of these proteins are outlined in Table 2.3.

Glycoproteins

Protein zero (P0). P0, a major protein of PNS myelin is expressed in all myelinating Schwann cells. The role of the P0 molecule is cell adhesion, promoting and maintaining tight compaction of myelin. One of its domains contributes to the intraperiod line.

Peripheral myelin protein 22 (PMP22). This is probably also concerned with adhesion between lipid and protein molecules. PMP22 is also found widely outside the PNS.

Myelin associated glycoprotein (MAG). MAG is believed to participate in signal transduction during glial differentiation, axonal recognition, adhesion and neurite outgrowth. MAG is located in the Schmidt–Lanterman incisures, paranodal loops at nodes of Ranvier, in external and internal mesaxons and the peri-axonal Schwann cell membrane itself.

Periaxin. The primary localization of this PNS-specific myelin protein is close to the peri-axonal membrane (rather than an integral membrane protein; cf. P0, MAG and PMP22).

Epithelial cadherin (E-cadherin). Cadherins are calcium-dependent adhesion proteins. In Schwann cells, E-cadherin is the major adhesive glycoprotein in non-compacted regions of the myelin sheath.

Basic proteins

Myelin basic proteins

Both CNS and PNS contain peripheral membrane polypeptides known as myelin basic proteins (MBPs). MBPs are believed to participate with P0 in the major dense line and compaction.

Protein P2

P2 is a fatty acid-binding protein, with postulated roles in the assembly, maintenance and remodelling of myelin.

Other proteins

Cyclic nucleotide phosphodiesterases (CNPs) are concentrated in the outer perimeter of the myelin sheath, the outer mesaxon, Schwann cell surface membrane and peri-axonal region.

Proteolipid proteins (PLPs) are localized in compact myelin and thought to have a structural role in the intraperiod line.

Connexin 32 (Cx32) is a component of gap junction channels. It is found at paranodal regions and at Schmidt–Lanterman incisures.

Myelination and axon–Schwann cell interactions

In a developing nerve, a bundle of naked axons is surrounded by a single Schwann cell layer. Schwann cell–axon contact triggers Schwann cell proliferation. The axons become segregated and as maturation continues a one-to-one relationship develops – each Schwann cell investing a single axonal segment. The Schwann cell elongates and rotates as myelin develops about the axis of the axon, to form the nodal spiral structure seen on microscopy.

The precise nature of the axonal signal for myelination remains obscure. However, when Schwann cells receive the signal to myelinate, various transcription factors (Oct-6, Krox-20, Sox-10) participate in gene expression to ensure the particular myelinating phenotype of the individual Schwann cell.

Sensory nerve endings

A single nerve fibre has the same kind of endings on all its terminals, comprising a physiological sensory unit, receiving information from a receptive field. In the skin, each receptive field covers some 5 mm^2 on a finger tip and 2 cm^2 on the upper arm. Sensory units of different modalities frequently supply the same patch of skin (Figures 2.8 and 2.9).

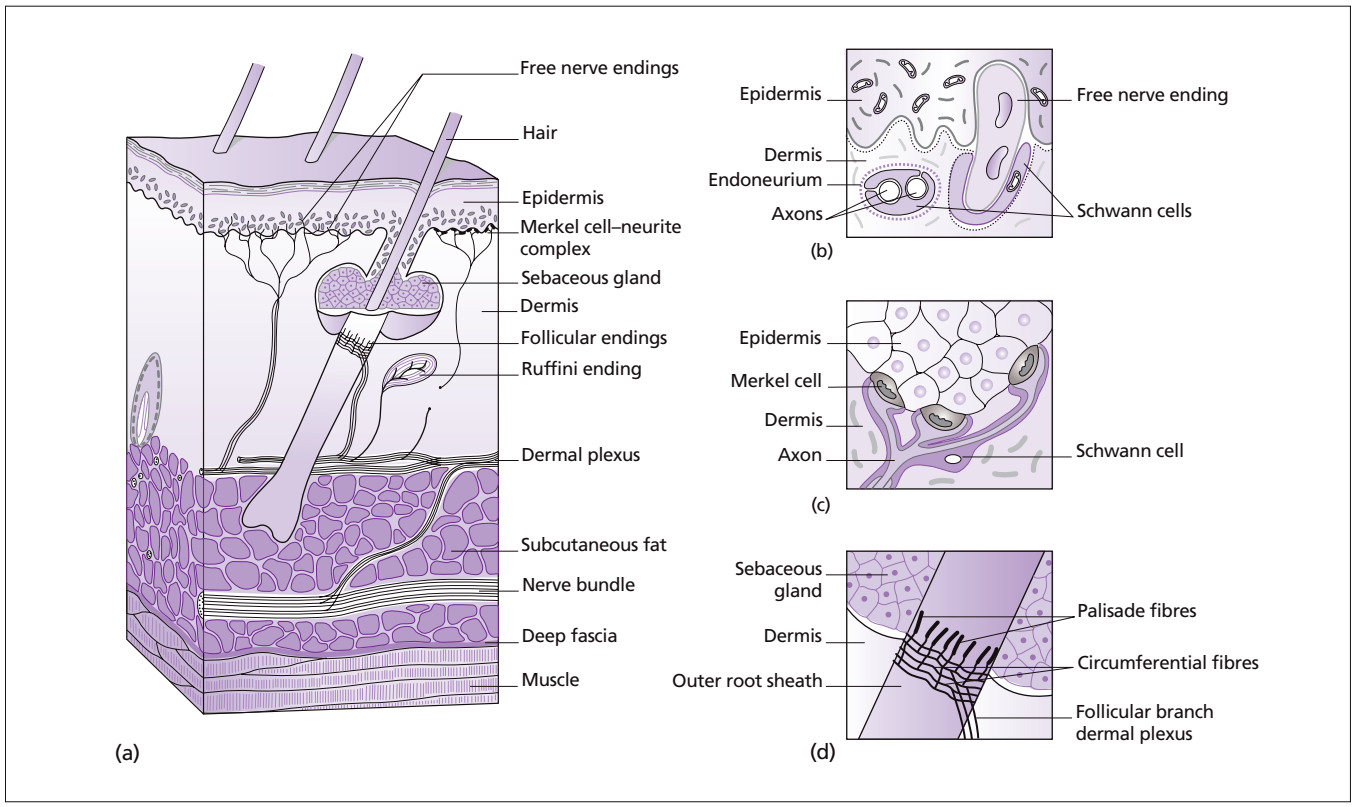

Figure 2.8 Three examples of nerve endings in hairy skin. (a) General arrangement. (b) Free nerve endings. (c) Merkel cell–neurite complex. (d) Palisade and circumferential nerve endings.

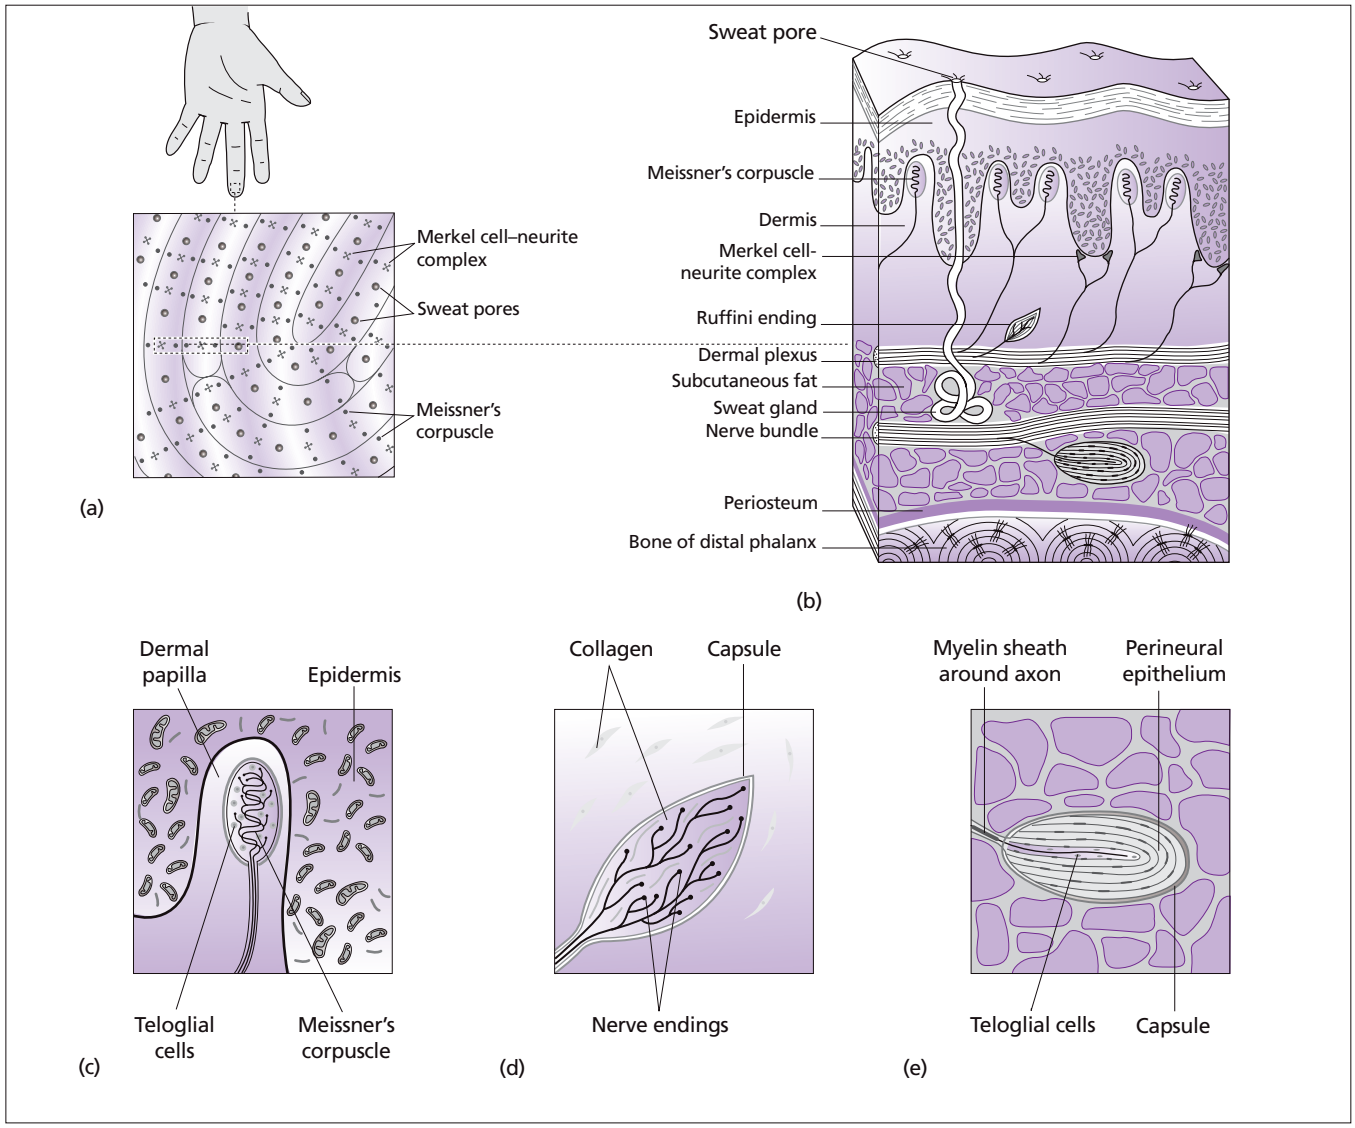

Figure 2.9 Example of nerve endings in non-hairy skin. (a) Finger tip: Meissner's corpuscles and Merkel cell–neurite complexes. (b) Section through skin of finger tip. (c) Meissner's corpuscle. (d) Ruffini ending. (e) Pacinian corpuscle.

Nerve endings are:

- Free;
- Follicular;
- Encapsulated; or
- Merkel–neurite complexes;
- Muscle spindle flower spray and annulospiral endings.

Free nerve endings (naked axons) that have lost both peri-neural and myelin sheaths form a dermal and subepidermal network and innervate joints, ligaments and capsules. Some are thermoreceptors, others nociceptors. Some nociceptors (from finely myelinated Aδ fibres) respond fast to severely painful stimuli (e.g. pinching). Others, from slowly conducting C fibres, are polymodal nociceptors, capable of sensing mechanical stimuli, heat, cold and chemical irritants. The axon reflex is mediated by C fibres.

Follicular nerve endings fire when a hair is being bent. A circumferential rim of nerve terminals surround an inner palisade, adjacent to each follicle.

Meissner's and Pacinian corpuscles and Ruffini endings are encapsulated by an inner membrane of modified Schwann cells (teloglia), a middle peri-neural layer and an outer coat of connective tissue. All are mechanoreceptors:

- Meissner's corpuscles, most numerous on finger pads, detect delicate changes in texture (to 20 μm in elevation) and are rapidly adapting.
- Pacinian corpuscles are subcutaneous, 2–3 mm in diameter and are plentiful (approximately 300) in each hand and foot and also embedded in the periosteum in the limbs. They are exquisitely sensitive to vibration, object detection and release.

• Ruffini endings in the skin respond to shearing stress (skin movement).

Merkel–neurite complexes are expanded nerve terminals applied to Merkel cells (tactile menisci) in the skin basal epithelium. They respond to sustained pressure. These mechanoreceptor afferents are separated into four types using the Johansson–Vallbo classification. The pathophysiology of individual types of nerve terminal is in its infancy, but presumably changes within these sensitive structures cause unpleasant sensory symptoms.

Muscle spindle motor supply, annulospiral and flower spray endings

Primary Type Ia sensory fibres with annulospiral endings surround each intrafusal muscle fibre. Secondary Type II fibres (flower spray endings) lie beside each annulospiral ending. Fusimotor fibres are Aγ calibre and innervate the contractile intrafusal fibres of the muscle spindle, in contrast to the Aα extrafusal fibres of skeletal muscle (Figure 2.10).

Golgi tendon organs

Type Ib afferents form an entwining network around tendons. Golgi tendon organs signal force of contraction and effect negative feedback on agonist–antagonist muscle groups. An important function is to restrict joint oscillation.

THE WORKING BRAIN

Introduction

Neurones and glia are the structural and functional units of all parts of the nervous system. The remainder of this chapter outlines how these different parts operate, their structure and the connections between them. Some basic understanding of neuroanatomy is assumed, and is readily available from reference texts.

The approach here is to take a typical activity, to trace its origins, describe its features and outline neuro-anatomical pathways and control systems. Movement is discussed first, because it has a pivotal role in clinical assessment.

Mechanisms of movement

Skilled, coordinated, fast and appropriate movement is so highly developed in humans that almost all parts of the nervous system are involved – alertness, cognition, volition, mood, all sensory stimuli – vision, hearing, touch, pain, position sense, smell and the motor cortex, with the associated cortical areas, the spinal reflex arc, cerebellum, basal ganglia, motor nerves, neuromuscular junction and muscles themselves. The essential objects of

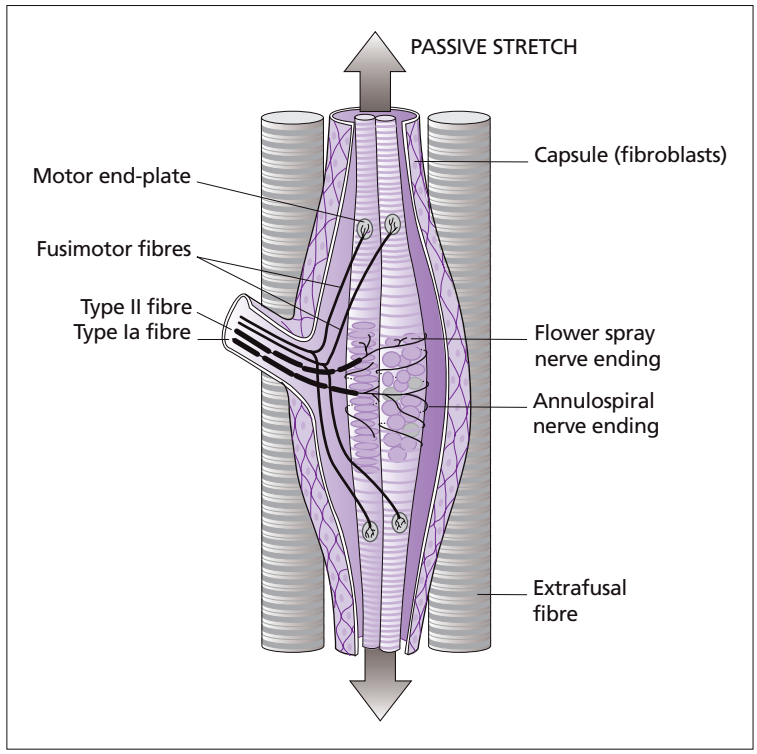

Figure 2.10 The muscle spindle.

movement are feeding, survival and, where possible, reproduction. In humans, movement assumed signal importance in the development and progressive use of tools to an extent that far exceeds the capacity of any non-human species.

Three central systems of motor control

All human movement is the product of activity in a highly interconnected motor network. All of the major motor pathways that generate eye, head, body and limb movements are under the control of three major systems:

- Cortical;
- Striatal (basal ganglia); and
- Cerebellar.

The major output from this network controlling limb movements is the corticospinal tract. This pathway originates from motor, somatosensory and limbic areas of the cortex; because all its fibres pass through the medullary pyramids at brainstem level, it is often referred to as the pyramidal tract. The tract is particularly well-developed in humans. Clinically, interruption of these fibres is recognized by abnormal signs of voluntary movement – weakness and poverty of movement, and abnormal reflex activity. The clinical signs associated with damage to the basal ganglia and cerebellum are fundamentally different.

The three systems referred to above are involved in two major motor loops: the cortex–basal ganglia–cortex loop and the cortex–cerebellum–cortex loop. The cortico-striatal and cortico-pontine fibres that provide the respective cortical projections into these two loops are very extensive. For the neurologist, the distinctive signs of damage to the basal ganglia are usually referred to as 'extrapyramidal' to distinguish them from the clinical signs of 'pyramidal' damage. However, while both the cerebellum and the basal ganglia influence eye and head movement mainly through their outputs to brainstem structures, it is the cortico-spinal system that provides the major output conduit for the activity generated in these two major motor loops that lead to limb movements. Therefore, it is important to distinguish 'extrapyramidal' signs or syndromes, a universally useful clinical term, but to be wary of the term 'extrapyramidal pathways'. This is because the latter implies activity in non-corticospinal pathways, i.e. those involving the basal ganglia. This cannot be reconciled with the fact that the main basal ganglia output pathway influencing movement is via its return projections via thalamus to cortex, and thence through the corticospinal 'pyramidal', tract.

The corticospinal (pyramidal) system originates in the cortex and delivers information to all regions of the spinal cord including anterior horn cells, (spinal motor neurones). Defective function is recognized from the distinct abnormal pattern of skilled voluntary movement, spasticity and reflex change.

The striatal (basal ganglia) system facilitates fast fluid movement via servo loops between cortex and basal ganglia. To the clinician, slowness (bradykinesia), stiffness (rigidity), rest tremor and various disorders of movement (dyskinesias) are the hallmarks of dysfunction in this system, often referred to as 'extrapyramidal' signs or syndromes.

The cerebellum and its connections have a role in the coordination of smooth, programmed movement and balance. Ataxia (limb and/or truncal) and action tremor are the cardinal features.

Corticospinal (pyramidal) system

Penfield's human cortical electrical stimulation experiments in the 1930s explored and mapped areas 4 (primary motor cortex,

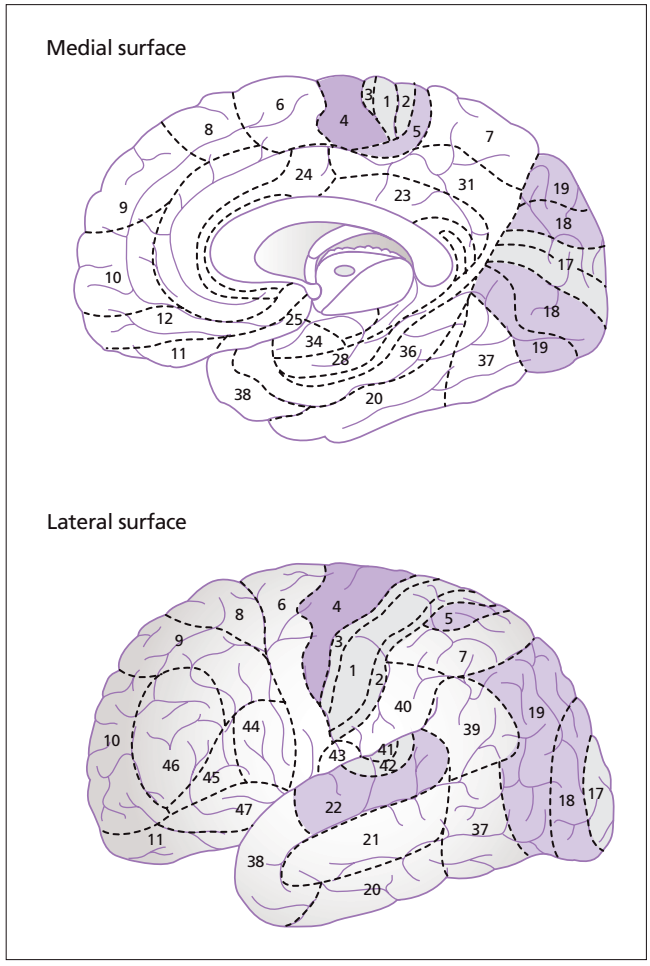

Figure 2.11 Cortical areas. (After Brodmann 1906.)

Principal motor areas

17	Primary visual cortex
18,19	Visual association cortex
41,42	Primary auditory cortex (buried from view, on superior temporal gyrus)
22	Auditory association cortex

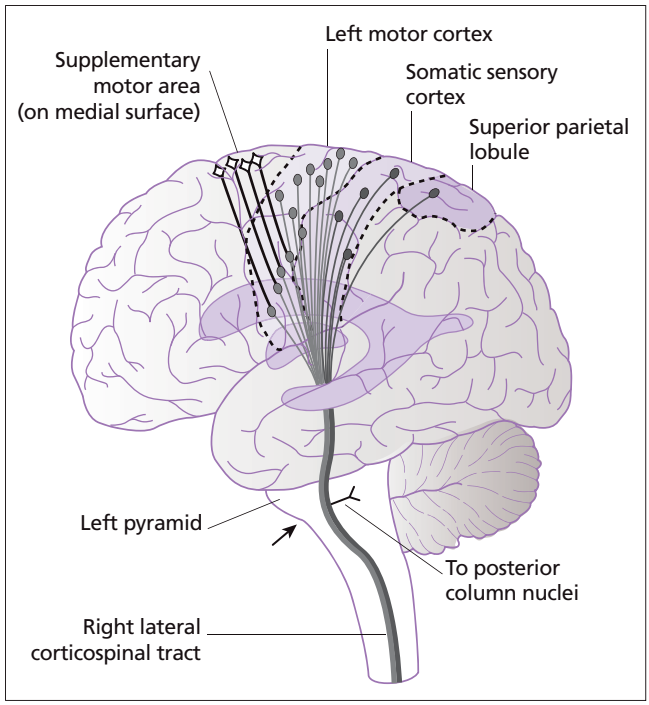

Figure 2.12 Cortical contributions to pyramidal tract.

M1) and 6 (premotor area + supplementary motor area; PMA + SMA), developing the earlier work of Fritsch and Hitzig in the 1870s and individual observations by Ferrier, Sherrington, Campbell and others in the late 19th and early 20th century. Brodmann's cortical areas are shown in Figure 2.11 and the cortical contribution to the corticospinal pathway in Figure 2.12, noting the contributions from primary somatosensory cortical areas 1, 2 and 3 – and all cortical sensory areas concerned with movement towards or away from an object. It is likely that a significant corticospinal projection also arises from the cingulate gyrus (areas 23 and 24).

Each corticospinal tract is made up of around 1.1×10^6 fibres and is one of the longer and most compact fibre systems in the human CNS. Some two-thirds of these axons originate from cortical areas 4 and 6, where the cell bodies are located in lamina V. Most of the remainder derive from parietal areas, including the somato-sensory cortex, posterior parietal cortex and area SII. The course of 90% of the fibres through the internal capsule, cerebral peduncle, pons and medulla is shown in Figure 2.13.

Pyramidal describes the roughly triangular cross-section of this tract in the medulla (see below), but has come to be used functionally (and interchangeably) with corticospinal to describe the pattern of physical signs with disease of this pathway. In fact, probably around 75% of the pyramid fibres continue into the spinal cord. After decussation, the fibres congregate within the cord in the lateral corticospinal tract and terminate widely along the whole length of the spinal cord, and in all layers of the spinal grey matter, including synapses on motor neurones in the

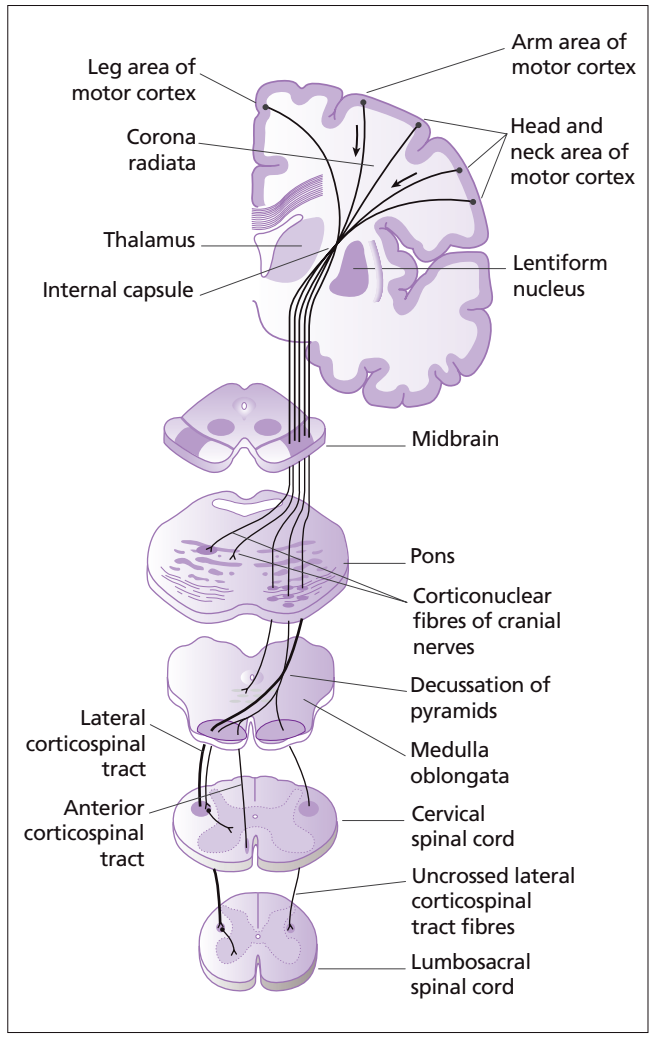

Figure 2.13 Corticospinal (pyramidal) motor pathways.

anterior horn. Of corticospinal fibres, 10% remain uncrossed, their neurones of origin outlining an ipsilateral somatotopic map, a point of little apparent clinical significance.

The comparative anatomy of the motor pathways shows us that in humans the corticospinal system is the major descending pathway and has to some extent replaced other descending systems. For example, the rubrospinal tract, which arises from the magnocellular divisions of the red nucleus, is probably vestigial in humans.

Movement direction and movement synergy

Neurones in area 4 are known to show patterns of activity that implicate them in the control of key parameters of movement, such as force, direction and timing of movements. The motor areas probably function to activate particular synergies of muscular action to bring about highly specific movements such as particular types of grasp. These synergies depend in part on the pattern of innervation by the direct cortico-motoneuronal

projections from primary motor cortex to specific groups of motor nuclei at spinal level.

Plasticity

In all primates, small cortical lesions cause initial paralysis (or slowing, depending on lesion size) of a limb, or part of a limb, followed by recovery within hours or days. This recovery is explained by changes in neighbouring cortical cell columns, i.e. plasticity. In the cord, local interneuronal mechanisms underpin movement synergies that function to provide individual skilled movements under the influence of different cortical signals. At a clinical level, following a hemiparesis, the early return of some fine finger or toe movement is a pointer to good recovery of function – a signal that a plastic process of compensation for the damage is under way.

Afferents to the primary motor cortex

The primary motor cortex does not act in isolation as the generator of fast skilled movement. Substantial afferent connections arrive from:

1 The opposite cortex via the corpus callosum. Most prominent are the dense links between cell columns controlling axial mucles, while the least dense are between distal parts of the opposite limbs. This might be expected – head and trunk posture cannot be under unilateral control, whereas the opposite is the case for fine hand movement.

2 Somato-sensory cortex. Cutaneous cell columns (areas 1, 2 and 3b) pass forward via short association fibres deep to the central sulcus. Typically, the more complex the subserved movement function (e.g. hand movements), the denser the connections. Proprioceptive cell columns in area 3a receive afferents from muscle spindles and synapse via short association fibres with area 4.

3 Cerebellum, via contralateral dentate nucleus and motor thalamus. Cerebellar impulses determine synergy and timing of cortical neuronal discharges (see below). The cerebellum receives a dense multimodal input of all sensory modalities, including vision.

4 Supplementary motor area (SMA, area 6) on medial surface of hemisphere. This part of area 6 is especially involved in motor planning, motor memory, intention and responds to internal cues. For example, the SMA is activated via the frontal lobe when a movement is intended. A major SMA function is programming motor sequences already within motor memory via a loop through the basal ganglia and projecting to area 4. Unilateral damage to SMA causes contralateral akinesia.

5 Premotor cortex (PMC, area 6 on lateral aspect of hemisphere). The PMC, some six times the size of area 4, is in general responsive to external cues, being active (on functional magnetic resonance imaging [fMRI]) when motor sequences follow visual or sensory cues, e.g. reaching for an object in view or feeling the shape of an object. The lateral PMC represents one of the major pathways through which vision is able to control fine movements.

Basal ganglia and 'extrapyramidal' movement disorders

The term basal ganglia describes neighbouring areas within the deep forebrain and midbrain involved in the control of movement. In practical terms this includes:

- The striatum (caudate nucleus, putamen of lentiform nucleus, nucleus accumbens);
- The pallidum (globus pallidus of lentiform nucleus) – a lateral and medial segment. The medial segment has as an anatomical extension, the pars reticularis of the substantia nigra;
- The subthalamic nucleus; and
- The pars compacta of the substantia nigra.

The complex circuitry between these anatomically recognizable structures is outlined here. The subject is not made easy by two factors: the difficulty distinguishing clear differences in ultrastructure between different parts of the basal ganglia – striatal neurones appear randomly scattered – and difficulty recognizing somatotopic differentiation in the majority of these structures, although such organization into body maps in the basal ganglia certainly exists. In many instances (cf. the cerebral cortex) individual diseases do not appear to affect one discrete area within this region, and thus localization of function to a particular zone is not immediately recognizable. These factors led in part to a paucity of interest in very evident disorders of movement in classical early 20th century neurology. Functional stereotactic surgery, deep brain stimulation, fMRI and advances in knowledge of the functions of neurotransmitters within the basal ganglia have brought a different focus to this field.

Extrapyramidal, the term coined by Kinnier Wilson in the 1920s, implies a loose but valuable recognition of clinical features of disorders of these structures. The term really implies no more than a clinical pointer towards a movement disorder distinct from one with hallmarks of corticospinal (pyramidal) or cerebellar disease. As noted above, care should be used to distinguish the clinically useful term 'extrapyramidal syndrome' from its use to describe a 'system' or 'pathway'. Usually, 'extrapyramidal syndrome' describes slowing and stiffness seen typically in idiopathic Parkinson's disease and more generally in the parkinsonism of other akinetic-rigid syndromes. However, extrapyramidal is also used (less frequently) to include many disorders of movement: tremor, chorea, hemiballismus or dystonia.

Basic circuits within the basal ganglia

The clinical focus is upon the complex motor loops, with dysfunction typified by Parkinson's disease.

Motor loops

There are a number of different neuronal servo-loops commencing and ending in the motor and frontal areas of the cerebral cortex. They all involve cortical projections to the striatum (putamen + caudate nucleus) and return projections to the cortex via different subnucleal divisions of the thalamus.

Within each loop there exist two interrelated motor pathways: direct and indirect pathways.

Transmission through the loops is controlled by activity in the nigro-striatal pathway, from the pars compacta of the substantia nigra to the lateral globus pallidus, where axons make two principal types of synapse, on excitatory D_1 (dopaminergic, direct pathway) and inhibitory D_2 (indirect pathway) receptors. Matters have become more complex with the discovery of several more dopaminergic receptor D subtypes.

In normal subjects, the nigro-striatal tract is tonically active, selecting preferentially the excitatory, direct pathway and leading, via the loop back to the cortex, to activation of the SMA before a movement. This early activation of midline cortex is thought to underlie the electrical readiness potential (Bereitschaftspotential). Other projections to the motor cortex interact with those from the cerebellum in modulating motor cortex outputs to the spinal cord.

Activation of the cortex (i.e. the intention to move):
- Stimulates (glutaminergic) putamen neurones (tonically facilitated by niagro-striatal D_1 input); which
- Inhibit (GABAergic) medial globus pallidus neurones; which
- Release (disinhibit) ventral lateral nucleus (VL) neurones; which
- Activate SMA.

The sequences can be seen in Figure 2.14.

The indirect pathway engages the subthalamic nucleus via:
- Striato-nigral fibres that inhibit putamen neurones; which
- Inhibit the lateral globus pallidus (GPL); and
- Act on the subthalamic nucleus (STN).

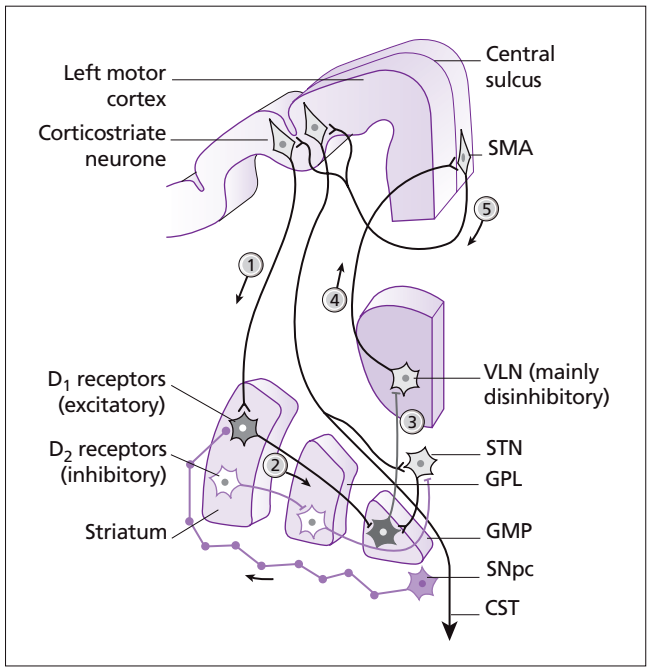

Figure 2.14 Striatal motor loops. CST, cortico-spinal tract; GPL, globus pallidus (lateral); GPM, globus pallidum (medial); SMA, supplementary motor area; SNpc, substantia nigra pars compacta; VLN, ventro-lateral nucleus (thalamus).

The subthalamic nucleus acts on the medial pallidum (somatotopically) to suppress unwanted movement. Destruction of the STN results in uncontrollable movements (see Hemiballismus, Chapter 5).

Normal functions of the motor loop

The basal ganglia do not initiate movement but they are active when action is generated by specific cell assemblies in the motor cortex:
- Scaling strength of muscle contraction and in collaboration with SMA;
- Programming appropriate movement sequences and suppressing others; and
- Controlling speed of movement

The putamen is believed to act as a store of memorized, acquired motor programmes, with an ability to sequence appropriately movements intended and pass information to the SMA.

Other basal ganglia circuits

- Cognitive loop: motor (volitional) intention;
- Limbic loop: emotional correlates of movement;
- Oculomotor loop: voluntary saccadic movements.

Cognitive loop

A large projection of fibres from the prefrontal cortex reaches the head of the caudate nucleus. Increased activity in the head of the caudate, and anterior putamen, globus pallidus and ventral anterior (VA) thalamic nucleus, occurs when new movements are performed by the opposite hand, suggesting a role in motor learning. The VA nucleus projects to:
- The premotor cortex in an 'open cognitive loop';
- The prefrontal cortex in a 'closed cognitive loop'.

These cortical connexions of the caudate point to a role of this loop in forward planning of complex motor intentions. As a corollary, when a motor task has become automatic, i.e. entirely learnt, the motor loop of the basal ganglia takes over.

Patients with Parkinson's disease have particular problems with new fiddly movements; they are unable to sequence and initiate them. Exceptional activity in this cognitive loop perhaps explains also rare temporary release phenomena: immobile patients with severe Parkinson's respond dramatically to great emotional stimulation – 'they can run down the fire escape'.

Limbic loop

This describes a loop from:
- Inferior prefrontal cortex; via
- Nucleus accumbens;
- Ventral pallidum;
- Medio-dorsal nucleus of thalamus; to
- Inferior frontal cortex.

This pathway is believed to be concerned with the visible expression of emotion – portrayed in facial expression (e.g. smiling), or in more general postures with emotional content such as submission, dominance or aggression.

The simian posture and facial masking of Parkinson's disease can be explained by diminution of activity in this richly dopaminergic pathway – features reversed, at least in part, by levodopa.

Oculomotor loop

This loop runs from:

- Frontal eye field and posterior parietal cortex (area 7); to
- Caudate nucleus; to
- Pars reticularis of substantia nigra (SNpr); to
- VA nucleus of thalamus; to
- Frontal eye field and prefrontal cortex.

An inhibitory GABAergic projection reaches the superior colliculus from SNpr. These inhibitory synapses are on neurones controlling saccades. Ocular fixation is accompanied by repetitive impulses (tonic activity) in SNpr. In other words, the eyes are held in one position of fixation by this tonic activity.

When a deliberate saccade takes place ('I want to look right'), the superior colliculus is disinhibited by the activated oculomotor loop. The superior colliculus neurones discharge, reinforcing the direct motor loop and facilitating rapid (almost instantaneous, 70–100 km/hour) conjugate eye movement. Put another way, the sequence is:

- Release of superior colliculus neurones;
- Gaze flicks to new target;
- SNpr resumes tonic activity;
- Gaze vigilance returns.

Slow eye movement (oculomotor hypokinesia) is evident in Parkinson's disease, although it is rarely a clinical issue because the accompanying axial movement (e.g. head turning) is slow. Ocular hypokinesia is explained by loss of dopamine in SNpr, and faulty disinhibition of superior colliculus neurones.

Cerebellum

To the clinician, cerebellar disease is recognized by the physical signs of action tremor, nystagmus, truncal and/or gait ataxia and scanning speech (Chapter 16).

Phylogenetically, functions of the cerebellum in fish were closely allied to the lateral line organs (fish vestibular system) – controlling the fish's horizontal and vertical posture in water. In quadrupeds, connections with the spinal cord became prominent, facilitating improvement in gait, running and turning. In bipeds, with emerging lateralized skills (e.g. hand) rich linkages developed between cerebellar lobes and cerebral cortex. These newer cerebellar structures became intimately concerned with coordination of ipsilateral limbs in addition to the vestibular and spinal phylogenetic heritage of this part of the hind brain. These aspects are illustrated in Figure 2.15.

There are three main zones of the cerebellum, each of which send its output to a distinct deep cerebellar nucleus:

1 Vestibulo-cerebellum is the central strip (vermis + fastigial nucleus), with primarily sensory afferents from the vestibular complex. Output: fastigial nucleus and brainstem vestibular nuclei.

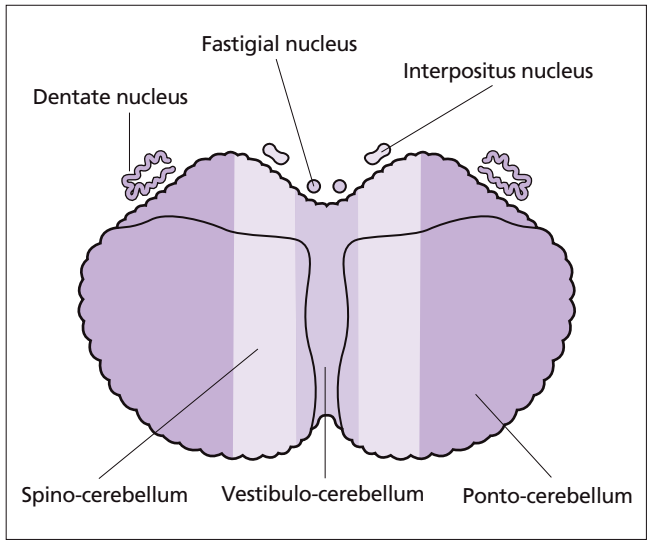

Figure 2.15 Zones of the cerebellum.

2 Spino-cerebellum occupies regions adjacent to the vermis, with major sensory input from the spinal cord. Output: interpositus nucleus.

3 Ponto-cerebellum (neo-cerebellum – lateral lobes) receives a massive neuronal input from the contralateral pontine nuclei, the main input of which comes from the cerebral cortex. Output: dentate nucleus. The neo-cerebellum is most developed and largest in humans.

Cellular anatomy

The cerebellar cortex has an outer molecular layer, an inner granular layer, with the piriform layer between the two (Figure 2.16). The granular layer consists of billions of small 6–8 μm diameter neurones (granule cells) with short dendrites. These dendrites receive excitatory synapses from mossy fibres that run to the cerebellar cortex, giving off collateral branches to the deep cerebellar nuclei. Granule cell axons pass to the outer molecular layer, dividing to form parallel fibres, running parallel to the cerebellar folia, to make excitatory synaptic contacts with dendrites of Purkinje cells whose cell bodies lie in the piriform layer.

Purkinje cells, large neurones with extensive dendritic trees, are interwoven by numerous parallel fibres. Each parallel fibre makes successive single (one-per-cell) synapses with 300–500 individual Purkinje cells. The action of each parallel fibre is excitatory – although many thousand parallel fibres need to act simultaneously to depolarize a single Purkinje cell.

From the contralateral inferior olivary nucleus, each Purkinje cell dendritic tree receives a single climbing fibre. This fibre makes synaptic contact with thousands of dendritic spines of a single Purkinje cell. A single action potential in a climbing fibre triggers a short burst of action potentials from each Purkinje cell, which then becomes temporarily unresponsive to the effects of parallel fibre inputs. Purkinje cell axons leave the cerebellar cortex, the only efferent axons to do so, to reach the deep

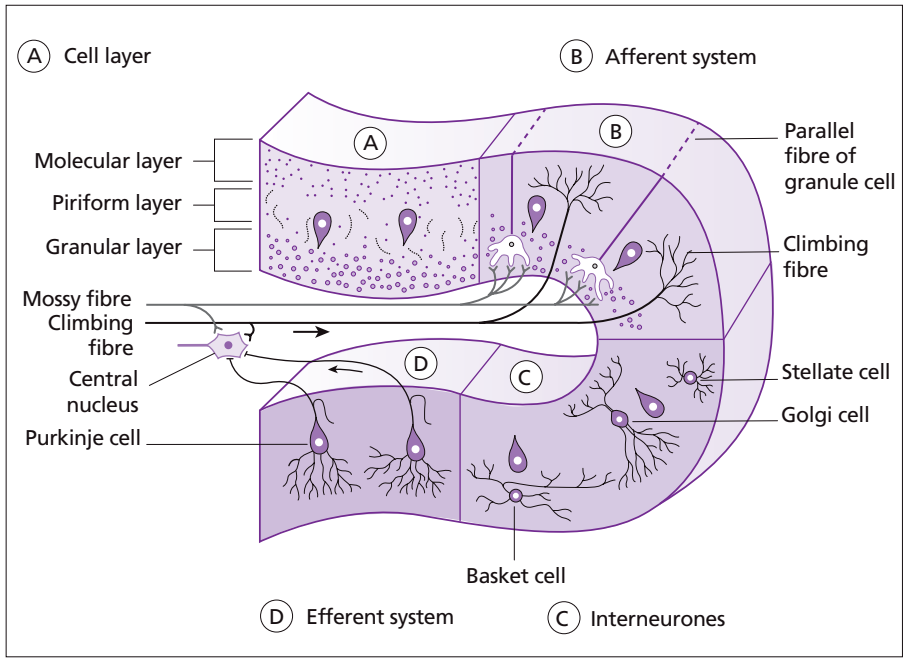

Figure 2.16 Cerebellar cortex cell systems.

cerebellar nuclei, upon which they exert a uniformly inhibitory action.

The molecular layer contains three further, largely inhibitory cell types: basket cells, stellate cells and Golgi cells.

Somatotopic representation in the cerebellum

Positron emission tomography (PET) and fMRI have largely confirmed the somatotopic representation deduced from animal studies (Figure 2.17). Corresponding fMRI activity for hand movement in humans is shown in Plate 2.2.

Afferent cerebellar pathways

The scope and complexity of these pathways is summarized here:

- From muscles and skin (trunk and limbs), information from the posterior spino-cerebellar and cuneo-cerebellar (cuneiform nucleus) tracts enter via each ipsilateral inferior cerebellar peduncle. The massive similar trigeminal input (from the head) enters via all three peduncles.
- Afferents monitoring activity in spinal reflex circuits, in the anterior spino-cerebellar tracts loop into each superior peduncle via the pons.
- Vestibular, auditory and visual pathways make up the tecto-cerebellar tracts to enter the ipsilateral superior peduncle.
- The ponto-cerebellar tract, mediating massive mossy fibre input from the cerebral cortex, enters the contralateral middle cerebellar peduncle.
- The olivo-cerebellar tract enters the contralateral inferior peduncle (climbing fibre input).

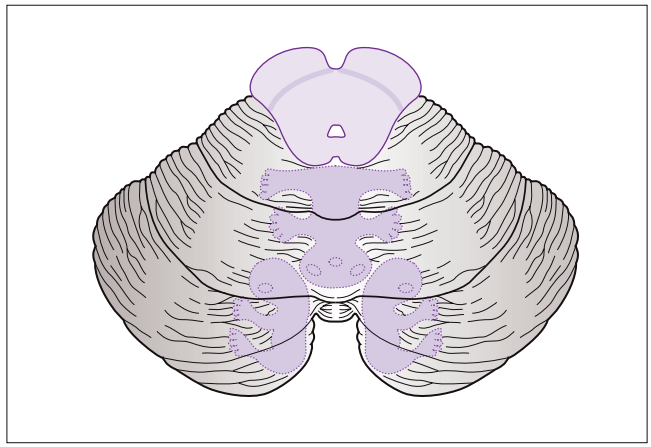

Figure 2.17 Somatotopic cerebellar mapping (based on animal data).

- Reticulo-cerebellar tracts enter via the inferior peduncles.
- Aminergic fibres (serotonin and noradrenaline) enter all three cerebellar peduncles from the brainstem – excitatory transmission in mossy fibres and climbing fibre terminals.

Olivo-cerebellar tract, learning, the red nucleus and novelty detection

The inferior and accessory olivary nuclei receive fibres from the ipsilateral sensorimotor (cerebral) cortex. These project as climbing fibres to each contralateral cerebellar cortex in a somatotopic order (accessory nuclei to an anterior cerebellar map, principal

nuclei to posterior). When primates are trained to carry out a repetitive motor activity, Purkinje cells show increased simple spike activity – an indication of increased mossy fibre and parallel fibre input. If the task is interrupted (e.g. if activity is physically obstructed), bursts of Purkinje cell complex spikes appear, caused by climbing fibre input. At least, they do so initially. If the obstruction is sustained, these complex spike bursts diminish and eventually disappear. This is one example of the role of the cerebellum in learned movement, for which there is now much evidence both in animals and in humans. The system acquires, or adapts to new motor activity. Additional connections to the olivary nuclei come from the visual association cortex and the spino-olivary tract.

Finally, the red nucleus receives collaterals from (cerebral) cortical fibres descending to the olive, and from cerebellar efferents en route to the thalamus. The principal output from the red nucleus is inhibitory to the ipsilateral olive. There is evidence to suggest that if an imbalance occurs between movement intended (cerebral cortex) and movement organized/learned (cerebellum), the red nucleus modulates cell groups within the olive to achieve harmony, and it detects novelty in an organized action. The coarse tremor seen in lesions of the red nucleus can be thought of as a breakdown of this harmonic, over-correcting each part of a movement.

Efferent pathways

The vestibulo-cerebellum projects to the vestibular system, the spino-cerebellum to the cord and the neo-cerebellum to the red nucleus, thalamus and motor cortex.

From each fastigial nucleus in the vestibulo-cerebellum, via the inferior peduncles, axons reach both (right and left) vestibular nuclei (Figure 2.18). Output from the medial and superior vestibular nuclei passes to the medial longitudinal fasciculus, and thus control conjugate lateral gaze. From lateral vestibular nuclei (of Dieter), efferent fibres pass to the vestibulo-spinal tracts; these help control balance and axial stability. Some fastigial outputs pass directly to the spinal cord, for control of head and neck movements.

From each nucleus interpositus (spino-cerebellum) axons travel in the superior peduncle, ending largely in the contralateral reticular formation (posture, gait) and red nucleus (motor learning).

In the neo-cerebellum, outflow from the dentate nucleus makes up the majority of the superior peduncle (dentato-

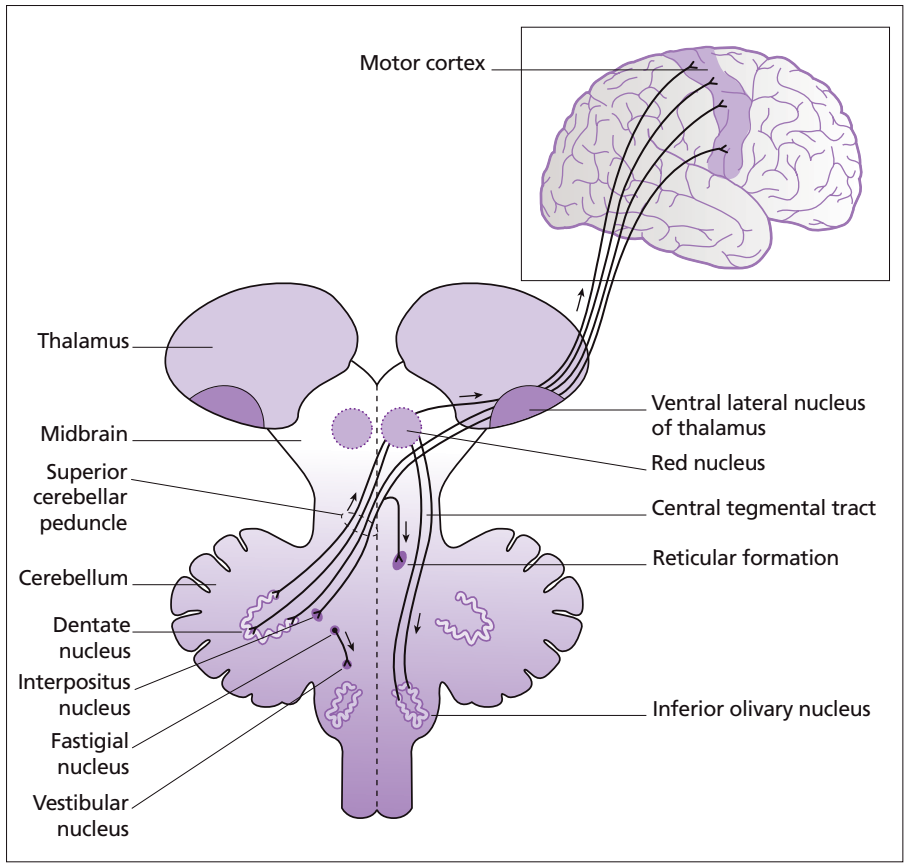

Figure 2.18 Cerebellar efferents.

rubro-thalamic tract), and crosses in the brainstem before reaching both red nucleus and motor thalamus. The latter sends onward projections to the cortex.

Clinical correlates

In contrast to the complexity of cerebellar micro-anatomy, physical signs of cerebellar disease are distinct, relatively straightforward to recognize but often hard to attribute to individual pathways (Chapters 3 and 16). A lesion of one lateral lobe, e.g. tumour or infarction, causes rebound and past pointing of the outstretched upper limb – a clinical correlate of the effect of obstruction to a programmed activity described above. Vermis lesions, e.g. medulloblastoma, affect primarily vestibular connexions. Truncal ataxia is often an early sign.

Anterior cerebellar lobe lesions (often bilateral, and typically caused by alcohol) cause gait ataxia, often with pronounced titubation. In chronic alcohol damage, substantial loss of all major neurone types develops (granular, Purkinje and molecular layer cells). Depression of tendon reflexes – an unusual cerebellar sign, and of rare clinical value – is explained by loss of tonic stimulation of fusimotor neurones connected via pontine reticulo-spinal fibres. Nystagmus (coarse, fast phase towards the side of the lesion, and dramatic when it occurs) is an inconstant feature of cerebellar lesions.

Finally, the (usually) temporary cognitive affective cerebellar syndrome is of interest. This comprises diminished reasoning, inattention, poor memory and flattening of affect, sometimes seen transiently after major cerebellar lesions, e.g following surgery or massive infarction. One explanation, suggested from functional imaging and some recent neuroanatomical studies, is temporary reduction in blood flow to cerebral cortical association areas, possibly because of diminution of expected impulses of cerebellar origin to the thalamus, and thence to prefrontal cortical areas.

Sensation and sensory pathways

The neurologist usually deals with sensation in its five clinical modalities: touch, nociception, temperature, joint position and vibration sense. The neuroscientist has a wider perspective, looking at sensation first as conscious or non-conscious. Conscious sensation is perceived, largely at cortical level. Non-conscious sensation is processed within the cortex too, but also within the cerebellum, via the vestibular system, in the reticular formation and widely within the CNS. It is often difficult to categorize clearly whether a sensation is conscious or non-conscious. For example, vertigo, the illusion of movement, is clearly conscious. However, the posture of the head in relation to the trunk is usually non-conscious. Both these sensations are mediated via vestibular pathways. Partly because of this problem, and in part because of the sheer complexity of the CNS, it is often hard to say where a particular sensory modality is localized or how it is perceived. Some of the essentials of the sensory pathways are summarized here, with a brief overview of a complex field. Circuitary within the spinal cord is dealt with in more detail in Chapter 15.

Conscious and non-conscious sensation

Conscious sensations are exteroceptive and proprioceptive. Exteroceptive sensations stimulate surface somatic receptors (e.g. touch, nociception, temperature) or telereceptors (vision, hearing, olfaction). Proprioceptive (conscious) sensations arise from joints, muscles, bones and the labyrinth. For example, vestibular pathways to the cortex enable us to perceive whether we are stationary or moving, and to discriminate between constant movement, deceleration and acceleration.

Non-conscious sensations are of two kinds:

- Afferent proprioceptive information (e.g. from muscles, joints, tendons, labyrinth) reaching the cerebellum, cortex, reticular formation and elsewhere; and
- Enteroception (e.g. afferents from the gut, heart or blood vessels).

Somatic sensory pathways in the cord and brain

Two major pathways deliver sensory information to the thalamus and thence to the cortex:

- Spinothalamic pathways (nociceptive);
- Posterior columns → medial lemnisci (touch, position, movement).

Each system consists of first, second and third order neurones. They have the following features in common:

- The cell bodies of first order neurones are in the posterior root (dorsal root) ganglia;
- Second order neurones decussate before reaching the thalamus;
- Third order neurones project from thalamus to cortex;
- There is somatotopic organization throughout the system; and
- Transmission can be controlled (inhibited/enhanced) between first to second, and second to third order neurones (see Gate control below, and Chapter 22).

Dorsal root ganglia – first order neurones

The arrangement of spinal nerves, dorsal and ventral roots, laminae of the posterior horn and named cell groups are illustrated in Figure 2.19. The complexity of information outlined in the figure is exemplified by the fact that a single nerve root ganglion serving a limb contains around 100,000 neurones, each enshrouded by satellite cells (modified Schwann cells).

Termination of dorsal root afferents

In the dorsal root entry zone, afferent fibres separate into medial and lateral streams. The lateral stream (Aδ and C fibres) divides into short ascending and descending branches within the postero-lateral tract of Lissauer. They then synapse in lamina I (marginal zone), lamina II (substantia gelatinosa) and in III–V.

The medial stream (Type I and II mechano-receptors) divides into ascending and descending branches in the posterior columns.

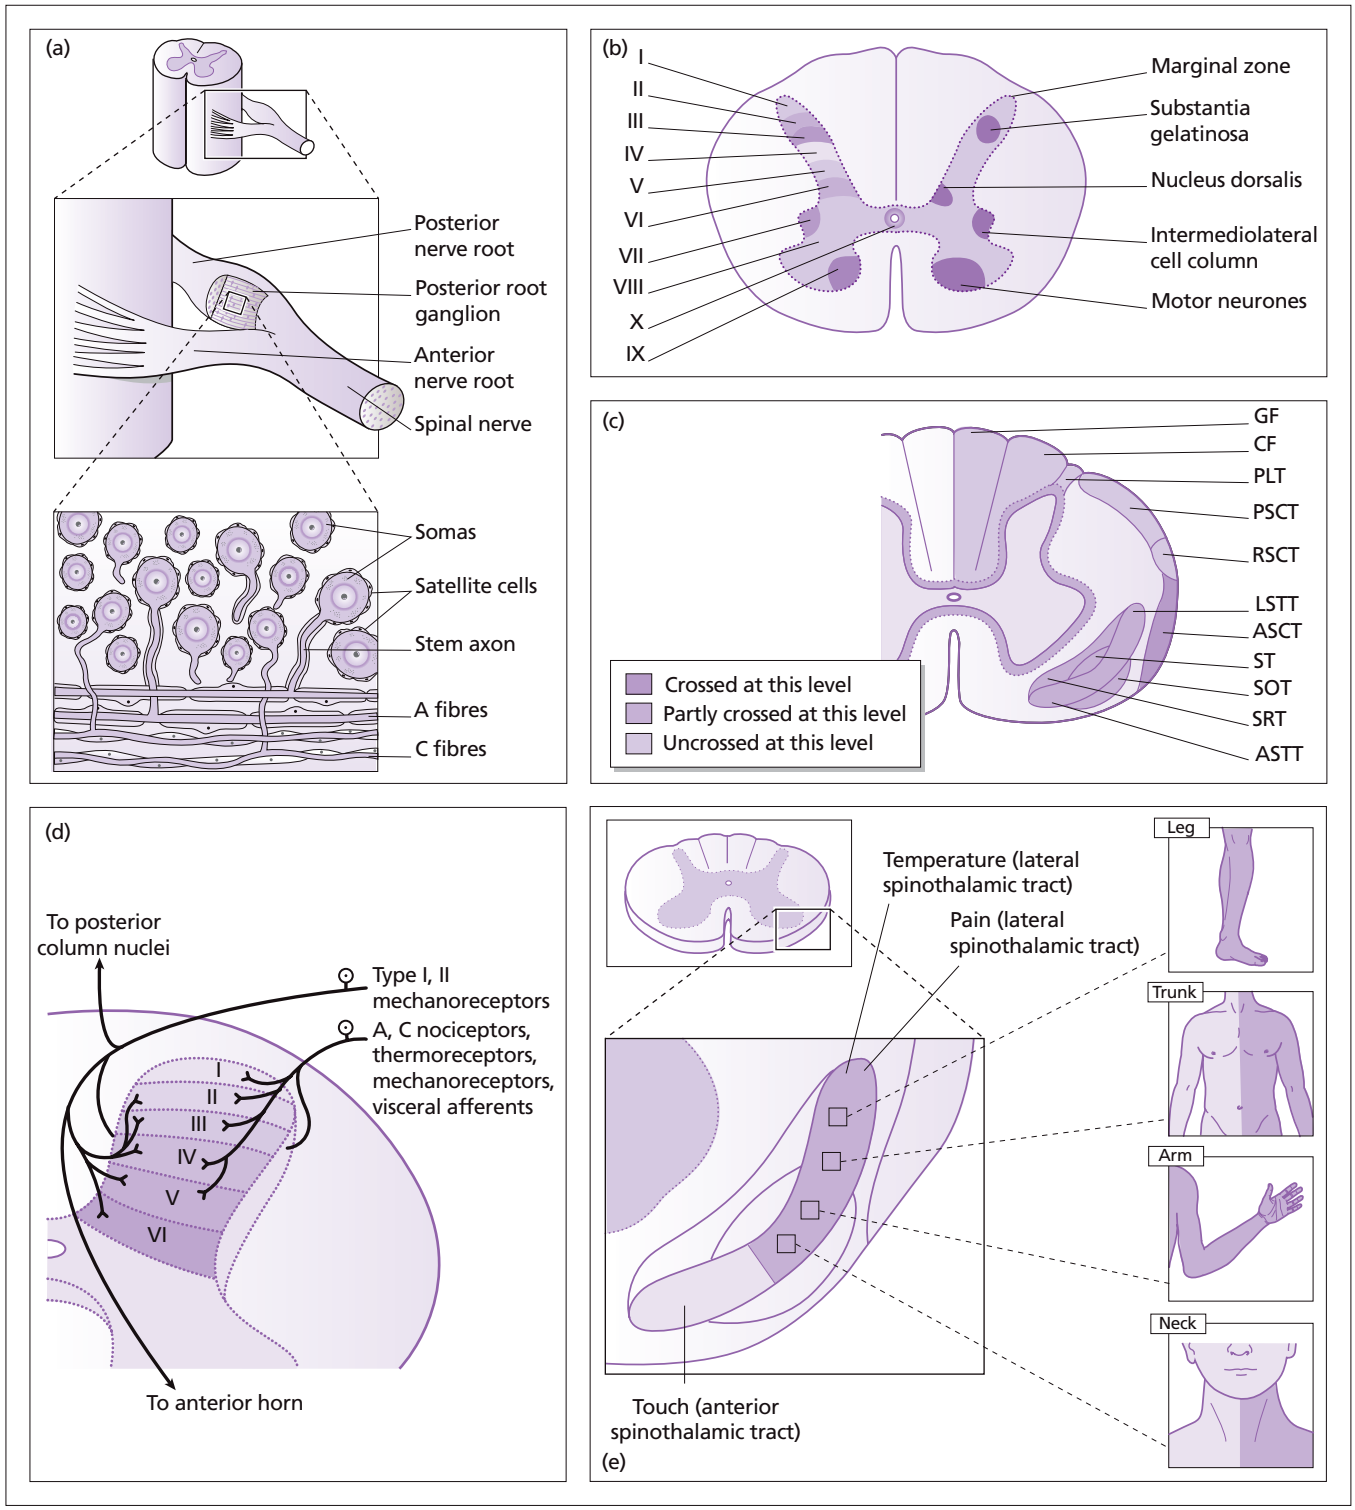

Figure 2.19 Sensation. (a) Posterior root ganglion. In lower figure, note T-shaped bifurcation of stem fibres. (b) Laminae (I–X) and named cell groups at mid thoracic level. (c) Ascending pathways at upper cervical level. ASCT, anterior spino-cerebellar tract; ASTT, anterior spinothalamic tract; CF, cuneate fasciculus; GF, gracile fasciculus; LSTT, lateral spinothalamic tract; PLT, posterolateral tract; PSCT, posterior spino-cerebellar tract; RSCT, rostral spino-cerebellar tract; SOT, spino-olivary tract; SRT; spino-reticular tract; ST, spino-tectal tract. (d) Targets of primary afferent neurones in the posterior grey horn. (e) Sensory modalities in spinothalamic pathway at upper cervical level.

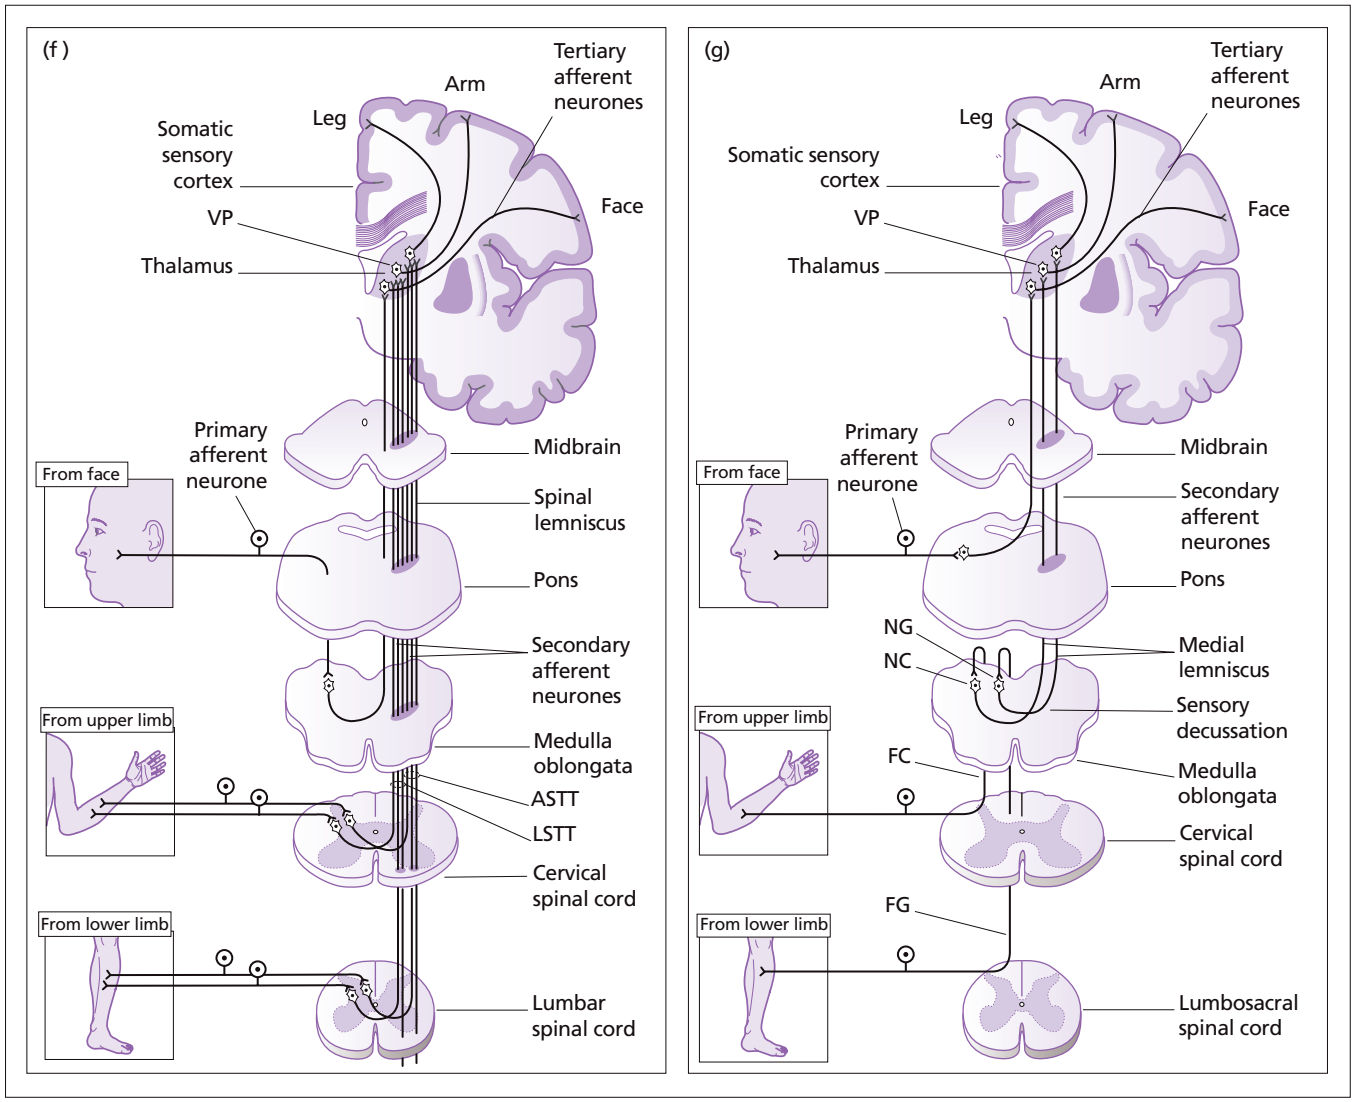

Figure 2.19 *Continued* (f) The spinothalamic pathway. ASTT, anterior spinothalamic tract; LSTT, lateral spinothalamic tract; VP, ventral posterior nucleus of thalamus. (g) The posterior column → medial lemniscal pathway. FC, fasciculus cuneatus; FG, fasciculus gracilis; NC, nucleus cuneatus; NG, nucleus gracilis; VP, ventral posterior lateral and ventral posterior medial nuclei of thalamus.

The shorter branches synapse in laminae II, III, IV, V and VI. The longer branches run throughout the posterior columns of the cord to the gracile and cuneate nuclei in the medulla.

Posterior column → medial lemniscus pathway

The fascicles of the posterior columns of the cord are formed partly by axons of posterior root ganglia (first order neurones) and partly by axons of second order neurones in the dorsal horn of the spinal grey matter. These axons all project to the gracile and cuneate nuclei in the brainstem, whose axons then decussate in the medulla to form each medial lemniscus (ribbon) that terminates in the lateral part of the ventral posterior nucleus of the thalamus. Thalamo-cortical neurones (third, fourth order) then project to the somatic sensory cortex.

Spinothalamic pathway

The anterior and lateral spinothalamic tracts consist of second order neurones passing from laminae I, II, III, IV and V of the posterior grey horn to the opposite thalamus. The two tracts merge in the brainstem to form the spinal lemniscus and then enter the ventral posterior nucleus of the thalamus. Third order thalamic neurones project to the somatic sensory cortex.

Other ascending pathways

The two sensory pathways described above tend to dominate clinical neurology. Other important sensory pathways dealing more with non-conscious sensation are mentioned briefly here.

Spino-cerebellar pathways (four on each side) are concerned with non-conscious proprioception (P) and the interaction

between spinal motor neurones and interneurones, i.e. the excitability of reflex arcs (R), and movements involving balanced activation of agonist and antagonist muscles:
- Posterior spino-cerebellar tract (P);
- Cuneo-cerebellar tract (P);
- Anterior spino-cerebellar tract (R);
- Rostral spino-cerebellar tract (R).

The spino-tectal tract passes information that relates to the orientation of the trunk and head towards a visual stimulus, from the spinal cord to the superior colliculus. This information is important in orientation reflexes to visual stimuli.

The spino-olivary tract sends tactile information to the inferior olivary nucleus and thence to the opposite cerebellar cortex. This pathway is believed to have an important role in motor learning.

Spino-reticular fibres originating in dorsal roots accompany the spinothalamic pathway in the cord. Their functions are arousal and reporting on the general content of a stimulus, e.g. whether it is noxious (pin-prick) or pleasurable (stroking). This is in contrast to the more analytical nature of the spinothalamic pathway which determines the precise nature, intensity and location of a stimulus.

The brainstem

One approach to the complexity of brainstem is to think of the region as a series of cell columns and fibre systems:
- Principal efferent (motor) pathways;
- Principal afferent (sensory) pathways;
- Cranial nerve nuclei;
- Reticular formation; and
- Traversing connections – autonomic, basal ganglia, cerebellar and vestibular.

As landmarks for localization, five simple guidelines are helpful:
1 Motor pathways lie in general ventrally.
2 Sensory pathways lie dorsally.
3 Cranial nerve nuclei (two longitudinal columns) denote the level in the superior–inferior (rostral–caudal) plane.
4 Most reticular formation (RF) nuclei lie laterally. Some (magnus raphe, median raphe) are midline.
5 Traversing connections (above) are found in all layers of the brainstem.

See also Chapter 3 (Figure 3.6).

Motor fibres

The cerebral peduncle transmits all the cortical efferent fibres to the brainstem (cortico-fugal fibres). Within the cerebral peduncle motor fibres are tightly packed. These are arranged, medially to laterally, to supply (Figure 2.20):
- Eye movements (E)
- Face (F)
- Upper limb (UL)
- Trunk (T)
- Lower limb (LL).

In the ventral pons motor fibres lie in separate bundles. Those for eye movements (E) and face (F) leave to reach their nuclei. The remaining bundles then recongregate in the upper medulla as the pyramidal tract or medullary pyramids. UL fibres remain medial; LL fibres lateral.

Crossing of motor fibres (pyramidal decussation) takes place below the medullary pyramids, so named because of the triangular cross-section of each. Topographical order is maintained: UL medial and LL lateral. UL fibres cross higher in the medulla than LL fibres. This makes it possible, although seldom seen, for tiny brainstem lesions to cause bilateral UL weakness (sparing LL), or weakness of one UL and the opposite LL, as well as the more common paraparesis with a brainstem lesion.

Motor fibres to cranial nerve nuclei

These cortico-bulbar motor fibres pass caudally in the genu (knee) of the internal capsule. Depending on the cranial nerve nucleus for which they are destined, some fibres cross the midline. They do so in varying proportions: some completely, some not at all and others in a ratio of about 50 : 50. Understanding these long-known innervation arrangements explains common clinical phenomena.
- Motor nuclei V (mastication muscles) receive 50% of fibres from each cerebral hemisphere: an internal capsule stroke usually causes no perceptible jaw deviation.
- Nuclei VII are supplied differentially, i.e. upper facial nuclear neurones are supplied 50 : 50 from each hemisphere (cf. V) and lower facial neurones are innervated by crossing fibres. Thus, lesions of the UMN facial motor pathway spare the upper face, i.e. the familiar fact that a unilateral stroke causes lower facial weakness.
- IX, X, XI, XII motor nuclear neurones (in nucleus ambiguus and hypoglossal nucleus) are supplied variably by cortico-bulbar fibres in different individuals, i.e. sometimes 50 : 50, sometimes more unilaterally:
- Following an internal capsule stroke, there is usually no unilateral palate, tongue or vocal cord weakness, i.e. innervation is 50 : 50 from each side;
- When unilateral deviation of the tongue is seen after a hemiparesis, it is simply that the supranuclear innervation of the XIIth nucleus is largely contralateral. There is no need to consider an additional lower motor neurone (nuclear) brainstem lesion (see Pseudo-bulbar palsy, Chapter 12).

The hypoglossal nuclei also receive projections from the RF (see motor nuclei of V and supratrigeminal nuclei below), cortical speech areas and cerebellum.

The situation for XI causes confusion. Uncrossed supranuclear fibres innervate XIth nuclear neurones for sternomastoid of the same side. Other supranuclear fibres cross to innervate XIth nuclear neurones for trapezius on the opposite side.

Clinical correlates (XI nerve)

In the normal person, as the left hand reaches out (right motor cortex, left anterior horn cells), the head turns (logically) to the left. This head turning is achieved by the right sternomastoid,

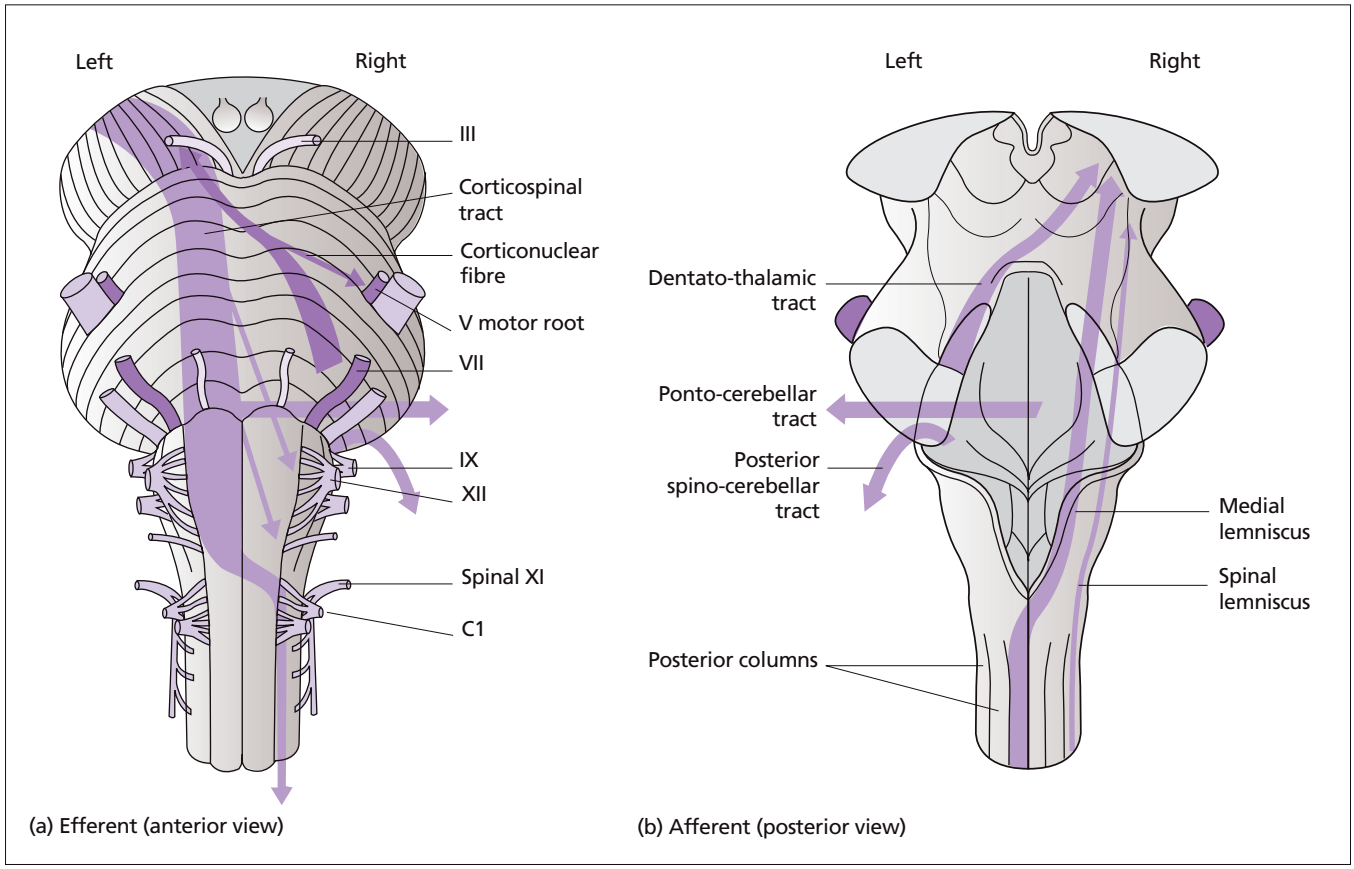

Figure 2.20 Brainstem main efferent (a) and afferent (b) pathways.

innervated ipsilaterally. With a left hemiparesis (e.g. right internal capsule stroke), it is this, the right, ipsilaterally innervated sternomastoid that is weak. Trapezius weakness (shoulder shrugging) is on the same side as the limb weakness in a hemiparesis.

Sensory pathways within the brainstem

The two sensory systems traverse the brainstem, to merge just before entering the thalamus:

- *Spinothalamic tracts:* pain and temperature sensation (spinal lemniscus);
- *Posterior (dorsal) columns:* light touch, two-point discrimination, light touch, kinesthesia (medial lemniscus)

Matters are then complicated by the massive Vth nuclei and their connections.

Spinothalamic tracts

Cell bodies are in dorsal root ganglia of the cord. Spinothalamic fibres cross the midline in the cord (within one to three segments of their point of entry) to form each spinothalamic tract. This ascends from the cord and comes to lie laterally in the medulla (with LL fibres lateral to UL fibres) until it merges with the medial lemniscus (ribbon-like structure) in the upper midbrain. Close to the spinothalamic tracts in the brainstem lie the descending sympathetic pathways.

Clinical correlate. A spinothalamic lesion in the brainstem causes loss of pain and temperature in the opposite limbs; an ipsilateral Horner's syndrome is also frequently present.

Posterior column → medial lemniscus

Cell bodies lie in the cuneate (UL) and gracile (LL) nuclei in the medulla. Axons decussate there and form the medial lemniscus. This ascends and rotates in the brainstem, maintaining LL fibres laterally and UL fibres medially, to coalesce with the spinothalamic tract (see above).

Vth nerve central pathways

The massive Vth nerve input enters the brainstem in the mid pons. Touch sensation and the corneal reflex afferents pass to the pontine Vth nucleus, and decussate to the opposite Vth pontine nucleus. Pain and temperature afferents enter the pons, but not the pontine Vth nucleus itself. They descend alongside the spinal Vth nucleus, enter the nucleus when they reach the medulla and upper cord and then decussate, to synapse on the opposite Vth spinal nucleus. The quinto-thalamic tract (or secondary, ascending tract of the Vth nerve) completes the route to the thalamus for nociceptive

and temperature information as the trigeminal lemniscus, the ribbon-like tract lying lateral to the medial lemniscus.

Clinical correlates

The corneal reflex is the most subtle sign of an emerging Vth nerve lesion (see Chapter 3). Peripheral Vth nerve lesions are usually recognizable from symptoms and signs within the cutaneous distribution of the divisions of the trigeminal nerve, V_1, V_2 and V_3. Central lesions affecting the spinal nucleus of V produce circumoral sensory loss (see onion skin distribution, see Figure 2.51, and Chapter 12). Facial numbness on one side with spinothalamic sensory loss in the contralateral limbs is diagnostic of a dorsolateral brainstem lesion. This crossed sensory loss can occur with a lesion anywhere between upper cervical cord and mid pons. When a cavity develops within the medulla (see syringobulbia below), bizarre patterns of facial and upper cervical sensory loss can be seen when the crossing central fibres of the spinal nucleus of V and quinto-thalamic tract are damaged. These are often dismissed initially as non-organic.

At a more general level, with such a magnitude of afferent information, Vth nerve sensation is highly sensitive and easily triggered. Trigeminal-mediated pain is exquisitely painful – consider toothache, trigeminal neuralgia and subarachnoid haemorrhage. The importance of the trigemino-vascular system in headaches is considered in Chapter 11.

Cranial nerve nuclear columns

A summary of the embryological development begins to explain the layout (Figure 2.21). Seven nuclear columns (four afferent, three efferent) contribute to the nuclear masses of the brainstem and cord. Motor cranial nerve nuclei are derived from two of these columns:

- III, IV, VI and XII arise from a paramedian nuclear mass known as the general somatic efferent (GSE) column; and

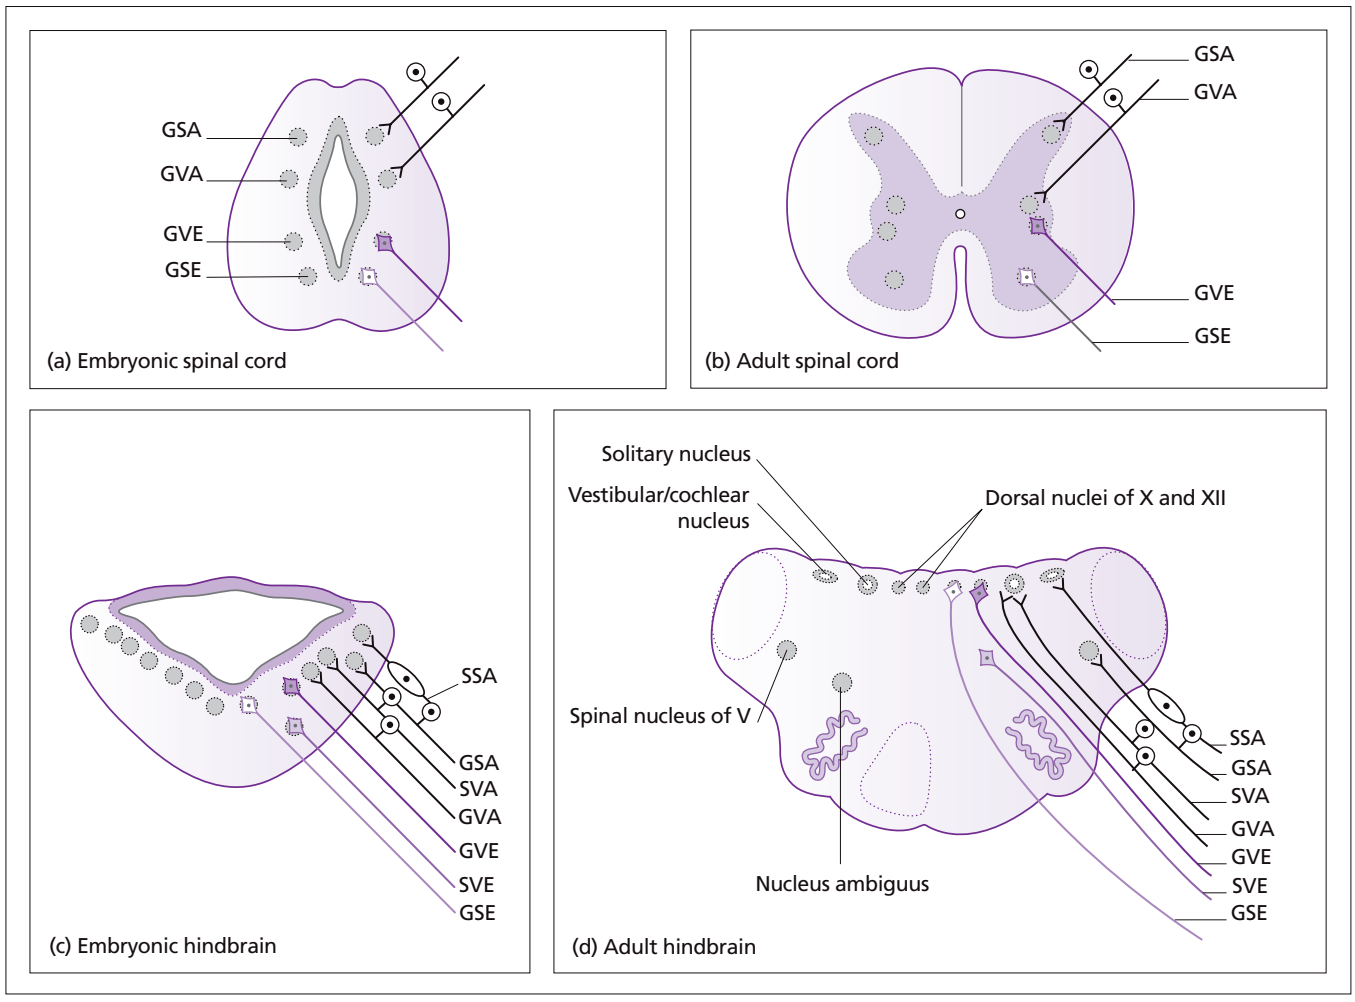

Figure 2.21 Seven nuclear columns of the embryonic brainstem and cord. GSA, General somatic afferent; GSE, General somatic efferent; GVA, General visceral afferent; GVE, General visceral efferent; SSA, Special somatic afferent; SVA, Special visceral afferent; SVE, Special visceral efferent.

• V (motor), VII, IX and X (nucleus ambiguus) and XI (spinal accessory nucleus) arise from ventro-lateral cells known as the special visceral efferent (SVE) column.

As the fetus develops GSE column nuclei III, IV, VI and XII remain close to the midline. The SVE nuclei move laterally along the lateral margin of the fourth ventricle.

Of the main afferent nuclei:

• The Vth nerve nuclei are described in some detail (see below);
• The vestibular nuclei (SSA) occupy a wide area in the pons, extending through the medulla to upper cervical cord (see below);
• The nucleus of the tractus solitarius (SVA) receives taste fibres and relays gustatory reflexes.

Functions

The intricacies of brainstem function are hard to summarize in a few paragraphs. One approach is to consider that phylogenetically the brainstem was, very largely, the brain of distant invertebrate ancestors. The reticular formation connected olfaction to reflex movement associated with alertness, respiration, autonomic function and feeding, and hence survival. As more advanced life forms developed, cranial nerve nuclei developed to subserve more specialized sensory functions, e.g. vision and hearing. With the emergence of cerebellum and cortex, the brainstem became by default the conduit, for all axonal impulses to and from those higher destinations, adding to its complexity.

Reticular formation

The biological role of the RF can be understood from its origins as a polysynaptic, slow conducting, central pathway that:

• Linked olfactory and limbic systems;
• Co-ordinated autonomic and reflex activity.

Phylogenetically, as vision and hearing assumed important roles together with olfaction, direct, lateralized pathways of these special senses bypassed the RF. In mammals, the older pathways were superceded by fast direct linkages between cortex and sensorimotor systems.

In humans, the RF means the polysynaptic, modulating, neuronal network within the brainstem, although the system extends further – caudally into the cord and rostrally to thalamus and hypothalamus. It is of importance in:

• Respiratory control;
• Sleep, wakefulness, arousal and mood;
• Cardiovascular control;
• Pattern generation of some reflex motor activities, e.g. chewing, swallowing, conjugate gaze;
• Micturition, bowel and sexual function;
• Sensory modulation (see Gate control below, and Chapter 22); and
• Autonomic and reflex activity generally.

Aminergic neurones are prominent in the RF:

• Serotoninergic RF neurones form a ubiquitous network throughout the raphe nuclei;
• Dopaminergic neurones occupy substantia nigra and ventral tegmental nuclei;
• Noradrenergic neurones are congregated in the locus caeruleus (floor of fourth ventricle) and through the pons, medulla and midbrain;
• Adrenergic neurones occupy principally the medulla;
• Enkephalins are also involved (peri-aqueductal grey matter).

Essential anatomy

This is outlined in Figure 2.22. The raphe nuclei (raphe: Greek = seam, pronounced 'raffay') are the major source of serotinergic neurones in the neuraxis.

Alongside the median raphe nuclei lie the paramedian RF (magnocellular and gigantocellular neurones) on each side. Each paramedian network blends into the lateral RF (parvocellular neurones).

The lateral RF is largely afferent, receiving input from all sensory pathways, especially:

• Olfactory system (via median forebrain bundle, next to the hypothalamus);
• Visual pathways (via superior colliculus);
• Auditory pathways (via superior olivary nucleus);
• Vestibular pathways (via medial vestibular nucleus); and
• Somatic sensory and trigeminal system (spino-reticular tracts, pontine Vth nuclei).

The paramedian RF is a smaller efferent polysynaptic distributive pathway to:

• Thalamus;
• Spinal cord (via pontine and medullary reticulo-spinal tracts); and
• Cardiovascular and respiratory regulators.

Functions

The wide range of RF function is outlined below. There is no overriding central function, in the sense that there is no recognisable clinical condition that affects the RF as a whole. However, changes within the RF have prominent effects, principally on respiratory control, sleep and wakefulness, cardiovascular control, patterns of primitive movement and sphincters and mood. These are outlined here.

Respiratory control

This is achieved via:

• Dorsal and ventral respiratory nuclei;
• Medullary chemosensitive area; and
• Carotid chemoreceptors.

Cyclical automatic respiration is modulated by the dorsal and ventral respiratory nuclei in the medulla. The dorsal nucleus is mainly inspiratory (efferent connections to respiratory muscles) and the ventral, expiratory. A third medial paracentral nucleus adjacent to the locus caeruleus is involved in initiating and driving respiratory rhythms. The dorsal respiratory nucleus receives excitatory impulses from the medullary chemosensitive area. These cells in the lateral RF at the level of the IXth nerve

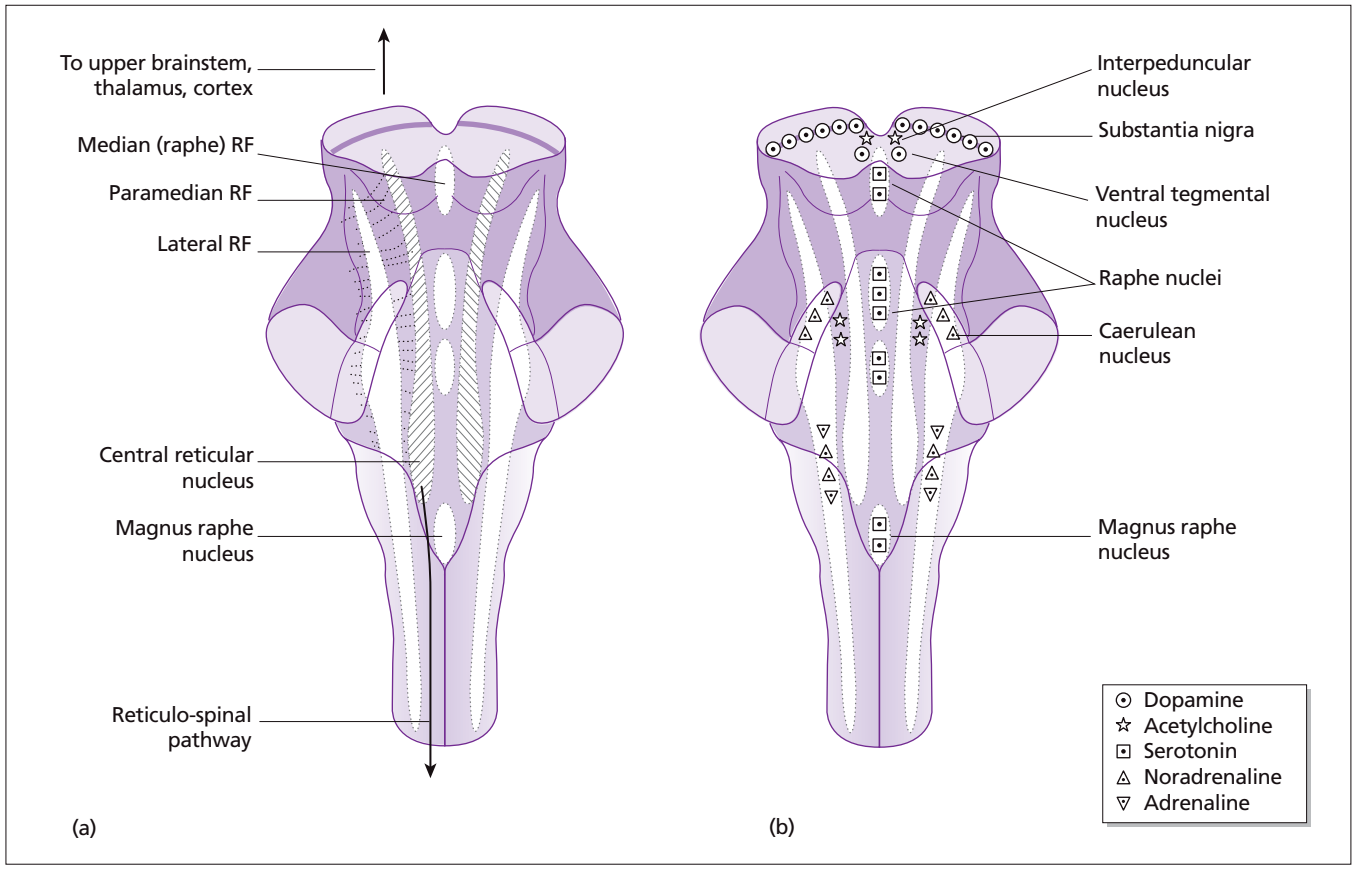

Figure 2.22 Reticular formation. (a) Subdivisions (nuclei); (b) Principal neurotransmitter cell groups.

nucleus and 4th ventricle choroid plexus are exquisitely sensitive to H^+ ion concentration. Sampling of pCO_2 takes place here: any increase in H^+ ion concentration stimulates the dorsal respiratory nucleus.

Carotid chemoreceptors (glomus cells at the carotid bifurcation) are also exquisitely sensitive to changes in arterial pO_2, and/or a rise in arterial pCO_2. Impulses pass via the sinus nerve (a branch of IX) to stimulate the dorsal respiratory centre.

The ventral respiratory nucleus is largely expiratory. It acts as an inhibitory oscillator during normal breathing and is engaged via GABAergic internuncials with the dorsal respiratory nucleus. During increased ventilation (e.g. exercise) the ventral respiratory nuclei activate anterior horn cells supplying expiratory accessory and abdominal muscles.

Sleep, wakefulness and mood

In animal models, destruction of raphe midbrain neurones or depletion of serotonin results in prolonged insomnia. The ascending reticular activating system is the term used to harness this concept of activation of the cortex by the RF. This effect is seen on EEG during arousal from sleep – high amplitude slow (delta) waves are replaced by fast (alpha) waves. The principal cellular candidates for this role are:

- Cholinergic neurones near the caerulean nuclei; or
- Histaminergic neurones in the tubero-mamillary nuclei.

Following arousal the waking state (and EEG activity) appears to be sustained by continuing activation by these neurones and by activation of the basal nucleus of Meynert in the basal forebrain. As a corollary, inactivity within the ascending reticular activating system is inherent in the mechanisms of coma.

The limbic system and RF are mentioned in Chapter 21 and the orexin-hypocretin system in Chapter 19.

Cardiovascular control

The solitary nuclei in the medulla receive afferents from baroreceptors in the carotid sinus and aortic arch. The barovagal and barosympathetic reflexes modulate blood pressure and cardiac output (Chapter 23).

Patterns of primitive movements

- Conjugate gaze – pontine centres for lateral and vertical gaze;
- Chewing – supratrigeminal premotor pontine nucleus;
- Respiration – medullary respiratory nuclei;
- Swallowing, coughing, sneezing, vomiting, crying, salivation;
- Locomotor pattern generators.

These movements are primitive only in phylogenetic terms. They are initiated by complex rhythmical patterns of neuronal activity within the brainstem.

Micturition control

A micturition control centre (MCC or M centre) is in each paramedian pontine reticular formation (PPRF). Axons from magnocellular neurones pass directly to parasympathetic (motor) neurones at S2–4 in the cord. Stimulation of the M centre in the PPRF produces a rise in intravesical (bladder) pressure and relaxation of the external sphincter. The latter is brought about by excitation of GABAergic interneurones from the L (lateral) centre in the PPRF. These pass to and synapse in Onuf's nucleus in the cord (parasympathetic motor innervation of the bladder muscles). The bladder begins to empty.

The essential anatomy of cortical and subcortical influences on normal micturition are included here (Figure 2.23). Neurones in lateral (right) peri-aqueductal grey matter (LPAG) receive fibres

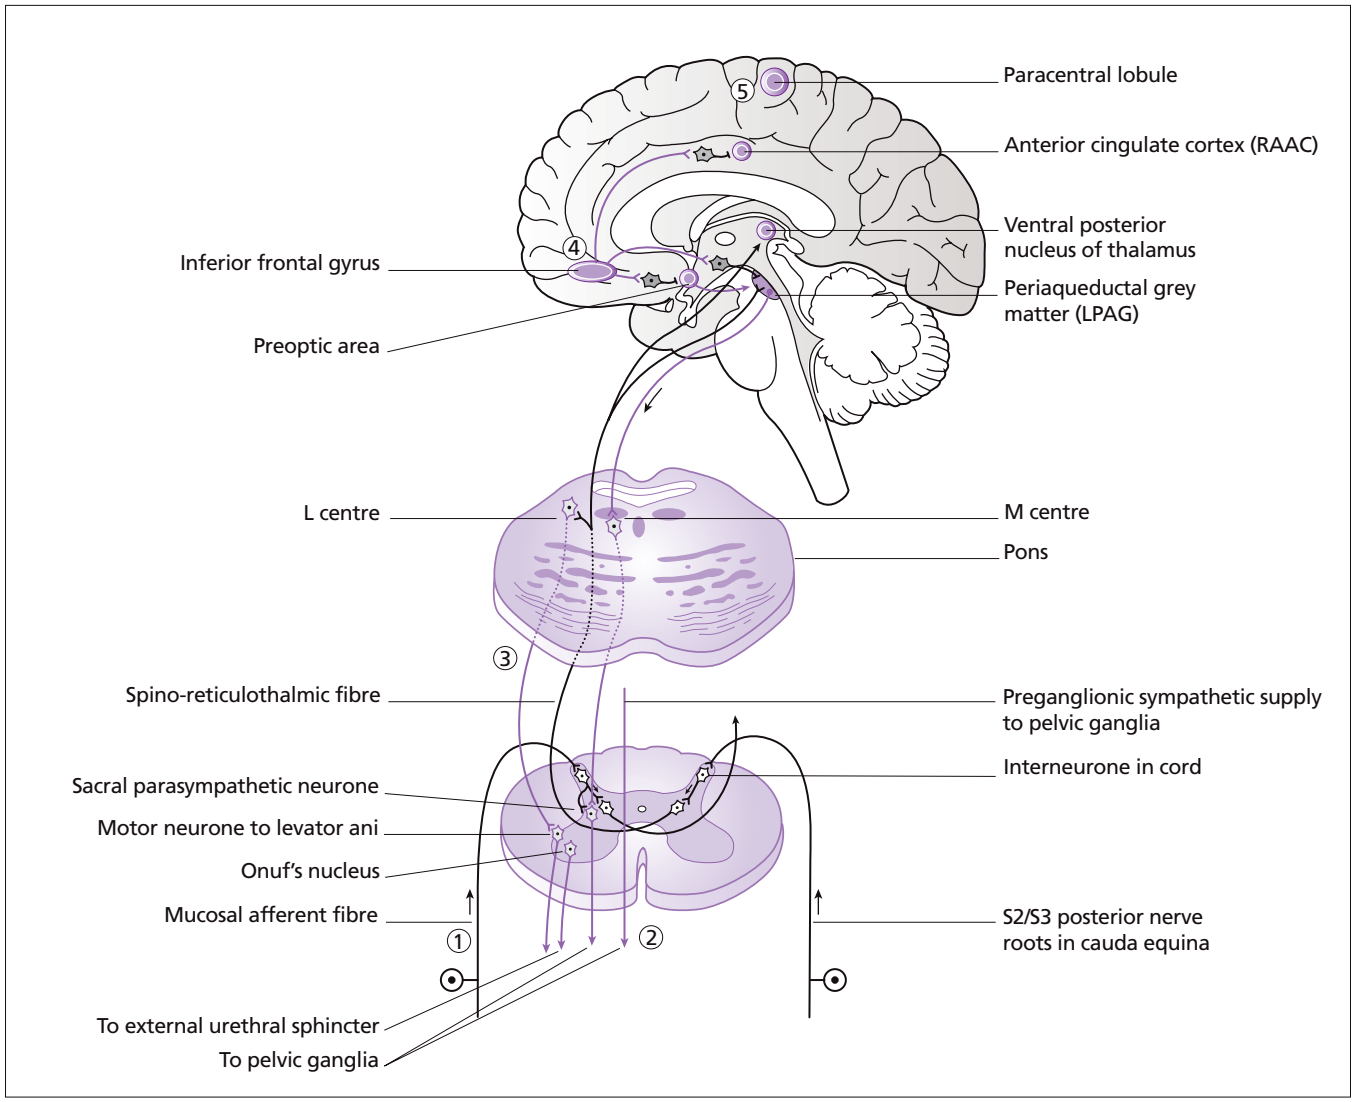

Figure 2.23 Neuroanatomy of micturition control:

1 As intravesical pressure increases, bladder detrusor and trigone stretch receptors are activated (S2, 3 and 4).

2 Spino-reticular fibres relay impulses → thalamus, midbrain and pons. Right PPRF L centre, LPAG, RACC are activated.

3 Sympathetic activity increases + parasympathetic activity inhibited. Bladder compliance increases. Bladder continues to fill.

4 Spino-reticular fibres via PPRF L centre activate the Onuf's nucleus (sacral cord). External sphincter tone increases: micturition is prevented.

5 Urgency is perceived when bladder becomes full. If time and/or place are unsuitable, the inferior frontal gyrus becomes activated, RACC is suppressed. M centre, LPAG and PON are suppressed.

6 Voluntary micturition is accomplished, when appropriate, by M centre activation → relaxation of the external sphincter accompanied by increase in intravesical pressure/active (voluntary) contraction of abdominal muscles.

from the sacral posterior grey horn and project excitatory fibres to the M centre. The ventral posterior nucleus of the thalamus also receives sacral fibres. The LPAG also receives excitatory fibres from the pre-optic nucleus (PON).

The right anterior cingulate cortex (RACC) is activated when the bladder fills (intravesical pressure increases). The right-sided bias (not seen exclusively) is believed to be related to emotional and topographical aspects of where and when it is appropriate to micturate. The inferior frontal gyrus is activated when the time and/or place to micturate are deemed unsuitable. The LPAG, RACC and PON are inhibited.

Gate control: sensory modulation

The anatomy and role of the RF in the control of pain, better termed supraspinal antinociception, is summarized in Figure 2.24. Gating (Chapter 22) involves the control of synaptic transmission between one neurone (or set of neurones) and the next. While gating of nociceptive inputs is but a theory and still debated, it remains a useful model.

Tactile sensory transmission is probably gated at the posterior column nuclei (see above). Nociceptive transmission from the trunk and limbs is gated in the posterior grey horn of the cord, and from the head and neck in the spinal V nucleus.

The seminal structure here is the substantia gelatinosa, rich in excitatory glutaminergic neurones and inhibitory GABAergic and enkephalinergic neurones. Unmyelinated C fibres mediate dull, intense, prolonged, poorly localized pain, largely via excitatory substantia gelatinosa interneurones and thence via lateral spino-thalamic tracts to the thalamus. Short, sharp, well-localized pain is mediated by finely myelinated Aδ fibres. These synapse directly on dendrites of relay neurones of the lateral spino-thalamic tract.

Large A (mechano-receptor) afferents from hair follicles and skin synapse on anterior spinothalamic relay cells and send collaterals to inhibitory (GABAergic) gelatinosa cells. These then synapse on lateral spinothalamic tract relay cells.

Gating of C fibre activity can be enhanced by stimulating A fibre afferents (e.g. rubbing, transcutaneous electrical nerve

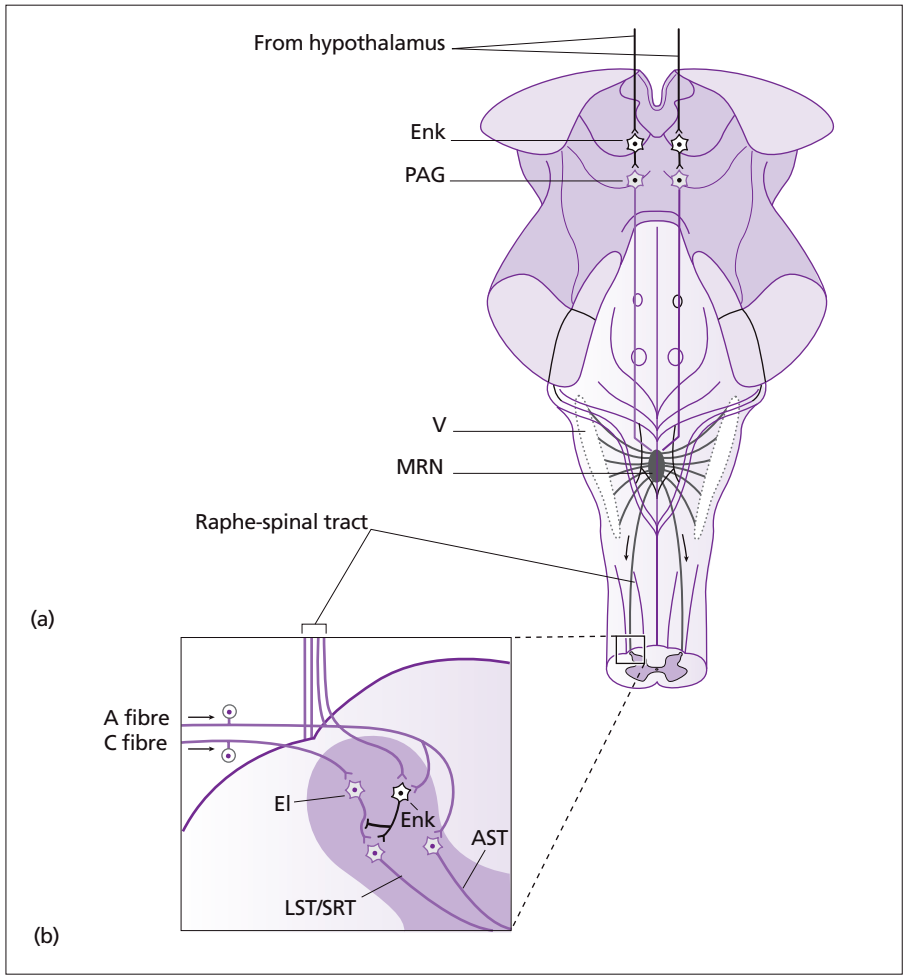

Figure 2.24 Anatomy of sensory modulation.
1 The magnus raphe nucleus (MRN) in the medulla is the origin of raphe-spinal fibres in the tract of Lissauer that synapse in the substantia gelatinosa of the cord at all levels.
2 Many RF raphe-spinal fibres are serotoninergic. They excite inhibitory interneurones in the posterior grey horn of the cord.
3 Peri-aqueductal grey matter (PAG) projects (an excitatory system) to the MRN.
4 Hypothalamic and enkephalinergic interneurones exert tonic inhibition on PAG neurones. Inhibitory impulses from the hypothalamus disinhibit (release) PAG excitatory neurones.
5 Passage of purely tactile information – into AST – is not impeded.
6 The corticospinal tracts terminate widely in the spinal dorsal horn, including the substantia gelatinosa; one of the important functions mediated by this pathway is probably supraspinal control of sensory input.
Enk: enkephalinergic interneurones
PAG: peri-aqueductal grey matter
MRN: magnus raphe nucleus;
EI: excitatory interneurones;
LST: lateral spinothalamic projection cell;
SRT: spinoreticular projection cell;
AST: anterior spinothalamic tract

stimulation [TENS]) or enhancing RF inhibition from the magnus raphe nucleus (MRN), e.g. stimulus-induced analgaesia, sleep, drugs, implanted stimulators that increase central gating of pain.

Limbic system, hippocampus and related structures

The limbus (Latin = rim) was coined by Broca in the late 19th century to describe cortex bounded by the corpus callosum. The hippocampus takes its name from Greek, originally for a horse + monster (ἵππος + κάμπος) and later a seahorse, that the hippocampus clearly resembles in coronal cross-section.

The limbic system includes:

- Hippocampi, mamillary bodies and septal area;
- Insulae, cingulate and parahippocampal gyri; and
- Amygdala – subcortical nuclear masses adjacent to each temporal pole.

Other subcortical regions nearby are the nucleus accumbens, medial dorsal nucleus of the thalamus, hypothalamus and part of the reticular formation. The frontal cortex above the orbit (orbitofrontal), the temporal pole, the corpus callosum, choroid plexus and lateral ventricle are also neighbours (Figure 2.25).

The parahippocampal gyri are the main interfaces between hippocampi (known as allocortex) and the cerebral neocortex. The entorhinal cortex is the anterior section – area 28. This is six-layered cortex, exchanging fibres between the four neocortical association areas and the hippocampus. Each fornix, looping over the medial dorsal thalamic nucleus into the mamillary body, provides a second route between neocortex and hippocampus.

The planes, contours and nomenclature of the hippocampal formation (subiculum, dentate gyrus, hippocampus) are complex. Looking from above, imagine a horseshoe lying tilted in the floor of the lateral ventricle. One (lateral) arm is the hippocampus. The other arm twists into the loop of the fornix to follow the contour of the thalamus (Figure 2.26).

The familiar coronal cross-section of the hippocampus – the seahorse-like outline – has its head in the lateral ventricle and a tail leading to the entorhinal cortex. The dentate gyrus is surrounded by the seahorse's head.

Additional terminology comes from the ancient descriptive name for the hippocampus, Ammon's horn (Ammon = Egyptian ram deity + cornu = horn), hence cornu ammonis (CA) zones which divide the hippocampus into four (Figure 2.26). Pyramidal cells are the main cell types seen in the subiculum and hippocampus and granule cells in the dentate nucleus. Inhibitory GABAergic interneurones are present throughout the area.

In functional terms, this area of the brain is intimately involved in memory, arousal and mood – and pathologically in the genesis of epilepsy (see hippocampal sclerosis, Chapter 6). The summary that follows outlines majority views in a complex field within which there is continued debate. Much original work was derived from clinical observation in humans. Extrapolation and conjecture from primate studies, and more recently fMRI, have added new insights into the roles of these areas. Their clinical relevance in epilepsy, memory and mood – and in dementia – are dealt with in the relevant chapters (6 and 7).

Afferent hippocampal connections

The perforant path passes from the entorhinal cortex to dendrites of dentate nucleus granule cells. The alvear path passes from the subiculum to the alveus, the ventricular face of the hippocampus. Mossy fibres, the axons of granule cells synapse in CA3 pyramidal cells. CA3 pyramidal cell axons pass into the fimbria, giving rise to Schaffer collaterals between CA3 and CA1. CA1 projects to the entorhinal cortex. Visual, visuo-spatial and auditory afferents also reach the region:

- Auditory fibres from the superior and middle temporal gyri to hippocampus;
- Visuo-spatial data from area 40 (supramarginal gyrus); and
- Visual association data (object shape and colour/facial recognition) from the occipito-temporal region to the peri-rhinal cortex (adjacent to the entorhinal) and thence to the hippocampus.

Diffuse afferent connections (poorly identifiable anatomically) also reach the hippocampus (Table 2.4) largely via the fornix.

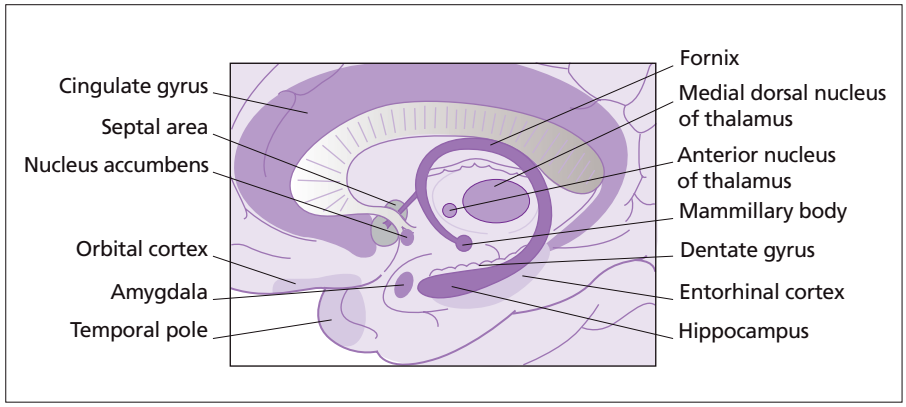

Figure 2.25 Limbic and subcortical areas: medial view.

1 Afferents: from sensory association cortex
2 Entorhinal neurones → perforant path → dentate gyrus
3 Dentate granule cells → CA3
4 CA3 neurones → fimbria and CA1
5 CA1 neurones → subiculum
6 Subiculum neurones → fimbria
7 Subiculum neurones → entorhinal neurones
8 Entorhinal neurones → sensory association cortex

Table 2.4 Diffuse afferents to the hippocampus.

Neurotransmitter	Source	Clinical association
Cholinergic	Septal nuclei	Memory
Noradrenergic	Caerulean nuclei	Arousal
Dopaminergic	Ventral tegmentum	Movement/thought disorder
Serotinergic	Raphe nuclei	Mood

Efferent hippocampal connections

First, the entorhinal cortex projects to neocortical association areas. Secondly, axons in the fornix (Latin = vault or arch) project forwards from the subiculum and hippocampus itself. Components of the fornix are:

- Fimbria (Latin: fimbriae = thin projections, forming a fringe).
- The crus (cross) arches up below corpus callosum, joins opposite the fornix to form the trunk and hippocampal commissure.
- The trunk divides into the two pillars of the fornix.

Each pillar divides around the anterior commissure:

- Precommissural fibres pass to the septal area;
- Post-commissural fibres pass to the anterior hypothalamus, mamillary body and medial forebrain bundle.

Each mamillary body (Latin: mamilla = nipple) projects to the anterior nucleus of the thalamus, thence to the cingulate cortex.

Papez's circuit (James Papez, 1937; Figure 2.27) is the loop:

Hippocampus → fornix → cingulate cortex → entorhinal cortex → hippocampus.

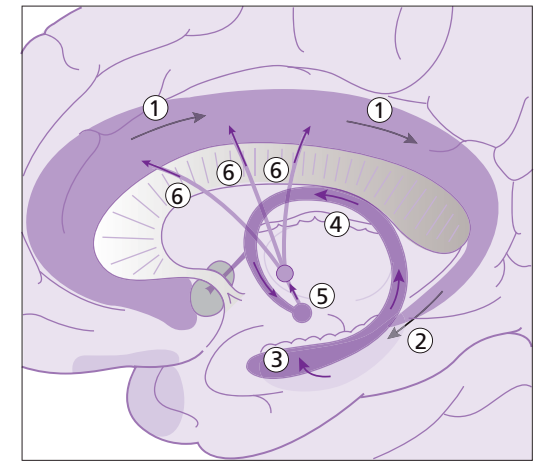
This is a useful concept that has stood the test of time, although perhaps with more anatomical than clinical day-to-day relevance (Chapter 21).

Declarative memory and long-term potentiation

Data-based (declarative) memory, the ability to retain and retrieve new factual information, is lost when the anterior hippocampus is damaged. Procedural memory is preserved (e.g. how to change a wheel, thread a needle, assemble a jigsaw, ride a bicycle). The hippocampus is not involved in procedural memory – there is growing evidence that the cerebellum is the principal structure involved in these procedural or motor memories.

Long-term potentiation (LTP) is a phenomenon seen widely within the nervous system but especially within the dentate gyrus and hippocampus. As its name implies, target cells remain sensitive to a fresh stimulus a long time (hours) after stimulation.

LTP can be demonstrated in animals both in perforant path → dentate granule cells and Schaffer collateral → CA1 connections. A brief, several millisecond stimulus to either Schaffer collaterals or perforant path induces this long-lasting sensitivity in target neurones following GABA receptor activation. New synapses appear (within minutes), while older generations of synapses expand. It is believed that LTP is of fundamental importance in learning. LTP is enhanced by opioid peptides, norepinephrine and dopamine released within the perforant path.



1. cingulate gyrus
2. → entorhinal cortex
3. → hippocampus
4. fornix
5. mammillo-thalamic tract
6. anterior nucleus of thalamus → cingulate cortex

Figure 2.27 Papez's circuit.

ACh muscarinic activity within the hippocampus is also significant in learning. Hyoscine in small doses blocks memory for lists and numbers. (Hyoscine = scopolamine, the 'truth drug' of 007, CIA and KGB repute. Recall is frequently distorted by hyoscine and hallucinogenic effects are frequent – making it of no real value for this purpose.) Physostigmine blocks the effect of hyoscine. This was the original basis for anticholinergic therapy in Alzheimer's disease.

Kindling

Clinically, the term is used (if often conjecturally) to describe development of seizure activity in a specific area of brain contralateral to or distant from an epileptic focus. At a neurophysiological level, it means a group response within neurones that increases following a uniform strength stimulus. This phenomenon is unique and, as far as is known, confined to the amygdala and hippocampus.

Insula, cingulate cortex and parahippocampal gyrus

The insula can conveniently be divided into three:

1 *Anterior:* a cortical centre for pain (on fMRI);
2 *Posterior:* connects with the amygdala and entorhinal cortex (emotional responses to and memories of pain); and
3 *Central:* possible language functions.

The cingulate cortex, part of Papez's circuit merges into the posterior parahippocampal gyrus behind the splenium. The anterior cingulate (part of the rostral limbic system – amygdala,

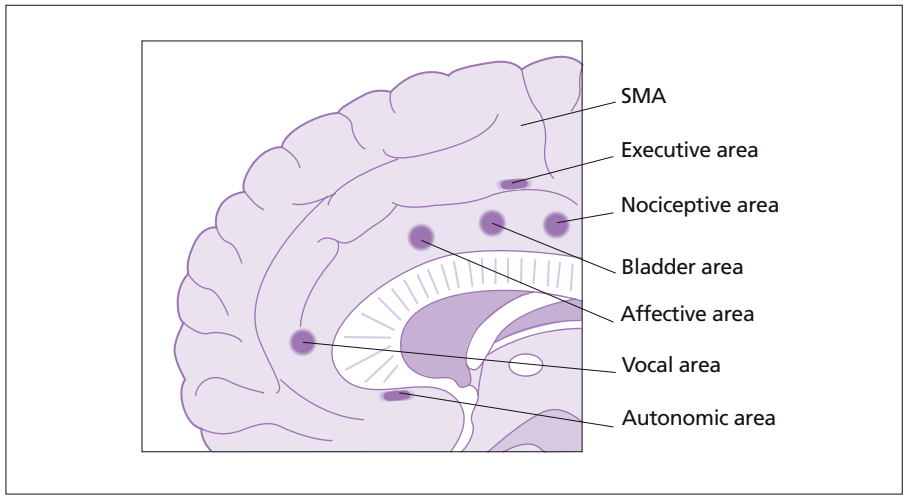


Figure 2.28 Six functional zones: anterior cingulate cortex (medial view).

ventral striatum and anterior insula) has six functional zones (Figure 2.28):

1 *Executive:* connected to dorso-lateral prefrontal cortex (DLPFC) and SMA;
2 *Nociceptive:* afferents from thalamus (medial dorsal nucleus);
3 *Affective* (emotional): happy thoughts light this area on fMRI – and the amygdala switches off. Anterior cingulectomy was once performed for aggressive psychopathic behaviour;
4 *Micturition:* activity seen on bladder filling;
5 *Vocalization:* active during decisions about syntactic construction. Reduced regional blood flow is seen in some cases of stammering;
6 *Autonomic:* respiratory and cardiac – responses to emotion, sweating and blushing.

Amygdala

Amygdala is Greek for an almond. This is a substantial nuclear group anterior to the caudate nucleus tail. Fear and anxiety are mediated via the amygdala – a glance at the afferent and efferent pathways of Tables 2.5 and 2.6 indicates the widespread connections and potential pathways for everyday experiences, e.g. feeling unwell, hypotensive and sweaty at the sight of blood.

Nucleus accumbens

Stimulation of these areas of the ventral striatum (nucleus accumbens, ventral olfactory tubercle, ventral caudate and putamen) leads typically to a sense of well-being akin to a shot of heroin, attributed to excessive dopamine release flooding the prefrontal cortex and nucleus itself. Almost every drug of abuse increases dopamine levels in these areas. Ninety-five per cent of nucleus accumbens neurones are spiny GABAergic projection neurones; 5% are cholinergic neurones (non-spiny, a.k.a. aspiny neurones).

Septal region

Afferents to the septal nuclei come from:
- Hippocampus (via fornix);
- Brainstem, via medial forebrain bundle (monoaminergic neurones);
- Amygdala, via the diagonal band of Broca; and
- Olfactory tract, via medial olfactory striae.

Table 2.5 Amygdala afferents – to the lateral nucleus.

Type	Subcortical origin	Cortical origin
Touch	VP nucleus of thalamus	Parietal cortex
Hearing	MGB	Superior temporal gyrus
Vision	LGB	Occipital cortex
Smell		Piriform lobe
Memory		Hippocampus/entorhinal cortex
Cardiac	Hypothalamus	
Pain	RF	Insula
Cognitive		Orbital (frontal) cortex
Attention/anxiety	Locus caeruleus	Basal nucleus of Meynert

LGB, lateral geniculate body; MGB, medial geniculate body; RF, reticular formation; VP, ventral posterior (nucleus).

Table 2.6 Amygdala efferents – from the central nucleus.

Pathway/distant target nucleus	Effect
PAG	Pain suppression (anti-nociception)
PAG	Freezing (in fear)
Locus caeruleus	Wakefulness/arousal
Medullary norepinephric neurones (to lateral grey horn)	Increase in pulse and blood pressure
Hypothalamus/dorsal nucleus of vagus	Slowing of pulse/syncope
Hypothalamus (corticotrophin RF)	↑ Cortisol secretion
Parabrachial (thence to respiratory) nuclei	Hyperventilation/apnoea

PAG, peri-aqueductal grey matter; RF, reticular formation.

Efferents travel in two principal pathways:
1 Striae medullaris → habenula nucleus → habenulo-interpeduncular tract → interpeduncular nucleus; and
2 Septo-hippocampal tract.
The interpeduncular nucleus participates in sleep–wake cycles (with the locus caeruleus).

The septo-hippocampal tract is believed to have a role in generating temporal cortex theta EEG activity. Synchronous discharge of hippocampal pyramidal neurones is thought to be the origin of this underlying rhythm.

Stimulation of the septal region in humans produces pleasurable sexual sensations and/or orgasm. In animals, destructive lesions have been shown to cause extreme anger – known as septal rage.

Basal forebrain

This region lies between the olfactory tract and infundibulum (caudally) and the amygdala. The magnocellular basal nucleus of Meynert is the largest single nuclear group here, its cholinergic neurones extending throughout the cortex (Figure 2.29). The basal nuclei, septal nuclei and neurones in the diagonal band of Broca are sometimes known simply as basal forebrain nuclei. The floor of the basal forebrain, the anterior perforated substance, is traversed by branches of the anterior cerebral arteries. Tonic cholinergic activity in the cortex, emanating from the basal forebrain nuclei, is concerned with maintaining wakefulness, thus facilitating perceptive activity within the cortex. Cholinergic activity is believed to enhance LTP in pyramidal cells of the cortex.

The thalamus

The paired conjoined thalami are among the larger nuclear masses of the brain. They are highly complex relay stations. In contrast to this complexity, the clinical neurology is relatively sparse, but of increasing relevance with the further development of stereotactic surgery and neurostimulation. The following is a practical clinical guide to the anatomy and function.

Divisions and connections are shown in Figure 2.30. It can be simplified by noting the large 'Y', of thalamic white matter – the internal medullary lamina – that divides the nuclei into three cell groups:
1 Anterior (within the 'Y');
2 Medial dorsal; and
3 Lateral nuclei.
Lateral nuclei are divided into ventral and dorsal tiers. The medial and lateral geniculate bodies lie posteriorly. The reticular nucleus surrounds each thalamus laterally, separated by an external medullary lamina traversed by thalamo-cortical fibres. The three functional groups of thalamic nuclei (somewhat uninformatively named) are:
1 Relay (specific) nuclei;
2 Association nuclei; and
3 Non-specific nuclei.
Principal connexions are shown in Table 2.7.

Cortical connections

Four, largely afferent connections from thalamus to cortex run in the anterior, posterior, inferior and superior thalamic peduncles in a cruciform arrangement:
1 The anterior thalamic peduncle reaches the cingulate gyrus and prefrontal cortex via the internal capsule (anterior limb).
2 The superior thalamic peduncle reaches the motor, premotor and sensory cortex via the internal capsule (posterior limb).
3 The posterior thalamic peduncle reaches the occipital, posterior parietal and posterior temporal lobes (also via internal capsule).
4 The inferior thalamic peduncle reaches the anterior temporal and orbital cortex.

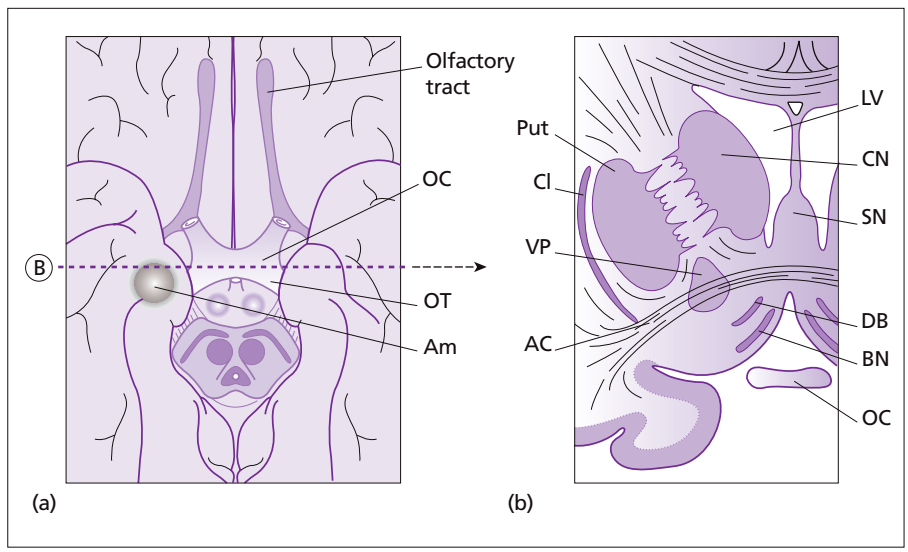

Figure 2.29 (a) Basal view of forebrain. Table 2.7 Thalamic nuclei: sources and destinations of fibres.

Source	Thalamic nucleus	Destination
Mamillary body	Anterior	Cingulate gyrus
Globus pallidus	VA	Prefrontal cortex
Globus pallidus	VL (anterior)	Supplementary motor area
Cerebellum (dentate nucleus)	VL (posterior)	Motor cortex
Head somatic afferents	VPM	Somatic sensory cortex (S1)
Trunk + limb somatic afferents	VPL	Somatic sensory cortex (S1)
Inferior colliculus (auditory)	Medial geniculate body	Primary auditory cortex
Superior colliculus (vision)	Lateral geniculate body	Primary visual cortex
Parietal lobe	Lateral dorsal	Cingulate cortex
Superior colliculus + parietal lobe	Pulvinar + lateral dorsal	Visual association cortex
Reticular formation	Intralaminar	Cortex – many areas
Thalamus	Reticular nucleus	Thalamus

VA, ventral anterior nucleus; VL, ventral lateral nucleus; VPL, ventral posterior nucleus, lateral; VPM, ventral posterior nucleus, medial.

Each fan of these sensory fibres forms part of the corona radiata (between the internal capsule and the cortex).

Specific (relay) thalamic nuclei

These nuclei of the ventral tier are connected to distinct motor and sensory areas of the cortex:

- Anterior and ventral anterior (VA) nucleus (Table 2.7).
- The anterior part of the ventral lateral nucleus (VL) receives fibres from the pallidum and relays them to the supplementary motor area.
- The posterior part of VL receives fibres from the opposite superior cerebellar peduncle (from the dentate nucleus) and relays to the motor cortex.
- Ventral posterior nucleus (VP). This receives all axons of the medial, spinal and trigeminal lemnisci (see below) and projects to the somatosensory cortex. The somatotopic arrangement is shown in Figure 2.31. The medial part (VPM) deals with the head; the lateral (VPL) with the limbs and trunk. Within each part of the VP there is segregation of sensory modalities – proprioception at the front, nociception at the back, with touch in the middle.
- The ventral intermediate nucleus (VIM), located between VL and VPL provides a direct route for somatosensory input to the motor cortex. VIM is of significant importance in the functional neurosurgical treatment of tremor (Chapter 5).

Within the VP there is no evidence of gating (cf. the substantia gelatinosa) or modulation – the system is either off (no pain) or on (intense pain). This perhaps helps to explain the sinister, persistent and untreatable pain of the thalamic syndrome, when a stroke disconnects VP from the sensory cortex (see Chapter 22).

- The medial geniculate body is an auditory system nucleus;
- The lateral geniculate body is a nucleus of the visual system.

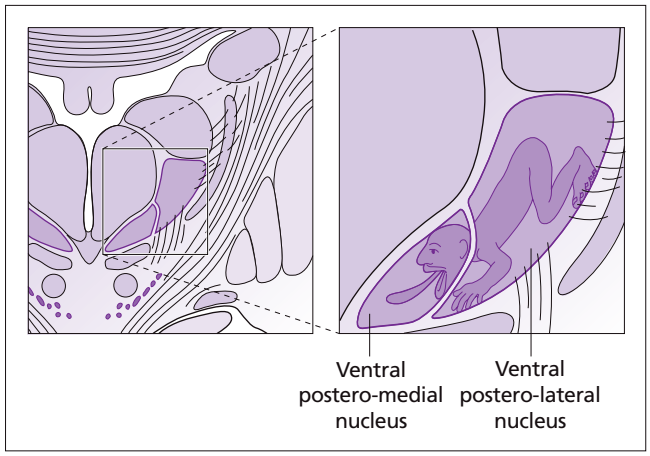

Figure 2.31 Thalamus (coronal section): ventral posteromedial and ventral posterolateral (VPM/VPL) nuclei – postulated somatotopic projection.

Association thalamic nuclei

These are so called because they are connected to association areas of the cortex:

- The lateral dorsal nucleus is connected to the cingulate cortex (memory).
- The medial dorsal nucleus is connected to entire prefrontal cortex, olfactory and limbic systems (mood, executive function, cognition, memory, associations of smells).
- The pulvinar and lateral posterior nucleus project to the visual and parietal association cortices, having received fibres from the lateral geniculate. Also, a direct pathway, from optic tract via superior colliculus reaches the visual cortex, without relaying through the lateral geniculate – involved in attention within the visual field, but outside conscious perception.

Non-specific thalamic nuclei

These nuclei are non-specific in the sense that they are not thought to be directly involved with individual sensory modalities. The intralaminar nuclei are the rostral termination of the reticular formation. Aminergic afferents reach the region from the midbrain raphe nuclei and the locus caeruleus. Prolongation of such excitatory aminergic activity in thalamo-cortical fibres is one effect of tricyclic drugs, and a possible mode of their action in chronic pain. There is widespread onward connection from intralaminar nuclei to the cortex.

The shield-shaped reticular nucleus connects to all thalamic nuclei. Each thalamo-cortical fibre connects to a reticular nucleus neurone via a collateral. Reticular nucleus cells respond by a GABAergic inhibitory response to the corresponding thalamic nucleus – terminating a sensory stimulus (Figure 2.32). During sleep–wake cycles, thalamo-cortical neurones are constantly inhibited during sleep (consider the effect of sleep/sedation on pain) and constantly active (disinhibited) during wakefulness.

Hypothalamus

The multiple paired nuclei of each hypothalamus (about 4 g apiece in humans) lie each side of the third ventricle. They are involved in two allied neuro-effector control systems:

1 Autonomic nervous system; and
2 Pituitary axis.

In one sense the hypothalamus is a central neural effector of basic survival. Consider its role in:

- Temperature homeostasis;
- Regulation of food and water intake;
- Defence, arousal and sleep–wake cycles;
- Sexual activity.

Looked at in another way, the hypothalamus mediates central control of all endocrine and all autonomic activity.

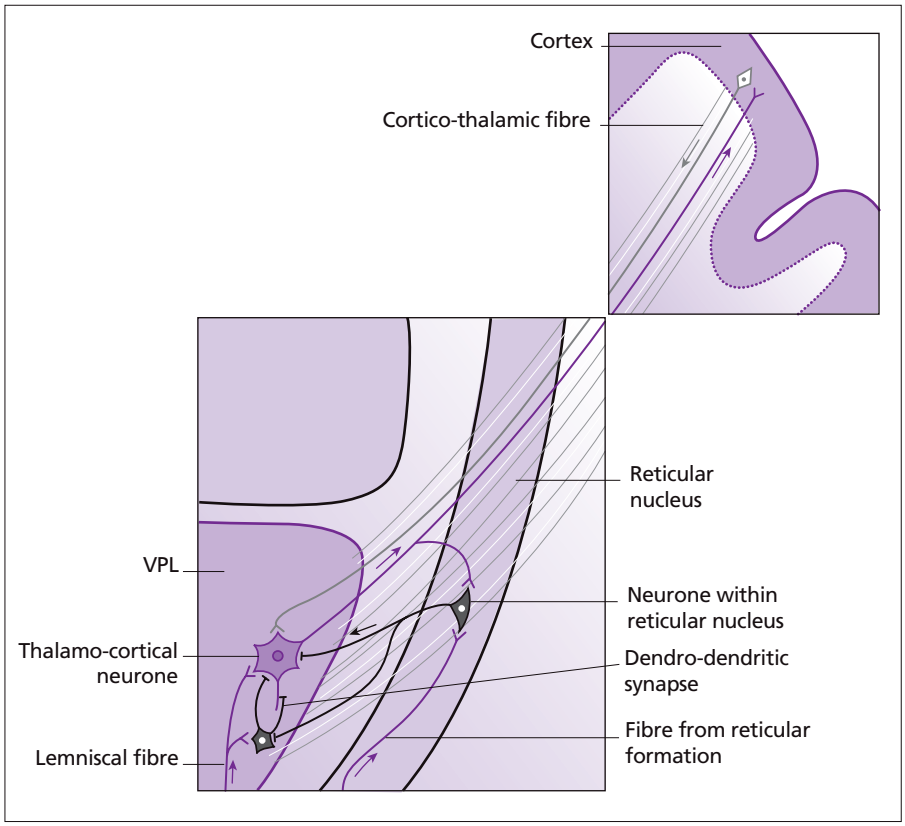

Figure 2.32 Connections from reticular nucleus of thalamus. VPL, ventral postero-lateral nucleus.

The essential nuclear anatomy is outlined in Figure 2.33 and the three groups of nuclei are listed in Table 2.8. The median forebrain bundle (aminergic fibres) merges with and lies lateral to the lateral nucleus of the hypothalamus on each side.

Arterial and capillary supply

Delicate perforating branches of the anterior communicating artery supply the hypothalamic region. Hypophyseal branches of the internal carotid artery supply the pituitary itself:

- *Superior hypophyseal artery:* anterior pituitary;
- *Inferior hypophyseal artery:* posterior pituitary.

Each hypophyseal arterial system forms a second capillary portal system that surrounds the neuroendocrine cells. Hormones are liberated into venous blood, draining into the cavernous sinus. These fenestrated portal capillaries are outside the blood–brain barrier.

Neuroendocrine cells

These neurones, cells specific to the region, both conduct action potentials and also liberate into the bloodstream peptide and other hormones, the latter having been synthesized in the endoplasmic reticulum and stored in Golgi complexes. The peptides are attached to long-chain polypeptides – neurophysins. Cell bodies of neuroendocrine cells lie in the region of the pre-optic nuclei and tuber cinereum. The principal nuclei that also contribute to this system are:

- Supra-optic;
- Paraventricular;
- Ventromedial; and
- Arcuate nuclei.

Small neurone (parvocellular) axons in the tubero-infundibular tract reach the median eminence, where releasing factors (RH) and inhibiting factors (IH) are liberated. Large neurone (magnocellular) axons form the hypothalamo-hypophysial tract that passes to the posterior pituitary.

Anterior pituitary axis

The hormones of the anterior pituitary axis will be familiar. (Table 2.9). All known RH/IHs, with the exception of prolactin IH, are peptides. Prolactin IH is dopamine. The complex control systems for these hormones, outside the scope of this chapter, include:

- Traditional feedback loops;
- Depolarization by action potentials entering from the limbic system and reticular formation (e.g. arousal effects);
- Hyperpolarization by local GABAergic neurones;
- Inhibition by opiate-releasing neurones (numerous in the hypothalamus); and
- Activation directly of anterior pituitary endocrine cells by opiates and endorphins.

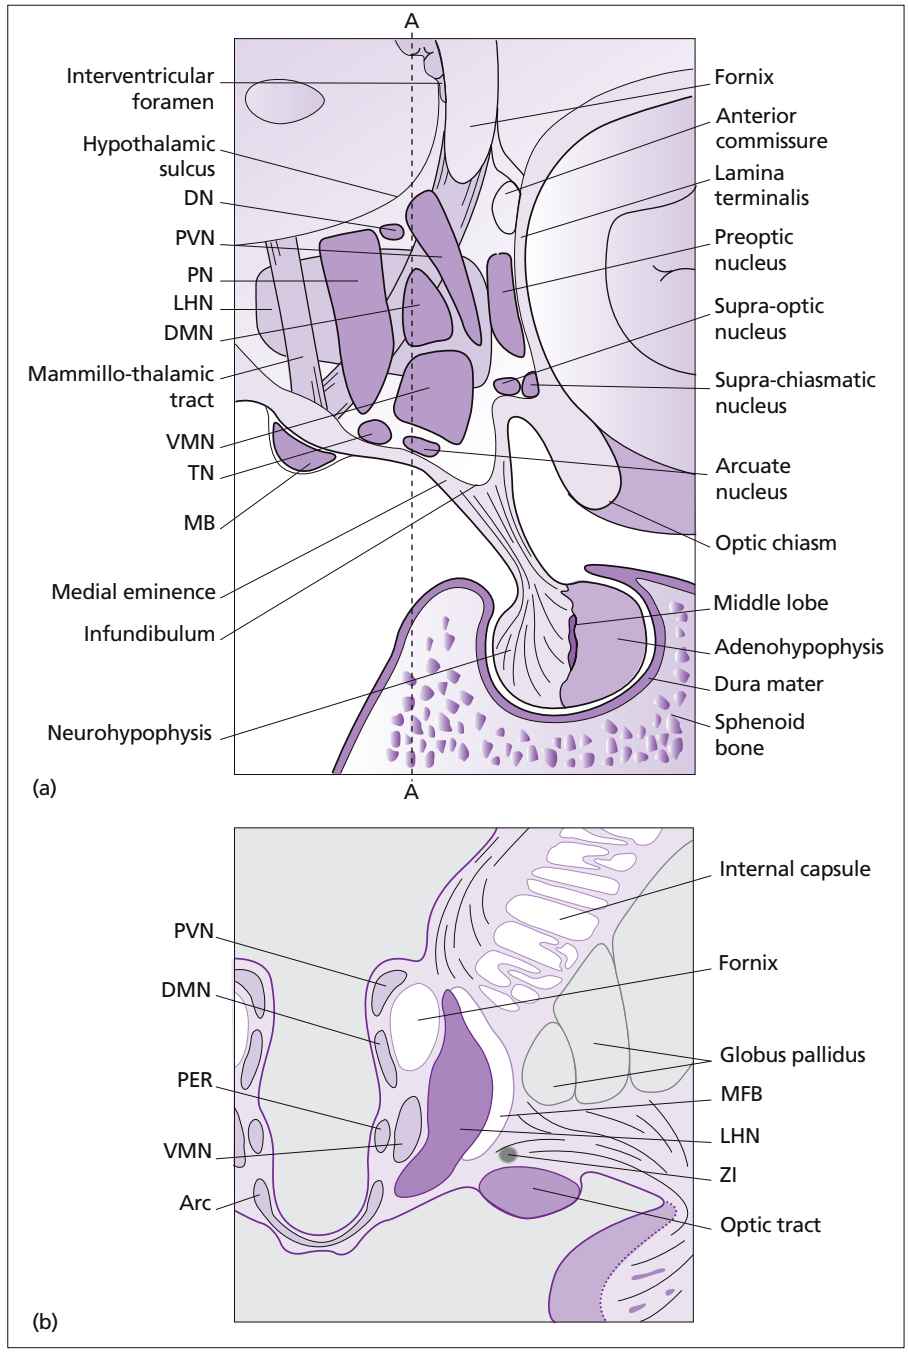

Figure 2.33 Hypothalamic nuclei. (a) Saggital section. (b) Coronal section through A–A. Anterior	Middle	Posterior
Pre-optic	Paraventricular	Posterior
Supra-optic	Dorsomedial	Mammillary body
Supra-chiasmatic	Lateral	Tuberomammillary
	Ventromedial	Dorsal
	Arcuate	

Table 2.9 Pituitary and hypothalamic releasing/inhibiting hormones (RH/IH).

Anterior lobe hormone	RH/IH
ACTH	Corticotrophin RH
FSH/LH	Gonadotrophic hormone RH
Growth hormone	Growth hormone RH and IH
Prolactin	Prolactin RH and IH
Thyrotropin	Thyrotropin RH

ACTH, adenocorticotrophic hormone; FSH, follicle-stimulating hormone; LH, luteinizing hormone.

Posterior pituitary axis

Each hypothalamo-hypophyseal tract passes from large (magnocellular) neurones of the supra-optic nucleus and paraventricular nucleus to the posterior pituitary (neurohypophysis). There are also contributions from peri-ventricular neurones (opiate and peptide neurotransmission) and brainstem (aminergic) neurones.

Vasopressin (antidiuretic hormone) and oxytocin are secreted by specific neurones in both supra-optic and paraventricular nuclei, the hormones being housed in axonal secretory granules (Herring bodies) before being released into the capillary system within the posterior pituitary itself.

Circumventricular organs

This term refers to six groups of specialized neurones and glial cells adjacent to the ventricular system that have an intimate relation to fenestrated capillaries:

1 Neurohypophysis;
2 Median eminence;
3 Vascular organ of the lamina terminalis (VOLT);
4 Subfornical organ;
5 Area postrema;
6 Pineal gland.

Functions are outlined in Table 2.10.

Sympathetic and parasympathetic hypothalamic activity

Posterior hypothalamic stimulation produces noradrenergic sympathetic effects:

- Heart rate ↑;
- Blood pressure ↑;
- Pupil dilatation;
- Gut stasis.

Anterior hypothalamic stimulation produces muscarinic parasympathetic effects:

- Heart rate ↓;
- Blood pressure ↓;
- Pupil constriction;
- Peristalsis.

The axonal pathway projects from anterior and posterior hypothalamus to autonomic nuclei in the brainstem and cord – via the dorsal longitudinal fasciculus in the midbrain and pons (see below).

Temperature regulation

Thermosensitive neurones in the hypothalamus respond to core temperature changes. Spino-reticular tracts also deliver information to these hypothalamic neurones from skin thermal receptors. The autonomic effector sympathetic system alters skin blood flow and sweating via the posterior nucleus of the hypothalamus – axons pass direct to the lateral horn of the cord. Increase in core temperature is achieved by:

- Skin vasoconstriction;
- Abolition of sweating;
- Shivering/muscular activity; and
- Behavioural responses, e.g. crouching, huddling.

Hypothalamic temperature-sensitive neurones also respond to exogenous pyrogen, setting the central thermostat to a higher level, and are also involved in the production of central pyrexia (Chapter 19).

Water intake and thirst

The zona incerta, a strip of cells beside each lateral nucleus of the hypothalamus, controls thirst. Lesions of this region lead to neglect of drinking, and stimulation (in animals) to thirst and excessive water intake. Many other mechanisms also contribute to osmotic homeostasis, e.g. serum sodium and glucose levels and renal function.

Appetite

Balance in activity between the lateral and ventromedial hypothalamic nuclei constitutes, in theory at least, a satiety centre in humans. In experimental models:

- Lateral hypothalamic (feeding centre) stimulation causes overeating;
- Lateral hypothalamic destruction causes lack of interest in food;
- Ventromedial hypothalamic (satiety centre) stimulation inhibits eating;
- Ventromedial hypothalamic destruction (bilateral) causes gross obesity.

Table 2.10 Circumventricular organs.

Organ	Function	Comment
Neurohypophysis	ADH secretion	See text
Median eminence	Anterior pituitary hormone release and inhibition	
VOLT + SFO	Facilitate ADH secretion	Axons to supra-optic and paraventricular nuclei (feedback loop: low blood volume → kidney → renin → angiotensin II → VOLT/SFO → ADH)
Area postrema	Chemoreceptor (emetic) centre	Reflex vomiting (situated at obex of 4th ventricle)
Pineal gland (body)	Melatonin	Sleep–wake cycles

ADH, antidiuretic hormone; SFO, subfornical organ; VOLT, vascular organ of the lamina terminalis.

Serotoninergic activity down-regulates the appetite set point, and vice versa, selective serotonin re-uptake inhibitors (SSRIs) and other antidepressants tend to increase appetite.

Mood, sexual arousal, wakefulness and memory

Mood. Aggression or docility are features of experimental lateral/ventromedial hypothalamic imbalance. Obese animals with ventromedial lesions become aggressively enraged. Underweight, ventromedially stimulated animals are docile. Hunger stimulates arousal. The relevance of this in day-to-day human behaviour is unclear but might explain why some people become angry when they are not fed at the time they expect food.

Sexual arousal. Specific neurones (INAH3 cells) in each pre-optic nucleus are more numerous in males than in females. This is an area rich in androgen receptors, activated by testosterone and which when experimentally stimulated induces (male) sexual activity.

In females, neurones rich in oestrogen receptors are found in the ventromedial nucleus: experimental stimulation induces sexual arousal.

Wakefulness. The suprachiasmatic nucleus is involved in setting sleep–wake cycles via putative pineal gland connections.

Arousal is mediated via richly histaminergic neurones in the posterior hypothalamus (the tuberomammillary nucleus). These project widely (medial forebrain bundle, cortex, brainstem, cord). Hypersomnolence in humans is seen when the posterior hypothalamus is damaged bilaterally.

Memory. The mammillary bodies are stations on Papez's circuit (fornix → mammillary bodies → mammillothalamic tract → anterior nucleus of thalamus). Mammillary body destruction produces a dramatic amnestic syndrome.

Generally, for an area so intimately involved in activities essential for life, lesions of the hypothalamus are surprisingly unusual in day-to-day neurology. The area appears resilient. One reason may be quite simple: bilateral hypothalamic destruction is necessary to produce clinical effects.

Cranial nerves

Olfactory nerve and its cortical connections

This afferent system, more highly developed in some animals than in humans, comprises:

- Olfactory neuronal epithelium;
- Olfactory nerves;
- Olfactory bulb and tract; and
- Olfactory cortical areas and connections.

Olfactory epithelium

This epithelial layer covers about one-fifth of the upper nasal cavity. Basal stem cells, unique among neurones in mammals, transform in a regular 4–8 week cycle into fresh highly specialized bipolar neurones. These neurones lie between sustentacular (supporting) cells (Figure 2.34). Their dendrites are ciliated processes containing olfactory receptors that line the receptive area. Afferent axons traverse the cribriform plate, guided by olfactory ensheathing cells, a specialized form of glia. There are two chemosensory systems within the nasal mucosa, the olfactory system and trigeminal afferents that respond to irritants, e.g. ammonia and the sensation of coolness, e.g. of menthol; the trigeminal system is mentioned no further here.

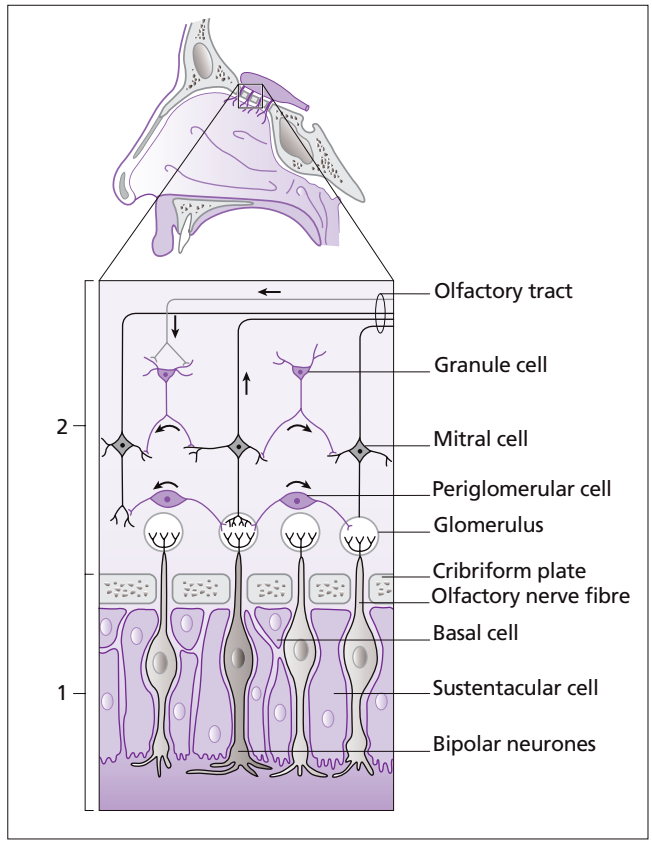

Figure 2.34 Receptor cells of the olfactory system.

Olfactory bulb and tract

Each bulb consists of some 50,000 mitral cells that make synaptic contact with epithelial bipolar neurones in several thousand glomeruli, surrounded by glia. Active glomeruli, stimulated by receptive bipolar cells, inhibit neighbouring glomeruli through a GABAergic pathway via peri-glomerular cells. Mitral cells are also under the influence of deeper granule cells, with which they make dendro-dendritic contact. Stimulated granule cells suppress other mitral cells, selectively, again via GABAergic synapses.

Cortical connections

Each afferent pathway remains entirely ipsilateral, but the anatomical tract divides in the anterior perforated substance into

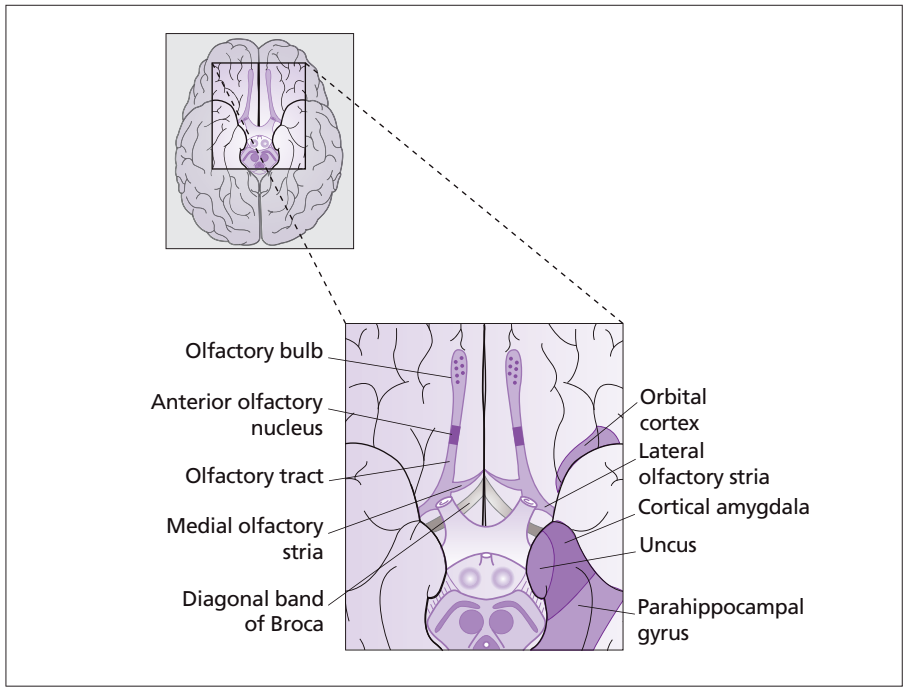

Figure 2.35 Anatomy of the olfactory tract region.

medial and lateral striae. Lateral olfactory stria afferents pass to each piriform lobe of the anterior temporal cortex (this includes part of the amygdala, uncus and parahippocampal gyrus) and thence to the posterior orbito-frontal cortex. Each medial olfactory stria contains efferent axons from each anterior olfactory nucleus – scattered neurones in the olfactory tract.

The perception and intimate complexity of different aromas is achieved by groups of cortical neurones that respond to particular sequences of action potentials. The widespread central connections of the olfactory cortex make possible association of particular smells with individual memories, both visual and topographical, recent or distant. Anosmia is discussed in Chapter 12.

Neurotransmission in the olfactory system

The practical neurology of anosmia occupies but little space in a busy out-patient clinic – and testing of discrimination of the sense of smell is frequently omitted altogether or simply accepted as normal. However, advances in the neurobiology of olfaction have broadened our understanding of this special sense and highlighted the way the cortex achieves separation and recognition of such complex afferent data.

The cilia of the bipolar neurones lining the olfactory epithelium lie at the start of a complex sequence:

- Odorant molecules bind to odorant receptor proteins;
- G-protein (G_{olf}) stimulation follows;
- Cilial adenyl cyclase is activated;
- ATP is liberated and cyclic AMP (cAMP) generated;
- Cation channels open (Na^+ and Ca^{2+}channels) →;
- → Opening of Ca^{2+}-activated Cl^- channels; and thus
- → Membrane depolarization, an excitatory action potential and propagation along the axon of a bipolar cell.

There are around 1000 odorant receptor genes. These are expressed on individual bipolar cells, i.e. there are around 1000 receptor cell subtypes, a large number, but vastly insufficient to account for the appreciation, in humans of about 100,000 different smells, or for an even more highly tuned sense of olfaction in many mammals.

In olfactory neurones, the single second messenger is cAMP, i.e. the channels are cAMP-gated. Each receptor subtype is broadly tuned – each responds to various similar odorants – and, correspondingly, each odorant can stimulate more than one receptor subtype. Thus each bipolar cell yields potentially ambiguous information. A further selection process takes place at the level of the glomeruli.

Each olfactory bulb contains some 2000 spherical glomeruli 50–200 μm in diameter. The endings of around 25,000 primary olfactory bipolar receptor axons end in the glomeruli, forming synapses with about 100 (only) second order olfactory neurones. The association between individual receptor subtypes and a particular glomerulus is precise. Receptor neurones expressing one gene, although scattered throughout the epithelium, converge on several (only) glomeruli in each olfactory bulb.

Within each glomerulus there is excitation and inhibition (e.g. see Mitral cells above) and thence it is the temporal coding of afferent impulses that determines the particular perceived smell by cortical receptive fields. Olfactory cortical neurones recognize a particular 'tune' of impulses as an individual smell.

The projection of each olfactory tract is direct to phylogenetically ancient regions of the cortex, in contrast to most other sensory input which passes first to the thalamus before reaching the cortex. From the olfactory cortex, there are projections to areas throughout the brain.

Finally, not all olfactory perception is at a conscious level. Pheromonal perception in humans undoubtedly exists – probably accounting for some part of the process of sexual attraction. Pheromones are, for example, of critical importance in lepidoptera, enabling attraction to take place over several kilometres in moths between males and females. There is evidence to support the existence of a vomero-nasal receptor organ in humans in the lateral nasal mucosa. Central pathways in humans remain unknown and the neurochemistry of pheromonal activating systems conjectural.

Optic nerve and the visual system

The visual pathway is summarized in Figure 2.36. The essential features will be familiar. This section focuses on individual aspects of this complex and highly developed special sense. Visual field defects and other clinical details are also discussed in Chapter 13.

Retinal structure

The eight retinal cell and fibre layers are shown in Figure 2.37:

- Photoreceptors (2) – rods and cones – are applied to the pigment epithelium (1), adjacent to the choroid.
- Ganglion cells (7) are the source of action potentials conducted by axons that form the retinal nerve fibre layer (8) and pass into the optic nerve.
- Two sets of retinal neurones – horizontal cells and amacrine cells – are arranged transversely.

The essential circuitary is shown in Figure 2.38.

Photoreceptors and bipolar cells

Cone photoreceptors are sensitive to bright light, colour and shape. They are clustered in and around the fovea. Photoreceptor end-feet synapse with bipolar cells and horizontal cells processes. Cone bipolar cells are either:

- ON bipolars, i.e. switched ON (depolarized) by light, or inhibited by neurotransmitters released when light levels fall. They synapse and converge on ON cone ganglion cells.
- OFF bipolars have an opposite response. They synapse and converge on OFF ganglion cells.

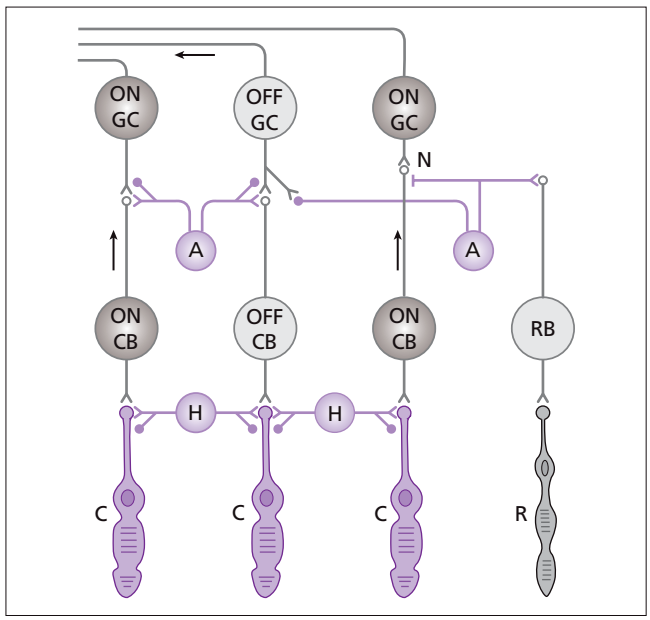

Figure 2.38 Basic circuit diagram of the retina. A, amacrine cell; C, cone; CB, cone bipolar; GC, ganglion cell; H, horizontal cell; N, nexus (gap junction); R, rod; RB, rod bipolar.

Horizontal cells extend dendrites between photoreceptors and bipolar cells with which they make inhibitory contacts. Bipolar cells (and hence retinal ganglion cells) outside the immediate zone of excitation are inhibited. This has the effect of restricting retinal activity to the area under direct photic stimulation (centre–surround antagonism).

Rod photoreceptors are active in conditions of low illumination. They are insensitive to colour – dimly lit objects are perceived in shades of grey. Like cones, rods display centre–surround antagonism, between white and black. They too synapse with ON and OFF bipolar cells.

Rod bipolar cells activate ON and OFF rod ganglion cells via amacrine cells. Amacrine cells have 6–10 dendrites that emerge from one aspect of each cell body. Over one dozen types of amacrine cell are recognized, with different transmitters, e.g. ACh, dopamine, serotonin. Their action is to modulate (turn ON or OFF) groups of ganglion cells. Visual functions include enhancement of contrast and detection of subtle movement by retinal rods.

Ganglion cells, of either ON or OFF variety, are activated by bipolar neurones. An ON ganglion cell is activated by a point light source and inhibited (via horizontal cells and appropriate bipolars) by a surrounding ring of light (annular inhibition). An OFF ganglion cell reacts in reverse fashion, being inhibited by a point source and excited by an annulus of light.

Colour recognition within the retina – red, green and blue

Colour opponency is the response that characterizes specific ganglion cells. Ganglion cells are either:

- ON-line for green + OFF-line for red;
- ON-line for red + OFF-line for green;
- ON-line for blue + OFF-line for yellow.

Colour recognition is achieved by specific individual cones because they are sensitive to particular wavelengths of electromagnetic energy.

Heterogeneity of rods, cones and ganglion cells

The majority of both rod and cone ganglion cells are parvocellular (small, P cells) – small receptive fields receptive to shape and colour. A minority are magnocellular ganglion cells (large, M cells) – large fields, particularly receptive to moving objects.

The specialized region of cones is the fovea and its central 100 μm, the foveola – the area that has the highest sensitivity for object discrimination and colour appreciation (Figure 2.39). Several anatomical features of the foveola enhance sensivity:

- Midget cones in the foveola have one-to-one synaptic contacts with midget bipolar cells and ganglion cells (outside the foveola sensitivity is less acute);
- Superficial layers of the retina have long neurites, the cell bodies being dispersed around the fovea rather than covering the cones – this allows light to strike midget cones directly.

Optic nerve, chiasm and optic tract

Each optic nerve (a CNS structure rather than a peripheral nerve) contains between 800,000 and 1.5 million ganglion cell axons, with a supporting infrastructure – astrocytes, oligodendrocytes, blood supply and meningeal sheath. The chiasmal decussation, optic tract and optic radiation are illustrated in Figure 2.40.

Each optic tract (comprised of uncrossed temporal-half and crossed nasal-half retinal axons) divides into a medial and a lateral root. The medial root of each optic tract enters the midbrain. It carries:

- Fibres serving the pupillary light reflex – passing to the pretectal nucleus;
- Fibres from retinal M cells – scanning movements – to the superior colliculus;
- Fibres to the reticular formation (parvo-cellular) – arousal function; and
- Fibres relaying from superior colliculus, to pulvinar and visual association cortex – the extra-geniculate visual pathway.

The axons of lateral root of the optic tract synapse in the lateral geniculate body (LGB) of the thalamus. The LGB is six-layered:

- Three cellular laminae receive crossed fibres and three uncrossed;
- The two deepest laminae (magnocellular) receive axons from retinal M ganglion cells (movement detection);
- The four outer laminae are parvocellular, receive axons from P ganglion cells (detail and colour).

Optic radiation

The optic radiation (syn. geniculo-calcarine tract), its ordered somatotopic arrangements and cortical targets are shown in Figure 2.40. The radiation is the most prominent white matter bundle in the posterior part of the brain. Important anatomical features are as follows:

- The radiation enters the posterior (retrolentiform) part of the internal capsule, runs beneath the temporal cortex and alongside the posterior horn of the lateral ventricle.
- Meyer's loop – forward-sweeping fibres in the anterior temporal lobe. These are from the upper part of the visual fields and run to the lower half of the occipital cortex.

Occipital cortex

The optic radiation is seen macroscopically as a pale stripe (stria) of myelinated fibres within the primary visual or striate cortex (Brodmann area 17) before synapsing with spiny stellate cells of cortical layer IV. Francesco Gennari (1752–1797) was a medical student in Padua when he described the occipital striae that bear his name.

The spiny stellate ganglion cells are arranged in alternating ocular dominance columns (alternating inputs between left and right eyes). Thus, impulses from identical points on each retina arrive in the striate cortex in side-by-side columns. Further differentiation is achieved by a hierarchy of cell groups:

- Spiny stellate cells produce simple responses – to fine slits of light in a particular orientation.
- Some pyramidal cells produce complex responses – to broad slits (bars), orientated at a particular angle and either stationary or moving broadside in one direction across the visual field.
- Other pyramidal cells are hypercomplex, responding to L-configurations.

The mechanism of this hierarchical system is explained by convergence:

- Several simple cell axons converge on to complex cells; and
- Complex cell axons converge on to hypercomplex cells.

The primary visual cortex can be thought of as a complex pixellated screen, detecting position in the visual fields, shape and movement. Area 17 (V1) does not interpret what we perceive to be vision – i.e the area does not 'recognize' a face or describe an object. Recognition, i.e. perception is achieved by connections with the visual association cortex, with the temporal lobes and memory circuits. The value of vision is also enhanced by eye movement, and by moving the head, limbs and/or trunk in relation to visual stimuli. The cortical eye fields are intimately involved in these processes.

Visual association cortex and V1–V5 terminology

Brodmann areas 18 and 19, also known as peri-striate or extra-striate (syn. visual association) cortex contain cortical cell columns concerned with feature extraction. This means that certain cell groups respond to geometry (i.e. shape), some to perception of height/depth (stereopsis) and others to colours with the ability to differentiate between many hues. The regions contain cell groups that recognize these particular attributes of objects. Afferents arrive primarily from area 17. There are also direct thalamic projections from the pulvinar.

The V1–V5 nomenclature, based more on functional imaging findings than the descriptive anatomy of the older (Brodmann)

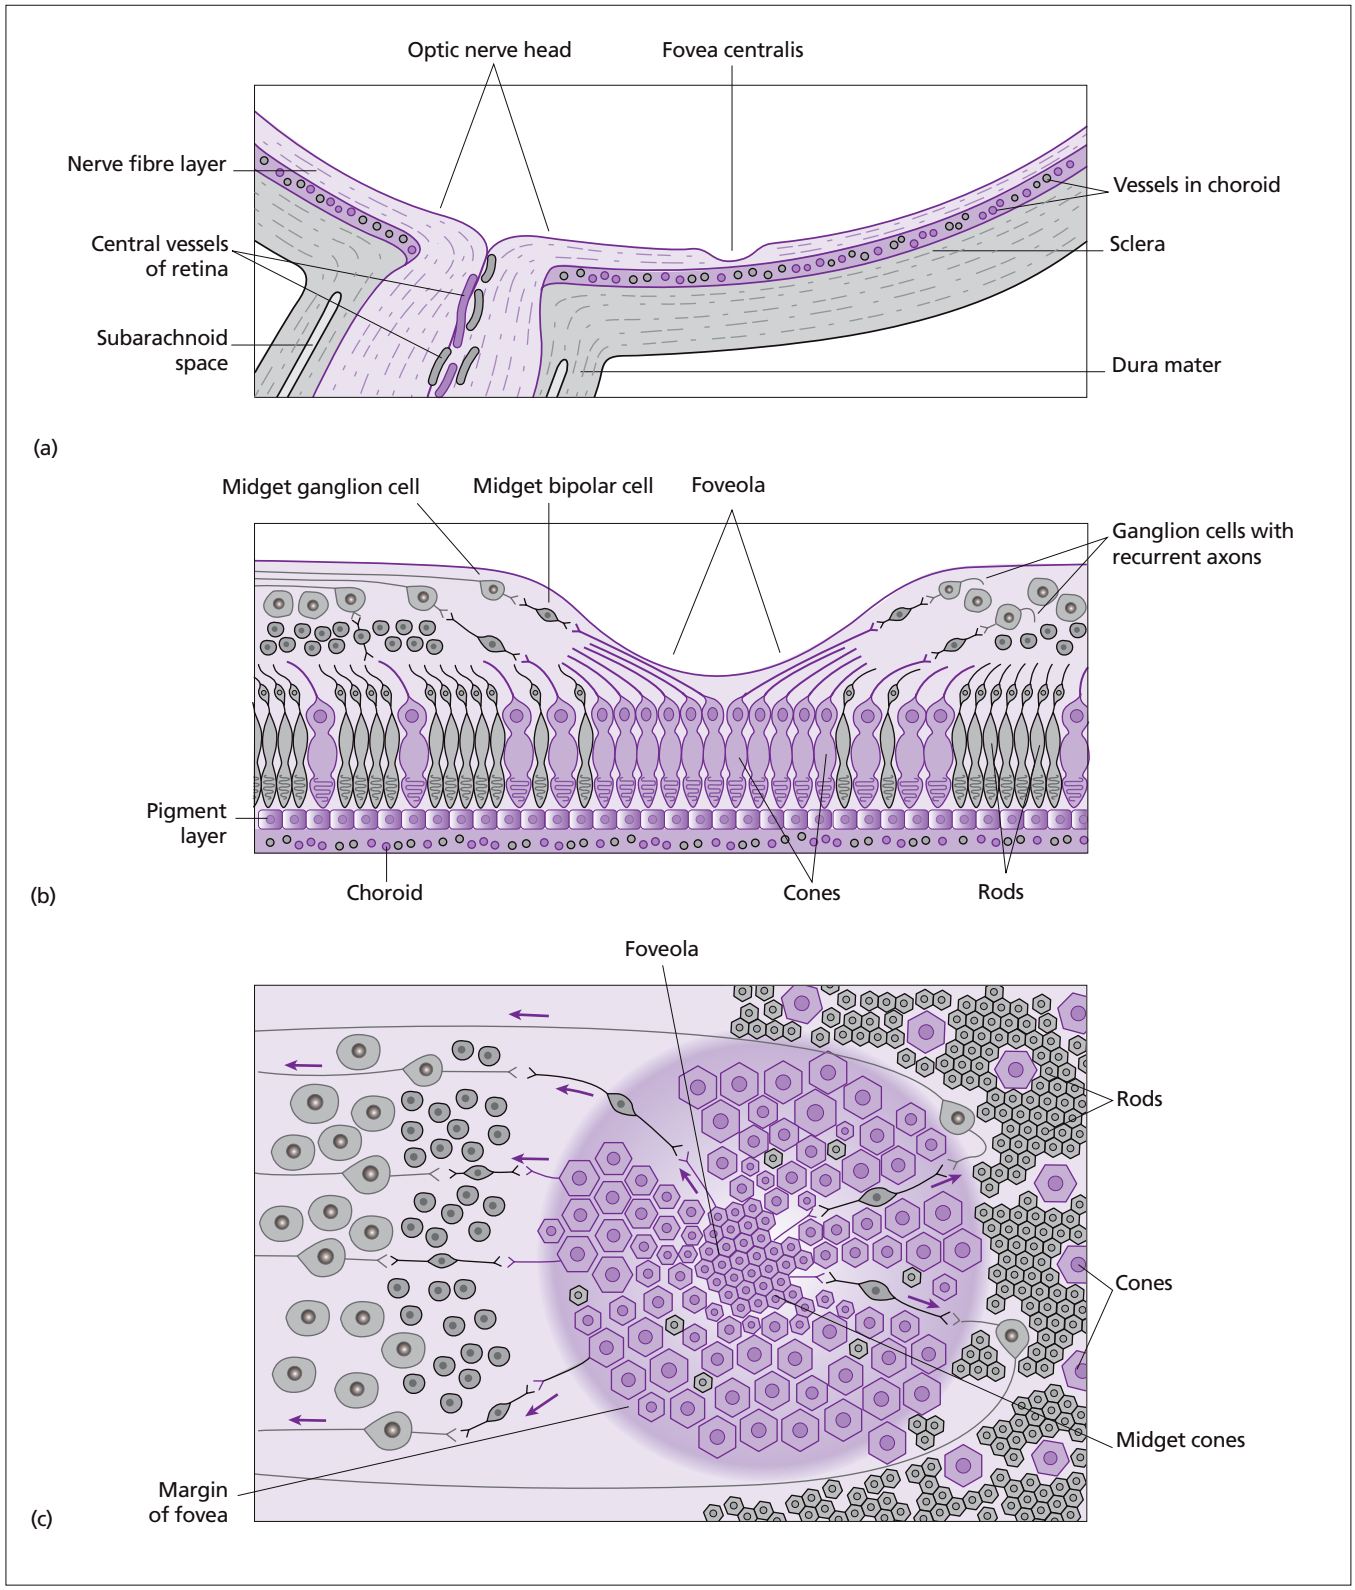

Figure 2.39 The fovea. (a) Horizontal section through the optic disc and fovea. (b) Fovea and foveola. (c) Fovea and foveola (surface diagram).

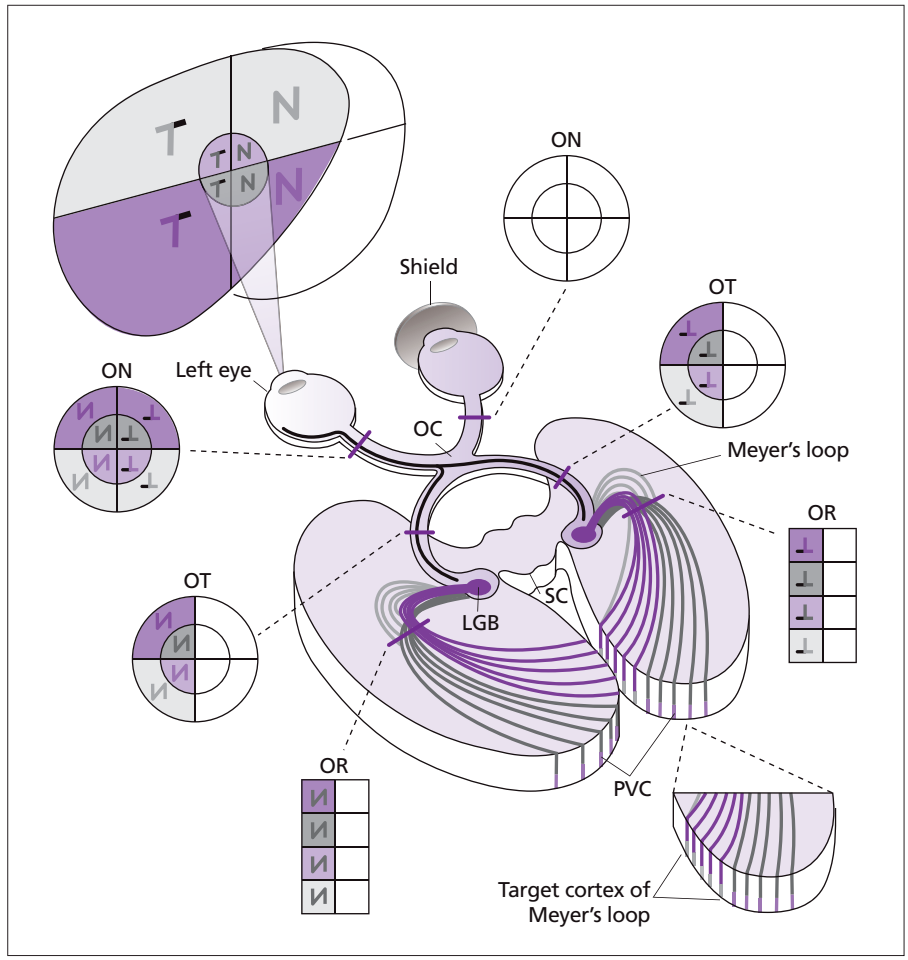

Figure 2.40 Optic nerve chiasm and optic radiation. Temporal field of left eye to primary visual cortex. LGB, lateral geniculate body; N, nasal; OC, optic chiasm; ON, optic nerve; OR, optic radiation; OT, optic tract; PVR, primary visual cortex; SC, superior colliculus; T, temporal. Note: inversion of visual field, Meyer's loop, lateral geniculate body. Foveal axons travel in lateral portion of fan of fibres within optic radiation, to reach occipital pole (posterior part of primary visual cortex).

system, is now widely used (Table 2.11). The lateral and medial parts of area 19 (V4, V5) contain specialized connections sometimes known as 'where and what' visual pathways:

- 'What' is the ventrally placed, medial stream of object recognition (V4);
- 'Where' is the lateral, dorsally situated stream concerned with location (V5), with projections to the posterior parietal lobe.

'What'

Three principal types of visual recognition take place in this region:

1 Recognition of forms, shapes and categories of objects (generic or canonical identification) takes place in the lateral zone.

2 Human face recognition (generic identification – 'this is a face') takes place in the mid zone.

3 Colour recognition takes place medially (Figure 2.41).

More sophisticated recognition of individual objects and faces involves area 20 (inferotemporal cortex) and area 38 (temporal pole cortex). Objects and faces that are threatening generate activity (via areas 20 and 38) in the amygdala and inferofrontal cortex.

'Where'

The lateral part of area 19 is particularly responsive to movement in the contralateral hemifield (Figure 2.42). The main projection is to area 7 (posterior parietal cortex), long known as the area affected in disorders of spatial recognition (e.g. astereognosis, see Chapter 3). Area 7 is involved in:

- Movement perception;
- Stereopsis (three-dimensional vision);
- Spatial sense (relative position of objects to each other).

Area 7 also receives fibres from the pulvinar ('blindsight fibres'). Fibres project to the ipsilateral frontal eye field and premotor cortex. Functional imaging shows increased cortical activity in area 7 in response to a moving object in the contralateral hemifield (covert attention). During saccadic gaze and/or limb movement towards the object both area 7 and area 5 are activated (overt attention).

Cortical eye fields

Conjugate eye movement is controlled by discrete regions within the grey matter. These are shown in Plate 2.3, Table 2.12. The complexity is evident. fMRI has been of value here, not only confirming clinical data, but also variability between individuals.

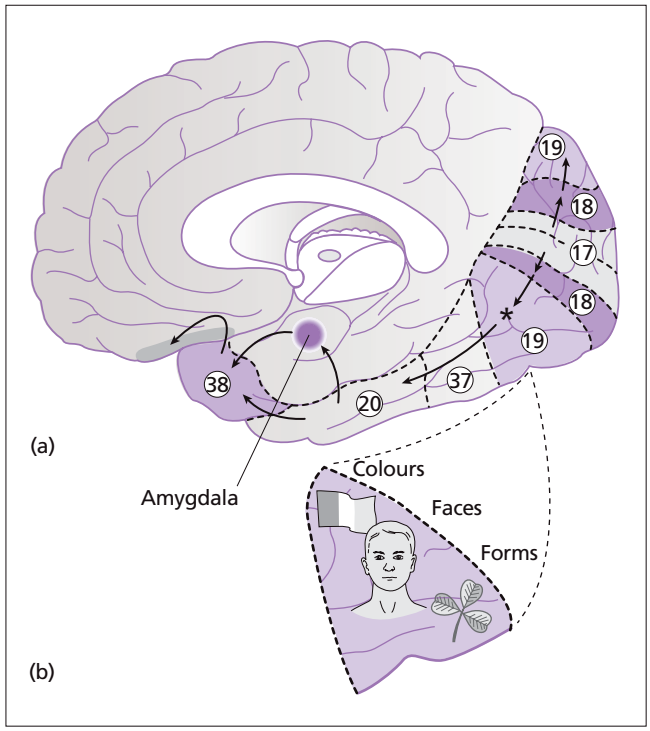

Figure 2.41 'What' visual pathway – medial surface of right hemisphere. (a) Asterisk indicates area for identification (fusiform gyrus) in left visual field. (b) Detail of ventral portion of area 19 – colours, faces and forms.

Table 2.11 V1–V5 and Brodmann areas: primary visual and visual association cortex.

V Region	Brodmann area
V1	Brodmann area 17
V2	Brodmann area 18
V3	Brodmann area 19
V4	Identification modules in fusiform gyrus in area 19 (antero-medial)
V5	Movement dedection modules in area 19 (antero-lateral)

Three different mechanisms are involved in driving conjugate, i.e. yoked (Latin: jugum = a yoke) gaze:

- *Scanning:* saccades, i.e. rapid movement from one target to another;
- *Tracking:* smooth pursuit of a target across the visual field;
- *Compensation:* maintenance of gaze during head movement via vestibulo-ocular (fixation) reflex.

Voluntary saccades are initiated in the frontal eye fields. Smooth pursuit movements originate in the occipital and parietal cortices (Table 2.12). Velocity detectors in the upper pons receive information via the medial root of the optic tract. Fixation is achieved by visual pursuit modulated by input from the vestibular system (head and neck movement) and smooth ocular movements by the cerebellar flocculus.

Automatic scanning movements are generated by retinal action potentials in the medial portion of the optic tract, via the pulvinar and area 7. These are also influenced by the cerebellar vermis and

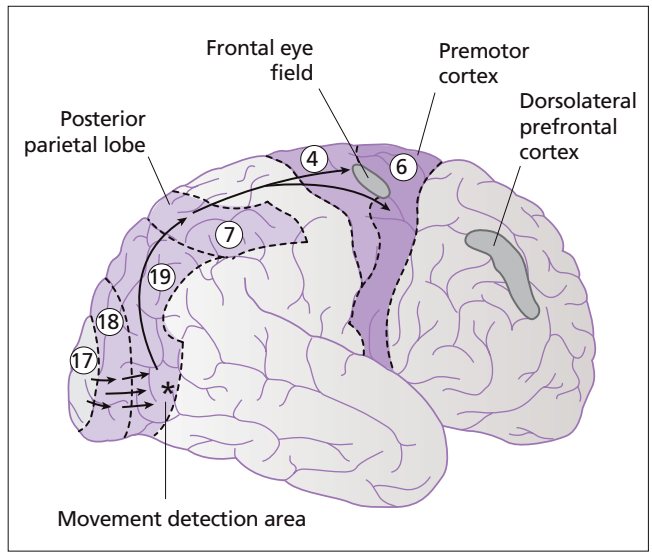

Figure 2.42 'Where' visual pathway – lateral surface of right hemisphere. Asterisk indicates area for movement detection in left visual field (Area 19). R, frontal cortical eye field activates conjugate saccades towards left visual field.

Table 2.12 Seven cortical areas involved in saccades: afferents, efferents, functions.

Eye field	Afferents	Efferents	Functions/comments
DLPFC	Visual association cortex	SC, ipsilateral FEF, SEF, CCx	Voluntary saccades, approach and withdraw decisions
CCx	DLPFC, FEF, SEF	SC, ipsilateral FEF	Emotional significance of object; paying attention
SEF	DLPFC, PEF, Area 22	SC, ipsilateral FEF	Motor planning, multiple saccades
FEF	DLPFC, opposite FEF, PEF	SC, opposite PPRF, ipsilateral CCx	Voluntary saccades
Area 22	Auditory association area, PEF	Ipsilateral SC, neck movement	Saccades to sound source
PEF	'Where' pathway, pulvinar, DLPFC	Ipsilateral FEF, SC	Reflex (responsive) saccades
OC	Visual pathway	All cortical eye fields and SC	Interpretion and visual pursuit

CCx, cingulate cortex; DLPFC, dorso-lateral prefrontal cortex; FEF, frontal eye field; OC, occipital cortex; PEF, parietal eye field; PPRF, paramedian pontine reticular formation; SC, superior colliculus; SEF, supplementary eye field.

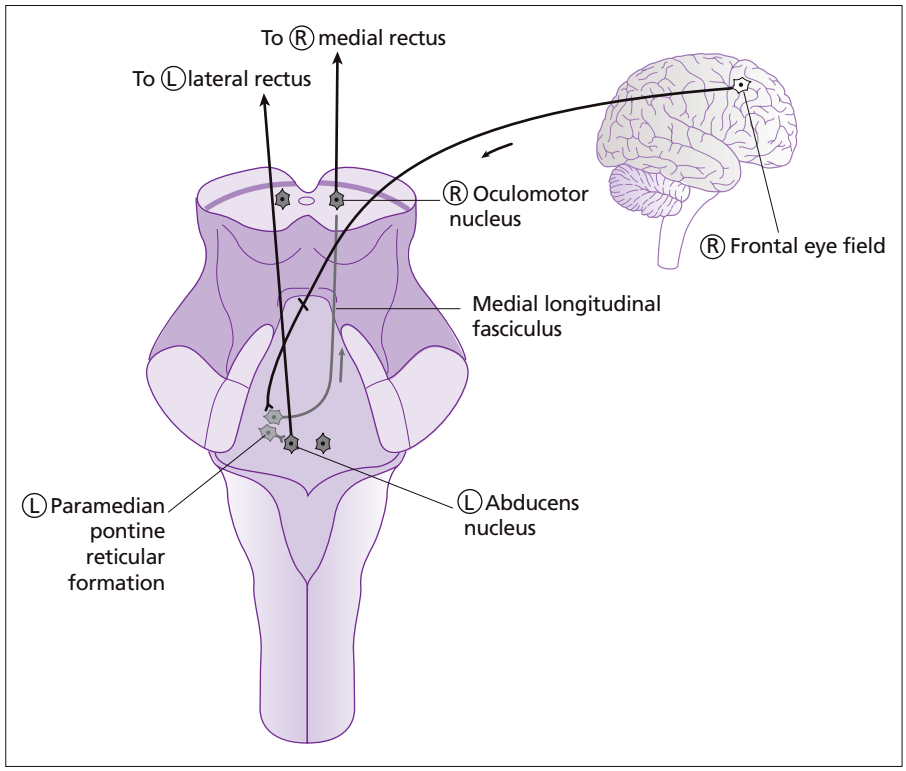

Figure 2.43 Midbrain: posterior view: voluntary congugate eye movement →left.

vestibular system. This explains some automatic movements, e.g. hands being in position to catch a rapidly moving ball before it becomes visible.

Eye and pupil movement below the level of the cortical eye fields consists of:

- Conjugate gaze mechanisms within the brainstem;
- Pupillary light reflexes;
- Individual cranial nerves III, IV and VI and the muscles supplied;
- Near and far responses.

Gaze centres in the brainstem

Horizontal (lateral) gaze centres lie in the right and left PPRF adjacent to each abducens nucleus. Upward gaze is controlled by the rostral interstitial nucleus (RiN) close to the pretectal nucleus (IIIrd nucleus level). This lies at the rostral end of the medial longitudinal fasciculus (MLF). This bundle connects each PPRF and abducens nucleus with the portion of the IIIrd nucleus that supplies the medial rectus – thus yoking together abduction in one eye with adduction in the other. The downward gaze centre is ventral to the RiN at the same level (Figure 2.43).

Pupillary light reflex

The pathway from retinal ganglion cell to post-ganglionic parasympathetic fibres and onwards to the iris (sphincter pupillae) is shown in Figure 2.44.

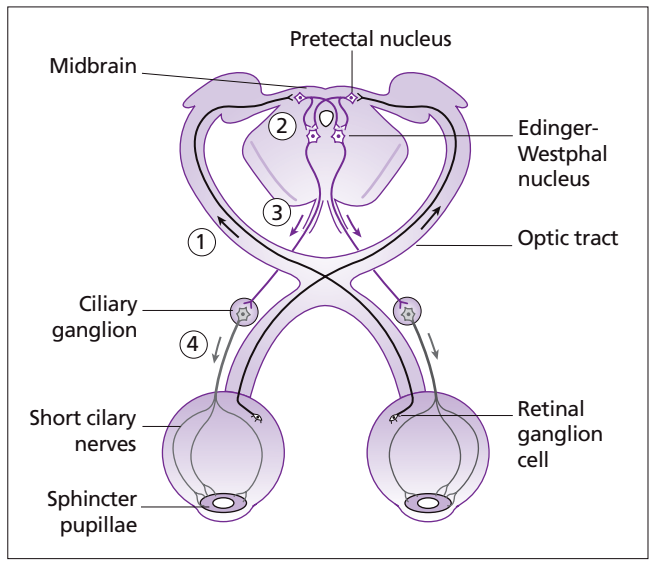

Figure 2.44 Pupillary light reflex pathway:
1 Retinal ganglion cell via optic tract – synapse at pretectal nuclei
2 Interneurones to both Edinger–Westphal parasympathetic nuclei (components of oculomotor IIIrd nerve nuclei)
3 Parasympathetic (preganglionic) fibres travel within III to synapse in the ciliary ganglion
4 Fibres (post-ganglionic) run within short ciliary nerves to terminate on sphincter pupillae.

III, IV and VI: third, fourth and sixth nerve nuclei and nerves

Some essential anatomy is summarized here (Figure 2.45). The features and relevance of lesions of these nerves and their nuclei are discussed in Chapters 3, 13, 14 and 19.

Oculomotor nucleus and IIIrd nerve

This compound nucleus, adjacent to the peri-aqueductal grey matter at superior colliculus level consists of neuronal cell bodies that supply:

- Five striated muscles: medial, superior, inferior recti, inferior oblique and levator palpbebrae superioris;
- Muscles supplied by the parasympathetic system: ciliaris (ciliary muscle) and sphincter pupillae, via the Edinger–Westphal nucleus.

The oculomotor (III) nerve passes through the midbrain tegmentum, emerges into the interpeduncular fossa, crosses the apex of the petrous temporal bone, enters the cavernous sinus and leaves in two divisions within the superior orbital fissure. Parasympathetic fibres travel in the lower division and leave in the branch to the inferior oblique muscle. They synapse in the ciliary ganglion, pierce the sclera and, via the short ciliary nerves, reach ciliaris and sphincter pupillae.

Trochlear nucleus and IVth nerve

The nucleus is at the level of the inferior colliculus. Each IVth nerve then decussates, emerges from the back of the brainstem, passes around it and enters the cavernous sinus (just below III). The nerve passes through the superior orbital fissure to supply the superior oblique muscle.

Abducens nucleus and VIth nerve

Each VI nucleus, lower in the brainstem than III and IV, lies in the mid pons at the level of the facial nucleus. The nerve runs a long intracranial course, initially beside the basilar artery, thence

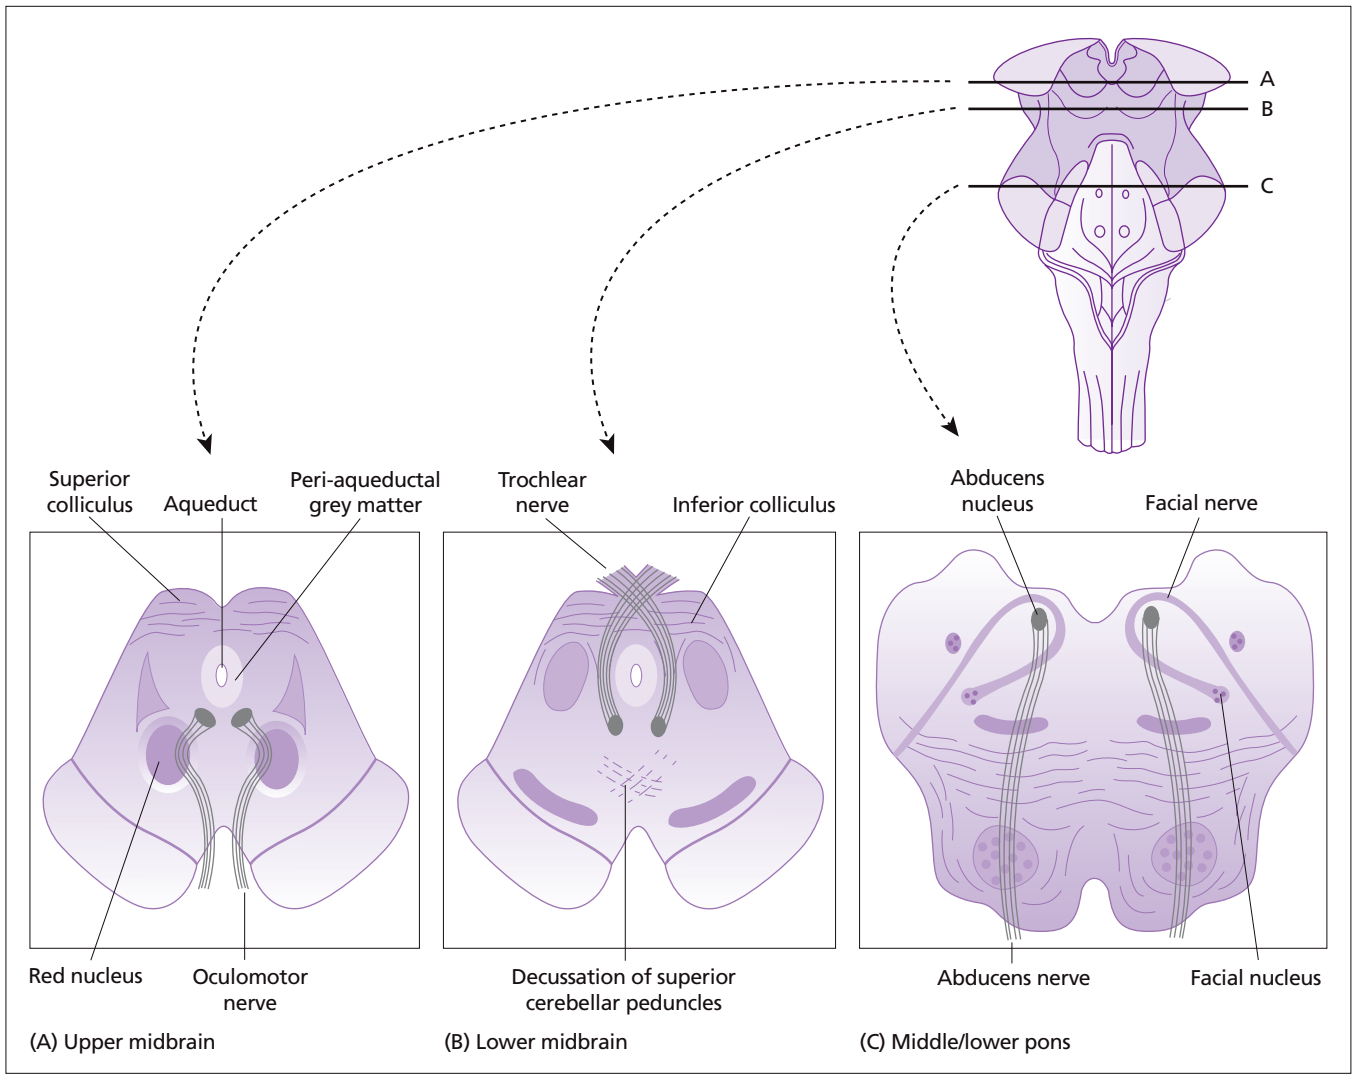

Figure 2.45 Origins of III, IV and VI: transverse sections of brainstem.

over the petrous temporal bone. Within the cavernous sinus it is applied to the internal carotid artery (Figure 2.46). Like III and IV, VI runs through the superior orbital fissure. VI innervates the lateral rectus muscle.

Motor units and sensory connections

These ocular muscle motor units contain 5–10 muscle fibres (cf. 500 or more in biceps and large striated limb muscles) and comprise A, B and C fibres:

- A fibres (fast twitch) are involved in saccades;
- B fibres (slow twitch) are used in smooth pursuit; and
- C fibres are involved in maintaining parallel visual axes and tonically active, when awake.

Proprioceptive pathways from the extraocular muscles extend widely – to the mesencephalic nucleus of V and to the cuneate nucleus in the medulla. Peripheral afferent projections from the neck muscles and output projections from the vestibulo-cerebellum to these nuclei assist coordinated simultaneous movements of the neck and head in response to changes in gaze.

The near response

Three responses combine to enable gaze to focus on a near object:

1 Covergence of the ocular axes is brought about by contraction of the medial recti;

2 The ciliary muscle contracts – the lens bulges passively, the thicker lens shortening its focal length (Figure 2.47); and

3 Sphincter pupillae contracts – concentrating light through the central part of the lens.

Retinal impulses pass via the lateral geniculate body to the occipital cortex, thence to the visual association cortex which analyses stereoscopically the object in view. Thence, the efferent pathway reaches the Edinger–Westphal nucleus and vergence cells within the reticular formation.

The far response

To bring a distant object into focus, the ciliary muscle must be inhibited – allowing the suspensory ligament to become tight and flatten the lens. Sympathetic impulses cause this relaxation of the ciliary muscle via β_2 receptors. This dilates the pupil (contraction of dilator pupillae) via α_1 receptors.

Sympathetic pathway to the eye and face

The sympathetic system originates in the hypothalamus. Central efferents decussate in the midbrain and are joined by ipsilateral fibres running within and from the reticular formation. The pathway descends in the cord, emerges in the first ventral thoracic root and reaches the sympathetic chain. These preganglionic fibres synapse in the superior cervical ganglion. Post-ganglionic fibres run within adventitia of branches of the internal and external carotid arteries. The internal carotid system is accompanied by two sets of fibres. One joins V_1 in the cavernous sinus, but leaves this nerve in the short and long ciliary nerves to the smooth muscles of the eye (dilator pupillae, ciliaris and tarsal muscle levator palpebrae superioris). The second forms a plexus around the internal carotid artery. Branches reach the skin of the forehead and scalp. (Horner's syndrome is discussed in Chapter 13.)

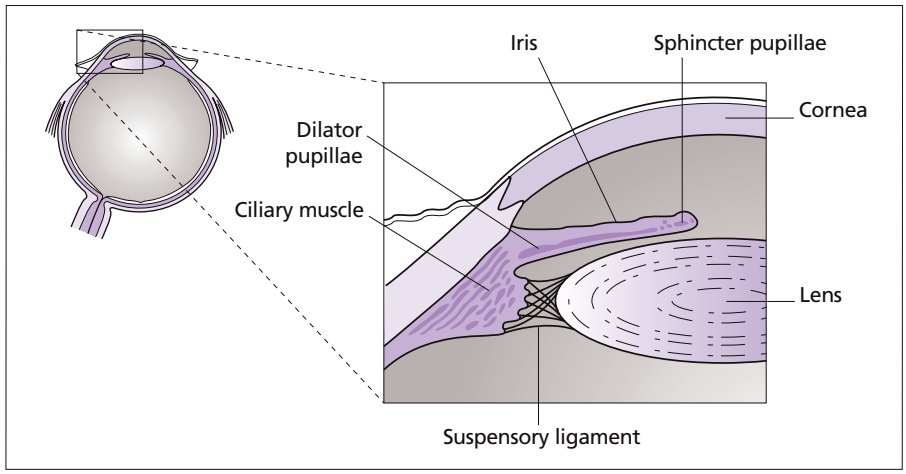

Figure 2.47 Dilator and sphincter pupillae, lens and ciliary muscle.

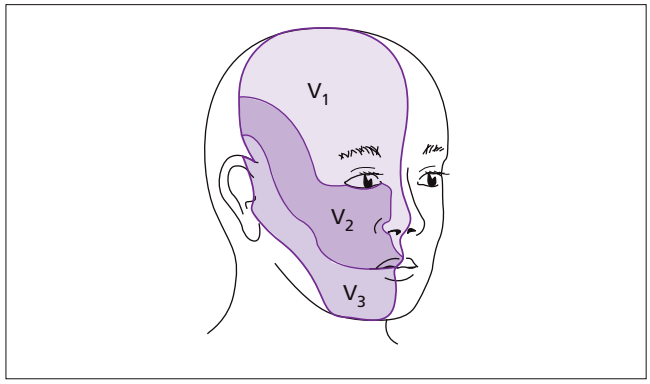

Figure 2.48 Cutaneous distribution of the three divisions of Vth nerve. (From Patten J. *Neurological Differential Diagnosis*, 2nd edn. London, New York, Springer, 1996, with permission.) Precise distribution varies amongst published sources.

External carotid sympathetic fibres are intimately related to all branches of the external carotid artery (e.g. superficial and middle temporal, facial, maxillary, middle meningeal, posterior auricular and lingual ateries).

V: trigeminal nerve and nuclei

The trigeminal nerve and its nuclei form a massive sensory input via the ophthalmic (V_1), maxillary (V_2) and mandibular (V_3) divisions. The sensory cutaneous distribution of the three divisions in Figure 2.48 will be familiar.

The Vth nerve carries sensation from:

- The eyes;
- Dura mater of anterior and middle cranial fossae;
- Adventitia of cerebral and basilar vessels;
- Paranasal sinuses;
- Teeth;
- Oral and nasal mucous membranes; and
- Facial and masticatory muscles.

A summary of the essential neuroanatomy follows.

Motor nucleus of V and supratrigeminal nuclei

Each Vth motor nucleus in the tegmentum of the pons supplies muscles of mandibular arch origin (Figure 2.49). Supranuclear connections run from each motor cortex to both these V motor nuclei, but largely to the contralateral. Within the reticular formation (see below) are the supratrigeminal nuclei, lying at the upper poles of the V motor nuclei. These generate masticatory rhythms. Muscles supplied via V_3 are:

- Temporalis;
- Masseter;
- Pterygoids and digastric;
- Infrahyoid muscles; and
- Tensor tympani and tensor palati.

Paralysis of one motor root causes deviation of the opening jaw to that side. The motor root is the efferent arc of the jaw jerk, a monosynaptic reflex.

Sensory Vth nuclei

There are three sensory Vth nerve nuclei (Figure 2.49):

1 Mesencephalic;
2 Principal (pontine); and
3 Spinal.

Mesencephalic Vth nucleus

Peripheral processes enter the sensory root via the trigeminal mesencephalic tract. The mesencephalic nuclear neurones are unique – they are cell bodies of primary sensory neurones. Their peripheral origins are the stretch receptors of masticatory muscle spindles (V_3) and stretch receptors of peri-odontal ligaments of the teeth (V_2, V_3) and some fibres from the eye and eye muscles (V_1). Central processes of the mesencephalic afferents descend through the tegmentum of the pons (tract of Probst). Most terminate in the supratrigeminal nucleus; others reach the main part of the motor nucleus, the pontine Vth nucleus and even the dorsal nucleus of the vagus (Figure 2.50).

Principal (pontine) Vth nucleus

These paired nuclei are homologues of the spinal gracile and cuneate nuclei. They process touch discrimination from the mouth, nose and face.

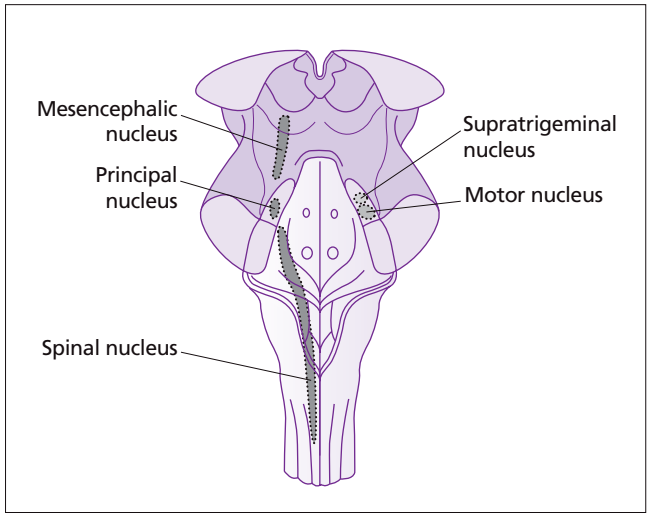

Figure 2.49 Trigeminal nuclei within the brainstem.

Spinal Vth nucleus

These paired nuclei extend from the pons to spinal level C3. Each main spinal Vth nucleus (pars caudalis) receives pain and temperature afferents from the entire trigeminal area and beyond.

Each nucleus is microscopically a continuation of the outer laminae (I–III) of the posterior horn of the cord. Pain modulation (see below) is similar to the situation in the cord (although exquisitely sensitive) – enkephalinergic and GABAergic connections in the substantia gelatinosa and serotoninergic fibres from the reticular formation (magnus raphe nucleus).

Each Vth spinal nucleus receives input from three principal sources:

1 Gasserian ganglion (trigeminal afferents);
2 IX and X; and the
3 Upper three cervical posterior roots (C1 is vestigial or absent).

Trigeminal afferents are the central processes of Gasserian ganglion neurones. Topographical representation within the nucleus is linear (mouth rostral) but layered, like an onion centred on the mouth (Figure 2.51). Peripheral fibres carry pain, temperature and touch centrally (facial skin, teeth, sinuses, cornea, temporomandibular joints, dura of anterior and middle fossae). Afferents from IX and X (middle ear, Eustachian tube, pharynx, larynx) also reach each inferior sensory ganglion of IX and X. Cervical

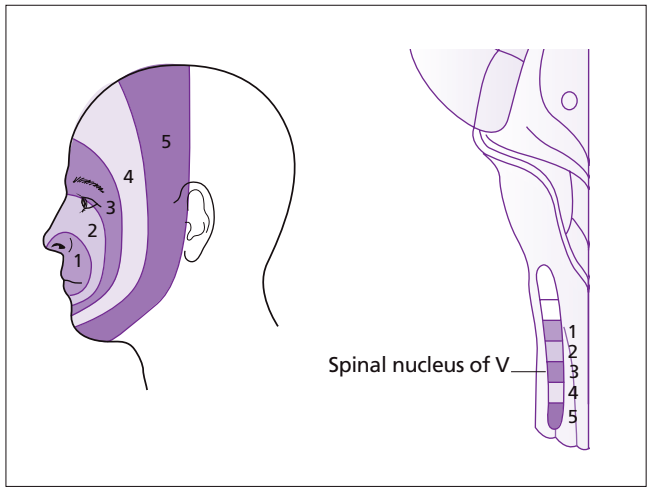

Figure 2.51 Spinal Vth nucleus and its facial distribution.

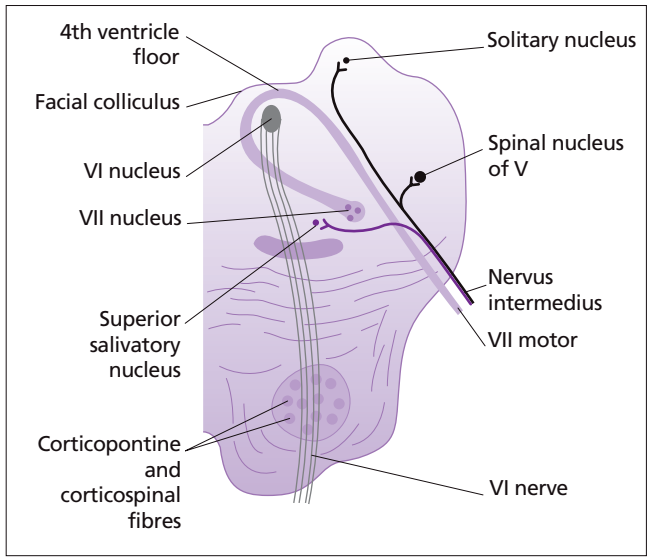

Figure 2.52 Pons: facial nucleus, facial and abducens nerves.

afferents (dura of posterior fossa and cord, cervical joints) ascend through the hypoglossal canal.

Trigemino-vascular system – innervation of cerebral vessels

V_1 lies close to the internal carotid artery in the cavernous sinus. Afferent V_1 fibres and autonomic fibres accompany the carotid artery, follow its branches and form a network throughout the intracranial vasculature. The role of this important system in the pathogenesis of headache is discussed in Chapter 11.

Trigemino-thalamic tract, lemniscus, cortical projection and reticular formation

The spinal Vth nucleus gives rise to the lower part of the trigemino-thalamic tract. This crosses the midline, ascends in the pons and carries pain, temperature and touch. Within the pons the tract is joined by fibres from the principal (pontine) Vth nucleus to form the trigeminal lemniscus – the ribbon of trigeminal fibres that terminates in the ventral posterior medial nucleus of the thalamus (Figure 2.50). Thence, third order afferents pass from the thalamus to the substantial facial area of the somatic sensory cortex.

Trigemino-reticular fibres synapse in the lateral RF (parvocellular neurones). They mediate the effect of slapping or irritating the face (arousal).

The jaw jerk and other masticatory reflexes

Spindle afferents from jaw muscles make direct synaptic contact with Vth motor nuclear neurones. Supranuclear lesions of the Vth motor nucleus (see Pseudo-bulbar palsy, Chapter 12) are accompanied by an exaggerated jaw jerk. This is a monosynaptic stretch reflex.

Other masticatory muscle reflexes (jaw closing in response to food in the mouth, and jaw opening – inhibition of jaw closure, chewing, snapping) are mediated via the pattern-generating supratrigeminal motor nuclei. They are of little diagnostic significance, but explain the potential hazard of being bitten by stuporose patients (or sleepy animals).

The corneal reflex

The afferent pathway is largely via pain fibres in the naso-ciliary branch of V_1. The efferent pathway is via VIIth nerve innervated muscles – bilateral blinking (Chapters 3, 12 and 19). While this is so, the clinical reality in an out-patient clinic is first that the patient feels (and reports) the unpleasant stimulus. Secondly, there is visible lacrimation and conjunctival injection in a normal eye, but these visible features diminish when there is a Vth nerve lesion. The upper five-sixths (or so) of the cornea is innervated by the ophthalmic division (V_1), while the lower sixth sector (from about 5 to 7 o'clock) by the maxillary division (V_2). Depression of the corneal reflex is the first sign of a Vth nerve lesion – a matter of signal importance in the early diagnosis of cerebello-pontine angle lesions in the era before non-invasive imaging.

VII: facial nerve

The facial nerve arises from the VIIth nucleus in the pons and before leaving the brainstem loops around the abducens (VI) nucleus (as the internal genu), creating the facial colliculus in the fourth ventricle floor (Figures 2.52 and 2.53). The nerve leaves the skull via the stylomastoid foramen (its only constituent). Principal motor branches supply muscles of facial expression. A small motor branch supplies the stapedius. VII also carries sensory taste fibres from the anterior two-thirds of the tongue via the chorda tympani.

Supranuclear connections allow the facial muscles to respond both in volitional and emotional activities, and bilaterally in many common habitual situations – smiling, blinking, frowning

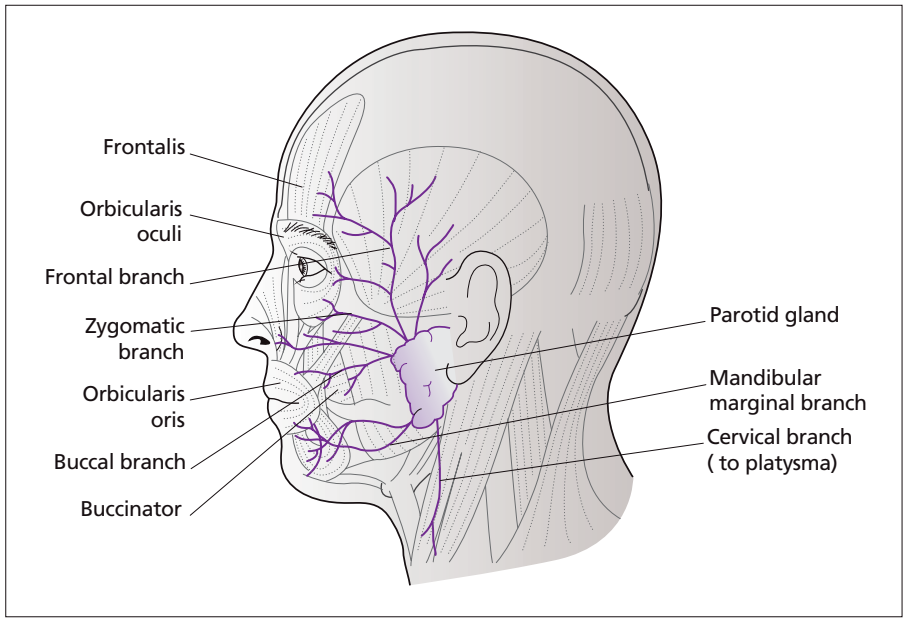

Figure 2.53 Principal facial branches of VIIth nerve.

Table 2.13 Reflexes involving V, VII, VIII and II.

	Corneal reflex	Jaw jerk	Pout reflex	Blink (light)	Blink (noise)	Stapedius
Receptor	Cornea	Masseter (spindles)	Lips	Retina	Cochlea	Cochlea
Afferent	V_1	V_3	V_2, V_3	Optic nerve	Cochlear nucleus	Cochlear nerve
1st synapse	V spinal nucleus	V motor nuclei	V principal nucleus	Superior colliculus	Inferior colliculus	Cochlear nucleus
2nd synapse	VII nucleus (+ pain & lacrimation V)	(Monosynaptic reflex)	VII nucleus	VII nucleus	VII nucleus	VII nucleus
Muscle	Orbicularis oculi	Masseter	Orbicularis oris	Orbicularis oculi	Orbicularis oculi	Stapedius (see Chapter 14)

– and in several reflex actions (Table 2.13). Part of each VIIth nucleus supplying the upper face (principally frontalis) receives supranuclear fibres from each hemisphere. The face muscles are exquisitely responsive to emotional states, and to all sensory input; the limbic contribution is from the nucleus accumbens in the ventral basal ganglia.

Nervus intermedius, greater petrosal nerve and chorda tympani

Distal to the internal genu, the nervus intermedius (part of VII) acts as one stage of a complex conduit (i.e. both to and fro) for parasympathetic and special sense fibres (Figure 2.54):

- The parasympathetic root arises from the superior salivatory nucleus to form motor components of the greater petrosal nerve (→ pterygopalatine ganglion → lacrimal and nasal glands) and the chorda tympani (→ submandibular ganglion → submandibular and sublingual glands).
- The special sensory root consists of cell bodies that lie in the geniculate ganglion. Afferent fibres from taste buds in the anterior two-thirds of tongue travel in the chorda tympani. Those from taste buds in the hard palate travel in the greater petrosal nerve. Central processes enter the gustatory nucleus, part of the nucleus solitarius that also receives fibres from IX. Thence, second order neurones project via the thalamus, to anterior insular and cingulate cortex.
- Some geniculate ganglion cells also receive sensory impulses from skin around external auditory meatus (see Bell's palsy, Chapter 12).

VIII: vestibulo-cochlear nerve

The vestibulo-cochlear nerve contains primarily afferent axons of bipolar neurones whose cell bodies lie within the petrous temporal bone. Peripheral processes of these neurones are in contact with specialized neuro-epithelium of the labyrinth and cochlea. The two components of VIII (vestibular and cochlear) enter the junction between pons and medulla at the cerebello-pontine angle.

The neuro-otological system is complex – an entire subspecialty is devoted to it (Chapter 14). Vertigo – the illusion of

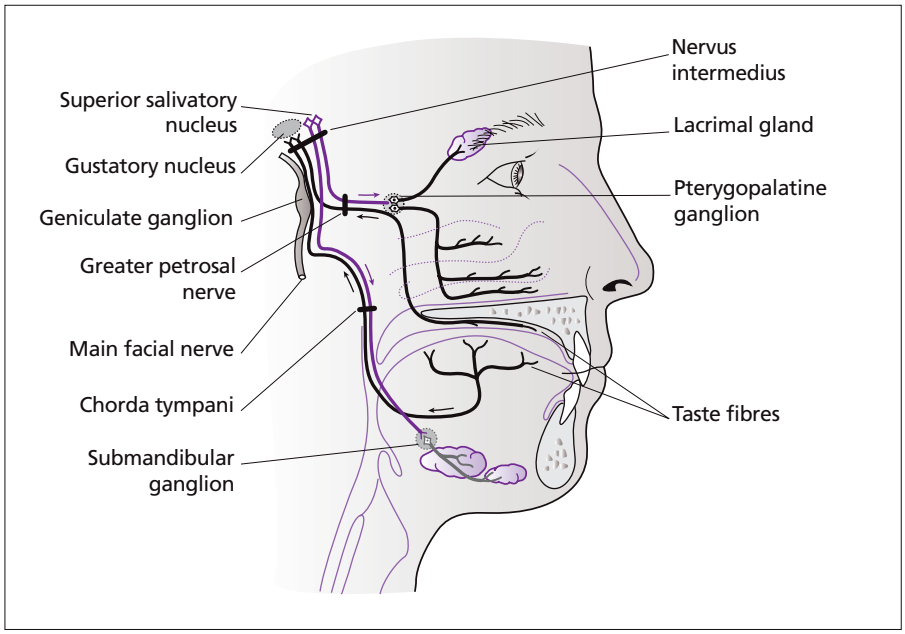

Figure 2.54 Nervus intermedius and its connections.

movement, with hearing loss and tinnitus – are the prominent symptoms. The purpose here is to outline the essential peripheral neuroanatomy and summarize the central connections (Figure 2.55).

Vestibular system

The dense petrous temporal bony labyrinth contains perilymph (like extracellular fluid) that provides a fluid housing for the membranous labyrinth that encloses the organs of balance. These are washed by endolymph: K^+ rich, Na^+ poor – similar to intracellular fluid.

Each labyrinth (Figure 2.55a) houses five sensory organs within the utricle, saccule and three semi-circular canals (or ducts). Each utricle and each saccule contains a macula. Each canal contains a crista within an ampulla:

- Maculae (two) are sensory organs of static head position;
- Cristae (three) are sensory organs of head movement.

The vestibular ganglion lies in the internal auditory meatus. Peripheral processes are applied to the five sensory organs. Central axons (i.e. vestibular nerve) enter the brainstem to synapse at the lateral, medial, superior and inferior vestibular nuclei (VN). Other connections are shown in Figure 2.55d.

The static labyrinth

In the erect posture:

- The utricular macula is essentially horizontal;
- The saccular macula is essentially vertical.

Hair cells in these maculae are in contact with vestibular nerve fibres via ribbon synapses (Figure 2.55b). Stereocilia (about 100/cell) and a longer process, a kinocilium (one/cell) projects into otoconia (ear sand) – a gelatinous matrix of calcium carbonate crystals. Each macula has a central groove, a striola. Cilia are arranged either side of each striola, as in a mirror. Depolarization takes place whenever kinocilia are parted from stereocilia.

The maculae respond to:

- Linear acceleration (e.g. walking);
- Vertical acceleration (e.g. falling); and
- Tilting.

The roles of the static labyrinth are to indicate head position in relation to the trunk, and to alter centre of gravity of the body and maintain upright (or other posture). The system is adapted to work within, and to compensate for the Earth's gravitational field.

The kinetic labyrinth

In the kinetic labyrinth, the ciliated, cellular arrangement of the static labyrinth is replicated in the cristae of the three semicircular canals, their ampullae and each cupula (Figure 2.55c). The cupula is a gelatinous projecting part of each crista within an ampulla – bathed in endolymph. Into each cupula, kinocilia project from hair cells.

The three cupulae are quite exquisitely sensitive to angular acceleration and deceleration. Endolymph remains relatively static. Each crista billows and deflects as this miniature sail-like organ is thrust against endolymph as head velocity changes in a particular plane.

Vestibular nuclei and central connections

Central axons of each vestibular nerve synapse at the lateral, medial, superior and inferior vestibular nuclei (VN) in the brainstem (Figure 2.55d).

The lateral vestibulo-spinal tract arises from the lateral VN (nucleus of Dieter). Fibres descend in the anterior funiculus of the cord to synapse with a complex variety of limb, neck and

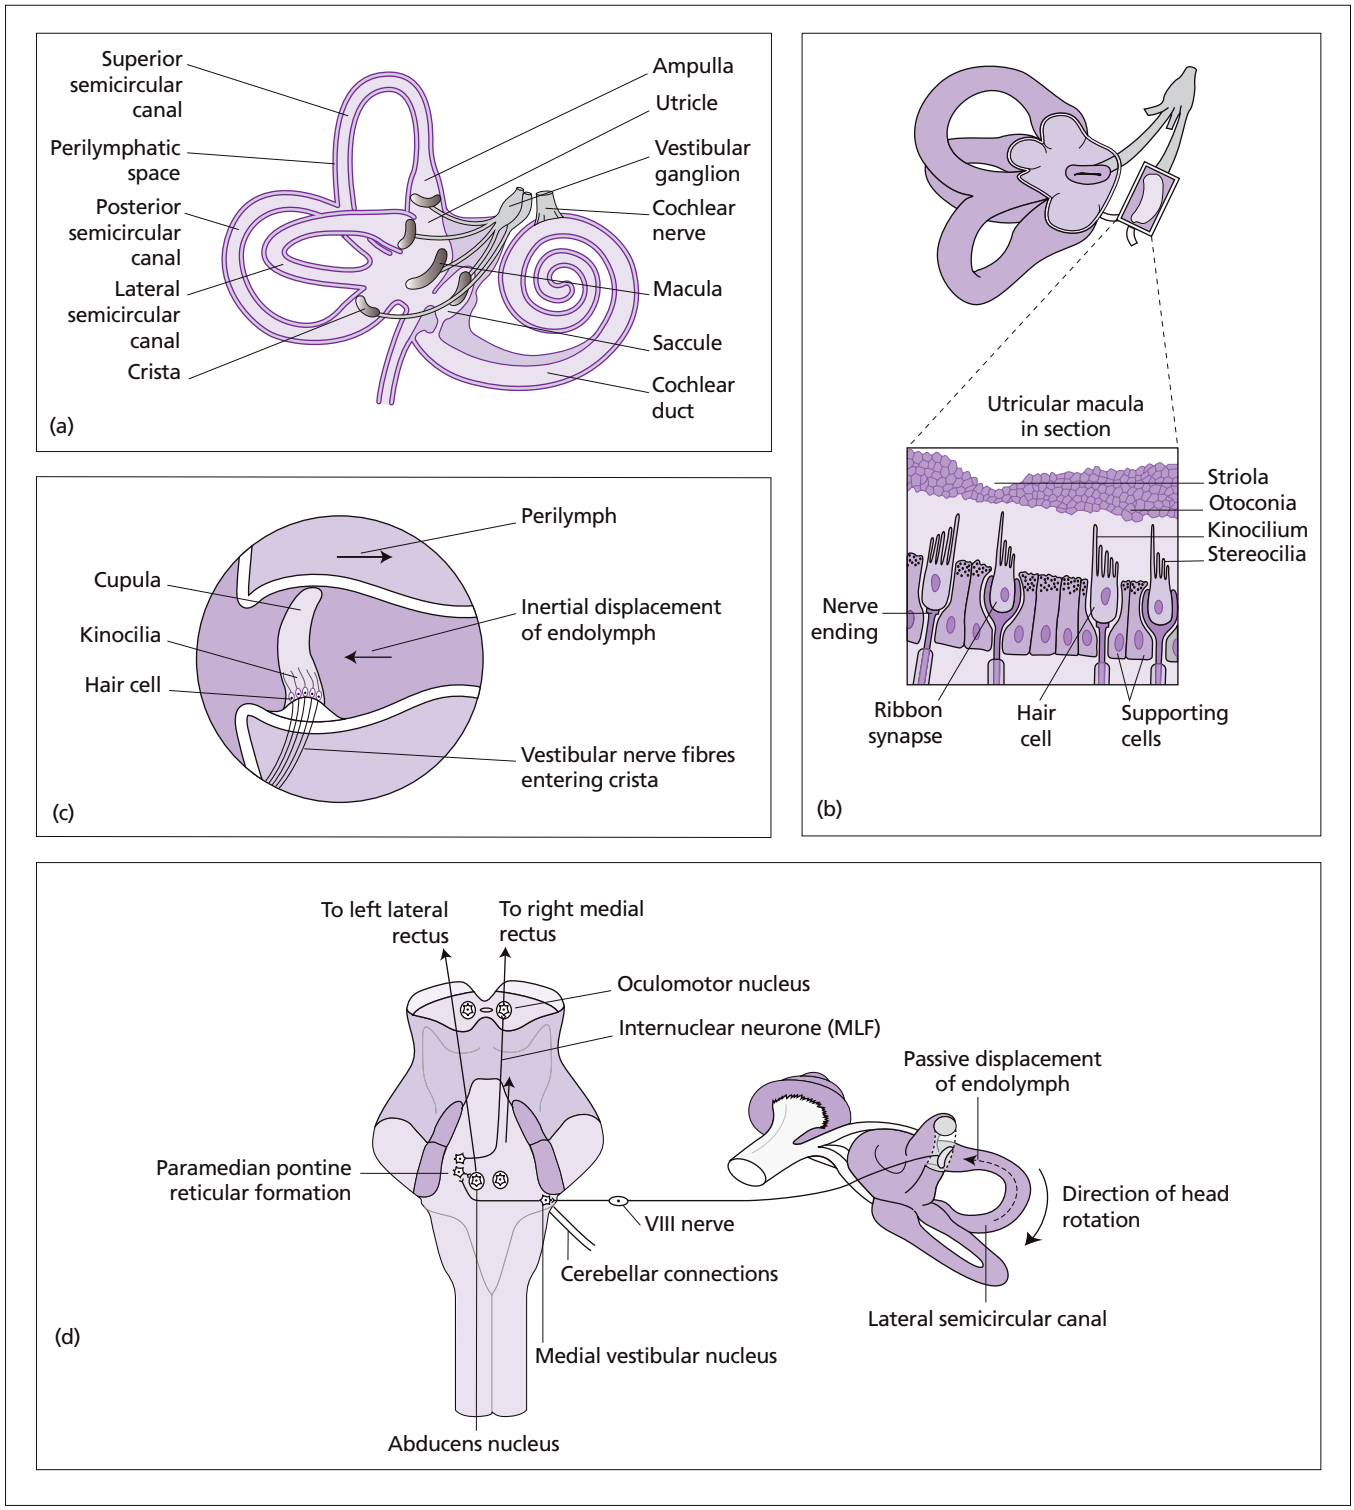

Figure 2.55 (a) Vestibulo-cochlear sytem and five vestibular sense organs. (b) Cells of static labyrinth. (c) Crista in ampulla of semi-circular canal. (d) Central connections, e.g. head rotation. MLF, medial longitudinal fasciculus.

trunk α and γ motor neurones concerned with posture. The flocculo-nodular lobe of the cerebellum has two-way connections with all vestibular nuclei.

The medial vestibulo-spinal tract arises in the inferior and medial VN, descends in the medial longitudinal fasciculus and ends in the cervical cord. Head and eye-righting reflexes are dealt with by this system; there are connections with the kinetic labyrinth.

Central second order neurones from the VN reach the contralateral VP nucleus of the thalamus. Third order neurones project to the various cortical areas – close to the facial area in the somatosensory cortex, to the insula and temporoparietal cortex. For vertigo, mystery surrounds the location of a cortical area specifically associated with this symptom, although electrical stimulation of somato-sensory cortex sometimes induces it. Vertigo is a relative rarity as an epileptic event – but vertigo does occur with focal seizure activity in the temporoparietal cortex.

One relevant feature of the vestibular system – and a reason why vertigo, nystagmus (and dizziness) have relatively poor localizing value – is that right–left imbalance in the system, at any level, produces symptoms and/or signs. (Nystagmus is discussed in Chapters 3 and 14.)

Auditory system

Normal binaural hearing is complex (Chapter 14). Sound quantity, quality, position, timing and relevance are detected via:

- Cochlea and cochlear nerve;
- Cochlear nuclei and central pathways; and
- Auditory cortex.

Secondary projections, that interpret the emotional content of sound, and music – and determine actions in response to sounds.

The afferent system is illustrated in Figure 2.56. Auditory efferents are mentioned in Chapter 14.

Cochlea

Hair cells, from which protrude stereocilia, form the principal auditory neuro-epithelium. They lie within the organ of Corti (spiral organ). The complex terminology is summarized below:

- The modiolus is the central bony pillar of the cochlea – it is in the line of the internal auditory meatus.
- The osseous spiral lamina projects from the modiolus. The cochlear spiral has two and half turns and is about 1 cm both in height and diameter.
- The basilar membrane is fixed to the tip of the spiral lamina. It extends across the cavity of the bony cochlea and is attached to the spiral ligament.
- The scala vestibuli and the scala tympani are the upper and lower chambers of the cochlea. They are filled with perilymph. They communicate via the helicotrema.
- The scala media lies above the basilar membrane and is filled with endolymph – and separated from the scala vestibuli by the vestibular membrane.
- The organ of Corti (spiral organ) lies on the basilar membrane. The organ contains a central tunnel (tunnel of Corti) containing perilymph diffusing through the basilar membrane.

The arrangement of inner and outer hair cells, tectorial membrane and ribbon synapses is shown in Figure 2.56. Their nerve supply (the cochlear nerve) is via bipolar spiral ganglion cells in the osseous spiral lamina. One inner hair cell has some 20 afferent fibres in contact with it.

Auditory transduction

The snug fit and sensitive articulation of the ossicles – 'the footplate of the stapes rests on the oval window' – transmits vibration, i.e. pressure waves through the tympanic membrane to the basilar membrane. The basilar membrane is tonotopic:

- Low frequency waves produce resonance where the fibres are longest – at the apical turn of the cochlea;
- High frequency waves (high-pitched sounds) cause short fibres in the basal part of the cochlea to resonate.

Cochlear nerve and central connections

Myelinated axons from some 25,000 large bipolar neurones form the cochlear nerve. The pathways are illustrated in Figure 2.56. The sequence is:

- Inferior and superior cochlear nuclei (termination of first order fibres);
- Trapezoid body (second order fibres), superior olivary nucleus to inferior colliculus;
- Inferior brachium via medial geniculate body to auditory cortex.

The primary auditory cortex is located in Heschl's gyrus on the anterior surface of the temporal lobe. In humans, destruction of this region on one side causes no perceptible deafness but an initial inability to localize sound. Hearing loss is produced rarely by central lesions – potential imbalance is compensated by bilateral representation. The usual focus of clinical neurology is the distinction between conductive and sensorineural deafness (Chapters 3 and 14).

Acoustic reflex pathways

Biologically important auditory automatic pathways include:

- Startle and waking responses, via the reticular formation.
- Dampening of sounds, e.g. the sound of one's own voice via tensor tympani (V) and the stapedius reflex (Chapter 14). The stapedius reflex consists of a contraction of stapedius muscle in response to loud noise. Hyperacusis occurs when the muscle is paralysed, e.g. in Bell's palsy (Chapter 12).
- Head turning and eye turning in response to sounds.
- Pleasurable experience, e.g. of music and rhythm.
- Automatic responses to the call (or command) of a dominant mate or pack leader.

IX, X, XI and XII: glossopharyngeal, vagus, accessory and hypoglossal nerves

These four cranial nerves are grouped together. These notes indicate their intricacy, multiple nuclei and complex pathways both

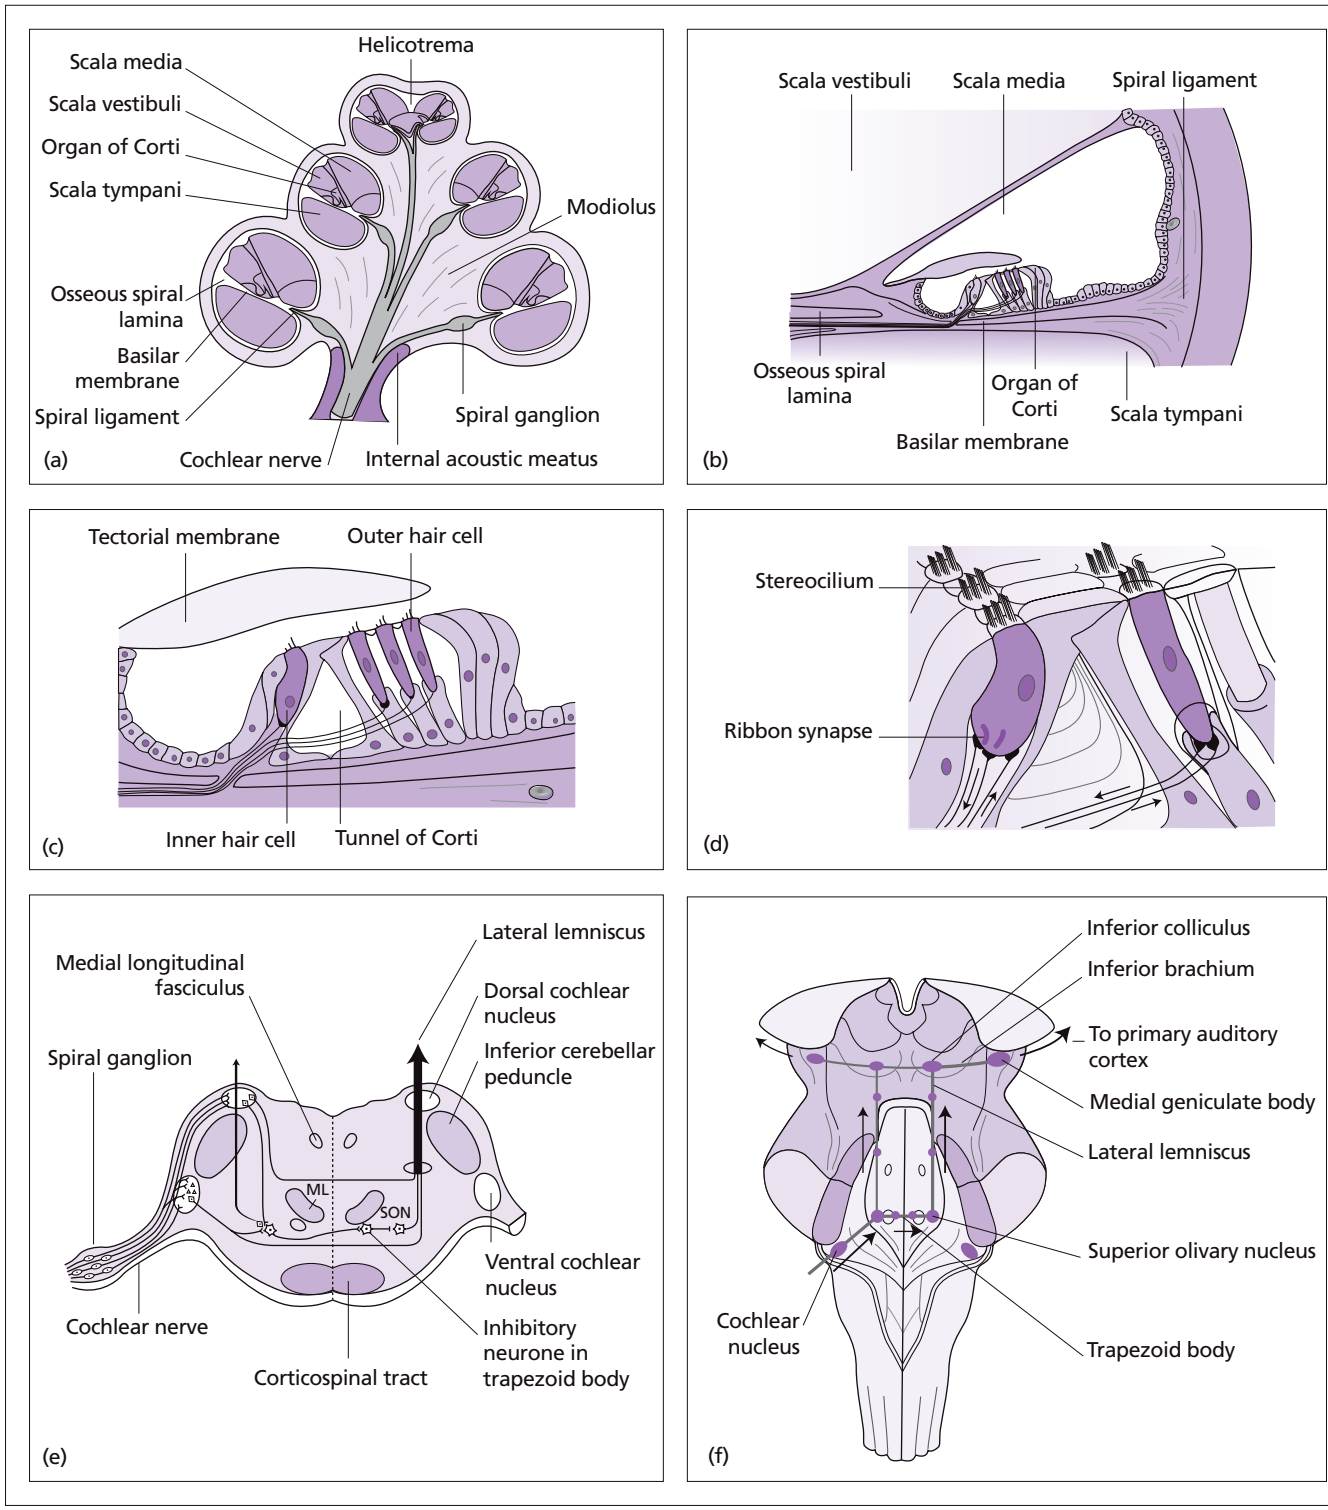

Figure 2.56 Outline anatomy of auditory system. ML, medial lemniscus; SON, superior olivary nucleus.

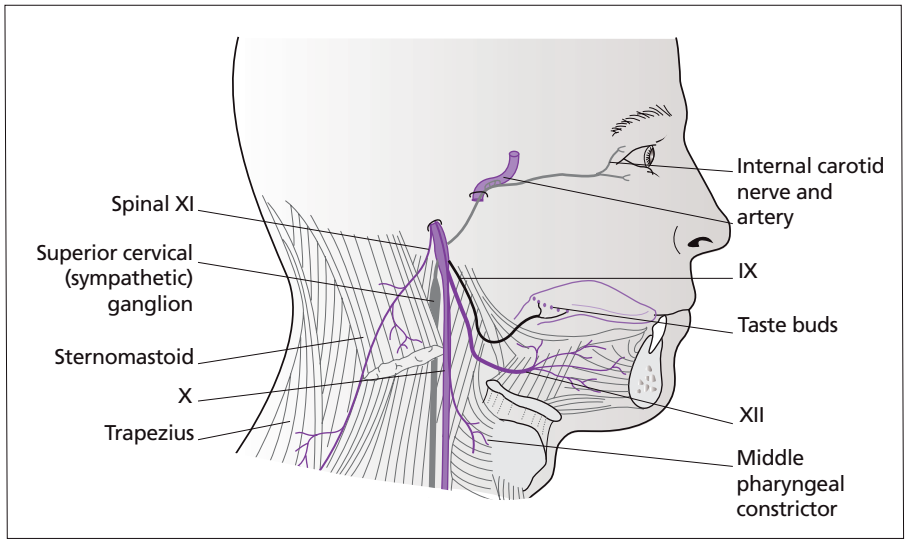

Figure 2.57 Distribution of IX, X, XI, XII & superior cervical ganglion.

afferent and efferent. Their distribution is shown in Figure 2.57 and the complex nuclear arrangement in Figure 2.58.

XI: spinal accessory nerve

The spinal accessory (XI) is the motor nerve to extrafusal and intrafusal fibres of trapezius and sternomastoid. The nuclear column (α and γ motor neurones) is in the anterior grey horn (lateral column) of the upper five segments of the cord, from which rootlets emerge (Figure 2.58b). The curious route of this nerve is upwards through the foramen magnum, then back, down and out through the jugular foramen. Some afferent twigs (cervical and thoracic nerves) combine with spinal XI as it pierces the trapezius, giving rise to a situation believed to be unique for the nerve supply of a muscle: muscle efferents (spinal XI) and muscle afferents (cervical and thoracic twigs) travel by separate pathways. This anatomical anomaly may be implicated in the extreme pain that follows section of motor roots of XI, or spinal XI in the neck.

In the posterior triangle of the neck, spinal XI is distinctly vulnerable (Chapter 12) – and readily damaged at biopsy of lymph nodes in this region.

Cranial accessory XI, glossopharyngeal IX and vagus X – and their nuclei

Groups of medullary neurones known as the nucleus ambiguus and the solitary nucleus contain some of the cell bodies of nerves IX, X and cranial XI.

The nucleus ambiguus (Figure 2.58b) provides special visceral efferent fibres of IX and cranial XI supplying:

- Pharynx (constrictor muscles);
- Stylopharyngeus and levator palati;
- Larynx (intrinsic muscles); and
- Oesophagus (striated muscles of the upper third, via the recurrent laryngeal nerve).

The solitary nucleus (Figure 2.58a,f) merges with its opposite number to form the commissural nucleus. The four functional regions of the solitary nucleus are:

1 Gustatory – afferents from tongue, epiglottis and palate;
2 Dorsal respiratory;
3 Baroreceptor – afferents from carotid sinus and aortic arch; and
4 Visceral afferent – afferents from gut and respiratory tract.

The cranial (accessory) nerve XI arises from the nucleus ambiguus in the medulla and leaves the skull through the jugular foramen. This nerve simply shares a dural sheath with spinal XI, without exchanging fibres. Cranial XI becomes incorporated into the vagus.

Glossopharyngeal nerve IX

The IXth nerve, almost entirely sensory, leaves the skull via the jugular foramen to reach the mucous membrane of the pharynx and the ear. The tympanic branch of IX (this leaves above the jugular foramen) supplies the tympanic membrane. Some central processes synapse with the spinal Vth nucleus. Some of the tympanic branch fibres are parasympathetic – they supply the parotid gland via the lesser petrosal nerve and otic ganglion. The oropharynx and posterior third of the tongue (touch) are supplied by fibres passing to the commissural nucleus. These provide the afferent limb of the gag reflex. Taste fibres (gustatory neurones in the circumvallate papillae of the tongue) terminate centrally in the gustatory nucleus. The carotid branch of IX contains two sets of fibres. One arises in baroreceptor neurones of the carotid sinus and passes to the solitary nucleus. The second arises in glomus cells (chemoreceptors) within the carotid body that terminate centrally in the dorsal respiratory nucleus. Stylopharyngeus muscle is supplied by branchial efferents of IX from the nucleus ambiguus.

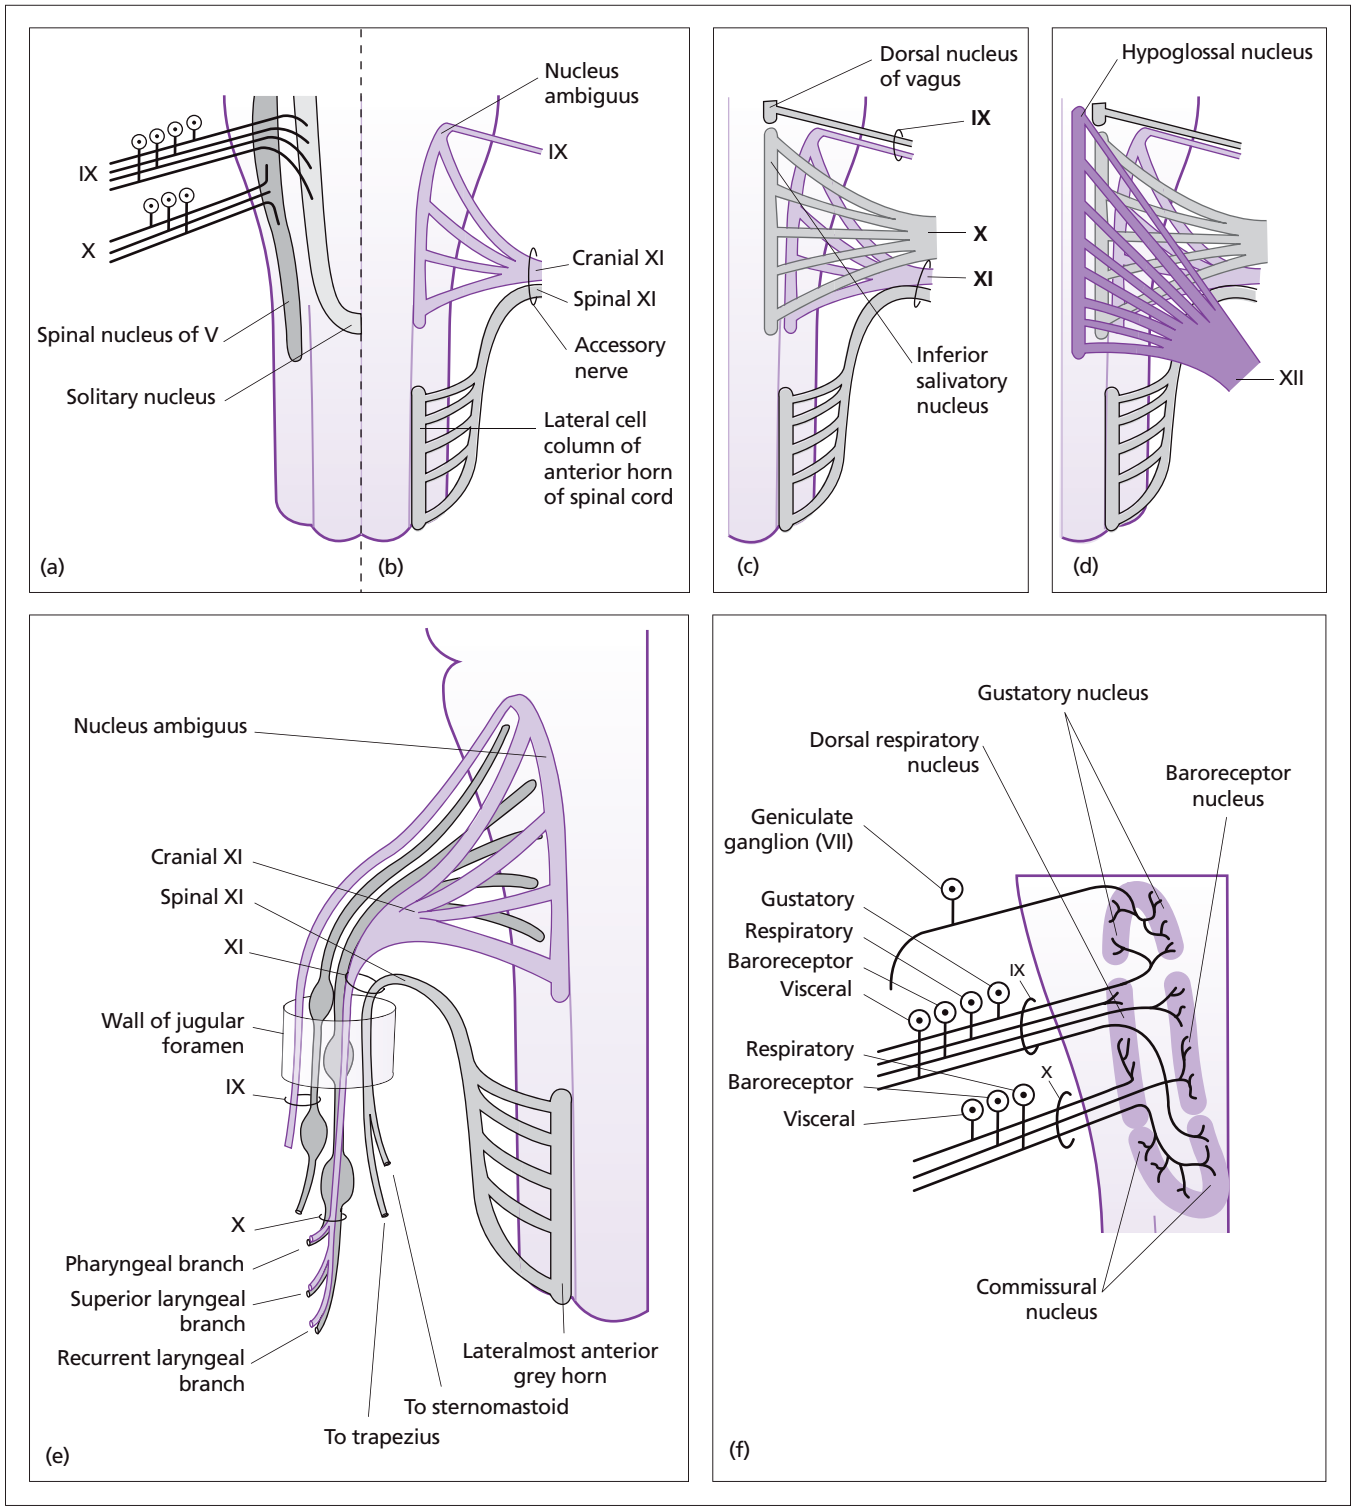

Figure 2.58 Nuclear arrangements of IX, X, XI and XII. (a) to (d): anterior views of brainstem (a) Sensory nuclei. (b) Motor nuclei (special visceral efferent column) of IX, cranial XI and spinal XI. (c) Motor (general visceral efferent) column of IX and X. (d) Hypoglossal nucleus (somatic efferent column) giving rise to XII. (e) Nucleus ambiguus (special visceral afferent column): fibres to IX, X, cranial XI. (f) Solitary nucleus: four functional nuclear areas.

Vagus nerve X

The vagus (Latin = wandering) is both the largest visceral afferent and a major parasympathetic nerve. Some fibres arise from the dorsal nucleus of the vagus (Figure 2.58c) and others from the nucleus ambiguus. Some cell bodies (afferent fibres) lie within the solitary nucleus. Its rootlets in the medulla are in series with cranial XI and IX. It emerges from the skull in the jugular foramen with these two nerves. In the jugular foramen are the two small sensory ganglia of the vagus: the jugular and nodose ganglia.

A summary of branches of the vagus follows:

• Parasympathetic (efferent) neurones to the heart, lungs and gut originate from the dorsal nucleus of the vagus and nucleus ambiguus.
• General visceral afferent fibres from the heart, lungs and gut have cell bodies within the nodose ganglion. Central synapses are in the commissural nucleus. These pathways serve:
• The cough reflex;
• The Hering–Breuer reflex (inhibition of the dorsal respiratory centre by pulmonary stretch receptors);
• The Bainbridge reflex (increase in pulse rate following right atrial distension); and
• Gut afferents signalling satiety (to the hypothalamus).
• Special viscerent efferent neurones in the nucleus ambiguus supply pharyngeal and laryngeal muscles, levator palati and muscles (striated) of the upper third of the oesophagus.
• The auricular branch supplies skin of the external auditory canal. A meningeal branch supplies meninges of the posterior fossa. Both have cell bodies in the jugular ganglion. Central processes also pass to the spinal nucleus of V (Figure 2.58a).
• Chemoreceptors of the aortic bodies, baroreceptors of the aortic arch and taste buds of the epiglottis, are also supplied. The latter synapse in the gustatory nucleus.

XII: hypoglossal nerve

The motor nerve to the tongue originates from the XIIth nucleus lying in the fourth ventricular floor (in the same cell column as II, IV and VI; Figure 2.58d). Nerve rootlets leave the medulla between the pyramid and olive, form two fascicles and exit the skull via the anterior condylar foramen (hypoglossal canal), just below the jugular foramen. The nerve passes between the jugular vein and internal carotid artery at the skull base to reach the muscles of the tongue.

The hypoglossal nerve, like its fellow lower cranial nerves, has connections with others – it receives twigs from the vagus, from the upper cervical roots, from the cervical sympathetic (see Superior cervical ganglion) and has connexions with the lingual nerve. Styloglossus, hyoglossus, genioglossus and geniohyoid are the muscles supplied.

A unilateral XIIth nerve lesion is followed by deviation of the tongue to that side and several weeks later by wasting and fasciculation. (The surface of the normal tongue when protruded often flickers slightly.) Lateral tongue deviation is the obvious sign, although rarely a spontaneous complaint. The larynx is also drawn to the side opposite a hypoglossal palsy on swallowing (see also Chapters 3 and 12).

Autonomic nervous system

The autonomic (i.e. self-regulating) system is a diffuse neural network with these components:

• Controlling centres (hypothalamus and reticular formation) that connect to:
• Preganglionic neurones (grey matter of brainstem and cord) that project via:
• Preganglionic fibres that leave the CNS, to synapse at:
• Peripheral autonomic ganglia (multi-polar neurones), the origin of:
• Post-ganglionic fibres (unmyelinated) that form terminal networks on:
• Target tissues.

Division into sympathetic and parasympathetic retains much of its original value. Chapter 23 outlines issues of particular clinical relevance and includes schematic diagrams of the system.

Sympathetic system

The sympathetic outflow is thoraco-lumbar. Preganglionic neurones are located in the lateral grey horn at lower thoracic, L1, L2 and usually L3 levels. From these spinal neurones, preganglionic fibres leave the cord via corresponding anterior spinal nerve roots to form each paravertebral sympathetic chain.

Thereafter, preganglionic fibres reach sympathetic ganglia by four routes:

1 Some ascend. These synapse in cervical (superior, middle) and stellate ganglia.
2 Others descend. These synapse in lumbar and sacral sympathetic ganglia.
3 Some synapse locally (at a nearby ganglion). Post-ganglionic fibres within T1–L2 spinal nerves supply T1–L2 vessels, skin and sweat glands.
4 Some traverse the sympathetic chain, leave as lumbar/thoracic splanchnic nerves (preganglionic) and reach mesenteric, coeliac, renal and pelvic ganglia.

Sympathetic activity dilates the pupils, increases sweating, increases blood pressure and heart rate, diverts blood from skin and gut to skeletal muscle and closes sphincters.

Parasympathetic system

Parasympathetic preganglionic outflow is cranial and sacral. Fibres emerge via:

• IIIrd, VIIth, IXth and Xth cranial nerves;
• Sacral nerve roots.

Cranial parasympathetic III, VII, IX and X fibres and subsequent ganglia

Preganglionic fibres synapse at four cranial ganglia and one diverse ganglia system:

• Ciliary ganglion, via III to the pupil (see Constriction to light and near reflex);

• Pterigo-palatine ganglion, via VII to the lacrimal and nasal glands (secretion);
• Submandibular ganglion, also via VII to submandibular and sublingual glands;
• Otic ganglion, via IX to the parotid gland; and
• Mural and intramural ganglia, via X to the heart, lungs, oesophagus, pancreas, gallbladder, stomach, small and large bowel.

Sacral parasympathetic fibres and ganglia
From the cord lateral grey matter of S2, S3 and S4 (at L1 vertebral level within the conus), preganglionic fibres lie in the cauda equina within S2–4 ventral nerve roots. They leave the region via sacral vertebral foramina to emerge as pelvic splanchnic nerves. These synapse at:
• Pelvic ganglia (paired) that supply the detrusor muscle and tunica media of the internal pudendal vessels and cavernous tissue of the clitoris/penis; and
• Mural ganglion cells in the distal colon and rectum.

Neurotransmission within the autonomic system

A brief introduction follows. There is significant variation at local level: rules established for one target organ do not always hold for another.

Neurotransmission at sympathetic and parasympathetic ganglia
This is cholinergic throughout the system. The preganglionic neurons liberate ACh at axo-dendritic synapses. Ganglion cell receptors are nicotinic.

Neuro-effector junction transmission at target tissues
Neurotransmitters are secreted along terminal dendrites at target tissues, e.g. pupils, blood vessels, secretory glands. The chief neurotransmitter at sympathetic neuro-effector junctions is noradrenaline, i.e. post-ganglionic transmission is noradrenergic. An exception is the cholinergic sympathetic supply to eccrine sweat glands. The chief neurotransmitter at parasympathetic neuro-effector junctions is ACh, i.e. post-ganglionic transmission is cholinergic.

Junctional receptors at target tissues
Two factors influence the effect of physiological stimulation of target organs:
1 The nature of post-junctional receptors; and
2 The nature of pre-junctional receptors.

Sympathetic system receptors
For noradrenaline, two varieties of α-adrenoceptor and two varieties of β-adrenoceptor are known to exist:
• Post-junctional α_1-adrenoceptors. These initiate contraction of dilator pupillae, arteries and arterioles, sphincters and vas deferens.
• Pre-junctional α_2-adrenoceptors. These inhibit transmitter release at both sympathetic and parasympathetic terminals.
• Post-junctional β_1-adrenoceptors. In the heart these increase the force of ventricular contraction. In the kidney they increase renin secretion in response to a fall in blood pressure.
• β_2-Receptors respond to circulating and locally available noradrenaline. Post-junctional β_2-receptors relax smooth muscle (e.g. in bronchi, pupil). Pre-junctional β_2-receptors on adrenergic terminals promote noradrenaline release.

Parasympathetic junctional receptors
These are muscarinic in action. Stimulation:
• Slows the heart rate (vagal tone increases);
• Causes bladder emptying, pupillary accommodation for near vision, intestinal peristalsis; and
• Initiates glandular secretion, e.g. lacrimation.

Other autonomic neurotransmitter systems
The complexity of the autonomic system is compounded by at least three further neurotransmitter lineages, known as non-adrenergic non-cholinergic (NANC) neurones:
• Dopamine is liberated from small interneurones in sympathetic ganglia, exerting a mild inhibitory effect on adrenergic neurones.
• Nitric oxide is important in the parasympathetic system as a powerful arterial dilator.
• Vaso-active intestinal polypeptide (VIP) is known to be active as a neurotransmitter in salivary and sweat glands. It acts as a co-transmitter to ACh and is a vasodilator, increasing blood supply to a target organ already stimulated by muscarinic parasympathetic activity.

The relevance of this basic autonomic neuroanatomy and neurotransmitter data is discussed in Chapter 23 and in appropriate clinical sections.

Acknowledgement

Professor MJT FitzGerald, Emeritus Professor, Department of Anatomy, University College, Galway and the publishers kindly agreed that figures from the award-winning textbook *Clinical Neuroanatomy and Related Neuroscience* (FitzGerald MJT, Folan-Curran J, 4th edition, 2002; WB Saunders, Edinburgh) were made available for the authors to use in the preparation of this chapter; this has proved invaluable.

3 The Language of Neurology: Symptoms, Signs and Basic Investigations

Charles Clarke, Richard Frackowiak, Robin Howard, Martin Rossor, Simon Shorvon

Introduction

Knowledge of neuroanatomy and basic neuroscience equips a clinician with the background essential for clinical work. However, there remains a distinct gulf between the science of neurology and its language, the medium used to interpret and communicate information about clinical features in health and disease. The purpose of this chapter is to outline some features of the practice of day-to-day neurology:

- To provide a framework for examination, clinical diagnosis and investigation;
- To mention the terminology used to capture concepts and patterns – the vocabulary of neurology; and
- To discuss some illustrative patterns essential to recognize.

Facets of the history of neurology and some subtleties of clinical practice are mentioned to provide a brief working overview.

Practical neurology is sometimes straightforward but remarkably difficult at other times. Our initial purpose as diagnosticians is to answer one question: whether or not there is a recognizable disease. In no other branch of medicine is recognition of clinical patterns more important, nor are they more reliable. Despite major advances in imaging, neurogenetics and neuropathology, clinical practice continues to follow a familiar traditional systematic approach:

- Assemble the elements of clinical observation in a structured layered fashion commencing with the simplest information, followed by physical signs and the results of appropriate investigations.
- Recognize by assessing and sifting the layers of information, the site of a lesion, its nature and/or the system affected.

Failure to follow this approach can lead to errors and especially misjudging the seriousness of a problem, either overestimating symptoms – thus leading to alarm and expense or, vice versa, missing a serious disease.

ISBN: 978-1-405-13443-9

Elements of diagnosis

The components of clinical diagnosis in neurology – its essence and singularity – are the clinical history and examination and the interplay between the two. Many people find neurology hard, both because of this interplay and also because of the breadth of the subject. Few specialties deal with such a wide range of conditions.

Some neurological conditions are wholly descriptive, such as migraine or epilepsy. We rely on a narrative of the patient or an eyewitness. In other situations, neurological signs play a pivotal part, e.g. the emergence of a spastic paraparesis. A complication occurs when one pattern of symptoms or signs might be explained by pathology in different parts of the nervous system or by different mechanisms, an example being the differential diagnosis of spastic paraparesis (see below). However, despite sophistication the nervous system has a relatively limited repertoire of symptom complexes. Examples of this are:

- Four limb numbness can be similar in character whether caused by a cervical cord lesion or polyneuropathy.
- A clumsy hand can be caused by a lesion in a peripheral nerve, root, spinal cord or cerebral cortex.
- With headache, the pain of a benign headache and the pain of a serious problem may be similar.

It is the pattern of symptoms and the presence or absence of signs that enable reliable diagnosis.

Diagnosis is a two stage process:

1 Do the history and physical signs point to the site of the lesion or lesions?

2 Does the pattern and tempo of symptoms point to a recognizable disease?

History

The narrative, from the patient, relatives or other witnesses provides primary data. This is vital information and a detailed history

of the symptoms or events at the onset of a neurological condition is often helpful as a first step towards a diagnosis. How to take the details of a present, past and family history is assumed. Three areas are mentioned where difficulties and pitfalls commonly occur.

First, vividness can only be provided by an account, taken verbatim, of events that have brought about a consultation. With the era of electronic records and abbreviation overtaking the written word, it is necessary to reaffirm the viability of simple narrative and record the story of what happened. For example, the phrase 'Fitted in bus on way to A&E – bitten tongue' is familiar medical shorthand seen in many emergency department computerized summaries. The inference is that a generalized tonic–clonic seizure has occurred. This may be the correct conclusion but to rely upon it is fraught with danger. The phrase does not indicate what the patient actually said:

> 'I was standing on the Number 73 bus near King's Cross first thing in the morning taking my mum to the hospital at University College. I felt all dizzy and sick, my eyes went all funny, then my legs went weak . . . and out I went. I came to on the floor, between the seats in a pool of blood. My mother says I fainted. But then the ambulance was called and they said I was shaking. I had bitten my lip quite badly. I was right as rain in five minutes but the lady in the ambulance said she thought I had had a fit.'

From this description of the circumstances – the brief duration of loss of consciousness and transient shaking – syncope seems likely, not the generalized tonic–clonic seizure implied by the original note. The effect of shorthand, jargon and misdiagnosis can have far-reaching consequences.

Secondly, it is important to identify the temporal pattern of symptoms, since these often provide clues to aetiology. Examples are:

- Intermittent, i.e. full recovery between symptoms. Common causes include epilepsy, migraine, transient ischaemic attacks and some rare genetic disoders such as paroxysmal dyskinesias.
- Fluctuating, chronic. MS is the typical example of a condition with this tempo.
- Progressive, chronic. Neurodegenerative and neoplastic disorders tend to follow this pattern.
- Acute or subacute progressive. These are usually infective or inflammatory disorders.
- Acute onset, single insult, with recovery. Vascular disease, i.e. stroke, is the typical example; Guillain-Barré syndrome is another.

The long time scale of some neurological conditions is important to bear in mind – for example a history of prolonged febrile convulsions in infancy may be of relevance to episodes of loss of consciousness developing in adult life.

Other aspects of the history can point to a diagnosis, such as the past medical or family history, the latter being of particular importance in many neurological conditions and frequently overlooked.

Thirdly, there is the matter of attitude, the balance between critical appraisal, sympathy and the role of the physician – and a reminder that our principal purpose is to help. Judgemental attitudes, while understandable, interfere with clinical diagnosis; they are a frequent cause of a patient or their family seeking a second opinion.

Attendance at a clinic for the first time often involves questions about very difficult emotive issues, hard to articulate. There is no such thing as a hopeless historian. The public is increasingly better and accurately informed. By contrast, the unsympathetic neurologist has been described too frequently and vividly to be discounted. Whether or not symptoms reflect a serious disease, patients do actually suffer from their complaints. That first visit frequently carries a burden – a serious diagnosis is all too often being questioned. Patients and their relatives hang hopes and fears upon single words, phrases and comments made by medical or nursing staff. Furthermore, depression, and psychiatric comorbidity are features of many neurological conditions, or effects of them. Anxiety is common in any clinical situation, serious or apparently trivial.

Nature of symptoms

Textbooks that provided the foundations of clinical practice emphasized the distinction between primary and secondary symptoms, and positive and negative phenomena. This approach needs to be understood and can be useful, although the classification is not rigid and slightly conjectural. Most anatomical brain, cord, root and nerve lesions are destructive. They cause negative symptoms of loss of function, e.g. paralysis. They may also cause positive secondary phenomena, typically features where neuronal inhibition is released, e.g. exaggerated tendon reflexes, clonus. Positive is also used to describe irritative, usually electrical phenomena such as seizures or myoclonus.

Abnormalities of function can thus be regarded in two ways:

1 Primary (direct) abnormalities, often negative: one part fails to work. Primary abnormalities can also be positive (irritative), e.g. focal seizures resulting from a cortical glioma, pain in the distribution of a trapped median nerve or hemifacial spasm.

2 Secondary (indirect) abnormalities, usually positive, often indicate over-activity resulting from release of inhibition (e.g. clonus).

Neurological examination

Preliminary assessment

Many features become apparent during conversation, during the narrative history: 'More can often be learned of a patient's disabilities by observing his ordinary actions, as dressing and undressing, walking when apparently unobserved . . . than by specific tests' was written by Gordon Holmes in 1946. We rely heavily on this apparently casual approach on a daily basis. It is the way we form an impression when meeting a new person, our own friends and colleagues, either socially or professionally. There is much to be learnt from perfecting this method of data gathering before more formal examination – provided one is not

judgemental. We all use such skills but can usually refine them. The following can be readily appreciated during the history prior to more formal examination on a couch:

- Greeting, manner, orientation, attention, mental state, mood, personal hygiene;
- Cognitive conversational clues – e.g. the mildly cognitively impaired patient turning towards a relative to answer a simple question;
- Speech, language and facial appearance;
- Gait and stance;
- Clumsiness, weakness of one side;
- Involuntary movements;
- Patterns of sensory symptoms;
- Evident risk factors, lifestyle, tobacco, alcohol, drug abuse;
- Obsessions, religion, illness beliefs, fears;
- Full details of episodes of disturbed consciousness, headaches, transient events;
- Degree of disability, aids – both in the home and outside, state benefits;
- Aspects of daily living, travel, driving, employment, dangerous sports;
- Evident endocrine or general medical clues;
- Relations with and attitudes to hospitals, practice staff and other specialists;
- Expectations and ideas about treatment.

Brief neurological examination

It is assumed that the reader can carry out a general examination and understands the rudiments of neurology. Detailed neurological examination for every case is simply impracticable in busy clinical life. In many settings we must learn to rely on a brief, robust, safe and practical examination tailored to the individual, and be guided by the history. The man who fainted on the bus does not need two-point discrimination to be assessed. A tendency to dwell on excessive detail of examination seemed to beleaguer generations of neurologists. Table 3.1 illustrates a brief neurological examination, completed easily within 5 minutes and readily adaptable to circumstance.

Table 3.1 Typical brief five part neurological examination.

1 Look generally at the patient	**4 Lower limbs**
General demeanour	Tone
Speech, language, cognition	Power (hip flexion, ankle dorsiflexion)
Gait, heel–toe, possibly Romberg's test	Coordination
Arm swinging	Reflexes
	Plantar responses
2 Head	**5 Sensation**
Fundi	Simply ask (in most cases): is it normal?
Acuity (if appropriate)	
Pupils	
Eye movements	
Facial movements	
Tongue	
3 Upper limbs	
Posture of outstretched arms	
Wasting, fasciculation	
Tone, power	
Coordination	
Reflexes	

Such an assessment combined with an appropriate general examination including blood pressure is highly unlikely to miss serious disease.

Detailed neurological examination

More detailed examination is sometimes necessary; the finer details of a full examination are valuable when complex cases are investigated. A scheme developed at the National Hospital is widely used and adapted into Table 3.3. Quite simply, this helps to avoid forgetting important data and records information for future readers. The order of examination presented here is the way in which most neurologists work and it is thus helpful to follow it.

Cognition and mental state

Much will have taken place during the clinical history. A record of a Mini Mental State Examination is a useful way to record the situation in appropriate cases. Many versions are in use (Table 3.2).

Table 3.2 Mini Mental State Examination.

Orientation	
Year, season, date, day, month?	(5 points)
Country, city, area, house number, street?	(5 points)
Registration	
Name three objects: 1 second to say each	
Ask the patient to repeat them	(3 points)
Repeat until the patient has learnt all three, count trials and record	
Attention and calculation	
Serial 7s: 1 point for each correct. Stop after five answers	(5 points)
Alternatively, spell 'world' backwards	
Recall	
Ask for names of the three objects repeated above	(3 points)
Language	
Name a pencil and a watch	(2 points)
Repeat the words: 'no ifs ands or buts'	(1 point)
Follow a three-stage command	(3 points)
Read and obey the following: 'Close your eyes'	(1 point)
Write a sentence	(1 point)
Copy a design	(1 point)
Total score	**(out of 30)**

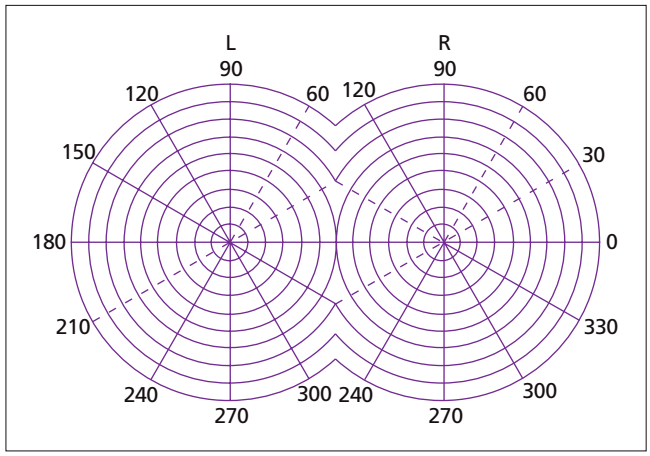
Reproduced with permission from www.alzheimers.org.uk.

Table 3.3 Detailed neurological examination.

Historical details
Main complaints
History of present illness
Past illnesses
Review of previous opinions, practice notes, etc.
Family history, with details of size of family
Social, personal, alcohol, drugs, tobacco, etc.
Travel, occupation, etc.
Review of systems:
- cardiovascular
- respiratory
- gastro-intestinal
- genito-urinary
- endocrine
- psychiatric history
- allergies – drug and other

Examination
Physical appearance, initial appraisal
Mental state and cognition, mini mental state examination
Speech, language functions, evidence of higher function problems
Skull and spine
Gait, stance, balance
Hand preference – writing, etc.

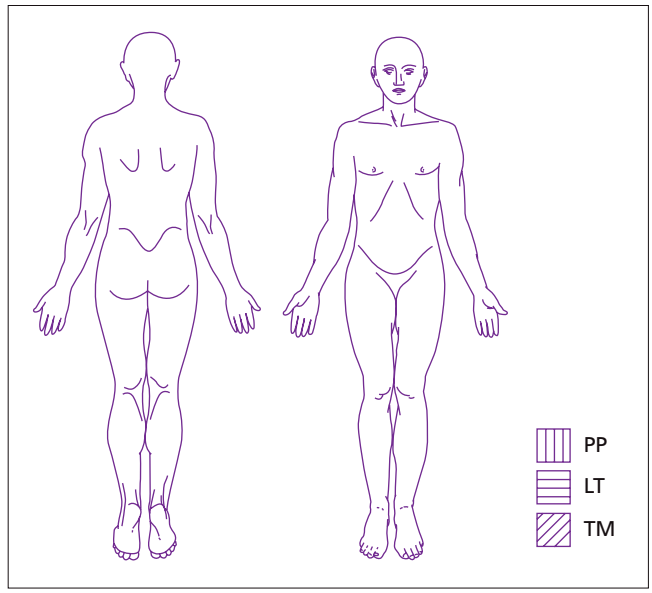
Cranial nerves
I. Olfaction
II. Visual acuity
Visual fields – describe/chart
Describe/chart



Fundus
Pupil (mm, shape, reactions)
III, IV, VI. Range of ocular movements, nystagmus
Inspection of each eye, proptosis, cornea, primary position of gaze
V. Facial sensation, corneal reflexes, jaw movement (masseter, temporalis), jaw jerk
VII. Facial symmetry, weakness, abnormal movement, taste
VIII. Hearing, Rinne, Weber, vertigo, nystgamus
IX, X. Swallowing, phonation, gag reflex, pharyngeal sensation
XI. Sternomastoids, trapezii
XII. Tongue appearance, speed, central protrusion, fibrillation

Motor system
Abnormal movements – describe
Posture of upper limbs – describe
Tone
Power
MRC Scale 1/5 and/or describe wasting, fasciculation, muscle consistency
Assess limbs, neck, diaphragm, abdomen
Coordination (finger–nose testing, alternating movements, foot tapping, etc.)
Reflexes:
- jaw jerk
- biceps jerks
- supinator jerks
- triceps jerks
- finger jerks
- abdominals (upper and lower)
- knee jerks
- ankle jerks
- plantar responses
- other reflexes (state)

Sensation
Assess: 1. Posterior columns: vibration (128 Hz, VS), joint position (JPS), light touch (LT), 2-point.
2. Spinothalamic: pain (PP), hot/cold (TM),
Chart findings: PP, TM, LT, etc.



General physical examination
Cardiovascular, BP, respiratory, abdomen, endocrine, skin, nodes, joints

Summary of findings

Formulation

Provisional diagnosis

More detailed screening tests are readily available. The Queen Square Cognitive Screening Tests are used widely; there are many others. These assess:

- Orientation and alertness;
- Language;
- Literacy;
- Praxis;
- Memory; and
- Right hemisphere function.

These screening tests provide an accurate assessment in a clinic or at the bedside and can be confirmed and explored by further detailed clinical psychometry (see below and Chapter 7).

Episodes of disturbed consciousness are discussed in Chapter 6, and coma, stupor and similar states in Chapter 19.

Skull, scalp and spine

Skull and scalp examination is often omitted. Abnormalities of contour, abnormal circumference, old burr holes or gnarled scalp vessels without a pulse may be found. Skull bruits are best detected by the following technique:

- Ask the patient to close both eyes, gently;
- Rest the bell of an old-fashioned stethoscope over one closed lid;
- Ask the patient first to open the other eye; and then
- To stop breathing, briefly.

This manoeuvre reduces extraneous noise from lid muscles and respiration.

Examine the spine and its contour. Assess for scars, stiffness, deformity, pain, bruits and for tufts of hair, dimples, sinuses or suggestions of congenital abnormalities.

Cranial nerves

I: olfaction

Two test substances from a selection of clove oil, peppermint, mint, eucalyptus oil – or simply soap, coffee or an orange – are adequate to determine whether the patient can distinguish between (not recognize) odours. More complex olfactory test kits are becoming more widely used, e.g. in Parkinson's or Alzheimer's disease (see also Chapter 12). Ammonia is sometimes used to assess trigeminal afferent responses; such a highly irritant substance should be handled with care, or avoided.

II: vision pupils and fundi

For visual acuity measurement a well-lit 3-m handheld Snellen chart is adequate for most purposes. Correction with the patient's lenses or a pinhole (easily fashioned from paper) may be needed. A record of acuity is one hallmark of a careful out-patient letter. See also Chapter 13.

Visual field examination to finger confrontation is highly reliable for picking up hemianopic or visual attention defects. Follow this when appropriate by confrontation using a 5-mm white and 5-mm red pinhead, or other target. The visual field is not a plane: move a target along the circumference of the visual field, some 50 cm away from the eye. Commence with the target at a point lateral to, and behind the visual field – out of sight, behind the ear – and move it forward, along the circumference of an imaginary circle of some 50 cm radius, towards the midline.

Using red and white-headed pins, individual techniques of field examination vary. One suggestion is to use simple positive phrases, e.g. with a white pinhead, ask the patient to: 'Say NOW, when you see the pinhead'; with a red pinhead, ask the patient to: 'Say RED, when you see the pinhead'.

Central field defects: use an Amsler grid. Or, simply ask the patient to look at newspaper text and indicate any holes in their vision.

Colour vision is speedily assessed with Ishihara plates (still in use after nearly a century), or with detailed 100 Hue Test cards.

Pupil reactions are seen best in low levels of illumination using a bright light shone through the lens, approaching slightly from the temporal side to avoid producing convergence. Subtle abnormalities of the pupillary response to light, e.g. an early Horner's syndrome, can sometimes be picked up by darkening the room. Cross-illumination – a pen torch at right angles to the visual axis – helps light up an iris of a darker shade. Putting these two together (direct and cross-illumination), many a pupil apparently unreactive in daylight (e.g. in old age – senile miosis) can be seen to constrict, if only a little. The swinging light test, especially in dim light can identify a relative afferent defect. Other abnormalities of the pupils are discussed in Chapters 13 and 19.

Fundus examination takes experience to perfect. The crux is to develop a suitable personal technique. Suggestions are:

- Have the patient seated, gazing horizontally – not at the ceiling. Suggest they gaze at some distant object. Mention there is no problem if they blink. These manoeuvres avoid one's own clothing or hair falling into the subject's face, help fixation and discourage following the ophthalmoscope light source.
- For the left fundus, try to look through the ophthalmoscope with your own left eye and vice versa. This encourages the patient see past you and to fixate. Also, do not close your own 'unused' eye; if this is hard to achieve, cover it with a free hand. This helps the viewing eye to focus on infinity through the ophthalmoscope, and allows your face to relax.

III, IV and VI: eye movements

Recently acquired double vision is a frequent reason for urgent referral and for many doctors a distinct cause of confusion/anxiety. The latter is especially so if the 'four formal rules' for diplopia (Table 3.4) are followed rigidly for every case. An alternative, shorthand system that relies much on recognition at a glance is the reality: every experienced neurologist uses some form of this approach. Such a simple scheme diagnoses most cases quickly, i.e. most diplopia can be assessed by ascertaining whether or not the abnormality fits one of four patterns.

Table 3.4 Four rules for recognition of a weak ocular muscle.

1 The false image is usually the less distinct and more peripheral
2 Diplopia occurs in positions that depend upon contraction of a weak muscle
3 A false image is projected in the direction of action of the weak muscle
4 Image separation increases in the direction of action of the weak muscle

A tendon hammer shaft is a convenient tool for the patient to follow.

VI: abducens nerve palsy

This causes:

- The complaint of double vision with two images side by side (i.e. diplopia with horizontal separation);
- An evident convergent squint;
- Double vision that disappears on looking away from the weak lateral rectus muscle and vice versa – worse towards the weak muscle in the obviously squinting eye; and
- No abnormality in reaction to light in the pupil.

Remember that a lateral rectus palsy can be caused either by a VIth nerve lesion or by disease of the lateral rectus muscle or neuromuscular junction.

III: oculomotor nerve palsy

A complete, e.g. compressive, IIIrd nerve palsy typically causes:

- Ptosis – the lid drops, covering the eye completely;
- A pupil that is large and unreactive to direct light (the contralateral pupil constricts normally);
- An eye (on lifting the lid gently) facing down and out.

The term partial IIIrd nerve palsy usually implies sparing of the pupillary and lid parasympathetic fibres; these lie on the undersurface of the IIIrd nerve and have a separate blood supply. The pupil remains normal. Ptosis is incomplete. The eye faces down and out. A complication of diabetes is a typical cause (Chapter 25).

Internuclear ophthalmoplegia

Damage in the brainstem to the medial longitudinal fasciculus causes an internuclear ophthalmoplegia (INO):

- Disconjugate horizontal eye movements, i.e. movements not yoked together – the eyes move horizontally at different velocities. One suggestion to help observe disconjugate movement is to look at the centre of the patient's forehead – otherwise there is a tendency for the examiner to fixate on one eye and miss what is happening to movement in the other;
- Incomplete adduction of one eye – and when this is so;
- Coarse jerk nystagmus is seen on lateral gaze in the other eye, i.e. on abduction

Internuclear ophthalmoplegia is described as left-sided when there is failure of left adduction, i.e. looking to the right. There are various varieties of INO (Chapter 13).

IV: trochlear nerve palsy

A distinct rarity compared to IIIrd and VIth nerve palsies, a IVth nerve palsy causes:

- A complaint of double vision on looking down, e.g. descending stairs;
- 'Twisted' images, i.e. one at an angle to the other;
- Head tilt away from side of superior oblique muscle weakness;
- No obvious squint.

Four rules for diplopia assessment

There are numerous other varieties of weakness of the extraocular muscles and the more detailed approach becomes necessary when cases do not fit into the patterns above. The four formal rules established in the early 20th century are logical, accurate and invaluable in such complex cases (Table 3.4). Even using them, some cases of ocular muscle disease (e.g. myasthenia, ocular myopathy) can prove difficult. It is usual to track movements in the shape of an H. Lateral movements are assessed, followed by elevation and depression at about 30° of lateral gaze. A minor degree of diplopia is an almost normal finding at the extremes of gaze; blurring and 'false-framing' of objects is also easily accomplished, either in error or deliberately, by converging on an object closer than one's natural near point.

V: trigeminal nerve – sensory and motor

Most people with sensory loss in the distribution of one or more trigeminal nerve branches complain of numbness and tingling in a clearly defined anatomical zone – making the detailed assessment of pain, temperature and light touch superfluous (Figures 2.48, 3.8 and 12.1). Many people have experienced V_3 sensory loss, following lidocaine at the dentist, so there is a familiar flavour to the symptom. The main exception to this obvious, descriptive altered sensation is the imperceptible loss of corneal sensation seen with an early acoustic neuroma, or other lesion at the cerebello-pontine angle (CPA). This is initially isolated, symptomless and only found by careful technique.

Corneal reflex: technique

Approach the cornea from the lower temporal side (avoid a visual threat) with a pointed wisp of cotton wool. For ease of access, gently draw down the lower lid. Rest the wool gently upon the infero-lateral cornea, not the conjunctiva – between 6 and 9 o'clock for the right eye. Ask the patient what they feel and observe the surrounding conjunctiva for the normal reddening and tearing. Someone with an early depressed corneal reflex may say 'I can feel you touch me but it isn't painful like it was on the other side.' When the corneal reflex is depressed, conjunctival injection and tears are markedly diminished.

The fine print of corneal reflex examination is this: V_2 supplies the lower 60° corneal sector, i.e. between c. 5 and 7 o'clock; V_1 the supplies the upper 300°. This is occasionally of clinical value.

Neurologists vary in the emphasis they attach to evident blinking versus pain (a VIIth nerve blink response to corneal nociception rather than discomfort) during testing the corneal. Many find it simpler to regard practical day-to-day examination of the corneal reflex as a facet of Vth nerve sensory examination rather than a V → VII reflex; the blink response is sometimes valuable in ITU (Chapter 19).

There are several other aspects of Vth nerve examination. These relate to the distribution of the three divisions of the nerve. First, the distribution of V_1 extends to the scalp – as far as the vertex (via the supra-orbital nerve). Supra-orbital nerve lesions, often traumatic or surgical, can cause headaches. Secondly, V_3 does not supply the skin of the neck: patients with non-organic facial sensory disturbance often complain of symptoms below the distribution of V_3 (mandibular division), i.e. including skin over the neck and platysma. Thirdly, C2 supplies the posterior scalp, including the area up to the angle of the jaw. Another symptom (or sign) is common – a slight change in temperature perception between one side of the face and the other. This is rarely of significance.

Finally, central lesions (brainstem) can cause circum-oral, 'onion skin' sensory loss (Chapters 2 and 12, Figure 2.51). Any complaints of sensory disturbance around the mouth should not be dismissed.

V motor examination

Motor lesions of V are unusual, but easy to miss unless jaw deviation (to the weaker side) is assessed carefully. The easiest approach is to look at the incisor teeth. Establish the centre line of the upper and lower incisors and see if the centre line remains central or moves laterally as the jaw opens against slight resistance. At this point, some neurologists tap the jaw jerk; others tend to leave this until the cranial nerve examination has been completed.

VII: facial nerve

A complete lower motor neurone (LMN) facial palsy affects all facial muscles on one side, whereas upper motor neurone (UMN) weakness affects lower parts of the face; this spares blinking and wrinkling of the forehead. This difference between UMN and LMN lesions is explained by bilateral innervation of parts of the VIIth nuclei supplying upper facial muscles (Chapter 2). There are some subtleties of facial examination. In early UMN facial weakness, all that may be evident is a hint of slowing or delay of a blink, spontaneous grin or grimace. There may be dissociation of voluntary and involuntary movement: formal 'show your teeth' examination can remain normal, but a spontaneous smile slow on one side.

For LMN lesions, divide up the face and suggest definite actions:

- *Frontalis:* 'Look upwards' usually produces furrowing the brow – the response required. A 'wrinkle your forehead' suggestion produces a variable grimace;
- *Orbicularis oculi:* try: 'Screw up your eyes tightly';
- *Alae nasae:* 'Wrinkle your nose';
- *Orbicularis oris:* 'Now try to whistle gently';
- *Risorius* (and others): 'And now please show me your teeth';
- *Platysma:* men who use a razor find this muscle easy to demonstrate – they tension the skin of the neck. With women, eversion of the lower lip is said to be one way to demonstrate platysma; another is a suggestion to: 'stick out your chin and grunt' – either seems inappropriate. Attempting to copy the examiner usually solves the problem.

Involuntary movement of the face, e.g. myokymia (see below and Chapter 12), fasciculation and minor degrees of hemifacial spasm can be hard to see. Illuminate the face well, and look closely.

Finally, as a practical point, the gradual emergence of patchy facial weakness is distinctly unusual in Bell's palsy – the most common cause of acute LMN weakness. If the facial weakness is minor or develops gradually over weeks, suspect some other, possibly sinister cause. In Bell's (Chapter 12) weakness is usually at its worst within 12 hours; there is frequently pain around the mastoid, hyperacusis and loss of taste.

VIII: auditory nerve

Testing is often unnecessary when there is no problem with hearing. If there is a degree of hearing loss, record the distance at which a whisper (or speech) is heard. The Rinne test is excellent for conductive deafness but of less value for the sensorineural deafness of particular interest to a neurologist.

Here is a simple pragmatic approach to the assessment of hearing:

- Record the distance a whisper is heard from the ear;
- Occlude gently both external auditory meati with the tips of each index finger. Rustle with each middle finger the skin/hair over the mastoid. This provides a rough-and-ready measure of bone conduction. If there is an evident difference between each ear, perceptive (sensorineural) loss is usually present. It is remarkable how accurate this is.

Rinne and Weber tests are discussed in Chapter 14. In practice, any suspicion of a CPA lesion will be followed up by detailed MR imaging and specialized audiometry.

VIII: vestibular nerve

Dizziness, vertigo and nystagmus are dealt with in more detail in Chapter 14. The basic balance tests are observation of gait and station, and Romberg and Unterberger tests (R+U). Opinions vary about the value of these latter two, named tests. One view is that they are obsolete, pointing out that injuries occur if the tests are carried out carelessly. The Romberg test (Dr Moritz Heinrich Romberg, 1795–1873) was originally of value in the diagnosis of tabes dorsalis. In this variety of neurosyphilis, joint position sense became so severely impaired that the patient would lurch wildly on closing the eyes. The Unterberger test ('Stand to attention with arms extended forwards, march on the spot and close the eyes') is a non-specific test developed in 1938 of either vestibular or

cerebellar problems – the patient turning towards the side of the lesion. One, perhaps cynical, view of these tests is to record theatrical responses in those with no organic disease – but in these cases particular care must be taken to avoid injury. Most find R+U tests of some value – Romberg's is useful for detection of subtle proprioceptive losses.

Nystagmus and vestibular testing are considered in more detail in Chapter 14. A common error is to over-diagnose as pathological a few beats of nystagmus at the extremes of lateral gaze – this is normal. Nystagmus must usually be sustained, and well within binocular gaze, to be pathological.

IX and X: glossopharyngeal and vagus nerves

Take these nerves together. Observe the uvula and fauces on saying 'Aaah'. Look for pooling of saliva and residual food remnants. Most neurologists no longer use the gag reflex alone as a measure of safety for swallowing. Many patients with an intact but hyperactive gag continue to swallow, but do so in a disorganized way and may aspirate; others with a depressed gag are shown on videofluoroscopy to swallow safely without aspirating. If there is a question of bulbar weakness or difficulty swallowing:

- Listen to the voice – this sounds 'wet' in the early stages of bulbar muscle weakness (Chapter 12);
- Ask the patient to cough;
- Look for deviation of the palate/uvula (away from the side of the lesion);
- Watch the patient begin to drink a glass of water, if this seems safe and look for spluttering, choking and pooling after a mouthful.

An isolated IXth nerve palsy – a rarity and hard to identify – causes impaired sensation on one side of the pharynx. Tickling the area with a cotton wool bud in the normal person causes discomfort and elicits gagging, via the vagus. In many patients, there is little need to test the gag reflex.

XI: accessory nerve

The most common cause of an isolated spinal accessory nerve lesion is a surgical complication of biopsy of a node in the posterior triangle of the neck. The nerve is superficial here and easily damaged en route to trapezius. Weak shoulder shrugging is seen. Weeks or months later, pain around the shoulder and upper scapula frequently develops – typically an intense intractable neuralgia. While examining trapezii and sternomastoids, look for winging of the scapula and at the neck muscles (Chapter 12).

XII: hypoglossal nerve

Tongue wasting and deviation to the weak side when protruded is the well-known sign of a unilateral XIIth nerve lesion. It is also useful to look at tongue movement generally. The speed and amplitude of tongue movement are diminished in bilateral pyramidal lesions and often early in Parkinson's disease. Tongue fibrillation, seen in motor neurone disease, should be diagnosed only when the tongue rests within the mouth. A few twitches of tongue muscles occur in normal people when the tongue is protruded.

Gait and disorders of movement

The pattern of walking and any major abnormal movements should have been noted in the initial appraisal. It is useful to reflect on that first impression and to carry out more a detailed analysis, either here or at another point in examination.

Record whether gait is:

- Normal and symmetrical without limp, or abnormal, perhaps in some ill-defined way;
- Spastic – narrow-based, stiff, toe-scuffing;
- Hemiparetic;
- Extrapyramidal – shuffling, festinant (hurrying), with poor arm swinging, or simply very slow;
- Apraxic – e.g. with gait ignition failure, or with walking difficulty but with preserved ability to move the legs rapidly whilst on a bed, or seated – normal bicycling movements;
- Ataxic – broad-based, unsteady;
- High stepping, foot drop, myopathic, antalgic, neuropathic; or
- Unusual in any other way, e.g. affected by disorders of movement, such as dystonia, chorea or myoclonus – or apparently theatrical and non-organic.

It is feasible to categorize most gait problems by observation, e.g. spasticity, chorea, festination, dystonia; but the real issue here is to avoid missing something subtle yet really quite evident. For example, fidgetiness of early chorea can easily pass unnoticed unless considered. Early dystonia is easy to miss. Many gait disorders labelled initially as non-organic or even deliberate turn out to be due to an organic movement disorder. A brief video – with permission – can be helpful.

Motor system

Limb function and motor abnormality is a pivotal part of neurological examination. This is an area where eponyms became attached to hard physical signs – Babinski being the lasting example.

Posture of outstretched upper limbs

The posture of the outstretched upper limbs is one useful way to begin. The manoeuvre establishes physical rapport with the subject and if you are an examination candidate demonstrates an understanding of neurology. The test provides a wealth of information.

Ask the patient to extend the bare arms symmetrically, palms uppermost, and then close the eyes. Upper limb wasting and abnormal movements become evident. Drift with pronation and descent towards the midline is a cardinal early sign of a pyramidal lesion – as valuable diagnostically as an extensor plantar. Postural tremor may appear. Rest tremor can vanish. Chorea, pseudochorea (seen in denervation and parietal lesions) and asterixis in hepatic disease may become apparent.

Gentle downward pressure is then applied at the wrists, and released. Rebound on one side suggests a cerebellar lesion.

Fatiguability of myasthenia appears as inability despite effort to maintain the arm outstretched horizontally (the basis for the arm outstretched duration test in myasthenia).

Non-organic weakness is often accompanied by aimless waving around.

Finally, the hands and nails can be examined.

Tone

The difference in character between pyramidal increase in tone (spasticity) and the rigidity of extrapyramidal disease requires two distinct examination techniques.

In Parkinson's disease the extrapyramidal lead pipe rigidity is detectable throughout the range of movement of a joint. Begin with the wrist, and take the hand through passive, slow, deliberate extension, flexion and rotation movements, so that the wrist joint is moved throughout its range. This elicits early signs of stiffness in forearm muscles and 'cogwheeling'.

By contrast, in limb spasticity, the early pronator catch or the beats of emerging ankle clonus will become apparent, but only if sought by brisk passive movements – supinating the forearm or dorsiflexing the ankle. Slow passive movements will miss these early pyramidal signs. Spasticity increases in line with the rate of passive movement. A catch of increased tone becomes apparent before demonstrable sustained clonus can be diagnosed, i.e. when there are four or more beats of clonus at the ankle.

Power

Various scales have been devised to record weakness, including suggestions for a 10-point system; the six-point, MRC 0–5 Scale is usually used (Table 3.5). This has two substantial limitations: the inability to record numerically a slight loss of power, and its dependence on effort/cooperation. A brief description, e.g. 'I could just overcome hip flexion' deals most effectively with a slight degree of weakness. 'Give-way' weakness implies poor effort. Testing skilled hand (and foot) movement is also important: ask the patient to play an imaginary piano and/or touch sequentially with the tip of the thumb the fingertips of the fifth, fourth ring and index fingers, back and forth. This is a useful test of pyramidal function.

Table 3.5 Six (Medical Research Council) grades of muscle weakness.

5	Normal power
4	Active movement against gravity and resistance
3	Active movement against gravity
2	Active movement with gravity eliminated
1	Flicker of contraction
0	No visible muscle contraction

Note: these UK Medical Research Council grades [0/5 to 5/5] were designed to record change in power during poliomyelitis. Although most applicable to LMN weakness they remain widely used.

Fatiguability should be assessed by repeating a movement if the story suggests this might be present. The slow relaxation of myotonia should also become apparent – provided one remembers to consider it.

Focal or general muscle wasting, fasciculation and muscle consistency should be assessed.

Coordination – cerebellar signs

Signs of early cerebellar disease (Chapter 16) may be suspected during initial assessment, e.g. recognizing dysarthria or tremor, noting an ataxic gait, or rebound when examining upper limb posture. Coordination testing can commence by looking for dysmetria (past pointing) and action tremor.

When testing for dysmetria, the patient is asked to place their forefinger on the point of a tendon hammer shaft, held at the limit of their reach, and then to touch the tip of their nose. For the next cycle, move the tendon hammer slightly to a different position. The finger–nose test is a not a measure of speed, although one frequently hears the suggestion: 'Do this as fast as you can.' Carrying out the test rapidly tends to miss early cerebellar signs.

Follow with a sequence of other cerebellar tests. Individual neurologists develop their own favourites. In early disease, one test will frequently be more abnormal than others – not itself a sign of localizing value, but an indication that a single cerebellar test is insufficient. For example:

- Circular polishing of the dorsum of the opposite hand with a single finger;
- Alternating forearm pronation and supination. Show the patient this test: with forearm vertical, make a rotational back-and-forth movement. Next, repeat the test with the forearm horizontal and palm uppermost. Again, show the patient how pronation–supination is combined with tapping the fingertips of one hand, back and front on the dorsum of the opposite hand.

The clumsy term dysdiadochokinesia is used to describe abnormality in this test, distinguishing it from dysmetria. More practical tests, such as screwing in a light bulb, are also sometimes helpful.

In the lower limb heel–shin test, ask the patient to:

- Raise one leg, touch the opposite ankle with the heel; and then
- Repeat this circular sequence of movement, i.e. raising the leg again. Simply gliding one heel up and down the opposite shin will miss early ataxia.

Foot tapping (against the palm of the examiner) is another useful test that brings out disordered lower limb coordination. In cerebellar disease, eliciting knee jerks with a pendular pattern, i.e. slow and swinging when the legs are dangled vertically over the couch, or finding the absent knee jerks sometimes seen in ataxic conditions, are rarely of much diagnostic value.

Cerebellar dysarthria is usually evident without resorting to asking the patient to pronounce 'West Register Street' (in Edinburgh) or 'baby hippopotamus' – but these phrases remain deeply etched into teaching.

Table 3.6 Interpretation of tendon reflexes.

Symbol	Description	Inference/notes
0	Absent with reinforcement	Almost always pathological
+/–	Present with reinforcement	Sometimes normal, but may be pathological
+	Present	Normal
+ +	Brisk	Normal
+ + +	Very brisk	Pathological if tone is increased; may be a normal finding
CL	Clonus	>3 beats of ankle clonus = pathological; 2 beats allowed

Do not miss the slow relaxing reflexes of hypothyroidism.

The nystagmus of cerebellar disease rarely occurs without other cerebellar features. Finally, remember that midline cerebellar disease (vermis lesions) can cause gait and trunk ataxia without cerebellar signs in the limbs.

Tendon reflexes

Strictly, these are the deep tendon reflexes (DTRs of US texts). The full-size tendon hammer (approximately 33 cm [13 in] shaft) is the preferred tool; miniature versions are discouraged. A soft rubber O-ring on the hammer is preferable to hard one. Make sure the patient is relaxed – with the head and thorax resting comfortably on the couch. The 0 to + + +and CL nomenclature is shown in Table 3.6. Minor degrees of reflex asymmetry are common in normal people, as are relatively reduced knee jerks compared with ankle jerks, and sometimes vice versa. Table 3.7 indicates spinal levels of the tendon reflexes.

Reinforcement, the method of attempting to elicit tendon reflexes that are at first sight absent, is achieved by several actions. One is to ask the patient to clench their teeth and then relax; another is to clench the hands. The original Jendrassik manoeuvre is to hook the fingers each hand together and pull firmly (Dr Ernö Jendrassik, 1858–1921, Budapest). Areflexia without other physical signs is not in itself an absolute abnormality, but is usually pathological.

Extensor plantar (Babinski) and Hoffmann reflexes

Dr Joseph Babinski (neurologist, Paris, 1857–1932) wrote the 26-line description entitled the 'phénomène des orteils' (toe phenomenon) in 1896. This, the extensor plantar response, is an indication of an UMN lesion of the brain or spinal cord. Babinski is said to have used a bodkin, a sharp instrument, originally an arrowhead, but an orange-stick is now the usual instrument. The crux of the matter is that if a reproducible upgoing toe can be produced by any reasonable stroking action on the sole, then this is abnormal. There are over a dozen additional ways to elicit a similar phenomenon, many eponymous, such as Chaddock, Gordon, Oppenheim and Gonda signs; none rivals the original Babinski.

Extensor plantars are exceptional in the normal adult, but are occasionally found. Dr Johann Hoffmann (neurologist, Heidelberg, 1857–1919) described finger reflex hyper-reflexia on flicking the thumb or forefinger. This is little used by most neurologists today; in practice, other UMN signs are usually evident.

Table 3.7 Spinal levels of tendon reflexes.

Spinal level	Reflex
C5–6	Supinator
C5–6	Biceps
C7	Triceps
C8	Finger jerks
L(3)–4	Knee
S1	Ankle

Superficial abdominal reflexes

Superficial abdominal reflexes are elicited by gentle stroking with an orange-stick. This evokes a subcutaneous twitch in each upper and lower abdominal quadrant in the normal subject. There is no need for the stimulus to be sharp or noxious. The superficial abdominal reflexes are lost with pyramidal lesions. They are sometimes hard to elicit, or may be absent in the obese, or following abdominal surgical or other scars. The level of absence of lower abdominal reflexes can help confirm a thoracic level in cases of cord compression (the umbilicus is at T10).

Respiration, the diaphragm and abdominal muscles

Respiration and the diaphragm can be assessed at the bedside, by observing inspiration and expiration, and the abdominal muscles. Selective weakness of the diaphragm causes paradoxical upward movement of the umbilicus; this is well seen with the patient supine during sniffing. If there is any question of respiratory failure, a prompt assessment of respiration is essential, e.g. measurement and monitoring of vital capacity, blood gases and chest X-ray.

Lower and upper motor neurone lesions

The features differentiating LMN and UMN lesions are outlined in Table 3.8. In UMN (pyramidal) lesions, the pattern of weakness is sometimes of value diagnostically. In the lower limbs, there

Table 3.8 Lower and upper motor neurone lesions.

Feature	Lower motor neurone	Upper motor neurone
Focal muscle wasting	Visible	Absent
Fasciculation	Visible	Absent
Fibrillation potentials	Recordable on EMG	Absent
Tone	Flaccid/normal	Increased/spastic type
Weakness pattern	Segmental, nerve or distal	Pyramidal + dexterity ↓
Specific tendon reflexes	Depressed/usually absent	Exaggerated
Clonus	Absent	Present
Superficial abdominal reflexes	Present	Absent
Plantar response	Flexor (normal)	Extensor

is disproportionate weakness of hip flexors, knee flexors and ankle dorsiflexors compared with their antagonist muscles, while in the upper limbs, all extensors and finger abduction are weaker than flexors and finger abduction. This is usually accompanied by reflex changes. In early UMN lesions, not all the features of Table 3.8 need be present. In a very early lesion, loss of finely skilled finger and toe movements, or simply drift of an outstretched arm can be the only sign of abnormality.

Sensory system

Sensory abnormalities are rarely found when the patient is articulate and there are no sensory complaints or other signs. Try to focus examination anatomically.

Assess first the posterior columns – vibration and joint position sense (VS and JPS). Then move to the spinothalamic tracts. This is an anatomical approximation, but it is useful.

- Test VS at the ankles using a 128 Hz tuning fork. Familiarize the patient with the test by placing the heel of the vibrating fork on the sternum.
- Test toe and then finger JPS – holding the sides of the digit, and taking it through the smallest movements.
- Quantification of JPS is achieved by recording responses at the toes, ankles and knees – and similarly in the upper limbs. VS can also be quantified similarly, to include recording its absence at the xiphisternum or even at the clavicles.
- Examine spinothalamic sensation first with cold metal and/or a disposable sharp object – not a needle or pin.
- Test light touch with a finger tip or cotton wool. Avoid stroking or tickling; these are related to spinothalamic modalities. Detailed touch tests with fine hairs of various calibres are obsolete.
- Chart areas of sensory loss or altered sensation. In loss of sensation move from the anaesthetic area to the area of normal sensation. In hypersentivity states move from normal skin towards hypersensitive skin.
- Two-point discrimination (0.5 cm on finger tips, 2 cm on feet) is useful for completeness if circumstances warrant it. A paperclip can be easily bent into a makeshift two-point tool if traditional discriminator forceps are not available.

Two areas of sensory examination require particular attention to detail:

1 Determination of a thoracic sensory level in a possible spinal cord lesion; and

2 Charting of areas of possible dissociated sensory loss in a suspected central cord lesion such as syringomyelia.

In an early compressive cord lesion, a distal sensory disturbance may not be a significant complaint. For example, if signs of a mild spastic paraparesis are found during motor and reflex testing, check sensation on the thorax and abdomen with care. Move up from the lower limbs, first to the lower abdomen using a cold tuning fork blade and ask if sensation changes. In the normal person (test it on yourself), sensory perception changes slightly at the groin, lower costal margin and again around the clavicle. Changes at other levels, with altered diminished sensation distally, may well be pathological. The level of a cord lesion can be determined in this way. Be aware that on the thorax, a sensory level on the back is typically slightly higher than on the front.

In syringomyelia, sensory loss may also be unrecognized by the patient. Painless burns or painless minor injuries should be noted. The areas of dissociated spinothalamic loss on the trunk and upper limbs can be bizarre, conforming to no obvious pattern, because the syrinx involves the crossing spinothalamic fibres in the central grey matter of the cord. Look also for loss of sensation to a sharp object on the posterior scalp (C2).

Generally, when complex sensory loss is questioned, it is a good plan to note the initial findings and return to the patient and re-examine after an interval specifically for sensory signs.

Formulation and diagnosis

Drawing together historical data and physical signs is an essential part of assessment but frequently skimped. To conclude that a fall with loss of consciousness and residual weakness is 'collapse ?cause' or 'probably a fit', an evident hemiparesis is 'a CVA' or a complex headache history 'migraine' (common comments in A&E notes) are not formulations any medically qualified person should reach. A structured approach is essential, teasing out features from the history and building in signs found on examination in an attempt to reach either a diagnosis or at least a direction for investigations. Such attention to detail can be hard in an emergency setting, but it is in acute neurology that many mistakes tend to occur. For example, cases of sudden headache are discounted as benign when the reality is a subarachnoid haemorrhage. This is not uncommon; a careful history and thoughtful appraisal can usually produce the correct answer, and usually safe management. Another common error is the distinction between a seizure and syncope; mistakes follow easily if one fails to adopt a simple, structured approach.

As a generalization, the history often points towards a pathological process, while examination either simply confirms one's

suspicions or suggests a more precise anatomical localization of that process.

Difficulties with the history and examination

It can be hard to sort out the secure details within the history, and hard physical signs and to distinguish these from less diagnostic but entirely real symptoms that have no serious underlying pathology. It is also sometimes taxing to formulate a diagnosis. However, it is necessary to try. Incomplete and sketchy formulation and omission of simple clinical information are the failings that occur most frequently. Lack of medical knowledge is seldom a problem.

To counter this, it is suggested that definite historical details and physical signs (e.g. a tonic–clonic seizure, sustained ankle clonus + extensor plantars) are separated from the less clear (vague weakness, dizziness without vertigo) and that localization and diagnosis are based on what is reasonably certain. Also, be prepared to recognize, accept and record uncertainty – it may not be clear whether the blackout was a fit or faint. It is obvious that this is advice easier to write than to practice.

Diagnostic tests in clinical neurology

In clinical neurology, as in many braches of medicine, the substantial majority of laboratory and other tests do not alter the course of a disease. However, we are surrounded by a world of technology, by tests that have illustrated features of conditions that were once unknown, by defensive practice and the need to provide reassurance that all has been done to eliminate conditions of a sinister nature. Over-investigation and screening tests have become common. It is essential to be aware of the cost–benefits of investigations and to attempt to target studies for some real purpose. The principal investigations of neurology are outlined here.

Imaging

There has been a revolution in clinical imaging. It is a salutary to recall that the first patient imaged by computerized tomography (CT) was in 1971 in London and for those in clinical practice before the 1980s, CT scanning was a novel test, sparsely available. At that time, carotid and vertebral angiography, air encephalography and myodil myelography were the standard investigations, and those only within specialist units. The human brain was first imaged by magnetic resonance (MR) in Nottingham, UK in 1978, while today, MRI is widely available; functional MRI (fMRI) is beginning to be used in clinical practice. The basic principles of modern imaging techniques, their roles and limitations are mentioned here.

Computerized tomography

A collimated X-ray beam moves synchronously across a brain slice 2–13 mm thick. Transmitted X-irradiation from one pixel, an element $<1\ mm^2$, is computer processed and a number (Hounsfield number) assigned to its density (air = −1000 units; water = 0; bone = +1000 units). Differences in attenuation (density) between air, bone, brain and CSF enable recognition of normal and abnormal tissue – infarcted brain, tumour, extravasated blood, oedema and abnormal bone. Enhancement with IV contrast media delineates areas of increased brain blood supply. Detailed cuts through bone outline fractures and lesions within the skull and spine.

CT scanning well demonstrates:

- Most cerebral tumours;
- Most intracerebral haemorrhage and infarction;
- Subdural and extradural haematoma;
- Free blood in the subarachnoid space;
- Lateral shift of midline structures and displacement/enlargement of the ventricular system;
- Cerebral atrophy;
- Intracranial calcification;
- Skull and scalp lesions; and
- Spine and spinal cord (and CT myelography)

CT remains a sensitive imaging test for subarachnoid haemorrhage and for skull lesions.

Limitations of CT

- Lesions under 1 cm diameter may be missed.
- Lesions with attenuation similar to that of brain are poorly imaged (e.g. MS plaques, isodense subdural haematoma).
- Grey–white matter differentiation is poor.
- Lesions with attenuation close to that of bone may be missed if near the skull.
- CT can miss lesions within the posterior fossa.
- The spinal cord is not imaged directly by CT (contrast is necessary).

Magnetic resonance imaging

MRI has rapidly become the gold standard for much clinical imaging and continues to develop. Its basis is described here.

The hydrogen nucleus is a proton whose charge creates a local electrical field. These protons become aligned by sudden strong magnetic impulses. Protons are then imaged with radiofrequency waves at right angles to their alignment. The protons resonate and spin, before reverting to their normal alignment. As this proton reversion takes place, images are made at different phases. In the scanner, tissue is subjected to a rapidly reversing magnetic field and the spin measured with each switch in field direction. Various sequences known as weightings are captured, e.g. T1, T2, T2*, STIR, FLAIR, diffusion-weighted imaging (DWI). The different sequences provide different tissue contrasts; thus imaging can be tailored to the clinical question. Gadolinium is used as an intravenous contrast medium.

MRI has advantages over CT in most areas of neurology:

- MRI distinguishes between brain white and grey matter;
- Spinal cord, nerve roots and large nerves are imaged directly;

• MRI has greater resolution than CT (around 0.5 cm – or even higher resolution, with powerful magnets);
• No radiation is involved;
• Magnetic resonance angiography (MRA) images blood vessels, aneurysms and AV malformations without contrast;
• MRI is useful in some muscle diseases, e.g. myositis, and can demonstrate wasting of skeletal muscle;
• MRI can differentiate between tissue with different contrast characteristics with more sensitivity than CT.

Tumours, infarction, haemorrhage, clot, MS plaques, posterior fossa, pituitary, foramen magnum and spinal cord are demonstrated well by MRI. Focal atrophy, for instance in hippocampal sclerosis is clearly seen.

Limitations of MRI are principally time and cost. Imaging one region takes about 20 minutes. Patients need to cooperate; claustrophobia is an issue. A general anaesthetic may be necessary. Open machines are available but produce images of lower definition than conventional magnets. Patients with cardiac pacemakers, vagal nerve stimulators or with ferro-magnetic bodies in the brain and eye cannot be imaged. Following lumbar puncture, MRI frequently shows diffuse meningeal enhancement with gadolinium for some days or weeks: this is a normal finding. Over-interpretation of changes seen with normal ageing, e.g. spinal degenerative changes, can cause difficulties.

Functional magnetic resonance imaging

Functional MRI (fMRI) depends on differential magnetic properties of oxygenated and deoxygenated blood. Active brain areas use more oxygen, thus changing the local magnetic environment. This causes change in the blood oxygen level dependent (BOLD) signal. This signal cannot be precisely calibrated, so it is usual to compare activated against control state to obtain a relative signal – or significant signal change. Other ways of using functional brain imaging responses include manipulating a behavioural variable and looking for correlated BOLD signal changes. Non-linear regional brain responses can be sought by imaging a task and control state under two or more contexts, e.g. the response to a specific memory task in the presence and absence of a memory-enhancer. Differences between between state and context are shown by a local BOLD signal change.

Clinically, fMRI is seldom requested or available for day-to-day practice, but it is used in pre-surgical mapping of language, motor and other functions to determine hemispheric dominance prior to epilepsy surgery and occasionally before brain resections for tumours. The technique has a major role in research into cognitive and degenerative disorders, into specialization within different brain areas (most notably in the visual system), into the brain networks that underlie memory, different varieties of headache and other complex phenomena. Network analyses have become highly sophisticated, allowing effects of recovery and treatment to be measured. Many new patho-physiological insights have been gained in relation to brain plasticity and recovery following stroke and traumatic injury. It is speculated that fMRI, allied to techniques such as EEG and magneto-encephalography might be used in neurodegenerative conditions, to seek out characteristic functional signatures in preclinical states.

Positron emission tomography and single proton emission computerized tomography

These functional imaging techniques track uptake and metabolism of radioisotopes. Positron emission tomography (PET) scanning is sometimes of great value in locating tumours, especially those clinically silent outside the nervous system.

Single photon emission computerized tomography (SPECT) scanning has provided some useful data in the research field and is sometimes useful in the localisation of seizures during the work-up for epilepsy surgery. SPECT has however been largely discarded as a tool in much general neurology, especially following traumatic brain injury.

SPECT scanning using ioflupane (an iodine-123 based product), also known as dopamine transporter (DaT) scanning, is becoming used to assess the integrity of the striato-nigral system. It is of some value in the diagnosis of Parkinson's disease and investigation of other extrapyramidal disorders (Chapter 5).

Isotope (99mTc-pertechnetate) imaging

This was in the past of value in the detection of vertebral and skull lesions (e.g. metastases) but is now largely superceded by MR and CT imaging.

Digital cerebral and spinal angiography

The value of and indications for these important invasive vascular techniques are discussed in Chapter 4.

Brightness-mode Doppler ultrasound

B-mode ultrasound is valuable in the detection of carotid artery stenosis and also used for imaging the orbit.

Clinical neurophysiology

Clinical neurophysiological measurement continues to play a very useful part in investigation. The tests generally available are outlined here, with notes indicating how a clinician can approach their interpretation.

Electroencephalography

Electrical potentials generated by largely synchronous activity of millions of neurones are recorded simultaneously from scalp electrodes in various complex montages usually via 16 channels. The precise sources of the rhythms first described clearly by Berger in 1929 remain somewhat elusive. The main role of EEG is in the diagnosis of epilepsy and the investigation of diffuse and focal brain diseases. EEG as a tool to localize brain pathology has largely been overtaken by imaging.

Videotelemetry, the technique that combines prolonged EEG recording for hours or days with simultaneous video recording of the patient is extremely valuable in assessment of attacks that are uncertain clinically and for the localisation of epileptic discharges during the work-up for epilepsy surgery (Chapter 6).

Specially placed EEG electrodes are also sometimes used (e.g. nasopharyngeal, sphenoidal and intracranial grid and strip

electrodes and intracerebral depth electrodes) to localize a seizure focus, prior to potential surgery. EEG sleep studies and EEG monitoring in coma are discussed in Chapter 19. The principal features of the EEG are summarised here; more detailed discussion of the value of EEG in epilepsy is in Chapter 6.

Alpha, theta, delta and beta activity in normal subjects

Alpha activity seen prominently in normal subjects over the occipital lobes is an 8–14 Hz (usually 11 Hz) roughly sinusoidal waveform with amplitude some 150 μV. Typically, alpha rhythm attenuates on eye opening. Amplitude of alpha rhythm is usually slightly higher over the non-dominant hemisphere.

Theta activity of 4–7 Hz is also seen, bilaterally and usually symmetrically. In normal subjects theta activity is more prominent below the age of 30 and during drowsiness. In many brain diseases excessive theta activity appears non-specifically.

Delta activity is a slower frequency, less than 4 Hz. Delta activity lower than 1 Hz is recorded from frontal electrodes during the first non-REM sleep period. Historically, the appearance of localized delta activity when awake was of some value in the diagnosis of hemisphere tumours.

Beta activity describes a rhythm faster than 14 Hz seen normally from frontal electrode recordings. Excess beta activity is seen as an effect of drugs such as barbiturates and benzodiazepines.

EEG artefacts

Various non-pathological waveforms are usually straightforward to recognize. The most common are due to eye opening – high amplitude frontal waves caused by scalp muscle contraction and eye movement. These need to be distinguished from (for example) frontal intermittent rhythmic delta activity (FIRDA), an EEG abnormality seen in raised intracranial pressure and deep midline lesions.

Epilepsy

Spikes, or spike-and-wave abnormalities (Figure 3.1), are hallmarks of epilepsy but it should be emphasized that over 50% of patients with epilepsy have a normal routine EEG between seizures. Epileptic activity is described as generalized when it is bilateral and focal (localized) when recorded over one or more electrodes. Localized spikes point to the location of an epileptic focus, for instance to temporal lobe structures. Hyperventilation, photic stimulation and sleep may enhance EEG epileptic activity but these studies are performed less commonly now than in the past: to provoke a seizure is not without risk to the patient.

'Sharp waves' describe waveforms that are not sinusoidal and may occur in patients who have seizures but in whom epileptic spikes are not seen. An isolated sharp wave, or sparse, poorly localised sharp waves are sometimes seen in the normal population.

The value of EEG in the management of seizures, in the choice of anticonvulsant drugs and in status epilepticus is discussed in Chapters 6 and 19.

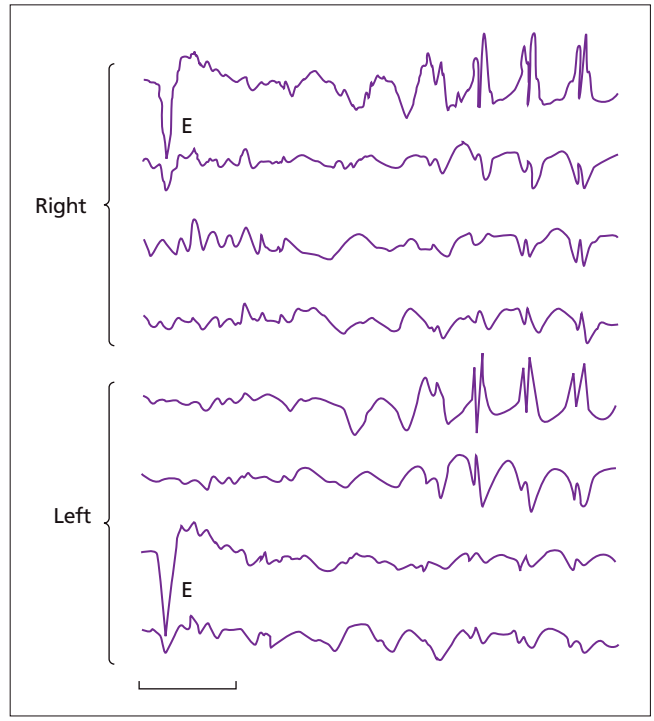


Figure 3.1 Normal electroencephalogram (EEG) activity followed by frontal spike and wave activity. E, eye movement artefact.

Diffuse and focal brain disorders

Recognizable EEG abnormalities appear in several diffuse and focal brain disorders, e.g.:

- Periodic lateralized epileptic discharges (PLEDS): seen in herpes simplex encephalitis, cerebral abscess or occasionally cerebral infarction;
- Repetitive generalized sharp waves at 0.5–1 second intervals: some prion diseases;
- High voltage stereotyped slow wave complexes, every 3–10 seconds: subacute sclerosing pan-encephalitis (SSPE);
- Triphasic slow wave complexes: seen in metabolic disorders, typically in hepatic coma.

Brainstem death

The EEG is isoelectric (flat) in brainstem death and may also be so in deep coma, e.g. with barbiturates and hypothermia. An isoelectric EEG is not necessary to confirm brain death (Chapter 19).

Clinical interpretation of EEG reports

Difficulties surround EEG reports, in part because interpretations are not standardized and in part because EEG traces can be very hard to interpret. Many clinicians will be unfamiliar with the detail of how to report an EEG and conclusions can only be drawn within a clinical context. Some useful (usually rhetorical) questions follow:

• Is there generalized epileptic activity?
• Is there localized epileptic activity?
• Is there generalized abnormal slow wave activity? If so, how specific is it?
• Is there localized slow wave activity?
• Could slow wave activity (theta, delta) reported be seen in the normal population?
• Is beta activity reported abnormal?
• Are 'sharp waves' reported truly pathological?
• In coma, is there EEG responsiveness to stimulation?
• And, finally, what can be concluded in a clinical context from this EEG report?

In an effort to mechanize EEG reporting, computerised and fractal analysis and pictorial EEG brain mapping have been employed, but none has proved generally useful in a clinical context. While EEG records are usually now paperless, written reports by the clinical neurophysiologist and technician remain the usual way in which results are presented.

Magneto-encephalography and transcranial magnetic brain stimulation

These are largely research tools used in the study of seizures and degenerative brain diseases. Transcranial magnetic brain stimulation now has a limited clinical role in central motor conduction velocity measurement. A copper coil (the magic halo) is positioned over the scalp. A current passing through the coil induces a magnetic stimulus sufficient to discharge cortical motor neurones. Muscle contraction is recorded from surface electrodes on an appropriate limb.

Clinical neurophysiological studies of nerve and muscle

Techniques of measurement and data interpretation from studies of peripheral nerves and muscle continue to advance. This is a brief overview of a complex subject. Further detail is in Chapter 9.

Electromyography

A concentric needle electrode (CNE) is inserted into voluntary muscle. The amplified recording from muscle (electromyography [EMG]) is viewed on an oscilloscope and heard through a speaker. From the CNE, three main features are seen and recorded:

1 Normal motor unit recruitment;
2 Denervation and reinnervation changes; and
3 Myopathic, myotonic, myasthenic and other changes (e.g. myokymia, cramps, hemifacial spasm, continuous motor unit activity).

Much depends upon the precise observations of the clinical neurophysiologist. Printouts of EMG traces are somewhat unhelpful compared with practical experience in an EMG laboratory, an essential element of training; with modern equipment it is usually possible to record video clips which allow review of EMG findings.

Normal motor unit recruitment

Normal muscle at rest is silent electrically although noise from motor end-plates may be heard if the CNE is placed nearby. End-plate noise is a steady 'shhhuush', not unlike 'seashell noise', and is composed of high-frequency 10–30 μV brief (<1 ms) potentials. When a single anterior horn neurone fires, all muscle fibres connected to it (i.e. the motor unit) contract. The contraction of each muscle fibre is not synchronous because of slight differences in conduction velocities down pre-terminal branch axons, giving the motor unit action potential a compound broad-based waveform lasting (depending on muscle type and age) normally up to 12 ms.

The interference pattern is the term used in EMG reports for the appearance (and sound) during muscular contraction of voluntarily activated individual motor units running together. During a gentle voluntary contraction, a single motor unit can be distinguished both audibly and on the oscilloscope. Initially, this single motor unit fires quite slowly at a rate of approximately 5 impulses/s, but at an increasing rate as voluntary contraction increases. It is then joined by a second motor unit, recognizable by its own waveform, then a third and so on. As voluntary contraction increases, more units are recruited and overlap so that individual units are no longer identifiable. This 'interference' between the units with increasing force of contraction produces the characteristic picture and sound known as a full interference pattern.

Chronic partial denervation

If one anterior horn cell (B) fails, as happens for example in motor neurone disease, adjacent anterior horn cells A and C produce sprouting axons that begin to re-innervate muscle fibres originally supplied by B. In chronic partial denervation, the EMG reflects this:

• Decreased number of motor units on voluntary contraction;
• Motor units are of larger amplitude than normal;
• The mean duration of each muscle action potential increases; new axonal sprouts conduct impulses more slowly than normal;
• Motor units may be of abnormal complexity (polyphasia); reversals of polarity are seen.

The EMG hallmarks on an oscilloscope of chronic partial denervation are thus reduced numbers of polyphasic, long duration, high voltage muscle action potentials.

Fibrillation, fasciculation, insertion activity and positive sharp waves

When a muscle is denervated, spontaneous contraction of individual fibres begins to occur, typically after some 7–14 days in limb muscles (depending on the site of lesion). These contractions produce tiny spontaneous fibrillation potentials of amplitude <10–200 μV (Figure 3.2). These have a triphasic or biphasic waveform with duration <5 ms and an initial positive (by convention displayed in the downgoing direction) deflection. In a limb, these movements of fibrillating subcutaneous fibres are invisible to the naked eye. However, in the tongue, involuntary movement of denervated fibres beneath the thin mucosa may be clearly visible (tongue fibrillation). Positive sharp waves are bi-phasic potentials with a longer duration (<10 ms) compared

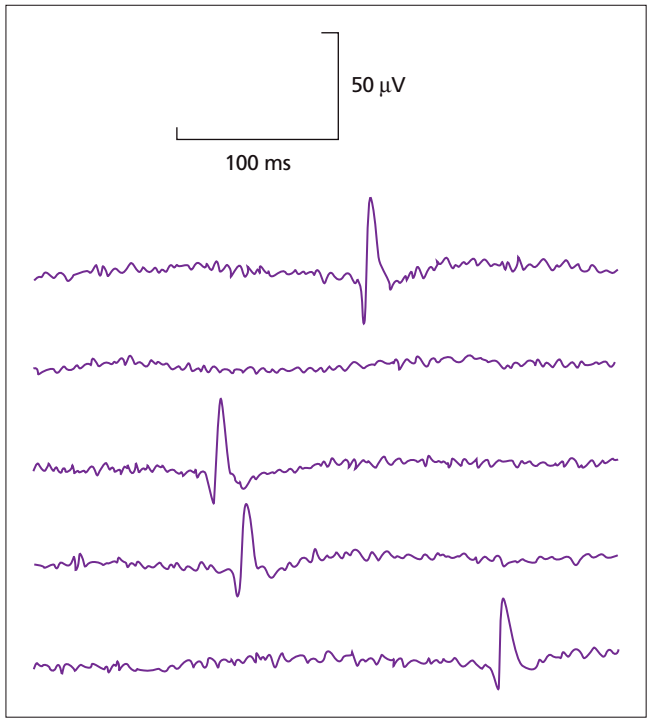

Figure 3.2 Fibrillation potentials from denervated voluntary muscle. (From Hopkins 1993, with permission.)

to fibrillations and usually with amplitudes of 10–200 μV (but occasionally, particularly when there are also chronic neurogenic changes, up to 2 mV).

Fasciculation describes the visible twitching of a muscle seen in various situations. In normal people, benign fasciculation is not uncommon in the calf muscles and may occur in other muscle groups. It is sometimes cause for concern, and particularly among those well-informed medically. In denervated muscle, fasciculation potentials having waveforms of similar dimensions to motor unit potentials are produced by spontaneous discharges of groups of muscle fibres that represent the motor unit. These cause visible persistent twitching (fasciculation), often widespread in motor neurone disease. Typically, the visible involuntary movement flits from place to place, moving on as soon as a twitch catches the examiner's eye.

Insertion activity describes the brief, <2 s volley of muscle activity provoked by the CNE impaling a muscle fibre. This volley becomes prolonged in denervated muscle, which develops exquisite sensitivity to mechanical distortion – showers of fibrillation potentials and positive sharp waves continue for several seconds after CNE insertion. Increased insertion activity describes these features of the prolonged discharges recorded from denervated muscle.

Myopathic EMG changes

Myopathic muscle has, on average, fewer than normal fibre numbers in each motor unit. As each motor unit shrinks, muscle action potentials become smaller in amplitude and of shorter duration. Surviving fibres may become sufficiently separated so that the spikes they generate do not summate to form the smooth contour of the normal motor unit. Damaged motor units are inefficient, generating less tension than their normal counterparts. Thus, for a given force, additional units must be summoned into activity. The myopathic EMG is characterized by:

- Individual units of low amplitude, of short duration and of polyphasic form;
- Rapid motor unit recruitment to a full interference pattern at lower than normal voluntary effort; and
- A recognizable crackly pattern on the loudspeaker.

Myotonic EMG changes

Myotonic muscle (e.g. dystrophia myotonica; Chapter 9) responds to mechanical or electrical stimulation with high frequency (as high as 150 Hz) action potentials lasting 2–5 seconds. The discharge frequency tends to diminish as the seconds pass producing a whine likened to a dive-bomber of propeller-driven vintage pulling out of its steep descent. A similar if softer sound can sometimes be heard through a stethoscope resting over a contracting myotonic muscle. Such dramatic EMG findings are of less critical diagnostic value than one might expect: myotonia is usually picked up clinically when power is tested. It is embarrassing for a neurologist to have myotonia recognized in the laboratory if they have missed it in the clinic – but it does happen.

Complex repetitive discharges (aka pseudomyotonic discharges) describes abnormal discharges that commence and end abruptly. These are the complex polyphasic high frequency waveforms seen in both chronic neuropathic and myopathic disorders.

Hemifacial spasm, cramps, myokymia, neuromyotonic discharges and stiff person syndrome

Hemifacial spasm (Chapter 12) is believed to be due to ephaptic transmission, i.e. transmission between adjacent facial nerve fibres. EMG shows isolated bursts of high frequency motor unit discharges of normal waveform. There is no denervation.

Muscle cramps in normal people are also seen as repetitive high frequency motor unit potential discharges typically at frequencies of 35 to 70 impulses/s. In myophosphorylase deficiency (McArdle's syndrome, Chapter 9), cramping sensations occur without these discharges.

Myokymia (Chapter 12) describes two facial phenomena:

- Quivering facial movements around the eye, common and invariably innocent, often said to be brought about by fatigue;
- Worm-like wriggling movement, persistent and usually around the chin. Such involuntary movement may be sinister and occurs in brainstem gliomas and MS.

In neurophysiological terms myokymia can be found in all muscles including facial muscles and is part of the spectrum of abnormal spontaneous activity that is generated in the motor

neurone. Myokymic discharges are rhythmic grouped repetitive discharges of the same motor unit at burst frequencies of typically 5 to 60 impulses/s separated by a brief pause and repetition.

Neuromyotonic discharges are rare high frequency (>150 imp./s) discharges of a single motor unit.

In stiff person syndrome (Chapter 5), continuous normal motor unit activity or low-frequency activity is found simultaneously in opposing muscle groups, as one might expect from the clinical features. The stiffness and pattern of firing is reduced by agents acting either peripherally or centrally (curare, IV diazepam, general anaesthesia).

Peripheral nerve conduction studies

Five electrophysiological measurements are of principal value in the study of neuropathies and peripheral nerve entrapment:

1 Motor conduction velocity (MCV);
2 Sensory conduction velocity;
3 Distal motor latency (DML);
4 Sensory (nerve) action potentials (SAPs or SNAPs); and
5 Compound muscle action potentials (MAPs or CMAPs).

Accurate electrode placement and attention to detail is essential. Additional information is gained from repetitive muscle stimulation, e.g. in myasthenia. Central conduction is assessed by techniques such as somatosensory evoked potentials (SEPs) and magnetic stimulation of the motor cortex (MEPs).

Unlike EMG in which the CNE attempts to record normal or pathological physiological responses from muscle fibres, peripheral nerve conduction studies (NCS) are carried out using supramaximal percutaneous electrical stimulation. The techniques measure conduction in the fastest myelinated nerve fibres. While NCS are extremely useful, conduction measurement should be viewed as a blunt instrument compared with the finesse of EMG methodology and interpretation. Motor conduction measurement is illustrated in Figure 3.3. Tables 3.9–3.11 illustrate some typical normal values from nerves commonly tested, – such normative data are often omitted from conduction study reports, because normal values vary with age and the precise technique used.

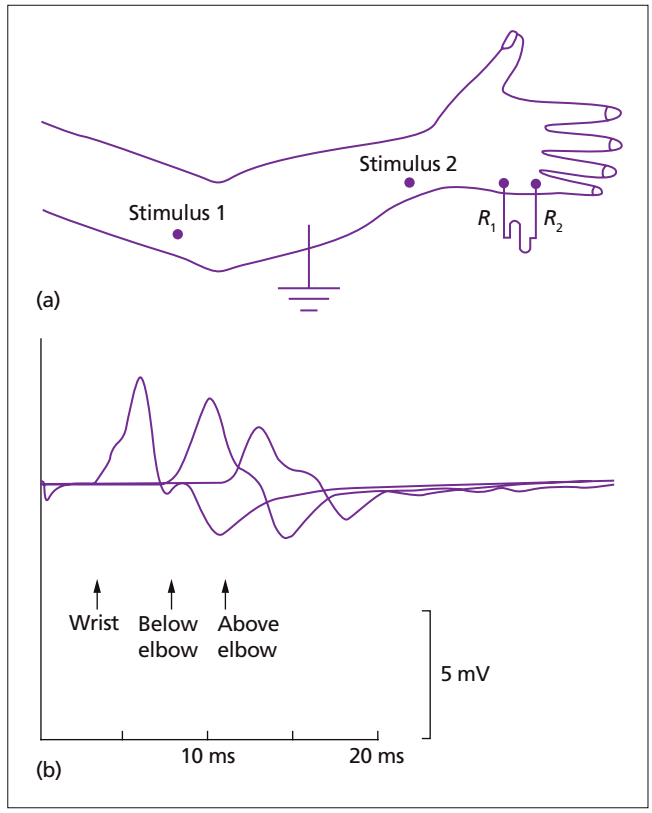

Figure 3.3 Ulnar nerve motor conduction studies: compression of nerve at the elbow. (From Hopkins 1993, with permission.)
R_1 and R_2: recording electrodes – abductor digiti minimi (ADM).
Stimulus 1 and 2: supramaximal stimuli above elbow and above wrist.
Traces: muscle action potentials MAPs from ADM from Stimulus 1, from Stimulus 2, and below elbow (stimulus not shown).
MAP amplitude from stimulation at wrist = 4.0 mV
MAP amplitude from below elbow = 3.0 mV
MAP amplitude from above elbow = 2.1 mV
MCV (calculated: distance/time) from below elbow → wrist = 52 m/s
MCV across elbow segment = 21 m/s
Conclusion: motor conduction block across elbow segment.

Polyneuropathy

In axonal neuropathies, MCV can be well preserved and there is primarily a reduction in CMAP amplitude. When the fastest conducting nerve fibres are affected there can also be a reduction in conduction velocity. SAPs are also usually lower than normal in amplitude. In demyelinating neuropathies, nerve MCV is markedly slowed, Slowing of motor nerve conduction below 38 m/s in the upper limbs and 30 m/s in the lower limbs cannot be explained by axonal dropout of fastest conducting fibres alone and is an unequivocal neurophysiological indicator for demyelination. SAPs are lost or diminished. These changes are discussed in more detail in Chapter 9.

Entrapment neuropathies

Increased distal motor latency in distal neuropathies such as in carpal tunnel syndrome, slowing of nerve conduction across the site of entrapment, such as in ulnar neuropathy at the elbow, and diminution of the relevant sensory action potential are hallmarks of nerve entrapment. Overall, MCV is preserved. Denervation changes occur in affected muscles when entrapment is severe.

F waves

These are small-amplitude muscle responses to a peripheral stimulus produced by antidromic discharges of anterior horn cells. Prolonged F wave latency or loss of F waves are seen in root lesions and in acute inflammatory polyneuropathies.

H reflexes

The H reflex (named after the neurophysiologist Paul Hoffmann, Freiburg, 1884–1962) is generated by electrical stimulation of proprioceptive afferents. Usually the tibial nerve is stimulated at

Table 3.9 Motor nerve conduction studies: normal values.

Motor nerve	Recording electrode	Amplitude (mV)*	Conduction velocity (m/s)	Distal latency (ms)*
Median	Abductor pollicis brevis	≥4.0	≥49	≤4.4
Ulnar	Abductor digiti minimi	≥6.0	≥49	≤3.3
Radial	Extensor indicis	≥2.0	≥49	≤2.9
Peroneal	Extensor digitorum brevis	≥2.0	≥41	≤6.5
Peroneal	Tibialis anterior	≥5.0	≥44	≤6.7
Tibial	Abductor hallucis brevis	≥4.0	≥41	≤5.8

* Distal latencies depend on distal distances used. Amplitudes are given as baseline to negative peak.

Table 3.10 Sensory and mixed nerve conduction studies: normal values.

Nerve	Electrodes	Amplitude (μV)	Conduction velocity (m/s)
Median*	Digit II → wrist	≥10	≥50
Ulnar*	Digit V → wrist	≥4	≥50
Radial	Snuffbox → wrist	≥15	≥50
Sural	Dorsum → ankle	≥7	≥40
Superficial peroneal	Foot → ankle	≥4	≥40
Medial plantar*	Medial foot → ankle	≥2	≥40

* orthodromic technique is traditionally used in the UK. Amplitudes for all sensory or mixed nerve studies are given as peak-to-peak values.

Table 3.11 F and H waves: normal values.

Nerve	Minimum latency (ms)
Median	F ≤ 31
Ulnar	F ≤ 32
Tibial and peroneal	F ≤ 56
Tibial	H ≤ 34

Values depend on limb length and age and there are only approximate guide for young adults of average size.

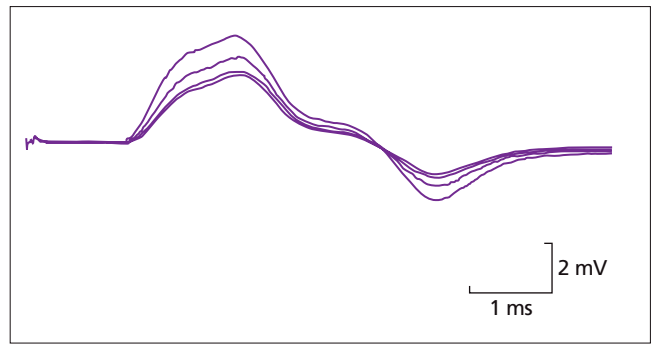

Figure 3.4 Myasthenia gravis. MAP recorded from ADM. 3 Hz stimulation at wrist. First response is 4.1 mV in amplitude. Second response is 3.2 mV. Third and fourth responses (superimposed) are 2.4 mV in amplitude. Decrement = 59% – typical of myasthenia. (From Hopkins 1993, with permission.)

the knee, and the muscle contraction of the triceps surae (gastrocnemius and soleus muscle) is recorded. This is the neurophysiological correlate of a monosynaptic stretch reflex via anterior horn cells. H reflexes are delayed when peripheral conduction is slowed, such as in polyneuropathies or in an S1 root lesion.

Neuromuscular transmission studies

Repetitive stimulation: myasthenia and myasthenic-myopathic syndromes

In myasthenia gravis a surface electrode, for example on proximal muscles such as trapezius or a facial muscle is positioned so that supra-maximal stimulation of the accessory or facial nerve, evokes the largest demonstrable response. The nerve is then stimulated repetitively at 3 Hz for several seconds. In myasthenia, if the neuromuscular junction is affected, the subsequent responses are substantially lower in amplitude than the first. This is illustrated in Figure 3.4. If repetitive nerve stimulation is not producing a decrement in a rested muscle, repetition of the investigation after an exercise for 30 or 60 seconds may do so.

In Lambert–Eaton myasthenic syndrome (LEMS), the converse is seen – facilitation (increase) of the motor response with high frequency stimulation. The amplitude of an initial response to low-frequency stimulation is lower than normal. However, repetitive stimulation at 20 or 50 10 Hz or brief voluntary contraction for 10 s produces an increment in amplitude three to four times that of the initial response. This magnitude of the response is not seen in myasthenia.

Jitter phenomenon in myasthenia gravis

In myasthenia gravis the phenomenon known as jitter can be recorded by single fibre studies. The specialized single fibre study electrode has a very small pick-up surface. Within a weakly contracting muscle, the voltage of one recorded muscle fibre potential is used to trigger the sweep. Action potentials from another fibre in the same motor unit are recorded with some delay. In normal muscle, the time difference between discharges from the two fibres remains close to constant and depending on age and muscle is often less than 50 microseconds. In myasthenia, abnormal neuromuscular transmission causes variation in depolarisation time and hence in the interdischarge interval; the second potential is seen to 'jitter' along the screen (Figure 3.5). Blocking, where one of the pair of muscle fibres intermittently fails to depolarise at all, is an expression of a more severe abnormality of neuromuscular transmission and the basis of the myasthenic decrement on repetitive stimulation, and of clinical weakness and fatiguability.

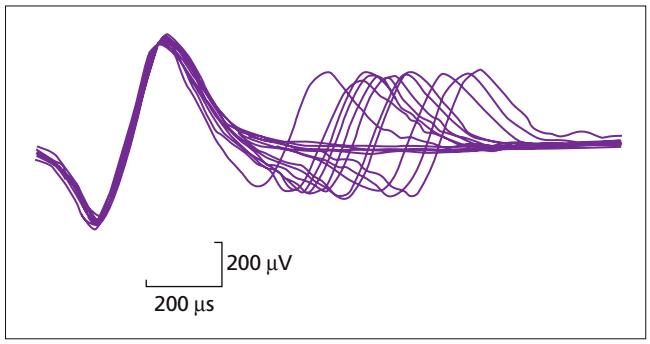

Figure 3.5 Jitter recorded in myasthenia gravis. (From Hopkins 1993, with permission.)

Cerebral-evoked potentials

Evoked potentials record the time for a visual, auditory or other sensory stimulus to reach the cortex. Visual evoked potentials measure amplitude and latency of a repetitive pattern visual stimulus to the cortex. Their value in day-to-day practice is chiefly to confirm previous retrobulbar neuritis (Chapter 10), which leaves a permanently prolonged latency despite clinical recovery. Brainstem auditory evoked potentials and somatosensory evoked responses are discussed in Chapters 10 and 14.

Specialized blood and urine tests

Much information can be gained from the routine blood tests of general medicine and these will not be dealt with here. Table 3.12 outlines some tests that may be unfamiliar to a newcomer to neurology and provides a reference base. Frequently, it is necessary to consult a clinical pathologist, microbiologist, neurogenetics laboratory or other specialist unit about specialized tests, their yield, relevance and cost (see appropriate chapters).

Cerebrospinal fluid examination

Examination of CSF – clear, colourless, almost acellular fluid around the brain, cord, nerve roots and within the cerebral ventricles – provides important collateral information about the structures that it bathes, the surrounding meninges, integrity of

Table 3.12 Some specialized tests in neurological diseases.

Clinical problem	Laboratory tests	Comments
Wilson's disease and rare cases of cord disease	Serum copper and caeruloplasmin	Extrapyramidal disorders below 40, liver disease; unexplained cord disease with normal B_{12}
Huntington's disease	CAG repeat assay	Chorea and extrapyramidal disease below 40 (see Chapter 5)
Hereditary neuropathies and ataxias	Various genetic tests, depending on features	See Chapters 9 and 16
Acquired neuropathies	Anti-ganglioside antibodies	See Chapter 9
Paraneoplastic syndromes	Anti-neuronal antibodies	See Chapters 7, 16, 20
Mitochondrial disease	Muscle biopsy, neurogenetic tests	See Chapter 9
Neurology with coeliac disease	Anti-endomysial and anti-gliadin antibodies	See Chapter 16
Leucodystrophy	Enzyme studies and genetic tests	See Chapter 18
Aminoacid metabolic disorder, e.g. homocystinaemia	Urinary and blood aminoacids	Homocystinaemia (cystathionine synthase deficiency) see Chapter 18
Adrenoleucodystrophy	Urinary very long chain fatty acids	See Chapter 18
Stiff person syndrome	Anti-GAD (glutamic acid decarboxylase) antibodies	See Chapter 5
Myasthenic syndromes	Anti-acetyl choline receptor, anti-MuSK antibodies, etc	See Chapter 9
Myopathies, dystrophies	Creatine kinase, striated muscle antibodies, genetic tests	See Chapter 9
Devic's syndrome	Aquaporin 4 antibodies	See Chapter 10
Porphyrias	Urinary porphyrins	See Chapter 18
Autoimmune limbic encephalitis	Voltage-gated potassium channel antibodies, thyroid microsomal antibodies	See Chapter 7

the blood–brain barrier and intracranial pressure. Traditionally, before the advent of non-invasive imaging, lumbar puncture (LP) and CSF examination were performed very frequently. Eponyms of that era such as the 'paretic Lange' used in the diagnosis of neurosyphilis and the 'colloidal gold reaction' are consigned to history. Today, indications for CSF examination are more specific and its role undoubted. However, the reality in observed clinical practice overall is that LP is still overused, its risks underestimated and the exceptional value of CSF examination in special circumstances neither widely understood nor are specific tests carried out with appropriate attention to detail. These notes outline the value, risks and procedure of LP and CSF examination. Cervical puncture is now so rarely performed that it will not be considered here. Ventricular CSF is sometimes examined in a neurosurgical setting, e.g. via a ventricular catheter.

Indications for LP and CSF examination

Principal indications for LP are:

- Diagnosis in an emergency in some cases of suspected meningitis and encephalitis;
- Studies of blood products within CSF following suspected subarachnoid haemorrhage (on occasion);
- Measurement of CSF pressure, e.g. idiopathic intracranial hypertension;
- Removal of CSF therapeutically, e.g. idiopathic intracranial hypertension;
- As an aid to diagnosis by assay of CSF constituents in various neurological conditions, e.g. MS, neurosyphilis, sarcoidosis, Behçet's disease, chronic infection, neoplastic meningeal involvement, polyneuropathy and some cases of dementia; and
- Intrathecal injection of contrast media and drugs.

In suspected CNS infection, meticulous attention should focus on examination for cells, cell types and microbiological tests. Close liaison between clinician and microbiology laboratory is essential. In addition to cell counts on fresh CSF, bacterial stains (Gram, Ziehl–Neelson), stains for fungi (India ink and others) and specific microbiological techniques (e.g. polymerase chain reactions for bacterial antigens, syphilis serology) are invaluable. Repeated CSF examination may be necessary in the diagnosis of chronic infections such as TB.

Clinical and laboratory procedures for CSF spectrophotometry (e.g. rapid transport of specimens) should be clearly established if estimations of CSF methaemoglobin and bilirubin are to be made following suspected subarachnoid haemorrhage. For any specific CSF test, such as oligoclonal band (OCB) and immunoglobulin G (IgG) estimations, requests should be clearly stated with the initial CSF specimens. Parallel blood samples (e.g. sugar, OCB) should be taken, when these are appropriate.

Informed consent, risks of LP, CSF removal and intrathecal drugs

The LP procedure should be explained to the patient and its potentially painful nature. Written consent should be sought and if at all possible obtained.

The principal risks of LP relate first to the removal of CSF. This changes the relatively steady state pressure relationships within the brain and spinal cord. Coning (see below) can occur. CSF often continues to leak through the puncture site in the lumbar dura. This commonly leads to low pressure (low volume) headaches (Chapter 11) and exceptionally to intracranial subdural haematoma.

Secondly, there are local complications at the site of LP:

- Local infection and meningitis;
- Trauma – local pain, nerve root damage;
- Bleeding;
- Spinal epidural haematoma; and
- Arachnoiditis (see Chapter 15).

Inappropriate intrathecal injection of drugs, e.g. antibiotics and cytotoxics, is also well-recorded, sometimes with fatal consequences. Such tragedies are typically a product of inexperience. LP should not be performed without clear risk appraisal in any event, especially in the presence of raised intracranial pressure.

Contraindications to lumbar puncture

- Suspicion of a mass lesion within the brain or spinal cord. Caudal herniation of the unci and cerebellar tonsils (coning) may occur if an intracranial mass is present and the pressure below is reduced by removal of CSF. Spinal cord compression may worsen (or even develop) if an unsuspected cord tumour is present. Such well-recorded but unusual complications can develop within minutes of lumbar CSF being withdrawn.
- Any cause of suspected raised intracranial pressure, without careful consideration;
- Local infection near the LP site;
- Congenital abnormalities in the lumbosacral region (e.g. meningo-myelocoele);
- Platelet count below 40×10^9/L and other clotting abnormalities, including anticoagulant drugs.

Unconscious patients and those with papilloedema must have CT or brain MRI before LP. These contraindications are relative: there are circumstances when LP is carried out despite them, e.g. clinically secure diagnosis of benign intracranial hypertension. The issue of unsuspected low cerebellar tonsils, that may descend further through the foramen magnum following lumbar CSF removal, may in future dictate that before LP, a brain MRI will be required, except in an emergency.

LP technique

The patient is placed on the edge of a bed or trolley in the left lateral position with knees and chin as close together as possible. The spine should be as horizontal as possible. An experienced assistant is invaluable. Several pillows are useful to help with the patient's alignment and comfort.

The third and fourth lumbar spines are felt and marked. The fourth lumbar spine usually lies on a line joining the iliac crests.

Using sterile precautions, 2% lidocaine (lignocaine) is injected into the dermis, raising a bleb in the skin of either third or fourth

lumbar interspace. Deeper injection of local anaesthetic should follow. The LP needle (22 gauge atraumatic disposable) is pushed through the skin in the midline. The needle is pressed steadily forwards, slowly and slightly towards the head, the operator feeling with the needle tip for the spinal interspace, pausing and/or re-aiming the needle if local resistance is encountered or substantial pain provoked. In difficult cases, radiological help may be necessary and LP carried out under screening control. When the LP needle tip is felt to penetrate the tense dura mater, the stylet is withdrawn and a few drops of CSF allowed to flow.

The CSF pressure is then measured by connecting a manometer to the shaft of the needle. Normal pressure is 60–150 mm of CSF. The CSF fluid level in the manometer oscillates slowly with respiration and transiently with the pulse and rises briefly on coughing or gentle pressure on the abdomen, assuming the bore of the needle is freely patent. CSF specimens are collected in three sterile containers. An additional fluoride sample for CSF sugar level, with a simultaneous blood sample, should be taken when relevant (e.g. in meningitis). CSF 5–15 ml is usually removed for diagnostic purposes. The tests carried out routinely are shown in Table 3.13.

CSF pressure and naked-eye appearance should be recorded in the notes: i.e. clear, cloudy, colourless, yellow (xanthochromic), red – and if red, whether or not the colour begins to clear after the first or subsequent sample. Patients are asked to lie flat after LP to avoid subsequent headaches, and to drink plenty, manoeuvres of uncertain value. Analgesics may be needed for post-LP headaches and occasionally treatments for prolonged low pressure headaches, e.g. epidural autologous blood patches (see Chapter 11). Post LP headaches often last several days but may continue for weeks or occasionally for longer periods.

Biopsy of brain, muscle and peripheral nerves

One of the difficulties in neurology compared with other clinical specialities is that CNS tissue is less accessible to biopsy than, for example, the liver, lung or intestinal mucosa. All biopsies in neurology require specialized techniques, involve risk and careful attention to detail – for collection of specimens, transport and processing. The detailed assessment of biopsies of muscle, nerve, brain and meninges are not considered here, but some general observations are helpful.

Biopsy of brain or of brain lesions, with or without meningeal biopsy, is carried regularly for diagnosis of brain tumours, for other mass lesions and other specific indications. Stereotactic procedures are employed increasingly (Chapter 20). If there is any question of an infective process, specimens for microbiological study should be collected in appropriate media with close liaison between operating theatre and laboratory. Brain biopsy is also of some value in diagnosing dementia and for rarities such as Rasmussen's disease, Whipple's disease or vasculitis. Biopsy should where possible be directed at structurally abnormal tissue, seen on imaging. 'Blind' biopsy of 'MRI-normal' brain has a low diagnostic yield. Meningeal biopsy is sometimes valuable in the diagnosis of chronic infection or inflammatory diseases, e.g. sarcoidosis. The principal risks are those of infection, haemorrhage or damage to the surrounding brain. However, in competent hands, morbidity is well below 2%.

Peripheral nerve biopsy (sural or radial) is commonly performed in the diagnosis of chronic neuropathies. The risks are few: infection is rare but painful paraesthesiae sometimes follow in the distribution of the nerve fascicles removed. A numb patch on the lateral aspect of the dorsum of the foot is to be expected following sural nerve biopsy and following radial nerve biopsy at the wrist, a patch (usually trivial) in the snuff box. Detailed microscopical studies are carried out, including electron microscopy. While many nerve biopsies do not alter management, any misgivings are brought roundly into focus by finding unexpected steroid-responsive chronic inflammatory demyelinating polyradiculoneuropathy (Chapter 9) or the occasional diagnosis of leprosy.

Muscle biopsy (deltoid or quadriceps) is a standard procedure for cases of inflammatory muscle disease, dystrophies, mitochondrial disease and metabolic myopathy with appropriate specialized stains and biochemical assays. All muscle biopsies should be processed by specialized laboratories with ready access to electron microscopy. Opinions have varied about the yield of open muscle biopsy or needle biopsy; open biopsy is now usual in most neurology units.

Neuropsychological testing

The Mini Mental State Examination and Cognitive Screening Tests are mentioned above. More detailed testing and recording

Table 3.13 Normal cerebrospinal fluid (CSF) appearance and constituents.

Observation/measurement		Comment
Appearance	Crystal clear, colourless	Normal CSF is crystal (gin) clear when held to the light
Pressure	60–150 mm of CSF with patient recumbent	Patient must be relaxed and needle patent to see lumbar CSF rise and fall in manometer
Cell count	<5/mm^3. *No* polys: mononuclears only	*One* polymorph/mm^3 *just* acceptable
Protein	0.2–0.4 g/L	Slightly raised protein <0.7 g/L rarely pathological
Glucose	$^2/_3$ to $^1/_2$ of blood glucose	CSF glucose <$^1/_2$ blood glucose suspicious
Culture	Sterile	Do not accept contaminants
IgG	<15% of total CSF protein	Usually only on request
Oligoclonal bands	Absent	Parallel blood sample

definitive deficits in cognition are of great value in clinical neurology. However, in no area of investigation is there more variation in reporting, nor in the scope of testing. In part, this is because of the various disciplines within which neuropsychology finds a place of importance – in neurology, in psychiatry and within many aspects of human behaviour. The tests performed are often complex, highly specialized and their precise details outside the knowledge of a general neurologist. Neuropsychological reports tend to vary in emphasis – some dwelling on perceived psychiatric diagnoses, others on treatment, while others – more within the ambit of daily clinical neurology – purely upon cognitive function. It is in the latter field that neurologists find most value. Cognition is, after all, the unique function of the human brain (Chapter 7).

Intellectual function overall

The Wechsler Adult Intelligence Scale-Revised (WAIS-R) is divided into subtests. The Verbal IQ with the National Adult Reading Test (NART) provides a measure of the premorbid optimal level of function. Performance IQ gives a measure of present overall cognitive ability.

Memory

Many tests to investigate different aspects of episodic memory are available:

- The Paired Associate Learning Test studies verbal memory;
- Story Recall addresses sequencing and importance of items within an incident;
- The Topographical Recognition Memory Test and Rey Figure Tests assess awareness and recall of spatial issues; and
- The Recognition Memory Test is available in Verbal and Visual versions.

Tests for verbal and non-verbal memory are useful in the localisation of damage to either the dominant or non-dominant temporal lobe, for instance in the work-up for possible epilepsy surgery.

Language

Spontaneous speech is assessed for fluency, articulation, prosody and nominal impairment. The Graded-Difficulty Naming Test measures nominal ability.

Literacy and calculation

Reading, spelling and calculation are assessed, for both speed and efficiency. The Graded-Difficulty Spelling and Graded-Difficulty Calculation Tests record the levels of attainment achieved.

Perceptual function

Many tests focusing upon perceptual tasks are available. Silhouettes, Object Decision and Incomplete Letters (usually incomplete large capitals E, N and K) address visual perception. The Number Location Tests and the Visual Object and Space Perception (VOSP) battery study spatial perception.

Frontal and executive function

Tests address the ability to solve problems and test judgement; unfortunately many frontal function tests are less reliable than one would wish for distinguishing whether or not a problem has an organic substrate. The Wisconsin Card Sorting Test is often used, testing the ability to display flexibility and choice in the face of challenges. After seeing a number of stimulus cards, the participant is given additional cards and asked to match each to a stimulus card – and not informed whether one match is correct before progressing to the next.

The Hayling Sentence Completion Test consists of two sets of 15 sentences apiece, each with the last word missing. A sentence is read aloud; the participant has to complete it.

The Behavioural Assessment of Dysexecutive Syndrome (BADS) is a battery of six tests and also questionnaires that require planning, initiation, monitoring and behaviour adjustment to various demands:

1 Rule Shift Cards (testing perseveration);
2 Action Programme (practical problems, e.g. extracting a cork from a narrow tube);
3 Key Search (finding a lost key in a field);
4 Temporal Judgement (judgement/abstract thinking, e.g. a dog's life expectancy);
5 Zoo Map (formulation/implementation of plans); and
6 Modified Six Elements (ability to time-manage).

Attention

Various tests of attention are used. Counting the number of letters A in a patchwork of letters is one of the simplest. Other named Tests of Everyday Attention (TEA) include Elevator Counting, Elevator Counting with Distraction, Telephone Search with and without Distraction.

Formulation and conclusions

The formulation carried out by the neuropsychologist draws together the results. It is vital that problems with concentration and attention are given appropriate weighting, especially when other clinical issues such as pain, clinical depression and anxiety related to illness are present. The neurologist needs to know above all whether non-organic factors might have influenced the test results. Thus, close liaison between neurologist and individual psychologist is important.

Terminology, or grammar of clinical neurology

Names for patterns of symptoms and signs can be called the vocabulary or grammar of clinical neurology – terms and phrases we use to describe and encapsulate particular conditions. The most common complaints worldwide, such as headaches, vertigo, dizziness, infections and recognizable neuromuscular disease and cognitive impairment, are dealt with in specific chapters. This is a brief overview of some important patterns seen in clinical practice.

Focal cortical disorders

The cortical mantle is exceeding highly developed and differentiated in humans. Dementia, i.e. global cognitive impairment, with its various causes and particular modular features that frequently involve episodic memory and other specific aspects of cognition, is by far the most common cortical problem (Chapter 7). This section outlines briefly features of the principal focal cortical lesions:

- Language disorders;
- Non-dominant hemisphere lesions;
- Frontal, temporal, parietal and occipital lesions.

While precise cortical mapping by clinical assessment has largely been superseded by imaging, an understanding of the variation between individual brains and a general working knowledge of the cortex is essential. This section summarizes some basic clinical aspects within this field, but the reader should be aware of its complexity, the wide variation in approach between the disciplines of neurology, neuropsychiatry and psychology. Many brain functions are not strictly localised: beware theories that appear simplistic, highly specific or didactic.

Language and its disorders

Within a cultural group, language is that combination of sounds or writing with symbolic meaning necessary for interactive communication. A phoneme is the shortest unit of language. A phoneme may have a different meaning in different languages. What sounds like 'we' (the pronoun) in English will sound like 'oui' [yes] to a person speaking French. Some phonemes have become almost universal, e.g. OK.

- Aphasia (*syn.* dysphasia) describes disorders of spoken language.
- Agraphia (*syn.* dysgraphia) describes disorders of written language.
- Acquired alexia (*syn.* dyslexia) is a disturbance of acquired reading ability.
- Dysarthria is disordered oral speech production (articulation).
- Dysphonia is abnormality of the noises made by passage of expired air over poorly vibrating or paralysed vocal cords.

Aphasia, strictly speaking, means complete loss of language function; dysphasia means a disorder of language function. The prefixes dys- and a-, for aphasia and these related communication problems, are used interchangeably in this section, as they are in practice.

The study of cerebral localization can be said to have commenced with recognition in the 19th century that the left hemisphere was the seat of language function in the majority of humans. In 1861, Paul Broca (1824–1880), professor of surgical pathology in Paris, described non-fluent (expressive) aphasia in a patient with a tumour in the left third frontal convolution. In 1873, Dr Carl Wernicke (1848–1905), who had qualified in Breslau just 3 years earlier, described fluent jargon aphasia (speaking unintelligible words) in a patient with a lesion more posteriorly placed, in the angular gyrus. Classic concepts, postulating the system overall, e.g. those of Lichtheim (Dr Ludwig Lichtheim, Breslau, 1845–1928) remain useful. To summarize these, first there are cortical modules for conceptual meanings, connected by transcortical pathways to a posterior (temporal) centre for processing phonemes. Secondly, via the arcuate fasciculus, language information passes to an anterior (frontal) centre for programming and delivering speech output.

Difficulty naming objects – nominal aphasia – soon became established as a screening test, or lowest common denominator for lesions over a wide area of the posterior frontal, temporal and lower parietal regions of the dominant hemisphere. Word retrieval in nominal aphasia correlates with frequency of a word in everyday life. Thus, slightly unusual objects, e.g. the winder button (stem button) rather than the wristwatch itself are preferable when asking the question: 'What is this called?'

This section summarizes features of four basic varieties of aphasia. Everyone finds the terminology difficult when more unusual and complex forms of aphasia are described. Mixed and incomplete varieties of aphasia are common.

Non-fluent aphasia (Broca's aphasia, motor or anterior aphasia)

This is the most common variety of aphasia following stroke. The hallmark is the slow, incomplete and laboured production of language, with a major breakdown of grammatical output:

- The patient is fully aware of the problem and often distressed.
- Nouns, more than conjunctions and adjectives are retrieved. Grammar and syntax are lost. Tenses of verbs are frequently incorrect.
- Perseveration is common.
- Prosody (normal rhythm) is lost.
- The ability to repeat phrases is lost.
- Comprehension is relatively preserved but complex multiple commands usually reveal some lack of understanding.

The lesion is around the left, third (inferior) frontal convolution, lower (inferior) motor cortex and nearby temporal insula. The closeness of the motor strip to Broca's area explains why contralateral UMN facial weakness and hemiparesis (or hemiplegia) are frequently seen. There may also be facial apraxia – dissociation between the idea and production of a non-verbal facial movement such as whistling. Cortical dysarthria describes the situation when this apraxia extends to speech itself, causing slurring and hesitancy.

Fluent aphasia (posterior, sensory or Wernicke's aphasia)

The essence of this variety of aphasia is the production of fluent speech with language that lacks meaning. Patients often appear to have little insight into an evident problem and are talkative. They may look bewildered and are sometimes agitated. Phonemic and semantic confusions are common and sometimes so prominent that neologisms (new, meaningless words) are formed with excessive outpourings of meaningless fluent jargon. Prosody tends to remain normal. The ability to repeat phrases is lost; comprehension is lost.

These cases are sometimes mistaken for a form of psychosis or psychiatric illness. If a patient with Wernicke's aphasia

recovers (which is unusual), they say they were unaware they were speaking rubbish and that they could not grasp what others were saying to them, as if listening to an incomprehensible language.

Conduction aphasia

Reduced ability to repeat spoken words or phrases but with reasonable comprehension are hallmarks of conduction aphasia, seen with a lesion of the arcuate bundle between posterior and anterior language areas (and other posteriorly situated lesions in the cortical language area). The pattern consists of:

- Fluent speech, with nominal dysphasia and semantic confusions;
- Poor repetiton;
- Relatively preserved comprehension.

Trancortical aphasias, motor and sensory

Preserved ability to repeat spoken words, phrases and sometimes longer passages defines transcortical aphasias. The arcuate fasciculus remains intact. Transcortical motor aphasia (TMA) describes a non-fluent aphasia caused typically by a lesion in the left anterior superior frontal region. Patients with TMA have halting and effortful spontaneous speech, with phrases typically of only one or two words. However, they retain the ability to repeat words, phrases or sentences. Repetition is believed to be preserved because the arcuate fasciculus remains intact. Comprehension remains reasonably normal.

Transcortical sensory aphasia (TSA) is caused typically by lesions behind Wernicke's area in the temporal–occipital–parietal region. TSA patients have poor comprehension but with fluent and reasonably grammatical speech, with preserved repetition. However, they tend to have semantic paraphasia, i.e. they do not use words that are correct, but substitute words of similar content, e.g. pear for apple, pen for writing paper.

Mixed transcortical aphasia (MTA) is characterized by both severely reduced language output and by impairment of comprehension, but with preservation of the ability to repeat words and phrases. Patients with this unusual form of transcortical aphasia have a major disability, with difficulty producing propositional language and understanding what is being said to them. However, they can repeat phrases and even long complex sentences, and finish a familiar poem or song, once they hear the beginning of the composition. Generally, in MTA, both Broca's and Wernicke's areas remain intact, and the arcuate fasciculus between them remains intact. The surrounding regions are believed to be damaged, isolating these areas.

Agraphia and acquired dyslexia

Written symbol comprehension is perceived in the region of the dominant angular gyrus. Lesions in this cortical region cause acquired alexia usually with agraphia and posterior aphasia. Isolated alexia without agraphia is seen with either anterior occipital lobe lesions and/or lesions of the splenium of the corpus callosum.

Temporal lobe lesions

Many small (<2 cm) unilateral temporal lobe lesions are silent in terms of cognitive abnormalities. Epilepsy is common (Chapter 6). Upper quantrantic hemianopia is seen when the forward-looping fibres (Meyer's loop, Chapter 2) are damaged.

A lesion in the dominant anterior temporal lobe extending more than 6 cm from the anterior pole often causes a posterior aphasia. Non-dominant anterior temporal lobe lesions are sometimes associated with inability to recognize faces (proposagnosia). Unilateral mesial temporal lobe lesions can also produce subtle changes in memory, often silent clinically until revealed by specific neuropsychological tests.

Bilateral temporal lobe lesions (e.g. following herpes simplex encephalitis) cause profound loss of memory for recent events. Bilateral temporal lobe injury in primates causes hypersexuality, hyperactivity and aggressive behaviour (Klüver–Bucy syndrome). Sometimes, in humans, there are elements of this (episodic temper dyscontrol) but the usual outcome is aimlessness, diminished libido and impaired potency.

Frontal lobe lesions

As in the temporal lobes, many small frontal lesions remain silent. Some (see above) cause anterior aphasia. Substantial damage (e.g. traumatic frontal brain injury, direct or contra-coup) causes a highly disabling lack of social control. Examples of this are:

- Abandonment of the usual social inhibitions – from somewhat inopportune, often rude 'frontal' comments to profound disturbances such as urination, exposure or masturbation in public.
- Inappropriate jollity (witzelsucht) – jokes and tales often overlong and unwanted.
- Apathy, lack of initiative and poor planning (dysexecutive problems).
- Irritability, anger, distractability, inappropriate placidity in the face of irritation or obsessional behaviour.
- Continuing one action when another is appropriate – motor perseveration.
- Utilization behaviour. The subject sees something, typically a tool – a tendon hammer or a stethoscope during a consultation – and begins to use it.

These frontal lobe features may be accompanied by a grasp reflex, sucking, pout and palmo-mental reflexes. Deep bilateral frontal lesions, e.g. small vessel disease in the elderly, can lead additionally to gait apraxia and failure to initiate walking (gait ignition failure), often with sphincter disturbance.

Frontal behaviour of lesser degrees has become a common plea in claims following minor head injury, trivial loss of consciousness and normal brain imaging. The patient and relatives are asked about features such as impulsivity, temper, socialization, fiscal ability, multi-tasking, planning, prioritization, depression and anxiety – common problems for many in stressful situations. There is a distinct lack of evidence that these complaints are caused by brain injury following a minor blow to the head.

Frontal lobe seizures are described in Chapter 6.

Occipital lobe lesions

Field defects of occipital lobe lesions are mentioned in Chapter 13. Neglect or even denial of virtually complete visual loss (Anton's syndrome) are sometimes seen following bilateral occipital lobe infarction. An explanation for 'blind sight' is provided by the preservation of the anterior visual pathways to the lateral geniculate bodies that are below the level of awareness. Epilepsy, with episodes of flashing lights or, rarely, more formed features, can occur with lesions in occipital lobes.

Parietal lobe lesions

These areas are concerned with the integration into perception of complex visual and somatosensory information – the awareness of body parts in space and their relation to objects. This has led to a complex nomenclature to describe many varieties of perceptual defect. Attempts to associate precise areas of the parietal lobes to particular functions or syndromes are bedevilled by variation between individuals, an indication that the brain is not divided into compartments in the way many classic texts described. The following are seen regularly with lesions of either parietal lobe:

- Attention defects in the contralateral visual field and neglect of the opposite side of the body. Lower quadrantic homonymous field defects occur when the optic radiation is damaged.
- Astereognosis – inability to recognize common objects placed in the contralateral palm despite apparently normal sensation or figures drawn there simply with the examiner's finger.
- Pseudo-athetosis and/or drift of an outstretched contralateral hand.

Sensory epilepsy is sometimes a feature of parietal lobe lesions.

Dominant parietal lesions

Inability to execute a skilled movement despite no discernable weakness may be seen – ideomotor apraxia. For example, the patient does not respond to verbal suggestions such as 'Imitate combing your hair' or 'Pretend to turn a key in a lock'. Typically, they are bewildered, moving the hand in a non-purposive way.

Gerstmann (Professor Josef Gerstmann, 1857–1940) described:

1 Right–left disorientation;
2 Inability to name each finger (little, ring, middle, index) – known as finger agnosia;
3 Inability to calculate; and
4 Dysgraphia in cases with dominant parietal lobe lesions.

Gerstmann's syndrome (1 + 2 + 3 + 4) is rare and may reflect the chance association of these parietal features.

Neglect of contralateral limbs is typically less prominent with dominant than non-dominant parietal lesions.

Non-dominant parietal lesions

Neglect of the opposite limbs and inability to comprehend spatial arrangements leads to patients becoming lost in familiar surroundings, to muddled dressing (dressing apraxia) and to constructional apraxia – inability to construct or draw shapes such as a house or a clock face. The left side of a picture drawn or described (e.g. numbers 1–5 on a clock face) will tend to be omitted by a right-handed patient with a right parietal lesion. Inability to recognize familiar faces (proposagnosia, see also temporal lobes) may occur – especially distressing for close relatives if this extends to themselves. Neglect of the contralateral limbs can extend to denial that the limbs are the patient's own.

Motor system abnormalities of the brain and spinal cord

The patterns of abnormality within the motor system are both distinct and recognizable – and the classes of disorder relatively few. Features of hemiparesis (and hemiplegia) and paraparesis, cerebellar syndromes and disorders of movement are summarized here.

Hemiparesis

Weakness of the limbs of one side resulting from a pyramidal tract lesion is known as hemiparesis, the term paresis indicating that weakness is not total – cf. hemiplegia, total loss of power following a stroke. The earliest physical signs of an early hemiparesis, sometimes before weakness becomes evident are scuffing of the toe of one shoe, drift of one outstretched upper limb and a trace of impaired fine finger and/or toe movement. Thereafter emerge the five principal features of a pyramidal lesion:

1 Increase in tone;
2 Weakness in a typical pattern (upper limb extensors weaker than flexors; lower limb flexors weaker than extensors);
3 Progressive loss of fine movement;
4 Unilaterally exaggerated reflexes; and
5 Extensor plantar response (Babinski) and absent abdominal reflexes.

These features gradually develop as a hemiparesis progresses or emerge following hemiplegia after a stroke. However, in either case there may not be a full house of these five abnormalities – to use the poker hand analogy. Not all these features of a UMN lesion are required to make a firm diagnosis.

As a corollary, to find weakness alone as the only feature of a hemiparesis is highly unusual and raises the question of whether or not the problem has an organic basis.

Cerebellar syndromes

Features of cerebellar disease are well-defined and straightforward to recognize compared to our knowledge of the complexity of cerebellar function (Table 3.14). The need to perform examination correctly to elicit early signs is emphasized.

In established cerebellar disease there are several important practical points. The first relates to clinical urgency. If an expanding mass lesion of the cerebellum is strongly suspected or found on imaging, there needs to be speedy liaison with a neurosurgeon. While all mass lesions of the brain are potentially serious, many cases of cerebral tumour above the tentorium can be dealt with in a somewhat routine expectant manner. With cerebellar tumours the rapidity of decline and development of tonsillar herniation over several hours can catch out the unwary.

Table 3.14 Principal features of cerebellar syndromes.

Lateral cerebellar lobe lesions
Rebound
Action tremor
Past-pointing
Dysdiadochokinesis
Dysarthria
Nystagmus (usually towards side of lesion) occurs if vestibular connexions are involved
Vermis lesions
Ataxia of stance, trunk and gait, sometimes with negative Romberg test (a test primarily of proprioception)

Table 3.15 Principal disorders of movement.

Akinetic-rigid syndromes
Idiopathic Parkinson's disease
Parkinsonism-plus
Drug-induced parkinsonism (e.g. phenothiazines)
Post-encephalitic parkinsonism
MPTP-induced parkinsonism
Childhood akinetic-rigid syndromes
Dyskinesias
Tremors
Chorea
Hemiballismus
Myoclonus
Tics
Dystonias
Paroxysmal dyskinesias
Drug-induced dyskinesias

MPTP: 1-methyl 4-phenyl 1,2,3,6-tetrahydropyridine,

Secondly, when a severe cerebellar syndrome is part of a multisystem degenerative processes, pyramidal features can be masked. Extensor plantars may be the only pyramidal sign. Finally, ascribing the ataxia of stance and gait of midline cerebellar lesions to non-organic causes has happened all too frequently. The many causes of cerebellar syndromes are discussed in Chapter 16.

Disorders of movement

The broad distinction between akinetic-rigid syndromes and dyskinesias is valuable. The principal disorders are summarized in Table 3.15 and discussed in more detail in Chapter 5. No amount of written description can surpass looking at movements, either in the flesh or on video.

Some presentations of movement disorders cause diagnostic difficulties regularly. First, when an akinetic-rigid condition becomes apparent, early idiopathic Parkinson's disease tends to be over-diagnosed and treated. The reality, which becomes evident some years later, is that the diagnosis is another, less common akinetic-rigid syndrome. Parkinson's disease (PD) is almost always obviously asymmetrical and should also be diagnosed with caution if rest tremor is not apparent. Progressive supranuclear palsy or multiple systems atrophy tend to be symmetrical from the onset, although the poverty of movement is similar to that seen in PD. Early Wilson's disease should always be considered in a akinetic-rigid syndrome with unusual tremor developing below the age of 40.

Benign essential tremor (BET) can cause difficulty. Usually in BET, tremor is seen when the limbs adopt a particular posture. However, there are forms of BET that mimic benign tremulous PD in the early stages. To complicate matters, occasionally action tremor is seen in BET, raising the possibility of cerebellar degeneration. The passage of time and keeping an open mind about the diagnosis for some months or longer usually sort out these difficulties.

Early chorea is also easy to miss, being mistaken for restlessness and normal fidgeting. A minor degree of dystonia can also escape recognition. Lower limb myoclonus can look remarkably like the ankle clonus of spasticity.

Finally, the diagnosis of a psychologically determined movement disorder is fraught with difficulty, and frequently turns out in time to be wrong when it is made early in the course of a condition. In movement disorder clinics, a substantial proportion of those originally labelled as functional, somatoform or diagnosed as conversion hysteria (whichever term is chosen) turn out in time to have organic disease.

Paraparesis

Spastic paraparesis – weakness of the lower limbs of cord or rarely, cortical origin – is one of the pivotal diagnoses of clinical neurology. Prior to the era of MRI, clinical examination had a vital role in differentiating between cord compression, a potential neurosurgical emergency, and the medical causes of paraparesis.

As with a hemiparesis, the clinical picture begins with subtle features:

- Scuffing the toes of shoes, often worse on one side;
- Stiffening of gait, but with retention of a narrow base;
- Noticeable beats of ankle clonus, e.g. on a step or kerbstone;
- Changes in lower limb sensation.

When cord compression is the cause, e.g. with a slowly growing thoracic meningioma, pain at the site of compression is associated with increasing weakness, spasticity and a sensory level, rising from below to the site of compression. The patient complains of numbness or altered sensation commencing in the feet that marches upwards gradually over weeks or months. Brown-Séquard features (pyramidal signs on one side, spino-thalamic on the other; see below and Chapter 2) may become apparent.

These features apply equally to tetraparesis (*syn.* quadriparesis).

The five principal features of a pyramidal lesion may not all be present. Pain may not be present in cord compression. The clinician must be wary and seek out subtle signs. Marked asymmetry can sometimes cause difficulty.

Two principal questions arise when spastic paraparesis is diagnosed clinically:

1 Is this caused by spinal cord compression?

2 Is this a result of one of the more common recognizable conditions in which paraparesis is part of the clinical picture?

- Multiple sclerosis
- Motor neurone disease
- Subacute combined degeneration of the cord
- Syringomyelia
- Parasagittal meningioma (rare).

Paraparesis is also caused by many other rarities – vascular anomalies of the cord, adrenoleucodystrophy, copper deficiency and lathyrism to mention four (see Spinal Cord Disorders, Chapter 15).

There can be many difficulties with the diagnosis of paraparesis, both in the process of referral to a neurologist and within the discipline of neurology itself. It is not helpful to write an exhaustive list of sources of error but several features are evident. The first issue is that in the community and in primary care, the emergence of difficulty walking is sometimes not taken seriously – and the early features of a paraparesis can pass unrecognized unless a physical examination is carried out. The onset of a disturbance of gait always demands an explanation.

A second issue within neurology is the misinterpretation of lower limb signs, thinking that they are pyramidal in origin when they are not. The following occur:

- Parkinson's disease affecting predominantly the lower limbs can be mistaken for spinal cord disease;
- Cortical myoclonus in the lower limbs can be mistaken for pyramidal ankle clonus;
- Stiffness of inflammatory muscle disease (e.g. polymyositis) with lower limb weakness can look like an emerging paraparesis;
- Brisk but normal lower limb reflexes are misinterpreted as pathological, thus prompting investigation for a paraparesis.

Brainstem syndromes

The complex anatomy of the brainstem is outlined in Chapter 2. Here, the features of some brainstem syndromes are drawn together, to encourage diagnosis by thinking in both vertical and dorso-ventral planes. Figure 3.6 is helpful as a schematic diagram. The hallmark of a typical brainstem syndrome is the coexistence of symptoms and signs of damage to motor and/or sensory fibres traversing the area vertically with damage to the cranial nerve nuclei of the brainstem. Syndromes involving oculomotor nerves III, IV and VI indicate upper or mid brainstem disease affecting the area dorsally. Mid and lower brainstem disease affects cranial nerve nuclei VII–XII.

Bulbar and pseudobulbar palsy are terms used to describe features of common lower brainstem syndromes (Chapter 12). Both cause dysarthria, dysphagia, drooling and respiratory problems. Bulbar palsy describes disease of the lower cranial nerves (IX, X, XII – nerves of the medullary bulb), their nuclei and the muscles these nerves supply. Pseudobulbar palsy is shorthand for UMN lesions of lower cranial nerve nuclei. MS, brainstem stroke and motor neurone disease cause pseudobulbar palsy, the latter usually both bulbar and pseudobulbar. Advanced PD and other extrapyramidal syndromes also cause poverty of movement of the bulbar muscles.

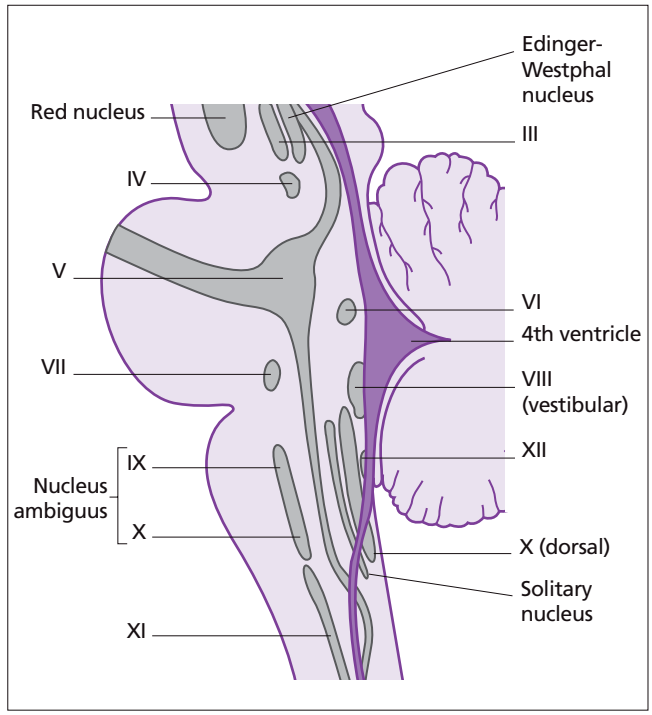

Figure 3.6 Brainstem: lateral schematic view. (From Hopkins 1993, with permission.)

Sensory abnormalities: patterns at different levels

Sensory symptoms and signs are difficult. The pattern of symptoms and their diagnostic meaning may be unfamiliar, examination time-consuming and its results less certain than the harder signs of reflex and motor abnormality. Eponyms, shorthand terms and phrases abound such as positive Tinel, tic douloreux, causalgia, anaesthesia dolorosa, lightning pains, Lhermitte, Brown-Séquard, dissociated sensory loss, suspended sensory loss, sacral sparing, thalamic pain and astereognosis. This section outlines the principal patterns of sensory disturbance seen in neurology.

An approach that some find valuable is to view sensory symptoms in one of two ways. First, if a sensory symptom is the principal complaint, such as the pain of trigeminal neuralgia (Chapter 12) or nocturnal tingling of the hands in early median nerve entrapment at the wrist (Chapter 9), its quality and distribution are frequently diagnostic. In other situations, the combination of the sensory history, sensory physical signs and additional neurological abnormalities on examination point to an anatomical diagnosis. An example is the use of sensory signs to determine a level of compression in the spinal cord when the principal feature is spastic paraparesis. Figure 3.7 summarizes various patterns of sensory loss at different levels.

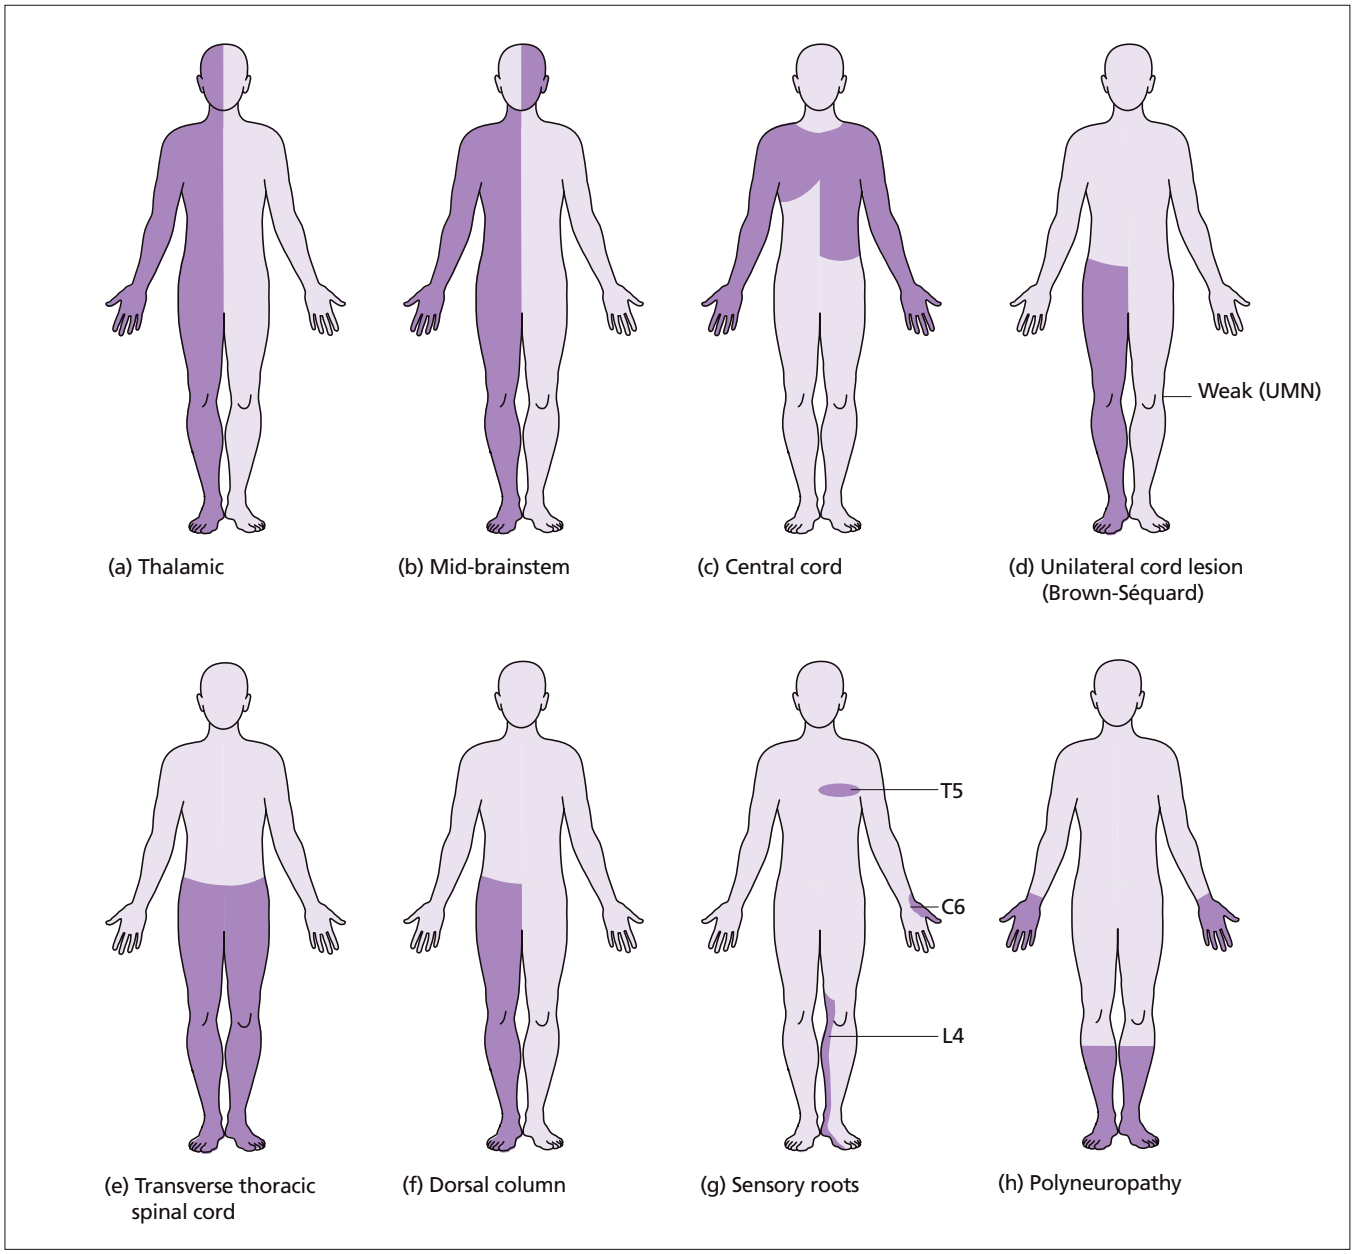

Figure 3.7 Principal patterns of loss of sensation.
(a) Thalamic lesion: sensory loss throughout opposite side (rare).
(b) Brainstem lesion (rare): contralateral sensory loss below face and ipsilateral loss on face.
(c) Central cord lesion, e.g. syrinx: 'suspended' areas of loss, often asymmetrical and 'dissociated', i.e. pain and temperature loss but light touch remaining intact.
(d) 'Hemisection' of cord or unilateral cord lesion = Brown-Séquard syndrome: contralateral spinothalamic (pain and temperature) loss with ipsilateral weakness and dorsal column loss below lesion.
(e) Transverse cord lesion: loss of all modalities below lesion.
(f) Isolated dorsal column lesion, e.g. demyelination: loss of proprioception, vibration and light touch.
(g) Individual sensory root lesions, e.g. C6 (cervical root compression), T5 (shingles), L4 (lumbar root compression).
(h) Polyneuropathy: distal sensory loss.
(From Clarke 2005, with permission.)

Sensory changes in peripheral nerve lesions

A lesion of an individual peripheral sensory nerve produces symptoms and signs within the distribution of the nerve. Nerve section is followed by complete sensory loss. Demarcation is clear-cut. The areas of sensory loss seen in individual sensory nerve lesions are discussed in Chapter 9. In nerve entrapment or partial damage, the quality of sensory disturbance varies between numbness, tingling and painful pins and needles. Dr Jules Tinel (1879–1952), the French neurologist, wrote about gunshot wound nerve injuries in 1916. He described painful tingling in the distribution of a damaged nerve when percussed – hence Tinel's sign, commonly positive when the median nerve at the wrist is tapped lightly, in cases of carpal tunnel syndrome.

Neuralgia (Chapter 22) describes pain of great severity in the distribution of a nerve or nerve root. In trigeminal neuralgia (tic douloureux, Chapter 12), the paroxysmal nature of the pain, its distribution and its electric shock-like quality is diagnostic.

Causalgia (complex regional pain syndrome type II, Chapter 22) describes chronic pain after nerve section or crush injury and is sometimes seen after amputation. Anaesthesia dolorosa is spontaneous pain occurring in an anaesthetic area. It is used to describe discomfort or chronic debilitating pain, developing for example after destructive procedures to the trigeminal nerve.

Sensory changes in polyneuropathy

Symmetrical, four limb, distal tingling, numbness or deadness are typical of polyneuropathy Sensory symptoms in the distribution of multiple individual nerves are seen in multiple mononeuropathy (Chapter 9).

Sensory root and root entry zone lesions

The distribution of spinal dermatomes is shown in Figure 3.8. Unlike peripheral nerves there is some overlap between adjacent

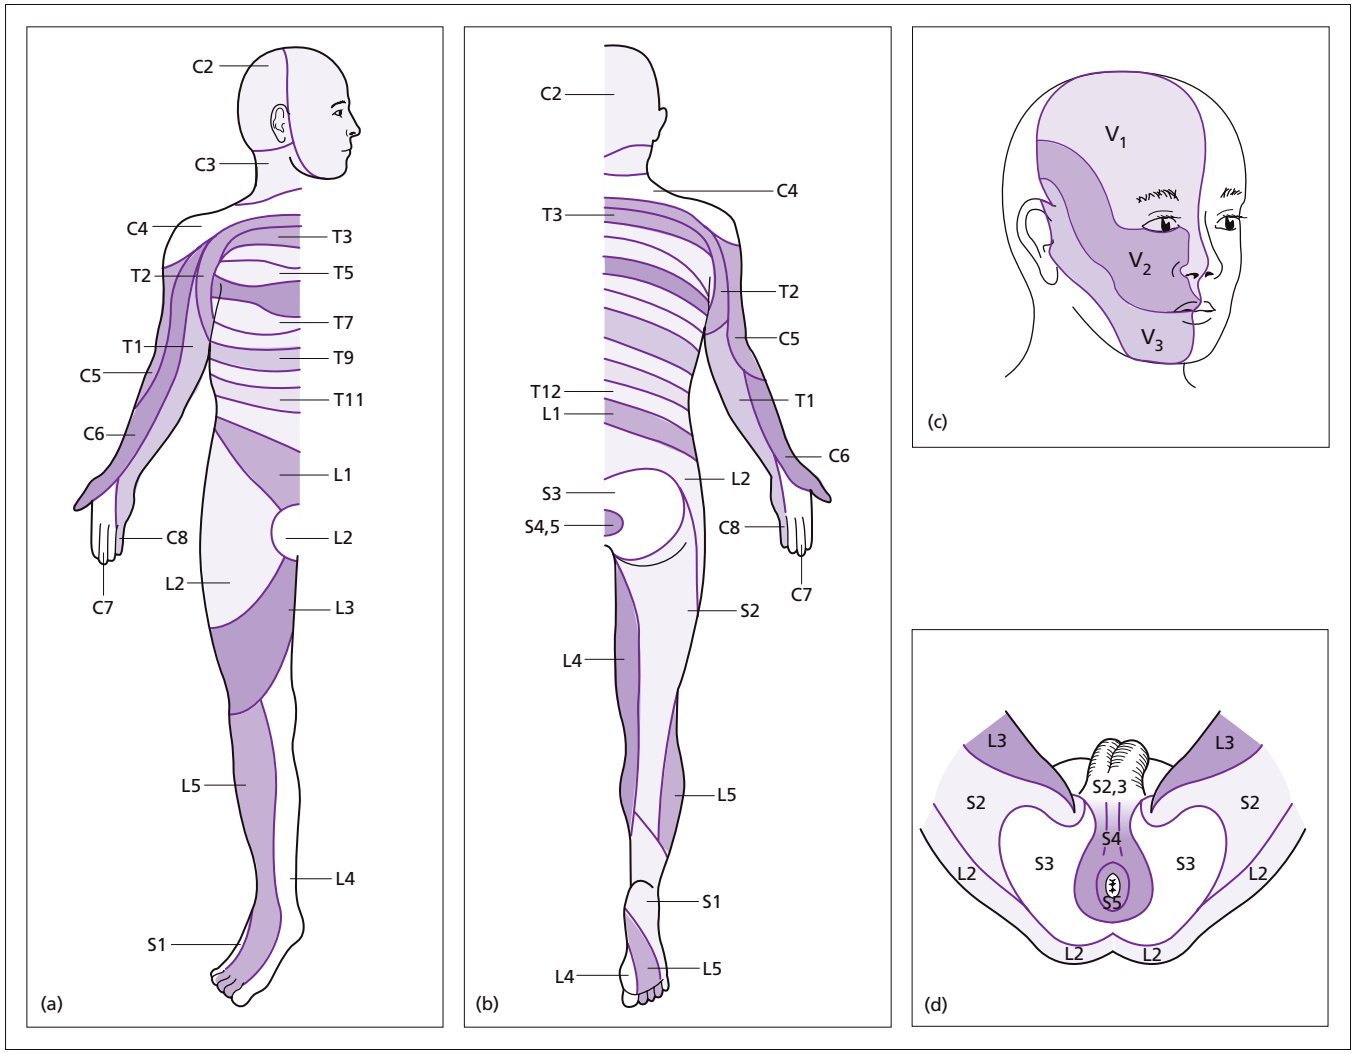

Figure 3.8 (a), (b) and (d) Spinal dermatomes. (From O'Brien 2000, with permission.) (c) Cutaneous distributions of divisions of Vth nerve. (From Patten 1996, with permission.) Precise distribution varies amongst published sources, especially for sacral dermatomes, perineum and Vth nerve.

dermatomes making the area of sensory loss following a single nerve root lesion smaller than shown. Root pain is typically perceived both within the dermatome and within the myotome (see below). It tends to be less well demarcated than pain seen in a peripheral nerve lesion. For example, with an S1 root lesion resulting from a lumbosacral disc, a sensory disturbance is felt down the back of the leg, typically without clear dermatome demarcation. Stretching of the nerve root (e.g. straight leg raising) or increasing local spinal CSF pressure (coughing, straining) typically makes matters worse.

When a root is affected within the cord, e.g. in tabes dorsalis, sudden, irregular, very intense stabbing pains involve one or more spots, typically on the ankle, calf, thigh or abdomen. These are known as the lightning pains of tabes and rarely seen today.

Neuralgia in the distribution of a nerve root can develop following shingles (post-herpetic neuralgia, Chapter 22). This is a persistent distressing burning pain.

Sensory changes in spinal cord lesions

Posterior columns

Symptoms, although they may be worse on one side, are often not clearly demarcated. Patients describe various patterns of symptoms:

- Band-like sensations around trunk or limbs;
- Limb clumsiness and deadness;
- Numbness and burning;
- Electric shock-like sensations.

Joint position sense, vibration, light touch and two-point discrimination become diminished below a cord lesion. Stamping gait and pseudochorea of the outstretched hands are the product of failing position sense.

Lhermitte's sign (strictly, a symptom) is a sudden electrical sensation down the back and into the limbs produced by bending the head forward, thus stretching the cervical cord. Lhermitte's is diagnostic of lesions of the posterior columns or occasionally caudal medulla. It is seen in:

- MS, typically in exacerbations
- Cervical myelopathy
- Radiation myelopathy
- Subacute combined degeneration of the cord (see below); and

occasionally in

- Cord compression, Behçet's, Arnold–Chiari syndrome and following trauma.

This sensory phenomenon was first noted by Drs Marie and Chatelin (Paris, 1917); Dr Jean Lhermitte re-described it in 1920, writing the seminal article some 4 years later.

Spinothalamic tract lesions

A lesion within the spinothalamic tracts of the cord that causes conduction to fail produces changes in pain and temperature sensation below its level. With compression from outside the cord, e.g. by a thoracic spinal meningioma (extramedullary cord compression, see below), the sensory level will tend to rise, having commenced in the lower limbs until the level of the compression is reached as the tumour increases in size. This is because of the lamination of spinothalamic fibres in the cord. It is important to examine sensation with this in mind. Extramedullary cord compression is likely to affect both principal cord sensory pathways, i.e. both posterior column and spinothalamic. The patient may notice the loss of spinothalamic sensation, e.g. being unable to gauge the water temperature of a bath with their foot.

When a lesion is within the cord (intramedullary cord lesion, e.g. a syrinx – a central cavity) sensory loss can initially be confined to the spinothalamic pathways. Spinothalamic sensory loss is thus dissociated from other sensory modalities: the phrase 'dissociated' sensory loss implies that a syrinx or other central cord lesion is suspected. 'Suspended' sensory loss is a term describing another aspect also seen typically with a syrinx – a patch of dissociated sensory loss does not extend to the lower limbs and is thus 'hanging', usually on the thorax or abdomen.

'Sacral sparing' is another phrase used to capture the phenomenon of preserved sacral and perineal sensation when a central cord lesion expands centrifugally, damaging first centrally placed fibres and reaching last the spinothalamic sacral fibres on the periphery of the cord.

As a cavity develops within one half of the cord, the dissociated sensory loss on the opposite side becomes associated with pyramidal signs (e.g. a spastic lower limb) on the same side as the cortico-spinal pathway involved. This finding carries the eponym 'Brown-Séquard'. Dr Charles-Edouard Brown-Séquard (1817–1894) published a treatise in 1849 on the neurological effects of traumatic hemisection of cord. Originally from Mauritius, Brown-Séquard was a physician at the National Hospital. 'Brown-Séquard findings' imply spinothalamic signs on one side and pyramidal signs and dorsal column dysfunction on the other. They point to a lesion in one half of the cord, on the same side as the pyramidal and dorsal column loss. The patient may report: 'My left foot feels numb and cold and I can't feel the bathwater, but it's my right foot that drags.'

Sensory changes in brainstem lesions

Complex patterns of sensory loss occur with lesions in the brainstem, their character depending on the level of the lesion. Trigeminal sensory loss (Chapters 2 and 12) and dissociated (spinothalamic) sensory loss in the limbs (e.g. lateral medullary syndrome, Chapter 4) are seen. Usually, the sensory disturbance is part of a complex of physical signs and the site of the lesion determined more from the involvement of cranial nerve nuclei and brainstem connections than by the pattern of sensory loss.

Sensory changes following thalamic lesions

Destructive lesions of the complex thalamic nuclei and thalamocortical projections are relatively unusual causes of sensory symptoms in clinical practice. Two principal patterns are found. When the ventral posterior nucleus, lateral (VPL) and ventral posterior nucleus, medial (VPM) thalamic nuclei (Chapter 2) are damaged, e.g. following a thrombo-embolic stroke, contralateral

hemi-anaesthesia develops immediately. All sensory modalities are usually affected. Sometimes, however, during the weeks or months following the stroke, as recovery ensues, highly unpleasant disabling persistent thalamic pain (post-stroke central pain, Chapter 22) develops in the partially anaesthetic limbs – usually as a permanent phenomenon. Such spontaneous pain does not develop following cortical lesions, nor following damage within the internal capsule or other basal ganglia nuclei outside the thalamus, but occasionally when the spinothalamic tract is damaged in the cord or brainstem.

Sensory changes in parietal lobe lesions

Features of parietal lobe lesions such as astereognosis, i.e. the inability to perceive the shape of an object, are mentioned earlier in this chapter. Focal sensory epilepsy, e.g. attacks of tingling or altered sensation, may be seen with parietal tumours. Of note, negative sensory symptoms, i.e. spontaneous distinct complaints of sensory loss, are unusual. It is more typical that a patient complains that a hand or limb 'doesn't work properly' or 'doesn't feel quite right'.

Mononeuropathy, polyneuropathy, root lesions

These notes summarize features of peripheral nervous system conditions, dealt with in detail in Chapters 9 and 12.

Mononeuropathy

Common isolated single nerve lesions (mononeuropathies) are distinct and easy to recognize once seen. Ulnar, median, radial, common peroneal (lateral popliteal), lateral cutaneous nerve of the thigh and sural nerve lesions are the most common. Most are caused by entrapment but there are other causes such as nerve tumours and vasculitis. Lesions of other peripheral nerves are relatively unusual. Cranial nerve lesions are discussed in Chapter 12.

Multiple mononeuropathy

This describes the occurrence of two or more such peripheral nerve lesions. The principal causes worldwide are leprosy, diabetes, hereditary neuropathy with liability to pressure palsies (HNPP) and various forms of vasculitis such as polyarteritis.

Polyneuropathy

Polyneuropathy (formerly known as peripheral neuropathy and polyneuritis) describes symmetrical conditions in which nerves die back – to cause combinations of peripheral sensory loss, muscle weakness and wasting with loss of tendon reflexes. It is frequently difficult to recognise clinically a neuropathy from its phenotype and to distinguish between genetic and acquired neuropathies.

Abnormal myelin appears more prone to inflammatory change than normal myelin: features of both genetic and inflammatory neuropathies can coexist.

Neurogenic muscle wasting

The crux of the matter is to distinguish between:

- Generalized muscle thinning – a normal finding in older age groups – and generalized loss of muscle bulk seen in cachexia;
- Widespread wasting seen in some myopathies, motor neurone disease and polyneuropathy;
- Focal wasting that follows denervation.

Focal neurogenic wasting is one hallmark of neurological disease. Neurological examination seeks out sites of predilection:

- Small hand muscles, supplied by ulnar and/or median nerves (T1);
- Guttering of the forearm flexors;
- Wasted anterior tibial compartment – sunken appearance lateral to the leading edge of the tibia;
- Wasted extensor digitorum brevis muscles – concave dished appearance of the small oyster-like muscles below each lateral malleolus.

Generalized thinning of muscles with advancing age is common and contributes to a gaunt appearance and spidery hands. However, the muscles are not weak on routine bedside testing. In pathological states, the muscles are weak. It is a reasonable approximation to say that muscles that are clinically normal (bulk, consistency and power) are almost always normal electrophysiologically and on biopsy.

Root lesions

The characteristics of a lesion affecting a nerve root are:

- Radicular pain;
- Wasting and weakness of affected muscles;
- Sensory loss or referred sensory symptoms; and
- Loss of or depression of one or more deep tendon reflexes.

Two descriptive terms are in common use. Radiculopathy is often applied to root lesions that are part of an inflammatory, vascular or neoplastic process, i.e. part of a disease, with derivative complex terms such as polyradiculomyelopathy. The phrase 'cervical or lumbar root problem' usually implies a compressive lesion, caused typically by degenerative disc and/or spinal disease. However, there is no real difference between the two; for simplicity the shorter English word, root, is preferred to the Latin *radix* to describe these common problems, but the more complex terms remain in widespread use.

Root pain or discomfort is caused by distortion or stretching of the meninges surrounding a nerve root and is perceived both in the myotome and the dermatome (Table 3.16). This clinical point is relevant in C7 root compression: pain is felt deep to the scapula (C7 muscles) and the sensory disturbance runs in the C7 dermatome to the middle finger. The triceps jerk is lost. For further discussion of root lesions see Chapters 9 and 15.

Cauda equina syndrome

The cauda equina ('horse's tail') describes the leash of nerve roots emanating from the lower end of the cord below vertebral body level L1/L2. Pressure (e.g. central L4/L5 disc) on the cauda equina

Table 3.16 Principal limb movements, nerve roots, muscles and peripheral nerves.

Movement	Root	Muscle	Peripheral nerve
Shoulder abduction	C5, (C6)	Deltoid	Axillary
Elbow flexion (supinated)	(C5), C6	Biceps	Musculocutaneous
Elbow flexion (mid-prone)	C5, (C6)	Brachioradialis	Radial
Wrist extension	(C6), C7, (C8)	Triceps	Radial
Tip of thumb flexion (and index finger flexion)	C7, C8	Flexor pollicis and digitorum profundus I, II	Median
Tip of ring and Vth finger flexion	C8	Flexor digitorum profundus IV, V	Ulnar
Thumb abduction	T1	Abductor pollicis brevis	Median
Finger abduction	T1	Dorsal interossei	Ulnar
Finger flexion	(C7), C8, (T1)	Long and short flexors	Median and ulnar
Hip flexion	L1, L2, (L3)	Iliopsoas	Nerve to iliopsoas
Hip adduction	L2, L3, L4	Adductor magnus	Obturator
Knee extension	L3, L4	Quadriceps femoris	Femoral
Ankle dorsiflexion	L4, L5	Tibialis anterior	Deep peroneal
Big toe extension	L5, (S1)	Extensor hallucis longus	Deep peroneal
Ankle eversion	L5, S1	Peroneal muscles	Superficial peroneal
Ankle inversion	L4, L5	Tibialis posterior	Tibial
Ankle plantar flexion	S1, S2	Gastrocnemius, soleus	Posterior tibial
Knee flexion	S1, (S2)	Hamstrings	Sciatic
Hip extension	S1, (S2)	Gluteus maximus	Inferior gluteal

affects all sacral roots streaming caudally. This causes loss of bladder and bowel control, numbness of buttocks and thighs with paralysis of ankle dorsiflexion (L4), toes (L4, L5), eversion and plantar flexion (S1). The S1 reflexes are lost (ankle jerks). This can occur rapidly over the course of several hours or less, sometimes with little back pain. An acute cauda equina syndrome is a potential neurosurgical emergency.

Difficulties can occur in the distinction between a cauda equina lesion and a lesion of the conus medullaris – the lowermost part of the cord, e.g. an MS plaque in the conus. In both, weakness, sensory loss and loss of sphincter control occurs. In an acute conus lesion lower limb reflexes are lost, as they are in a high cauda equina lesion. The emergence of extensor plantar responses and patterns of sensory loss typical of a cord lesion (sensory level in the abdomen, Brown-Séquard signs) usually enable distinction on clinical grounds.

Myopathy and neuromuscular junction disease

Muscle disease tends to produce symmetrical abnormalities. Details and difficulties in the diagnosis of muscle diseases are discussed in Chapter 9.

Inflammatory muscle disease (e.g. polymyositis) causes induration, pain and weakness. Dystrophies and most metabolic muscle diseases present typically with weakness alone; pseudohypertrophy (excessively bulky muscles) may be seen. Slow relaxation is a feature of myotonic conditions. Fatiguability is the characteristic of myasthenia gravis, and the reverse – increasing power on exercise sometimes a feature of LEMS.

Subacute paralytic conditions

This loose term is used to describe increasing weakness over the course of days, up to a wholly arbitrary period of 3 weeks. Spinal cord compression, poliomyelitis, Guillain–Barré syndrome, vasculitic neuropathies, myasthenia gravis, LEMS, botulism, periodic paralyses and MS are potential causes that require vigilance and specialist investigation (Chapters 8, 9 and 10).

Respiratory impairment is of critical importance and easy to miss in the face of severe progressive limb weakness. Such cases are some of the most challenging in acute neurology. Remarkably, even with widespread knowledge and understanding of these conditions, evidence indicates that initial paralytic symptoms are regarded as non-organic in about one-quarter of patients when they first seek help from a doctor.

Unexplained symptoms, abnormal illness behaviour and somatoform disorder

Symptoms that are unexplained or only partially explained by organic disease are features in 20–30% of new cases seen in any general neurology clinic. Many neurologists, especially in the distant past, have been tempted to think that deliberate symptom exaggeration and even fabrication are more frequent than they are thought to be today. The issue is that it is evident that many patients have symptoms that are worrying, painful, unpleasant or uncomfortable, but which do not reflect any serious underlying disease. This section briefly outlines one approach to symptoms of this nature. For example, unexplained fatigue, give-way weakness or paralysis and non-organic sensory loss are part of a

spectrum of symptoms for which no organic disease is found. In a more psychiatric context, abnormal illness behaviour is a diagnosis in common use; the phrase not only implies that the patient complains about symptoms in a way believed to be disproportionate but also reflects the attitude and reactions of medical staff – for example, unnecessary admissions to hospital, investigations or treatment. For example, about half of cases of apparent status epilepticus seen in A&E and some 15% of cases of recurrent seizures referred to epilepsy specialist clinics are believed to be non-organic, but these conditions are treated initially, very largely as if they were seizures. These matters are also discussed in greater depth in Chapter 21.

The first suggestion is to accept and understand that the great majority of patients do have the symptoms of which they complain. This comment excludes those involved in legal claims, where non-organic features are especially prominent and of more doubtful nature. The second is to exclude organic disease with all reasonable certainty. Specialized tests may be necessary to do this. The third requirement, for all neurologists, is to understand the psychiatric diagnoses that might lead to or explain such symptoms. These include:

- Anxiety and depression.
- Somatization disorder – symptoms in more than one system, usually lifelong, such as irritable bowel, chronic fatigue or unexplained pain with the implication that psychological problems have been somatized.
- Hypochondriasis – a state of fear, distress and anxiety about possible disease.
- Conversion and dissociative disorder – motor or sensory symptoms thought to relate to psychological factors.
- Somatic manifestations of depressive illness or anxiety.

Factitious disorder (symptoms to gain medical attention) and malingering (symptoms for material gain) are also possible, if rare explanations.

However, in many cases of apparent illness behaviour, no formal psychiatric diagnosis is apparent.

The approach to anxiety and/or aggressive behaviour needs qualification. Anxiety is ubiquitous – we all experience it. Most symptoms do not reflect serious disease but fear of illness is widely spread. This may all seem obvious, but there remains a tendency to equate anxiety with non-serious problems. The reality is that substantial anxiety occurs as frequently in sinister as in less serious medical conditions. Basic understanding of symptoms of a non-organic nature is necessary before embarking on the more specialist areas of organic neurology described in subsequent chapters.

4 Stroke and Cerebrovascular Diseases

Nicholas Losseff, Martin Brown, Joan Grieve

Introduction

Epidemiology

Stroke is a major public health problem, being the third most common cause of death after myocardial infarction and cancer, and the leading cause of adult disability. Stroke accounts for 11% of deaths in England and Wales. Every year about 110,000 people will have their first stroke and about 40,000 patients will have a recurrent stroke. About 24% of patients die within 30 days of their stroke. Stroke is more common than most people realize. Approximately one-quarter of 45-year-old men will have a stroke before they reach the age of 85 (Table 4.1). Stroke is a very labour-intensive and expensive condition to manage, mainly because of the long length of stay in hospital. At any one time, 1 in 5 acute hospital beds and one-quarter of long-term beds are occupied by stroke patients in the UK. The average length of stay in an acute hospital bed after stroke is about 28 days. Around half of all stroke survivors are left dependent on others for everyday activities: if a patient can return home, the burden on carers is significant.

About 5% of the UK National Health Service budget is spent on looking after stroke patients in England and Wales. The cost of looking after an individual patient with stroke is around £15,000 over 5 years. When informal care costs are included, this increases to around £30,000. Stroke will become increasingly expensive in the future because the number of people living with stroke will increase as the population of elderly people in many parts of the world continues to rise.

Stroke is also an important condition in young people and can occur at any age, including *in utero* and in the neonatal period (it is a major cause of cerebral palsy), in childhood and young adult life. One-quarter of all strokes occur in people below the age of 65.

Neurology: A Queen Square Textbook Edited by Charles Clarke, Robin Howard, Martin Rossor and Simon Shorvon
ISBN: 978-1-405-13443-9

The incidence and types of stroke vary in different racial groups. Asian people appear to have a higher incidence of intracranial atherosclerosis than Caucasians and the incidence rates of first ever stroke are higher in black people of African or Caribbean descent than Caucasian populations living in the same cities. However, whether these differences reflect genetic or social and environmental factors is uncertain.

Clinical approach to stroke

Stroke can be briefly defined as an acute focal neurological deficit resulting from vascular disease. The World Health Organization provides a longer definition: 'Rapidly developing clinical signs of focal (or global) disturbance of cerebral function, with symptoms lasting 24 hours or longer, or leading to death, with no apparent cause other than of vascular origin.' The use of the term stroke should be restricted to a description of the clinical event experienced by the patient. Appearances on brain imaging should not be described as showing a stroke, but instead the scan may show infarction or haemorrhage, which may either have been responsible for a stroke or may have been asymptomatic. Also, to say someone has had a stroke is not sufficient as a medical diagnosis. Accurate diagnosis of stroke requires the cerebral circulatory disturbance to be defined in terms of pathology (ischaemia, infarction or haemorrhage), its anatomical location within the brain (e.g. left middle cerebral artery territory) and the underlying mechanism (e.g. cardio-embolism). The task of the stroke physician is to make an accurate pathophysiological diagnosis in these terms to guide appropriate management. This requires a basic knowledge of the clinical and radiological patterns that different stroke syndromes produce and the underlying pathophysiology of stroke.

Stroke has traditionally been distinguished from transient ischaemic attack (TIA), the latter referring to focal neurological symptoms attributed to cerebral ischaemia lasting less than 24 hours, with complete recovery. The distinction is arbitrary. Some patients with TIA develop appropriately sited infarction on imaging despite rapid recovery of their symptoms, while others recover rapidly having had ischaemia evident on cerebral blood

Table 4.1 Cumulative probability (%) of a 45-year-old person having a stroke before the age listed in the left-hand column.

Age	Men	Women
65	3	3
75	10	6
85	24	18
90	33	28

flow studies. Many TIA cases both recover completely and have normal imaging and normal blood flow studies by the time of investigation. Most patients with TIAs recover within less than an hour. By definition, a stroke requires symptoms to have been present for over 24 hours, giving the impression that there is no hurry to make the diagnosis. In fact, those patients with acute neurological disturbances that may be the result of stroke require immediate assessment in hospital for consideration of reperfusion therapy, e.g. thrombolysis. Equally, patients with a recent history of TIA require urgent investigation and treatment to prevent a recurrence. The fact that a patient with a TIA appears to recover fully gives a false sense of security and that there is no urgency for assessment. However, in a UK population-based study in Oxfordshire, the average risks of recurrent stroke at 7 days, 1 month and 3 months after TIA were 8%, 12% and 17%, respectively. In patients with specific risk factors for recurrence, the 7-day risk may be as high as 31%. The need to emphasize these aspects of acute stroke and TIA has led to the use of the term 'brain attack' to emphasize to the public the urgency of the situation. It also has the value of emphasizing that acute focal neurological events have a differential diagnosis, in that stroke mimics will need to be distinguishable from stroke and TIA. The older term, cerebrovascular accident (CVA) should be avoided completely. Stroke is not accidental; the term CVA implies a negative approach to the patient and their illness.

The underlying pathology responsible for the persistent symptoms of stroke is either infarction or haemorrhage. Haemorrhage is subdivided according to location into intracranial haemorrhage and subarachnoid haemorrhage (Table 4.2). In about 85% of cases, stroke is secondary to infarction. When infarction involves only a small volume of the tissue (<1.5 cm in diameter on computerized tomography [CT]) secondary to occlusion of a penetrating artery, the resulting death of tissue is known as a lacune or a lacunar infarct. The underlying pathology responsible for lacunar infarction is often referred to as small vessel disease. This may also lead to asymptomatic changes on imaging of the deep white matter known as leuco-araiosis, discussed in more detail below. Lacunes are generally found in subcortical white matter or the basal ganglia. Larger infarcts usually involve a wedge of both cortical and subcortical white matter and result from occlusion of the trunk or branches of the major cerebral arteries, most commonly the middle cerebral artery (MCA). The size of infarction resulting from arterial occlusion will depend on the adequacy of the collateral supply

Table 4.2 Underlying pathology of stroke.

Pathology	Anatomical subdivision
Infarction	Small vessel (lacunar) infarction
	Total or partial territorial infarction
	Border-zone infarction
Intracranial haemorrhage	Lobar
	Deep/basal ganglia
	Posterior fossa
Subarachnoid haemorrhage	Aneurysm, AVM
Cerebral venous thrombosis	Vein, venous sinus

AVM, arteriovenous malformation.

via the circle of Willis and pial collateral vessels. Infarction may therefore affect all or only part of the territory of the occluded artery. Occasionally, infarction occupies the border-zones between arterial supplies, particularly if the infarction follows an episode of generalized reduction in cerebral blood flow (e.g. after cardiac arrest) or results from internal carotid artery occlusion. It is then known as border-zone or watershed infarction.

About 10% of acute strokes are caused by intracranial haemorrhage, i.e. within the substance of the brain. When the bleeding occurs from deep penetrating arteries, often secondary to small vessel disease, the centre of the haemorrhage is usually located within the basal ganglia, particularly the lentiform nucleus or the deep white matter tracts. More superficial haemorrhages are known as lobar haemorrhages and are more commonly caused by vascular malformations or cerebral amyloid angiopathy. In about 5% of cases, intracranial bleeding occurs primarily within the subarachnoid space. Subarachnoid haemorrhage is distinctive in that there may be no focal damage to the brain if the patient only has meningeal irritation, e.g. headache and/or neck stiffness. Subarachnoid haemorrhage is therefore not always classified as a form of stroke. However, the arguments are stronger in favour of including subarachnoid haemorrhage within the definition of stroke, because subarachnoid haemorrhage may be accompanied by intracranial haemorrhage with focal deficits. Also, subarachnoid bleeding frequently causes constriction of the intracerebral arteries, known as vasospasm, which can result in cerebral infarction with focal symptoms identical to that seen in other causes of ischaemic stroke.

The well-known vascular risk factors, e.g. hypertension, diabetes and smoking, are not in themselves causes of stroke, but instead promote the development of the underlying pathological processes, e.g. atherosclerosis, responsible for stroke. Their importance is therefore to provide targets for interventions to prevent stroke, rather than in diagnosis.

The majority of strokes result from arterial pathology but a small proportion, less than 1%, result from cerebral venous thrombosis. Although rare, this is an important cause to recognize because of the need for specific investigations and treatment. Cerebral venous thrombosis may cause isolated cerebral

infarction, haemorrhagic infarction, intracerebral haemorrhage or subarachnoid haemorrhage. Venous thrombosis can also present with raised intracranial pressure and epileptic seizures without focal cerebral features.

It is usually impossible to distinguish reliably between infarction and intracranial haemorrhage from the history and examination, although the features of subarachnoid haemorrhage are usually distinct. Cranial imaging is the only reliable method to distinguish between infarction and haemorrhage. Imaging also plays a major part in confirming the anatomical location of the pathology. The location may also provide clues to likely mechanisms. Other investigations are required to establish the underlying mechanism of the infarction or haemorrhage in order to plan appropriate treatment and prevention.

Medical assessment of the stroke patient on admission should concentrate on establishing the diagnosis in terms of pathology, anatomy and mechanism. It is important that initial assessment and the response to treatment and therapy should include an assessment of the patient's functional abilities, as well as their neurological examination. Validated scoring systems have been developed specifically for use in stroke patients. The most widely used scores for neurological impairment, based on the standardized neurological examination, are the Scandinavian Stroke Scale and the National Institutes of Health Stroke Scale (NIHSS). The most widely used functional outcome scores are the Barthel Index and the Modified Rankin Scale. A number of schemes have also been developed to assist in classifying subtypes of stroke. These include the Oxfordshire Community Stroke Project Classification, which divides stroke on clinical features alone into total anterior cerebral infarction (TACI, usually total middle cerebral artery territory infarction), partial anterior territory infarcts (PACI), lacunar infarcts (LACI) and posterior cerebral infarction (POCI). However, this classification is not particularly accurate in the first few hours after onset and only predicts the size of infarction on imaging in about three-quarters of patients. A more specific approach, originally developed for use in a clinical trial, is known as the TOAST Classification. This divides ischaemic stroke on the basis of detailed investigations, into atherothrombotic, cardio-embolic, small vessel occlusion, other determined cause and undetermined cause.

Ischaemic stroke

Important vascular anatomy

Heart and great vessels

The left ventricle gives rise to the ascending aorta and then its arch. Arising from the arch from right to left are the innominate, the left common carotid and the left subclavian arteries. The innominate bifurcates into the right subclavian, which gives off the vertebral and the right common carotid artery. The left subclavian gives rise to the left vertebral (Figure 4.1).

It therefore makes sense that embolic material arising from the heart or ascending aorta can enter any vessel or combination of vessels. An innominate plaque of atherosclerosis may cause embolism within the right carotid and right vertebral territory.

Extracranial and intracranial arteries

The internal carotid arteries (ICAs) begin in the neck at the carotid bifurcation, usually near the angle of the jaw, and ascend cranially. Note that it is the common carotid pulse that is palpated in the neck. The ICAs travel behind the pharynx but give off no branches in the neck. This makes them readily identifiable on angiography and distinct from the external carotid arteries which do branch. The ICAs enter the skull through the carotid canal in the petrous bone and then pass through the cavernous sinus. The cavernous carotid gives off the ophthalmic artery and then pierces the dura. The supraclinoid portion of the carotid gives off the anterior choroidal and posterior communicating artery before

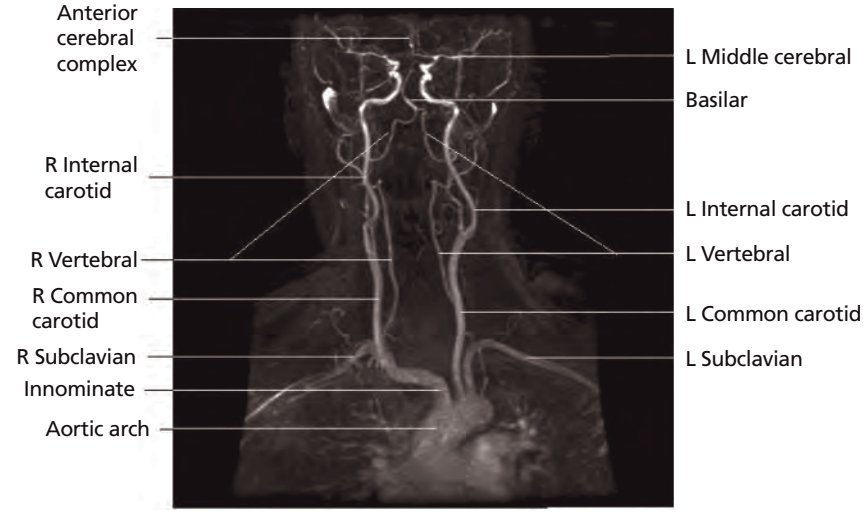

Figure 4.1 Great vessels, cervical and major intracranial arteries (contrast-enhanced magnetic resonance angiogram [MRA]).

bifurcation into anterior and middle cerebral arteries. The external carotids give branches to the neck, face and scalp. Some of these are easily palpated, e.g. the superficial temporal artery. The external carotids can act as a collateral blood supply to the hemisphere via meningeal branches, especially in the event of ICA occlusion. Often, the only clinical symptom of this is a throbbing unilateral temporal headache caused by diversion through superficial channels. Biopsy this at your peril.

The anterior choroidal arteries are small and course posteriorly along the optic tract. They give off branches to a zone between the other internal carotid branches (anterior and middle cerebral artery) and vertebral circulation. They supply perforating branches to the globus pallidus, posterior limb of the internal capsule, temporal lobe, thalamus and lateral geniculate body.

The anterior cerebral arteries (ACAs) course medially then run posterior over the corpus callosum. They supply the anterior and medial portions of the hemispheres, basal frontal lobes and caudate. Within the cortical territory of the ACA is the leg area of the homunculus. The two ACAs are usually joined together by an anterior communicating artery (ACOM) and there are various anatomic variations that dictate the pattern of ischaemic damage. In carotid occlusion the ACA territory is often spared because of collateral supply from the ACOM. If there is no ACOM then this mechanisms fails. Sometimes, both anterior cerebral arteries are supplied by a single carotid, so carotid occlusion may infarct both ACA territories or neither.

The MCAs course laterally after their origin; the proximal MCA trunk gives off numerous penetrating lenticulo-striate arteries to the basal ganglia and internal capsule. Near the Sylvian fissure the MCA trifurcates into small anterior temporal branches and large superior and inferior trunks. The superior trunk supplies the lateral portion of the hemisphere above and the inferior trunk the portion below the Sylvian fissure. Amongst its cortical supply the MCA supplies the arm area of the homunculus.

The vertebral arteries arise from each subclavian and are unusual in that they anastomose to form a larger artery, the basilar (Figure 4.2). The vertebral arteries course upwards and backwards entering the transverse foramina at C5 or C6. They run up through the intravertebral foramina exiting to pierce the dura and enter the foramen magnum. Their intracranial portions anastomose at the ponto-medullary junction to form the basilar artery. In the neck the vertebral arteries give off many spinal and muscular branches. The intracranial vertebral gives rise to the posterior and anterior spinal arteries, penetrating branches to the medulla and the posterior inferior cerebellar arteries. The basilar then runs up in the midline giving off the bilateral anterior inferior, superior cerebellar arteries and penetrating branches to the brainstem. At the ponto-mesencephalic junction the basilar terminates into posterior cerebral arteries. The posterior cerebral arteries give off perforating branches to the midbrain and thalamus, course around the cerebral peduncles and then supply occipital and inferior temporal lobes. The anatomy of the vertebral circulation is more varied than that of the carotid.

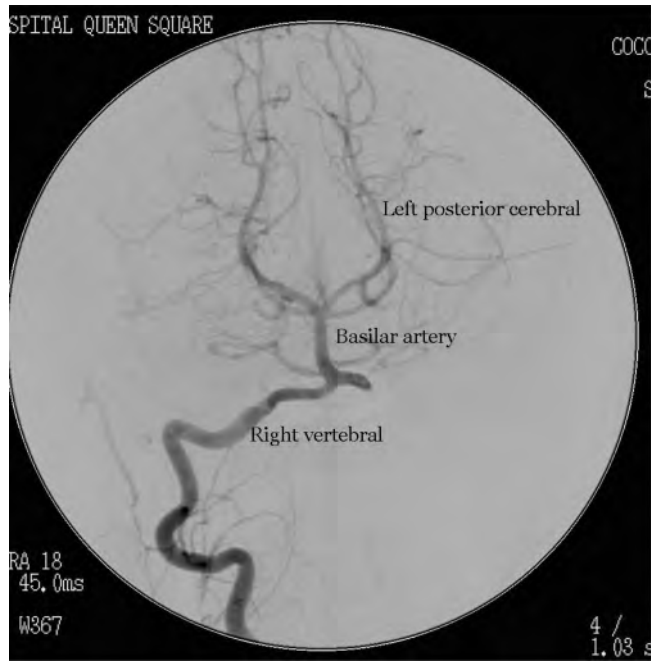

Figure 4.2 Vertebro-basilar circulation (catheter angiogram).

Commonly, one vertebral is hypoplastic or may terminate in the posterior inferior cerebellar artery (PICA).

The anterior, middle and posterior cerebral arteries are connected via communicating vessels and all these vessels together form the circle of Willis.

Venous anatomy

The cerebral veins may be divided into the venous dural sinuses and the superficial and deep venous systems. The dural sinus walls are formed by the layers of the dura itself and are situated at the junction of the falx and tentorium. The intracranial veins drain into the sinuses which then drain into the jugular veins. The ophthalmic and facial veins drain into the cavernous sinuses which lie symmetrically in the parasellar region. The important venous sinuses are the midline sagittal and straight sinus and the transverse sinuses (Figure 4.3).

Pathophysiology of ischaemic stroke

Thrombosis, embolism and hypoperfusion

There are three potential mechanisms of ischaemic stroke: thrombosis, embolism and hypoperfusion (haemodynamic failure). While these are inter-related, each mechanism can produce distinct clinical syndromes. It is important to think about these mechanisms when assessing patients as ultimately this guides treatment.

The effect of a localized blood vessel occlusion will depend on the following factors: the area of brain supplied by the vessel, the nature of the occlusion, the time that the occlusion lasts, its degree and anatomy of collateral circulation. Consider how these factors interact: one patient has a 95% internal carotid stenosis on which

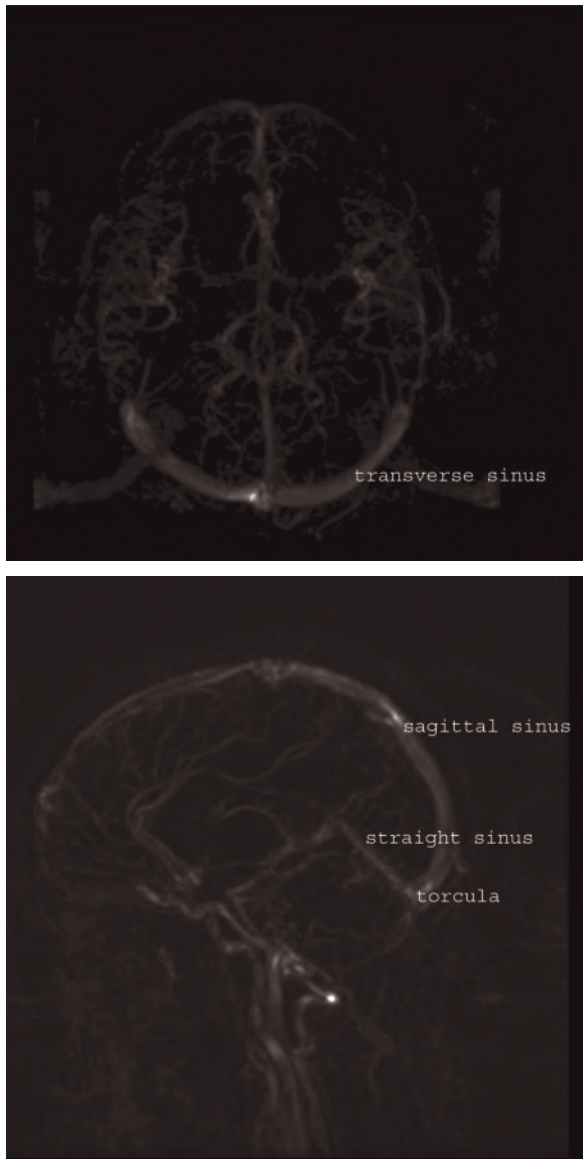

Figure 4.3 Venous anatomy (MRA).

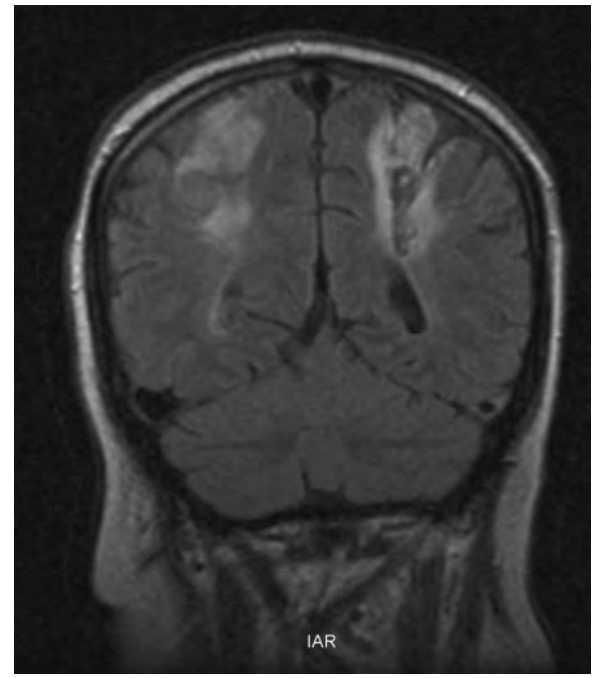

Figure 4.4 Border-zone infarction following carotid occlusion (Coronal MR FLAIR image).

a thrombus forms occluding the vessel. There may be no effects if this thrombosis remains localized (i.e. does not embolize to the brain) and the collateral circulation to the hemisphere above the occluded carotid is adequate. Conversely, even if the thrombosis remains localized, the absence of an effective collateral circulation may result in infarction of the whole of the carotid territory. If the collateral circulation is poor, then the most vulnerable areas will infarct; these are the areas with the poorest perfusion pressure and furthest away from the occluded artery. An example is shown in Figure 4.4 as a linear area of infarction in the border-zone between the anterior and middle cerebral artery territory. The occluded carotid is very unlikely to recanalize as the obstruction is principally hardened atheroma.

Another scenario is this: on the roughened surface of the 95% stenosis, platelets activate to form a white thrombus which embolizes to the brain. The thrombus may lodge in the origin of the anterior cerebral artery and have no effect because the territory has an adequate collateral circulation via the anterior communicator. Maybe it lodges at the origin of the MCA for an hour before it lyses. The meningeal collaterals over the surface of the hemisphere maintain some cortical areas for the time but the lenticulostriate perforators arising from the MCA origin are all blocked and the deep territory fails rapidly as there is no collateral blood supply. The deep territory has irreversibly infarcted but the superficial collateralized territory is hanging on. Unfortunately, the patient develops a pneumonia and becomes hypotensive: the tenuous collaterals can no longer perfuse the hemisphere. The entire hemisphere infarcts.

Stenosis and occlusion are distinct. Occlusion of a vessel may occur without pre-existent stenosis or other localized disease. This is usually a result of embolism from the heart, while arterial stenosis (e.g. of the internal carotid) is a risk factor for occlusion upstream by atheroembolism (e.g. MCA occlusion).

Thrombosis is difficult distinguish from embolism, but hypoperfusion may be more easily recognizable. However, it is important to think about the macroscopic mechanisms of ischaemia. It is unlikely that an occluded atheromatous carotid will recanalize with thrombolysis, but if the patient has border-zone ischaemia, then keeping up their blood pressure may help. Conversely, thrombolysis of fresh red cardio-embolic thrombus obstructing the proximal MCA is a practical proposition.

Patterns of stroke are discussed in detail later. The adequacy of collateral circulation depends not only on systemic perfusion pressures, but many factors including one's anatomical make-up and small as well as large blood vessels diffusely damaged by diabetes or hypertension.

Microscopic and metabolic changes

The brain is metabolically a highly active organ. Although it accounts for only 2% of body weight, it uses 20% of cardiac output when the body is at rest. Brain energy use is also dependent on the degree of neuronal activation. The brain uses glucose exclusively as a substrate for energy metabolism by oxidizing this to carbon dioxide and water. This metabolism allows conversion of adenosine diphosphate to adenosine triphosphate (ATP). A constant supply of ATP is essential for neuronal integrity and this process is much more efficient in the presence of oxygen. Although ATP can be formed by anaerobic glycolysis, the energy yielded by this pathway is small and it also leads to the accumulation of lactic acid. The brain needs and uses approximately 500 mL oxygen and 100 mg glucose each minute, hence the need for a rich supply of oxygenated blood containing glucose. Cerebral blood flow (CBF) is normally approximately 50 mL/minute for each 100 g of brain. By increasing oxygen extraction from the blood adequate compensation can be made even if blood flow is reduced to approximately 20–25 mL per 100 g/minute. Sophisticated systems exist that allow the cerebral circulation to maintain constant levels of CBF in the face of changing systemic blood pressure, usually called autoregulation. In the healthy state, CBF remains relatively constant when mean arterial blood pressure is 50–150 mmHg.

As cerebral blood flow falls, metabolic paralysis ensues and this may be reversible. However, if prolonged, infarction is inevitable. When CBF falls below 20 mL/100 g/minute, oxygen extraction starts to fall and changes may be detected on electroencephalography (EEG). At levels below 10 mL/100 g/minute, cell membrane functions are severely disrupted. Below 5 mL/100 g/minute, cell death is inevitable within a short time.

When neurones become ischaemic, a cascade of biochemical changes potentiate cell death. These pathophysiological changes have been of considerable interest to those developing treatments to lessen the damage caused by ischaemic stroke. In the ischaemic brain, ion channels fail, K^+ moves out of the cell into the extracellular space and Ca^{2+} moves in, where it further compromises the ability of the cell to maintain ionic homeostasis and leads to mitochondrial failure. Hypoxia leads to the generation of free radicals which peroxidize fatty acids in cell membranes causing further cell dysfunction. Anaerobic glycolysis results in lactic acidosis further impairing cellular metabolic functions. Excitatory neurotransmitter activity (e.g. glutamate) is greatly increased in areas of brain ischaemia because of increased release and failure of uptake mechanisms. These neurotransmitters are themselves toxic at these increased levels by causing further Ca^{2+} and Na^+ influx into cells through their actions on NMDA receptors. Hence, ischaemia triggers a vicious cascade of events leading to cell electrical failure and then death. At some point the process becomes irreversible even after reperfusion of tissues. Even if the severity of ischaemia is inadequate to cause necrosis, it may trigger apoptosis.

Ischaemic penumbra

The degree of ischaemia caused by blockage of an artery varies, partly depending on collateral supply. At the centre of an infarct the damage is most severe but at the periphery collateral flow may allow continued delivery of blood, although at a lower rate. This zone may become dysfunctional secondary to electrical failure although not dead and is referred to as the ischaemic penumbra. In any solar or lunar eclipse there is an umbra (the dense shadow) and the penumbra surrounding it. It is this outer zone that is further at risk following the onset of stroke. Sophisticated imaging can now define areas of irreversible brain damage and areas in which perfusion is suboptimal but where irreversible infarction has not taken place. The penumbra is the area of brain with the potential to survive. It is entirely likely that high-quality simple supportive management in the acute stage decreases the degree of this further secondary brain damage.

Pressure changes

Energy failure results in cytotoxic oedema where water accumulates inside cells. This is the radiological hallmark of early cerebral infarction and its distribution obeys vascular territories, unlike vasogenic oedema (extracellular accumulation) which spreads along white matter tracts. Significant brain swelling follows cytotoxic oedema increasing intracranial pressure and further decreasing CBF (Figure 4.5). Ultimately, coning may occur, after massive brain infarction or there may be important local pressure effects (e.g. brainstem compression following cerebellar infarction).

Risk factors and causes of ischaemic stroke

Ischaemic stroke is the result of vessel occlusion from *in situ* thrombosis, embolism or haemodynamic failure. Embolism may be from artery to artery (30–40%) or from the heart (30–40%). In 25% disease of the walls of small penetrating intracranial blood vessels is responsible for lacunar infarction.

Hence, the main risk factors for stroke are the risk factors for atheroma and heart disease (Table 4.3). Non-atherosclerotic vasculopathies and primary haematological disease are much less common.

Both the clinical syndromes and risk factors of lacunar stroke and large vessel occlusion overlap. Stroke is usually the result of a combination of risk factors coming together rather than a single entity.

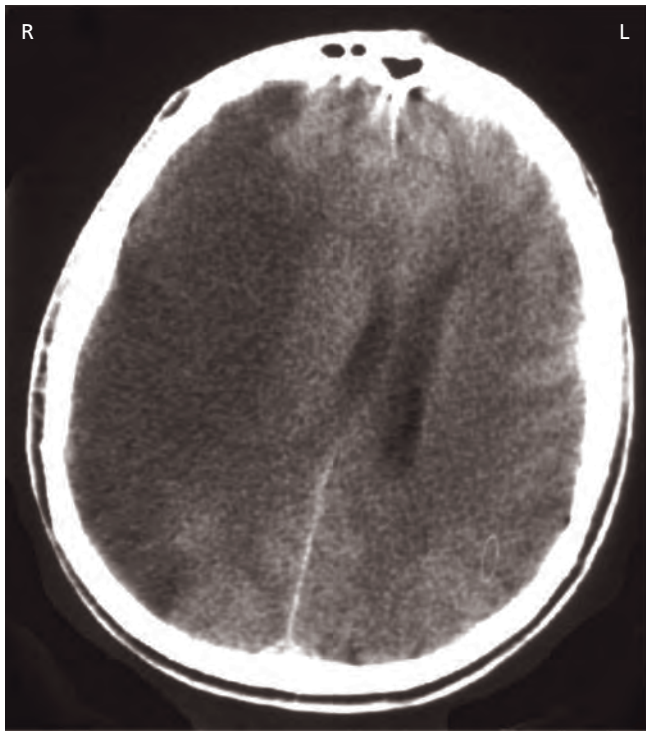

Figure 4.5 Cytotoxic oedema with brain swelling following right MCA occlusion (unenhanced CT).

Table 4.3 Major risk factors.

Age
Hypertension
Smoking
Diabetes mellitus
Atrial fibrillation
Heart disease
Dyslipidaemia
Alcohol
Obesity
Symptomatic and asymptomatic carotid stenosis
Drug misuse

Age, hypertension, smoking, lipids and drug misuse

The incidence of stroke rises dramatically with age, doubling each decade past 55 years. Half of all stroke occurs in the over-70 age group. At least 25% of the adult population have hypertension >140/90 mmHg. After age, this is the most important and modifiable risk factor. The Framingham data show a linear relationship between risk of stroke and arterial hypertension and this effect is seen across all levels of blood pressure.

Smoking remains a leading preventable cause of death and an independent risk factor for stroke. It particularly predisposes to carotid stenosis in men. Diabetes mellitus increases the risk of stroke by about two- to fourfold when compared with those without diabetes. The excess diabetic risk is independent of age and blood pressure status. High total cholesterol and low-density lipoprotein (LDL) correlate with atherosclerosis. Although low levels of high-density lipoprotein (HDL) correlate well with coronary artery disease, the relationship is less clear for cerebrovascular disease. Alcohol consumption demonstrates a J-shaped relationship; heavy drinking being associated with a higher risk of all stroke, both ischaemic and haemorrhagic. The presence of asymptomatic carotid disease carries a greater cardiovascular than cerebrovascular risk. Asymptomatic stenosis of greater than 75% carries an annual stroke risk of only 2% or less. In contrast, if the stenosis is recently symptomatic, the annual risk increases to 15% and is even higher if the stenosis is greater or the symptoms very recent. This is discussed in greater detail in the section on secondary prevention. Plaque structure rather than the degree of narrowing is important, with ulcerated heterogeneous plaques being more likely to rupture or allow thrombosis on their surface. Drug-related stroke is an increasing problem and may be multi-factorial. The mechanisms of stroke after drug misuse are very broad (Table 4.4).

Table 4.4 Mechanisms of stroke associated with drug misuse.

Complications of parenteral administration, e.g. heroin, cocaine
Infective or non-bacterial (marantic) endocarditis – infarction or haemorrhage from associated mycotic aneurysm
Direct embolization of particulate matter – infarction via right to left shunt (e.g. patent foramen ovale or pulmonary shunt) or from direct carotid administration
Acute severe hypertension (TIA, infarction or haemorrhage)
Arterial vasospasm (infarction or TIA), e.g. crack cocaine, cocaine, amphetamine, possibly cannabis
Arterial dissection
Hypersensitivity vasculitis: associated with amphetamine, heroin, cocaine and crack cocaine (headache encephalopathy, stroke-like episodes, seizures) – all rarely proven

TIA, transient ischaemic attack.

Another effect of drugs of abuse is rupture of a coincidental underlying aneurysm or arteriovenous malformation. This is a common cause of intracranial cerebral haemorrhage (ICH; either subarachnoid or parenchymal) in users of stimulant drugs (e.g. amphetamine, crack and cocaine). All patients with drug-related subarachnoid haemorrhage (SAH) or ICH need careful evaluation to exclude such causes based on the pattern of haemorrhage. In some patients, induction of antiphospholipid antibodies has been associated with cocaine and heroin. Whether they confer a specific risk is not clear and it must be noted that antiphospholipid antibodies are also associated with infection and vasculopathies of many causes.

Cardiac disease

Heart disease may be divided into high or low risk. Atrial fibrillation remains the most important cause of cardio-embolism (Table 4.5).

Table 4.5 Cardiac causes of stroke.

High risk	Atrial fibrillation (especially combined with other risk factors)
	Valvular heart disease
	Prosthetic heart valves
	Bacterial endocarditis
	Non-infective (marantic) endocarditis (Chapter 20)
	Cardiac surgery
Low risk	Myocardial infarction
	Ventricular/atrial aneurysm
	Cardiomyopathy (e.g. amyloid, alcohol, cocaine)
	Septal abnormalities (e.g. ASD, patent foramen ovale, atrial septal aneurysm)
Rare	Intracardiac lesions (myxoma, fibroelastoma)

ASD, atrial septal defect.

Atrial fibrillation is a common cardiac disorder, with up to 5% of the over-60-year-olds affected. Atrial fibrillation is an important risk factor for stroke, with a general risk of about 4% per year in patients who have not had prior embolic symptoms and about 12% per year in patients with prior TIA or stroke. Other coexistent risk factors (e.g. age, hypertension or left ventricular dysfunction) also increase the risk. Sick sinus syndrome through atrial dysfunction may also result in embolism. As many as 10–20% of patients with valvular hear disease have a stroke as the abnormal valve surface promotes thrombosis and embolization. The most important used to be rheumatic mitral stenosis but this is now overtaken by endocarditis on native or prosthetic valves. The manifestations of endocarditis are protean and include ischaemia, ICH and SAH, encephalopathy and meningitis. Endocarditis is much more common on prosthetic valves and often resistant to treatment. Non-infective endocarditis was first described by Libman and Sacks; the condition spans simple valve thickening to frank vegetations containing platelets and fibrin. Systemic lupus erythematosus (SLE), antiphospholipid syndrome and malignancy are potential causes.

After myocardial infarction (MI), there is a systemic embolism rate of about 3%. Most emboli will affect the brain. Most thrombi arise in the ventricle after anterior MI. Left ventricular thrombi can be detected in approximately 30% of patients after anterior MI. The thrombi develop within 3 days and embolism occurs on average 2 weeks after MI. Stroke is therefore rarely the presenting feature of MI, but this can occur in patients who have had an asymptomatic (silent) MI. The risk of stroke associated with impaired cardiac function is substantial.

Paradoxical embolus resulting from venous thrombosis entering the arterial circulation is an increasingly recognized and potentially important cause of stroke. However, in patients with a potential route for paradoxical embolism and stroke (e.g. patent foramen ovale), it is often not clear if emboli have been formed *de novo* in the heart or arose in the venous circulation, e.g. from deep vein thrombosis, to cause paradoxical embolism, or whether the stroke is unrelated to the cardiac abnormality.

Table 4.6 Haematological causes of stroke.

Important	Sickle cell disease
	Polycythaemia of any cause
	Thrombocythaemia
	Antiphospholipid antibody syndrome
Rare	Thrombotic thrombocytopenic purpura
	Paroxysmal nocturnal haemoglobinuria
	Leukaemia and myeloma
Uncertain (except by cerebral venous thrombosis or paradoxical embolus)	Activated protein C resistance +/– factor V Leiden mutation
	Protein C
	Protein S
	Antithrombin III deficiencies
	Prothrombin G20210 mutation
	Other thrombophilias
Other causes of hypercoagulability	Malignancy (especially stomach cancer)
	Vasculitis
	Homocystinuria
	Drugs (e.g. contraceptive pill, intravenous immunoglobulin)
	Nephrotic syndrome
	Disseminated intravascular coagulation

However, a classic triad is recognized that suggests true paradoxical embolism:

1 There is a reason for a venous thrombus (e g. taking the oral contraceptive pill);

2 The stroke happens at a time when shunting and paradoxical embolus are possible (e.g. during a Valsalva); and

3 The stroke syndrome is typically cardio-embolic (e.g. posterior cerebral artery occlusion or small cortical infarct).

The most common potential intracardiac shunt is patent foramen ovale (PFO). However, this is present in about 25% of the population, making its presence difficult to put into context. In young apparently idiopathic stroke, the incidence of PFO approaches 50%. Recent studies suggest PFO alone after stroke carries a small 2% risk per year of further stroke. However, this seems to be increased to 15% by the concomitance of an atrial septal aneurysm, suggesting that this may be the main source of embolism.

Stroke and the blood

Many haematological conditions can lead to stroke (Table 4.6), especially when other risk factors are present.

Sickle cell disease may produce stroke in childhood by intracranial stenosis and occlusion of the terminal carotid and proximal MCA. A channel of friable collaterals may form at the skull base (secondary Moyamoya syndrome, see below). In adults with sickle cell disease, ischaemic stroke is more frequently caused by small vessel disease or occlusion and often several other risk factors are present. There are many neurological phenomena associated with sickling and stroke is only one of them. Migrainous symptoms are common in patients with sickle cell disease.

Of the hypercoagulable states thrombophilia is commonly tested for in younger patients but rarely proven as a cause of stroke. Cerebral venous thrombosis is a far more likely mechanism of stroke associated with thrombophilia, but the latter may be relevant if there has been paradoxical arterial embolism. It is much more important to request a full blood count looking for polycythaemia and thrombocythaemia than a thrombophilia screen. The most common detectable abnormality in the population is activated protein C (APC) resistance; the others are very rare. Resistance to APC is one of the most commonly identified venous thromboembolic risk factors but there is no clear relationship to arterial stroke. APC resistance is inherited in a dominant fashion and in most patients associated with a single point mutation in the factor V gene (factor V Leiden). Patients may be homozygous or heterozygous.

Antiphospholipid antibodies and syndrome

One distinct haematological condition is the antiphospholipid antibody syndrome (APAS) in which arterial stroke is well documented. This is not the same as having antiphospholipid antibodies which may occur in association with other vasculopathies including atherosclerosis. Antiphospholipid antibodies have a pathogenic role in arterial and venous thrombosis. Ischaemic stroke is the most common arterial thrombotic event with APAS. Other neurological manifestations include neuropsychiatric features, movement disorders and migrainous headaches. There may be recurrent fetal loss and livedo reticularis. Antiphospholipid antibodies may be inferred by the presence of a circulating lupus anticoagulant or IgM and IgG antibodies. These antibodies may be present in patients with SLE, chronic infection and neoplasia but a rare subgroup has primary APAS with no other associated disease.

Non-atherosclerotic vasculopathies and other rare cases of stroke are discussed elsewhere in this chapter and in Chapter 25 (Table 4.7).

Clinical syndromes of cerebral ischaemia

Transient ischaemic attacks

We have tended to distinguish TIAs from completed stroke on an arbritary basis but the pathophysiology behind the cause may be identical (e.g. severe carotid stenosis) and both require urgent specialist assessment and investigation. The term brain attack, used by some to describe the acute presentation of TIA and stroke, emphasizes urgency. Careful history, examination and sophisticated neuroimaging often reveal that what has been labelled as a TIA is in fact associated with infarction. It is nevertheless useful to distinguish transient as opposed to persistent symptoms and signs, as the differential diagnosis of transient events is different.

The symptoms of transient ischemia are usually negative, maximal at onset and last typically for a few to 20 minutes.

The definition of TIA allows the symptoms to persist for up to 24 hours. We often think of transient ischaemia as indicating atherosclerosis within a specific arterial territory but TIAs may occur in the setting of multiple risk factors without imaging evidence of vasculopathy; or they may occur secondary to a haematological cause (e.g. antiphospholipid antibody syndrome). High-frequency attacks (several a week) are likely to be brought about by embolism from severe stenosis of a large artery; very high-frequency attacks (several a day) tend to follow from intermittent haemodynamic failure above a critically stenosed artery with poor flow. Such haemodynamic attacks may be distinguished by their diurnal variation (more common in the morning) and at times when blood flow is diverted elsewhere in the body, e.g. after eating or on exercise. Sometimes they present with limb jerking, similar to a focal motor seizure, that then gives way to weakness.

As a general rule, if a patient has more than three TIAs there should be an identifiable reason for them. If there is not a good reason evident after thorough investigation, then the diagnosis should be questioned. Common sites often ignored are found by examining the heart in detail (by trans-oesophageal echocardiography, TOE), the aortic arch (also best seen on TOE), the great vessels, the vertebral artery origins (difficult to image non-invasively) and the intracranial circulation.

TIAs are associated with a high rate of subsequent stroke: one-third of all untreated patients subsequently have a stroke. The immediate risk is high: 20% of strokes occur within a month and 50% within a year.

Within the carotid circulation (Table 4.8) the retinal circulation may be affected leading to transient monocular blindness (amaurosis fugax). This is usually described as a curtain or shutter coming down over one eye. Blindness usually lasts several minutes only; very occasionally, cholesterol emboli (a Hollenhorst plaque) may be seen after or during an attack. Hemisphere ischaemia is suggested by sudden onset contralateral weakness or dysphasia,

when the dominant hemisphere is affected. The symptoms of hemisphere ischaemia usually last up to 20 minutes. Sensory loss in isolation is less common.

Within the vertebrobasilar circulation, attacks may cause diplopia, facial or tongue numbness, dysarthria, vertigo and bilateral visual loss. In some cases it is not possible to decide whether anterior or posterior circulation has been affected: an innominate stenosis with embolism (rare) may produce attacks with mixed features.

Table 4.8 Symptoms of transient ischemia and other symptoms not of transient ischaemia.

Symptoms of transient ischemia	
Carotid territory	Monocular visual loss
	Unilateral weakness
	Dysphasia
Vertebrobasilar	Diplopia
	Vertigo/dysequilibrium
	Bilateral visual loss
	Bilateral weakness
Either	Headache
	Dysarthria
	Hemianopia
	Unsteadiness
	Sensory loss
Symptoms not usually suggestive of transient ischaemia	
Syncope	
Isolated amnesia	
Drop attacks	
Generalized weakness	
Confusional states	
Isolated vertigo	

It is very unusual for isolated vertigo (Chapter 14) to be caused by vertebrobasilar ischaemia but not impossible – after all, infarction may be asymptomatic. Isolated vertigo is usually the result of an isolated vestibulopathy.

TIAs are unlikely to be caused by haemorrhage, although occasionally microhaemorrhages (small foci of susceptibility artefact visible using T2* gradient echo MRI but not on conventional MRI or CT) are associated with TIAs (Figure 4.6). These patients usually have uncontrolled hypertension.

Alternative diagnoses

About a quarter of people attending specialist cerebrovascular clinics with possible TIAs have alternative diagnoses. The most common is migraine with focal symptoms. These are either part of an aura preceding headache (not usually confused with TIAs), or without headache (commonly confused) or following a migrainous headache – the extremely rare hemiplegic migraine. Stroke itself and TIAs are not infrequently accompanied by headache. Some serious conditions may cause both migrainous symptoms and infarction, e.g. cervical artery dissection, APS and giant cell arteritis.

The two main pointers toward migraine are positive phenomena and spread. Visual aura may consist of zigzag lines and scintillating scotomas. Sensory aura is tingling rather than numbness and in a mouth–hand distribution. Patients may complain of weakness but this is usually vague. Symptoms evolve slowly – taking several minutes for the visual disturbance to maximize, or for the tingling to spread from the hand to the face (the typical distribution). True hemiplegic migraine (Chapter 11) is a rare familial channelopathy and quite distinct from other forms of migraine.

Other commonly confused conditions are transient global amnesia and epilepsy. Transient global amnesia (TGA) is sometimes precipitated by Valsalva activated straining, e.g. immersion

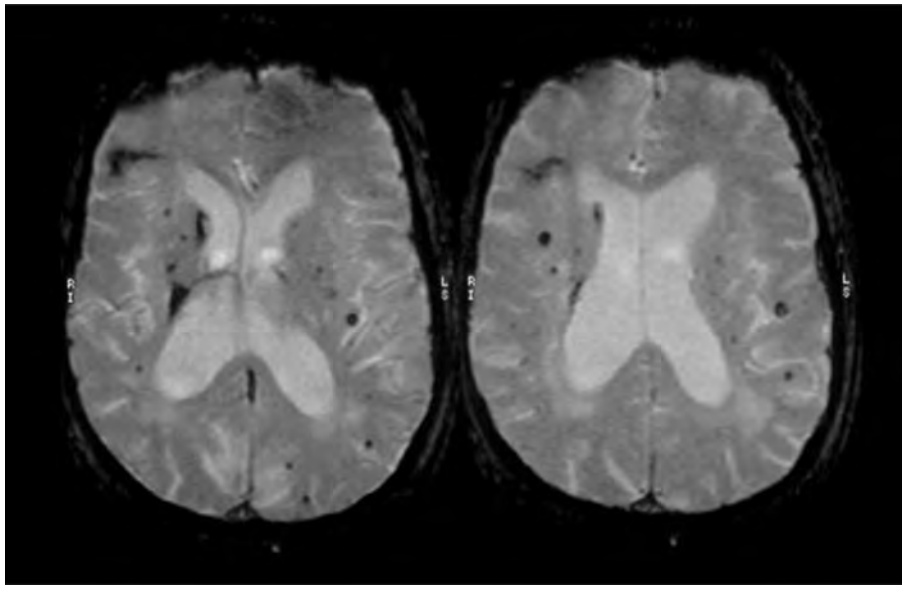

Figure 4.6 Multiple microhaemorrhages (MRI T2W).

Table 4.9 Differential diagnosis of transient ischaemia.

Migraine
Transient global amnesia
Epilepsy
Multiple sclerosis
Mass lesions, subdurals
Hypoglycaemia
Syncope

in cold water, travel or emotional stress. Hanging up curtains is one common precursor. Generally, in TGA, acute anterograde amnesia develops and patients usually appear bewildered and ask repetitive questions such as 'Where am I?' and 'What's going on?' There is no loss of personal identity as in a fugue state. The attacks last several hours and after recovery the patient has little recollection of the event. TGA is a heterogeneous disorder but in general is benign and not associated with a subsequent stroke risk. There does seem to be a subgroup of patients with small vessel disease underpinning the disorder and even rarer transient epileptic amnesia. Patients should be investigated with imaging and for vascular risk factors.

In addition, other serious intracranial pathology may cause transient symptoms such as tumours, subdural haematomas and multiple sclerosis. Hypoglycaemia may masquerade as all sorts of transient neurological disturbances but is rare in practice. Syncope can sometimes produce confusing clinical pictures including focal deficits.

Investigation when true transient ischemia is thought possible is the same as for completed stroke and is discussed below.

Lacunar stroke

Lacunes are small, subcortical or brainstem infarcts ranging 1–15 mm in size. They need to be distinguished from the dilated peri-vascular spaces commonly visible on MRI. This is easy with MR FLAIR imaging: although both may be white on T2, lacunes are also white on FLAIR, whereas a peri-vascular space is black. Lacunar infarction is caused by occlusion of small penetrating vessels most commonly arising from the MCA and basilar artery (Figure 4.7). Lacunes may be silent. They may be preceded by TIAs in some 20%; sometimes these are high-frequency attacks refractory to all treatments (capsular warning syndrome). Lacunar TIAs tend to be briefer and more stereotyped than large vessel TIAs. The two pathologies underlying vessel occlusion are usually lipohyaline change and/or microatheroma. Although lacunar infarction is also associated with carotid stenosis, it does not commonly happen as an embolic syndrome. The major risk factors for lacunar stroke are hypertension, diabetes and hypercholesterolaemia. Occlusion of small penetrating vessels is commonly asymptomatic but if eloquent structures are involved then the syndromes are fairly stereotypic. The most common sites for lacunar infarction are the putamen, pallidum, pons, thalamus, caudate, internal capsule and corona radiata.

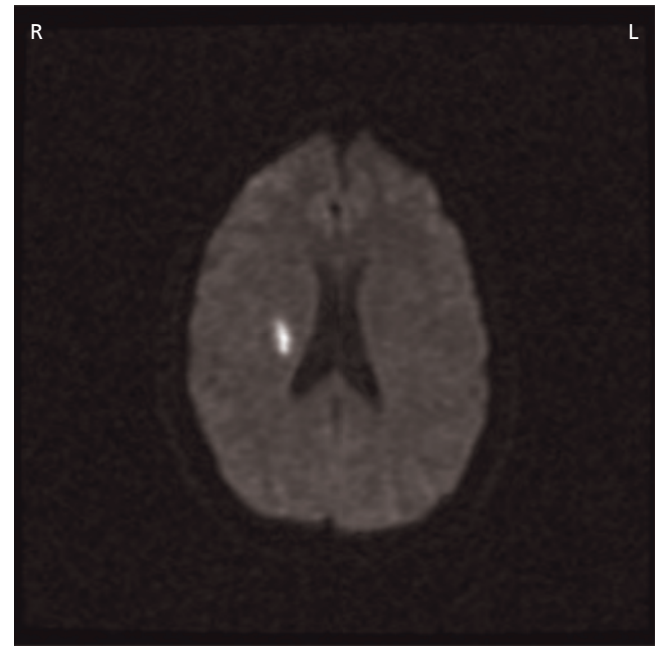

Figure 4.7 Lacunar infarction (diffusion weighted MRI).

Table 4.10 Common lacunar syndromes.

Pure motor
Sensorimotor
Pure sensory
Ataxic hemiparesis
Dysarthria/clumsy hand

The principal clinical feature of lacunar infarction is that patients lack cortical signs. Cortical signs include dysphasia, neglect syndrome, apraxia, hemianopia and conjugate eye deviation. It is difficult to tell clinically whether infarction has taken place affecting deep hemisphere structures or brainstem structures as the syndromes overlap. One is tempted to think that a profoundly dysarthric patient must have had brainstem infarction but this is unreliable. There are many lacunar syndromes but those commonly seen in practice are pure motor hemiparesis, pure sensory hemiparesis, sensorimotor hemiparesis, ataxic hemiparesis and clumsy hand-dysarthria syndrome (Table 4.10).

CT may not detect some smaller lacunar infarcts especially in the brainstem; MRI is much more sensitive. Often patients with lacunar infarction may have widespread changes and it can be difficult clinically to identify the symptomatic lesion. Appropriate patients should also have evaluation of the extracranial carotids, looking for significant stenosis. The large carotid endarterectomy trials have shown that carotid stenosis is a risk factor for lacunar

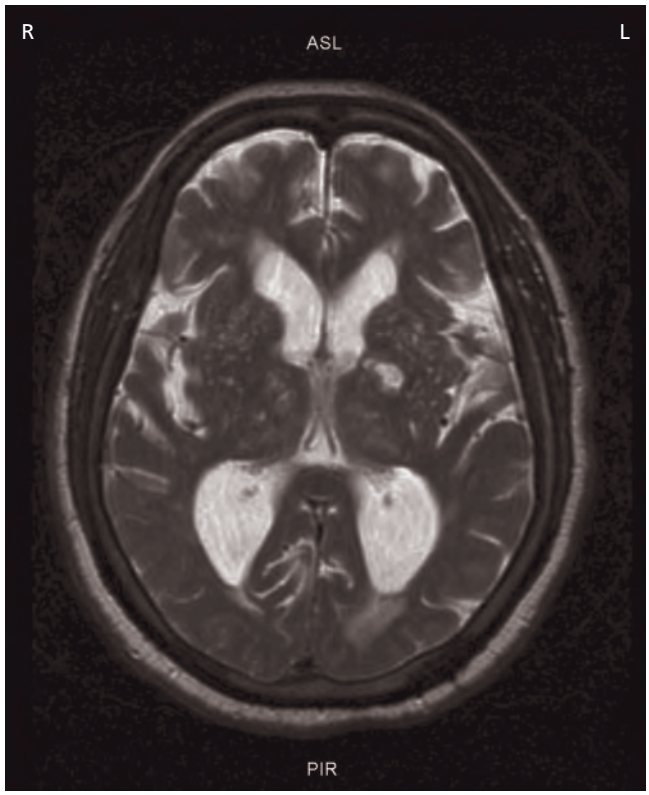

Figure 4.8 Diffuse small vessel disease (MRI T2W).

stroke. Those with severe carotid stenosis benefit from endarterectomy, in terms of secondary prevention but less than those with other syndromes. The mainstay of secondary prevention is control of hypertension, diabetes, antiplatelet agents and statins where appropriate.

If sufficient damage from repeated penetrating vessel occlusion takes place, global problems appear. These patients often have diffuse peri-ventricular change on CT and MR imaging, known as leuco-araiosis (Figure 4.8) and atrophy. They may develop gait apraxia (gait ignition failure, marche à petit pas) and postural instability with a predisposition to falling backwards, and dementia of a subcortical type with prominent lack of initiation and poor attention. Patients with small vessel disease may also be at greater risk of Alzheimer's disease (Chapter 7) and the two often coexist. These syndromes are distinct from multiple cortical stroke. Leuco-araiosis can also be found coincidently without overt symptoms or signs in those over 50 years especially with appropriate risk factors. There is an increased incidence of depression and subclinical cognitive impairment in these patients.

Rarer causes of lacunar syndromes

APAS can present with lacunar infarction; often these patients also have a history of migrainous phenomena and headaches. Anticoagulation may be needed. CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy) presents in a similar fashion (see below, and Chapter 25).

Large vessel occlusion

The pattern of infarction after large vessel occlusion will depend on many factors. The common risk factors listed above are important, but compared to lacunar infarction the emphasis skews towards large vessel stenosis and heart disease as sources of embolism.

The main clinical distinction between large vessel occlusion and lacunar infarction in the carotid circulation is the presence of cortical signs (eye deviation, dysphasia, neglect syndromes, hemianopia). The hemiparesis produced by MCA occlusion affects the arm more than the leg because of cortical involvement (the leg cortex is in anterior cerebral artery territory).

Internal carotid artery disease

The major cause of this is atherosclerosis, with stenosis in the distal common carotid artery extending to the proximal ICA and external carotid artery. Occlusive disease of other arteries commonly accompanies ICA stenosis; coexisting myocardial ischaemia and limb ischaemia are common. Atherosclerosis in the ICA produces its symptoms either by embolism, thrombus formed on ulcerated plaque, haemodynamic failure from severe stenosis (>95%) or occlusion.

An important clue to a potential ICA stenosis is transient monocular blindness, amaurosis fugax (the ophthalmic artery is the first branch above the ICA origin). Occasionally, the patient may develop a low flow retinopathy or global ischaemic ocular syndrome from a combination of small vessel and critical ICA stenosis. This may cause haemodynamic retinal symptoms including bleaching out of colours in sunlight and persistent after images from bright lights. Although a bruit may mark the presence of ICA stenosis and is an independent risk factor for stroke, the ICA flow can be so severely diminished that a bruit is absent. Embolism is most likely to produce a partial or complete MCA syndrome and is discussed below. Haemodynamic failure above a critical stenosis can lead to border-zone infarction. Horner's syndrome may be present when the artery is acutely thrombosed. Carotid occlusion occasionally presents with a stuttering deficit sometimes over many weeks.

Narrowing and thrombotic occlusion of the carotid siphon in the distal ICA is less frequent than at the origin but is usually caused by atherosclerosis. This may be more common in the Asian population. In younger patients, distal stenosis and occlusion may be caused by vasculitis, dissection or Moyamoya disease.

Middle cerebral artery occlusion

Total MCA occlusion

The MCA may be affected by embolism or thrombosis *in situ*. Patients with severe intracranial atherosclerosis have a high incidence of stroke because of thrombosis *en plaque*. People of Asian

and African descent seem particularly affected by intracranial stenosis. In Caucasians, while MCA occlusion is common, MCA stenosis is rare.

If the main trunk occludes and there are inadequate collaterals then the whole territory infarcts (Figure 4.9). The clinical picture produced is sometimes known as 'front-to-back' infarction with conjugate eye deviation (frontal lobe damage), aphasia (dominant hemisphere), hemiplegia, hemisensory loss and hemianopia (parietal and temporal lobe damage). Neglect syndromes where the patient is unaware of the hemiplegic side occur acutely with both non-dominant and dominant hemisphere damage but generally only persist with non-dominant damage. Patients with complete MCA syndromes occasionally develop fatal brain swelling (malignant MCA oedema) within 48 hours of onset, leading to death from coning. In appropriate cases surgical decompression is required (Figure 4.10).

MCA branch occlusions

These produce fragments of the syndromes described above. Upper branch occlusion affecting frontal structures produces hemiparesis, hemisensory loss, ocular deviation and non-fluent motor dysphasia (expressive) where the patient understands (intact temporal lobe) but cannot produce speech. Lower branch occlusions can affect the temporal lobe resulting in fluent dysphasia (receptive) where production of speech is good but incoherant and the patient does not understand.

MCA distal embolism

Small cortical branches occluded, e.g. by emboli, may present only with weakness or isolated cortical signs, difficult to distinguish from the effects of a lacunar infarct.

MCA deep infarction (striato-capsular infarction)

This tends to occur when collateral circulation protects the cortex but deeper structures (the striatum and capsule) become infarcted (Figure 4.11). This pattern of infarction is also seen with MCA stenosis and when emboli obstruct the lenticulo-striate perforators and then break up. Patients have unilateral motor and

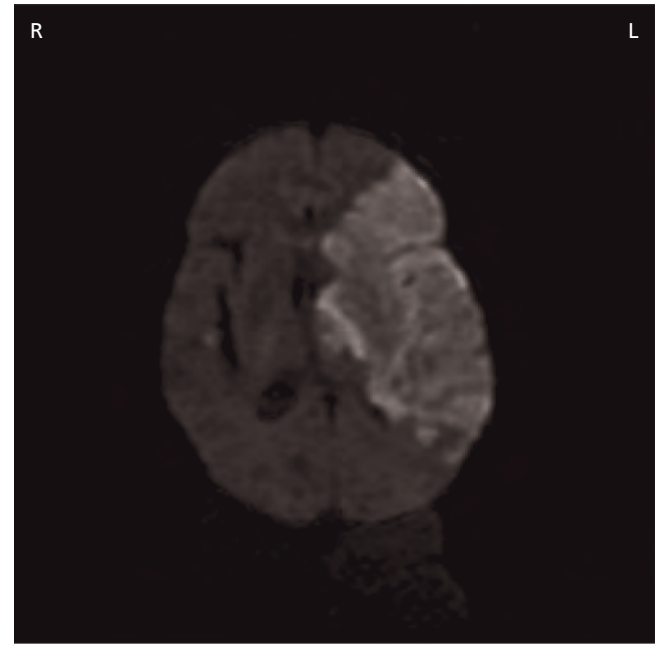

Figure 4.9 Complete MCA territory infarction (diffusion weighted MRI).

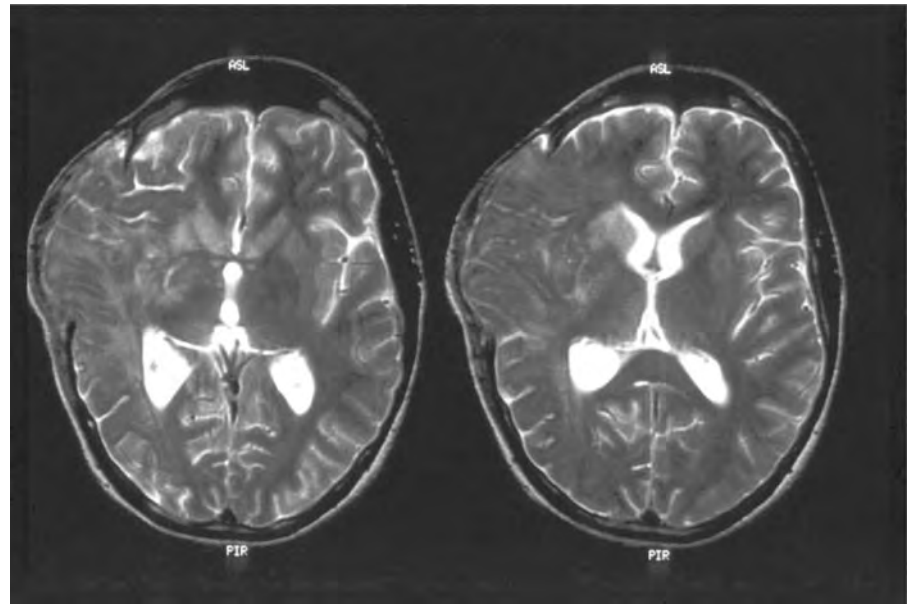

Figure 4.10 Malignant right hemisphere swelling relieved by surgical decompression following complete MCA territory infarction (MRI T2W).

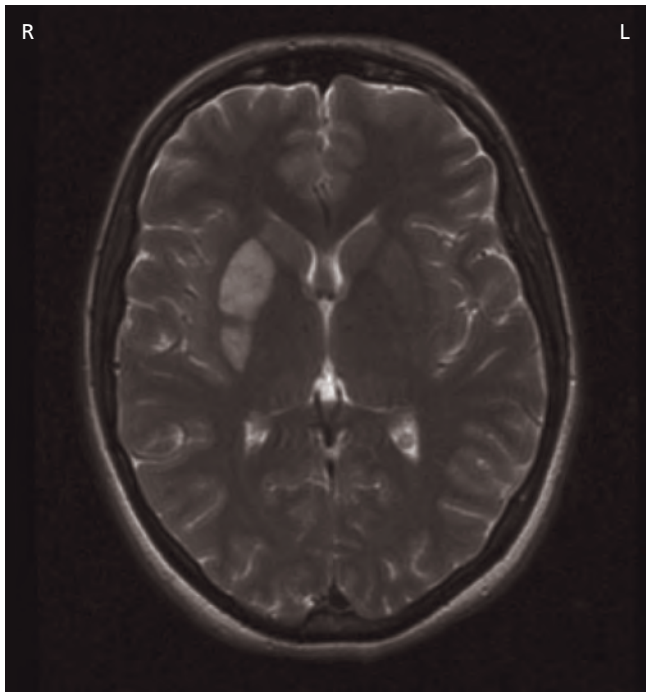

Figure 4.11 Striato-capsular infarction (MRI T2W).

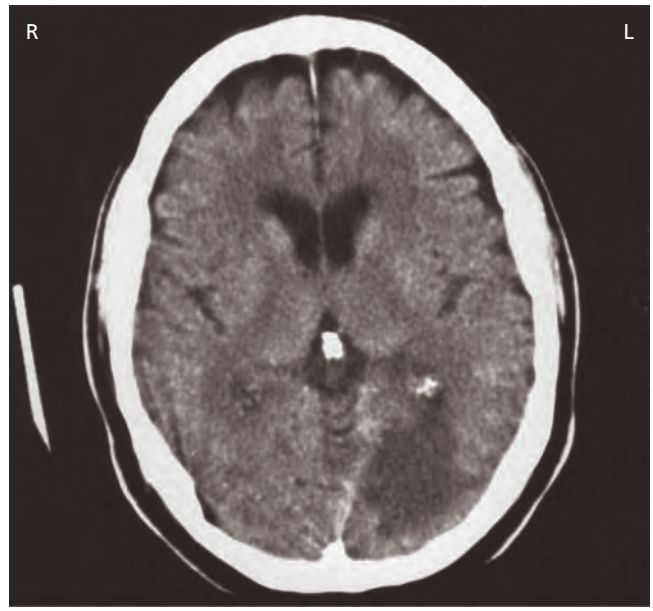

Figure 4.12 Infarction following posterior cerebral artery occlusion (unenhanced CT).

sensory loss but also exhibit cortical signs (unlike pure lacunar infarction). These cortical signs resolve more quickly than when the cortex itself is damaged. Striato-capsular infarction should prompt a search for cardiac and ipsilateral carotid sources of embolism.

Anterior cerebral artery occlusion

This territory is far less often affected than that of the MCA. Although the same risk factors apply, ACA territory infarction should raise the level of awareness for unusual aetiologies at play. This also occurs in the setting of SAH, secondary to vasospasm. The clinical features of ACA occlusion are contralateral hemiplegia. The leg is most affected as the cortical representation of the leg lies within the territory. Some patients may have motor neglect and apraxia.

Anterior choroidal artery occlusion

Syndromes include hemiparesis (face, arm and leg), prominent hemisensory loss and hemianopia, often temporary. However, unlike hemianopia associated with complete MCA infarction, other cortical signs may be subtle and transient.

Posterior cerebral artery

Occlusion of these arteries is commonly embolic. More patients with posterior cerebral artery syndromes are in atrial fibrillation than with other large vessel occlusions (Figure 4.12). The posterior cerebral artery (PCA) supplies principally the occipital cortex: an isolated hemianopia is common. When infarction is more anterior, affecting parieto-occipital areas, neglect syndromes may accompany the hemianopia. The PCAs also supply the thalami and posterior-medial temporal lobes. If these structures are involved the patient may present with confusion, dysphasia (thalamic) or memory impairment (thalamic or temporal). If both PCA territories are infarcted, as may happen when an embolus lodges at the top of the basilar, cortical blindness and confusion ensues. Sometimes, these patients may be left with tunnel vision and may recognize small but not large objects. Memory impairment, especially for new information, may be severe.

Vertebral artery

The most common pattern produced by occlusion of or embolism from the vertebral arteries is infarction of the dorsolateral medulla within the territory of the posterior inferior cerebellar artery causing a lateral medullary syndrome (Wallenberg's syndrome). This results in a Horner's syndrome, dissociated (temperature and pain) sensory loss on the ipsilateral side of the face and the opposite side of the body, nystagmus, ataxia of the ipsilateral limbs, and ipsilateral palatal and vocal cord paralysis. Vertebral embolism or occlusion may also result in more extensive infarction of the brainstem and cerebellum; these syndromes are discussed next. The most common site for atheroma to affect the vertebral artery is at its origin from the subclavian.

Basilar artery

Whereas the middle and posterior cerebral arteries are more often affected by embolism than *in situ* thrombosis, the opposite is true of the basilar artery. This is because the basilar is wider than its two feeding vertebral arteries and it can be affected by severe

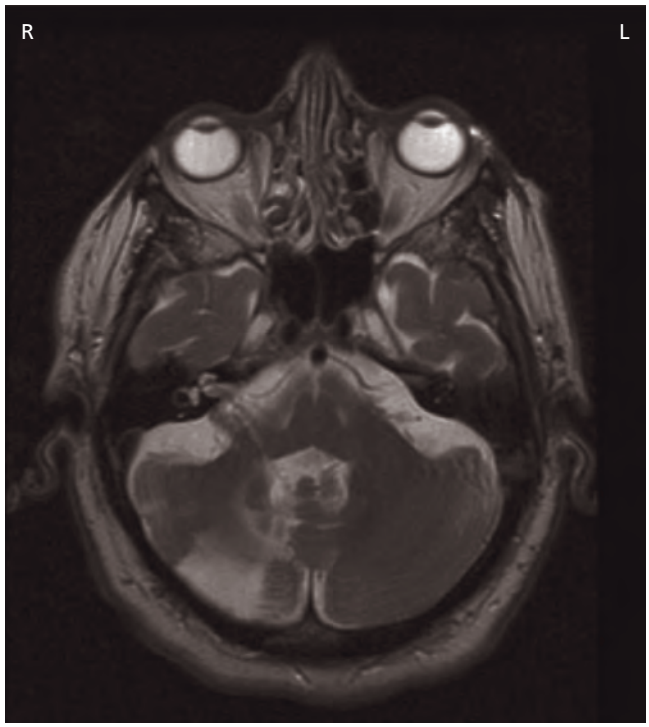

Figure 4.13 Brainstem and cerebellar infarction (MRI T2W).

atherosclerosis on which *in situ* thrombus can form (Figure 4.13). This may obstruct blood flow into perforating vessels supplying the central brainstem structures or the two upper cerebellar arteries. A number of clinical pictures may be encountered. In the medulla, lower cranial nuclei may be affected giving rise to a lower motor neurone type bulbar palsy. Upper motor neurone impairment of the same structure may cause a pseudobulbar palsy, with brisk facial reflexes, brisk jaw jerk and a spastic tongue. This is often accompanied by spontaneous laughter or crying (emotional lability). Above the medulla, pontine infarction can cause a VIth nerve palsy, gaze paresis, internuclear ophthalmoplegia and pinpoint pupils. Emboli may also lodge at the top of the basilar causing midbrain infarction with loss of vertical eye movement, pupillary abnormalities, coma or locked-in syndrome. Involvement of the origin of one or both of the posterior cerebral arteries may lead to a hemianopia or cortical blindness. All these syndromes will be accompanied by quadriparesis to some degree, which may be very asymmetric.

Watershed syndromes and ischaemic encephalopathy

The brain is particularly vulnerable to a global decrease in perfusion. Most frequently, this is caused by cardiac disease (arrhythmia or pump failure) and hypoxaemia, although hypovolaemia alone may result in these syndromes. Hypoxia without ischaemia (i.e. without reduction in blood flow) does not lead to cerebral infarction. The usual circumstance in which these patients are encountered is following cardiac arrest, severe blood loss and cardiopulmonary bypass in which embolism may also occur. Acutely in the non-anaesthetized non-comatose patient, global perfusion failure results in non-focal brain dysfunction (confusion, attentional deficits, light-headedness). Following a profound insult a number of watershed syndromes brought about by damage to the border-zone regions are recognized.

The area particularly vulnerable to reduction in perfusion pressure is the parieto-occipital cortex that lies at the superficial border-zone between MCA and PCA territories. This is the area furthest from the heart. Infarction of this region results in abnormalities of behaviour, memory and vision. The visual abnormalities are complex and include inability to see all the objects in a field of vision, incoordination of hand and eye movement such that the patient cannot locate objects in the visual field, and apraxia of gaze in which the patient cannot gaze where desired. Other areas of vulnerability are the deep border-zones within the subcortical white matter of the centrum semi-ovale, and border-zones between the ACA and MCA, and the hippocampi, where infarction may result in a Korsakoff-type syndrome. In severe cases, necrosis can follow within the basal ganglia, cerebellum and brainstem.

Vascular dementia

Dementia (i.e. cognitive deficits in multiple domains) can follow multiple cortical or subcortical lacunar infarcts (multi-infarct dementia). Typically, patients have a stepwise deterioration associated with other features of stroke. In diffuse small vessel disease, the onset may be more subtle with the more gradual onset of cognitive impairment (Chapter 7) often accompanied by gait apraxia where patients exhibit failure to initiate gait, postural instability (often falling over backwards) and a shuffling small-stepped gait. Patients with diffuse small vessel disease may have prominent attentional difficulties in excess of discrete cortical patterns of dysfunction and often present with periods of encephalopathy associated with new infarction. Multiple cortical infarcts, from large vessel occlusions, are much rarer as a cause of dementia. In addition, it is important to note that patients with vascular disease (clinically and radiologically) are at an increased risk of Alzheimer's disease and it is the latter that causes dementia in many patients with vascular disease (mixed dementia). This can be distinguished to some extent on clinical and neuropsychological grounds.

Intracranial haemorrhage

Intracranial haemorrhage may be intracerebral, within the cerebellum or brainstem (infratentorial), subarachnoid, subdural or extradural. This section deals principally with intracerebral haemorrhage (ICH) and infratentorial haemorrhage.

Approximately 10% of stroke is caused by brain haemorrhage with an annual incidence of 10–15/100,000 population. The incidence increases significantly after the age of 55 years and doubles with each decade to the age of 80. However, there has been a small

but progressive decline in the incidence of both stroke and brain haemorrhage, particularly in the last three decades, because of an improvement in the management of risk factors and secondary prevention; the control of hypertension in primary care has been of particular importance.

Despite being less common than ischaemic stroke, haemorrhage has a significant impact because the subsequent mortality is so high. In one study of over 1000 stroke cases, 30-day mortality for supratentorial and infratentorial ischaemic stroke was 15% and 18%, respectively. Mortality following supratentorial and infratentorial haemorrhage was 58% and 31%. Mortality rates of 90% following brain haemorrhage have been reported.

Spontaneous ICH results from intracerebral arterial rupture, particularly perforating vessels, or less frequently from the venous system. The haematoma expands following the path of least resistance, usually along white matter tracts, and occasionally into the ventricular system. Neurological deficit results both from direct tissue destruction and indirectly from local compression and mass effect, usually in proportion to both the volume of haematoma and its rate of expansion. Intraparenchymal haemorrhage can occur at any site, although some areas are more susceptible than others. Eighty per cent of such intraparenchymal haemorrhages occur within the cerebral hemispheres and some 20% are infratentorial.

Traditionally, brain haemorrhage has been thought to have a sudden devastating presentation. While it is true that patients who present in coma following vomiting, headache and neck stiffness are more likely to have had a haemorrhage than ischaemic event, it is wrong to believe that patients with less severe stroke syndromes can be diagnosed on clinical grounds to have had ischaemic strokes. This is particularly illustrated by the recognition of microhaemorrhage with T2* imaging which occasionally reveals minute bleeds as the underlying cause of clinical syndromes previously thought to have been caused by ischaemia.

Risk factors

The most important risk factor associated with brain haemorrhage is hypertension, found in 40–60% of patients. Compared with brain haemorrhages from other causes, this type of bleed is more frequently fatal, a reflection of both its high incidence and its tendency to occur in critical locations. Hypertensive bleeds occur in deep white matter (36%), pons (11%) and cerebellum (8%), regions that are supplied by the lenticulo-striate branches of the MCA or the paramedian perforating branches of the basilar artery. The underlying weakness of these vessels is caused by hyaline degeneration of arterioles promoted by long-standing hypertension. Identical pathology can be seen in elderly patients without known hypertension.

Other conditions important in the aetiology of brain haemorrhage are aneurysms (20%), vascular malformations (5–7%), coagulopathies (5–7%), tumours (1–11%), sporadic cerebral amyloid angiopathy and haemorrhagic infarction (Table 4.11). Non-medicinal use of cocaine and amphetamines may cause haemorrhage, although there is often an underlying vascular malformation in these cases.

Table 4.11 Causes of brain haemorrhage.

Hypertension
Anticoagulants
Amyloid angiopathy
Arteriovenous malformations
Aneurysms
Cavernous haemangiomas
Amphetamine/cocaine ingestion
Infective endocarditis
Tumours
Disseminated intravascular coagulation
Venous thrombosis
Cerebral vasculitis, malaria

Aneurysms are saccular or fusiform arterial deformities, the result of protrusion of the intima through a structural defect in the arterial muscular layer. Typical circle of Willis aneurysms, also known as berry aneurysms, most commonly cause SAH, although this is associated with intraparenchymal bleeding in 30% of patients. Mycotic aneurysms usually form in smaller cortical arteries when septic emboli lodge in the vessel. This is usually seen in the context of infective endocarditis, where up to 17% of patients develop cerebral emboli. Usually, these mycotic aneurysms thrombose, if the infection is treated adequately, and no further intervention is required. Rarely, the mycotic aneurysm continues to enlarge or ruptures; surgical intervention is necessary to clip and/or resect it. Arterial invasion by tumour or severe atherosclerosis occasionally lead to aneurysm formation, although rupture is rare. Other vascular malformations that cause brain haemorrhage include arteriovenous malformations (AVMs), cavernous malformations and capillary telangiectasia. Developmental purely venous anomalies were also thought to cause haemorrhage: current understanding is that it is the cavernous malformation commonly associated with the venous anomaly that is the source of bleeding.

One of the most important and potentially treatable causes is anticoagulation, especially when poorly controlled and combined with other risk factors. Any patients on anticoagulants with new focal neurology must be assumed to have bled until proven otherwise with urgent cranial imaging. In those that have bled, anticoagulation should be immediately reversed. Other causes of coagulopathy, including thrombocytopaenia, leukaemia and liver and renal failure, may also cause similar problems. Patients with coagulopathy are also much more likely to bleed into cerebral infarcts.

Cerebral amyloid angiopathy, characterized by deposition of amyloid in the media and adventitia of medium-sized hemispheric vessels, is an important cause of recurrent or multiple superficial haematomas in elderly patients, particularly when there is no history of hypertension. It is estimated that during the

seventh decade of life, 10% of the population develops amyloid angiopathy, increasing to 60% by the age of 90 years. There is a strong association with Alzheimer's disease.

Clinical syndromes

The rupture of a vessel or microaneurysm results in the sudden development of haematoma, of variable size. These haematomas characteristically then slowly enlarge, sometimes over a matter of days, leading to progressive focal neurological deficit and then deterioration of conscious level secondary to mass effect. Haemorrhage may be divided into a number of categories depending on location. These are deep (centred on basal ganglia structures), lobar, pontine and cerebellar. In all sites hypertension remains the most important risk factor and while amyloid angiopathy classically gives rise to lobar and not deep haemorrhage, hypertension is still the most important risk factor in lobar haemorrhage.

Deep haemorrhage

Haematomas may be centred on the putamen, caudate or thalamus. In putaminal haemorrhage the picture is of contralateral hemiparesis and conjugate deviation of the eyes towards the side of the haematoma (Figure 4.14). Cortical function may be impaired. If the mass becomes critical then signs of herniation ensue. These haematomas may rupture into the ventricles leading to intraventricular haemorrhage. In the case of putaminal haemorrhage the presence of ventricular blood implies a very large haematoma with a poor prognosis. Caudate haemorrhage is much rarer and small haematomas may readily rupture into the ventricles. When the lesion is large the picture is similar to putaminal haemorrhage but if small, haematomas may mimic subarachnoid haemorrhage with acute headache and meningism with little in the way of focal signs. Thalamic haemorrhage predominantly produces sensory change in the contralateral limbs. If local midbrain compression occurs the eyes may be forced into downward gaze with small poorly reactive pupils. Thalamic haemorrhage in the dominant hemisphere may produce dysphasia with notable naming difficulties.

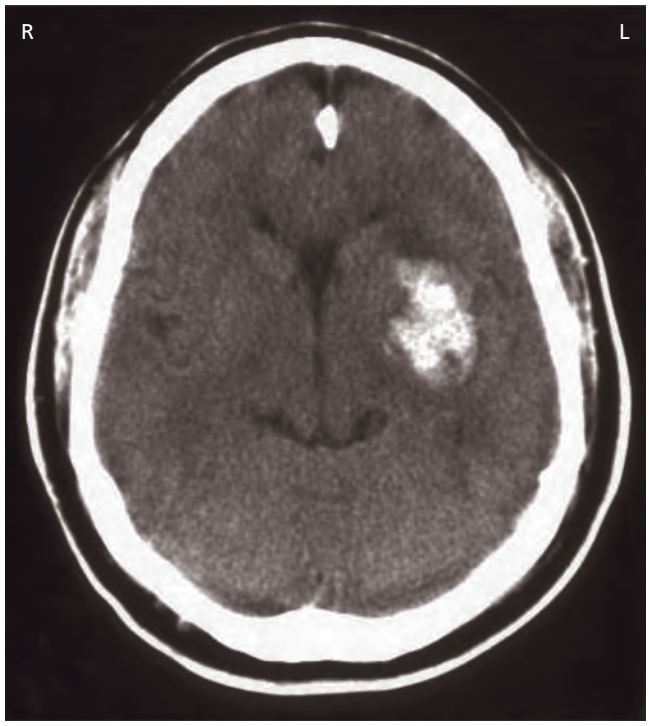

Figure 4.14 Large putaminal haematoma (unenhanced CT).

Lobar haemorrhage

These cortical lesions produce signs appropriate to their location. In the frontal lobe, eye deviation and contralateral hemiparesis is common. In the posterior frontal and fronto-parietal region, hemisensory loss is found, associated with dysphasia when the lesion is within the dominant hemisphere. Parietal lobe haemorrhage causes hemisensory loss and neglect/inattention syndromes. Bleeding into the dominant temporal lobe results in a fluent dysphasia with poor comprehension secondary to damage to Wernicke's area.

Lobar haemorrhages are more likely to be associated with structural abnormalities, e.g. a vascular malformation, than deep haemorrhages. Alternatively, amyloid, trauma, haemorrhagic transformation of infarction and a haemorrhagic tumour should be considered within the differential.

Infratentorial haemorrhage

The classic picture in pontine haemorrhage is coma associated with pinpoint pupils, loss of horizontal eye movements and quadriparesis. Hyperpyrexia and irregular respiratory patterns ensue. Although a large haematoma here is often fatal, the outcome may be surprisingly good.

Cerebellar haemorrhage accounts for some 10% of all brain haemorrhages. It is important to recognize as it may result in secondary fatal brainstem compression and hydrocephalus. Posterior fossa craniectomy to decompress the brainstem can be life-saving and patients may make an excellent functional recovery. The usual picture is of acute headache and vomiting with unilateral ataxia. Unilateral gaze paresis in association with ataxia or in isolation may occur and also skew deviation. When brainstem compression is present from the onset or develops later, the picture suggests a pontine haemorrhage, with the patient either presenting or deteriorating into coma. Emergency CT scanning is essential.

Intraventricular haemorrhage

This mimics SAH (see below) with headache, vomiting, neck stiffness and depression of consciousness. There may be associated pyramidal signs, particularly if associated with a parenchymal haematoma. This may be caused by extension of blood following deep haemorrhage, aneurysmal rupture or a subependymal angioma. This is particularly the case with caudate haemorrhage as this nucleus lies adjacent to the ventricular margin.

Specific issues in intracerebral haemorrhage

Brain imaging is mandatory, without delay. Although MRI is greatly superior to CT at refining the pathophysiological diagnosis, it is not currently available for most patients in the emergency situation. The appearances of haemorrhage on CT are also easier to interpret than on MRI, especially in non-expert hands and CT is therefore often the preferred imaging technique at presentation. Acutely, a CT is essential to distinguish infarction from haemorrhage or reveal mimics of the stroke syndrome such as tumour or subdural haematoma. Haemorrhages seen on MRI undergo complex changes depending on the image sequence, the proportion of oxyhaemoglobin, deoxyhaemoglobin and methaemoglobin, and its distribution; this may make interpretation difficult. However, signal loss on gradient echo MRI is more specific and sensitive to new and old haemorrhages than the older MRI sequences.

In appropriate patients it is necessary to exclude underlying vascular malformations with angiography. If performed in the acute situation, consideration should be given to repeating angiography once the mass effect of the haematoma has resolved. In 10% of cases where initial angiography is normal, a small arteriovenous malformation is demonstrated on delayed imaging. This is caused by occlusion of the arteriovenous malformation by the mass effect of the acute haematoma. In this situation either the angiogram should be delayed or repeated following resolution of the haematoma. MRI is often a useful complementary investigation in order to exclude underlying parenchymal lesions. Again this is best performed after some days once there has been resolution of some of the blood products.

Following a brain haemorrhage, the general supportive management issues are just as important as in ischaemic stroke. Medical treatment is aimed at correcting any underlying systemic disorder such as severe hypertension or coagulopathy, as well as preventing or limiting secondary complications such as pulmonary emboli, myocardial infarction and pneumonia. Aspirin (often taken as an over-the-counter preparation) should be stopped. Until recently, there were no specific drugs that had been shown to alter outcome. Initial trials of recombinant activated factor VII showed that this pro-coagulant appeared to reduce haematoma size and improves outcome when given within 4 hours of onset; however, phase IIb/IIIa studies have been negative. Further trials are needed to explore these findings. Frequent neurological assessments, as well as serial CT scans, are necessary particularly early in the clinical course when management can be modified accordingly.

Anticoagulant related haematomas often present as slowly evolving lesions. It is essential, even if they are small at initial imaging, to reverse warfarin immediately as delay may have devastating consequences. This maxim includes patients with prosthetic valves as the risk–benefit ratio is much in favour of anticoagulation reversal for a period of 2 weeks, after which the rebleeding rate is considerably lower. The rate of systemic embolism from thrombus on the prosthetic valve during this period is small.

Neurosurgical practice in relation to evacuating intracerebral haematomas varies. The middle of the road approach that the authors follow is to evacuate life-threatening cerebellar haematomas large enough to cause brainstem compression and hydrocephalus and superficial lobar haematomas that are causing marked mass effect. Few neurosurgeons will tackle deep-seated basal ganglia haematomas unless under exceptional circumstances, in the main because the associated morbidity is significant. The optimal management of this form of stroke beyond organized care is unclear from the evidence and the results of the recent Surgical Trial in Intracerebral Haemorrhage (STICH) suggested no significant benefit to surgical evacuation. In this prospective randomized study of over 1000 patients, there was no overall benefit from early surgery when compared with initial conservative management.

Prognosis

The prognosis of brain haemorrhage depends primarily on the location and size of the haematoma. These factors are closely followed by the patient's age, the cause of the haemorrhage and the development and severity of post-haemorrhagic complications such as cerebral oedema, hydrocephalus and raised intracranial pressure, as well as systemic complications such as pulmonary embolus, MI and pneumonia. In gauging prognosis and discussing possible outcome with a patient or their relatives, it is worth pointing out that improvement following haemorrhage tends to be more delayed than following infarction, and that there are some cases where eventual recovery is good following resolution of the haematoma.

Subarachnoid haemorrhage

The main cause of non-traumatic SAH is rupture of an intracranial aneurysm. This accounts for 85% of cases. SAH is a devastating condition with an overall case fatality of 50% (including pre-hospital deaths), with 30% of survivors being left dependant, with major neurological deficits. In spite of many advances in diagnosis and treatment over the last decades, the case fatality rate has changed little, if at all.

Non-aneurysmal peri-mesencephalic haemorrhage is seen in 10% of cases and carries a good prognosis with less frequent neurological complications. The remaining 5% of cases are caused by rare conditions, including AVMs (including spinal AVMs), cerebral vasculitides, tumours, dural arteriovenous fistula, dural sinus thrombosis, carotid or vertebral artery dissections, coagulopathy and drugs.

The annual incidence of SAH in UK is approximately 10/100,000, increasing consistently with age until the sixth decade, with a peak incidence at 55–60 years. There are marked variations in the incidence of SAH worldwide. The incidence is lowest in the Middle East and highest in Japan, Australia and Scandinavia, especially in Finland where SAH incidence is around three

times that of the rest of the world. The age-specific rates for SAH tend to be higher in those of Afro-Caribbean origin than Caucasian. There is female preponderance, with male : female ratio as around 1 : 1.8.

Risk factors

The risk of aneurysmal rupture depends on the size and location of aneurysm. The International Study of Unruptured Intracranial Aneurysms (ISUIA) documented a 5-year cumulative rupture rate for all aneurysms of the anterior circulation (except posterior communicating [PCOM] artery aneurysms) of 0%, 2.6%, 14.5% and 40% if sized less than 7, 7–12, 13–24 and more than 25 mm, respectively. The same risks for posterior circulation and PCOM artery aneurysms were 2.5%, 14.5%, 18.4% and 50%, respectively.

Most cases of aneurysmal SAH are sporadic; however, there is considerable evidence to support the role of genetic factors in the development of intracranial aneurysms. There is a strong association between intracranial aneurysms and heritable connective tissue diseases, although these form a small proportion of any case load of the order of 5%. These conditions include autosomal dominant polycystic kidney disease, Marfan's syndrome, pseudoxanthoma elasticum, Ehlers–Danlos syndrome and α_1-antitrypsin deficiency. Familial intracranial aneurysms account for 7–20% of patients with aneurysmal SAH. Approximately one-third of asymptomatic members of affected families will have evidence of intracranial aneurysms on angiography. In one study of 8680 individuals, the prevalence of asymptomatic aneurysms in the subgroups with and without a family history was 10.5% and 6.8%, respectively. The relative risk of siblings of SAH patients having a haemorrhage is six times that of the general population, with a threefold increased risk in parents – an overall fourfold increased risk in first degree relatives. Familial aneurysms tend to rupture at a smaller size than sporadic cases and often display genetic anticipation, with haemorrhages occurring at progressively younger ages in successive generations. The occurrence of aneurysms at identical and/or mirror sites is more frequent in familial cases and appears to be a function of the degree of kinship between affected individuals.

Environmental factors have been extensively studied and cigarette smoking is the only factor consistently identified, raising the risk 3–10 times that of non-smokers. This also appears to be a dose-dependent effect. The SAH risk decreases with the number of years since giving up smoking, with excess risk largely disappearing 2–4 years after cessation of smoking. Hypertension is almost certainly important but to a lesser degree, although there is conflicting evidence over its role as it is a common co-morbid condition. It seems that hypertension and smoking act as synergistic risk factors. The risk of SAH in hypertensive smokers is nearly 15 times that in the non-smoking non-hypertensive population. There is a strong temporal association between snorting cocaine (and other methods of ingestion) and both haemorrhagic and ischaemic cerebrovascular events. The use of sympathomimetic drugs, such as cocaine and methamphetamine, tend to increase the incidence and decrease the age at which aneurysmal rupture occurs; aneurysmal size at rupture also tends to be smaller.

Clinical features

The cardinal clinical feature is the sudden onset of a thunderclap headache. Headache is present in the majority of patients. This is usually of unique severity and sudden onset and is often accompanied by nausea and vomiting (77%). Thunderclap headache, although a cardinal feature, is non-specific and only 1 in 10 of those presenting with a sudden explosive headache will turn out to have had an SAH. There are no highly reliable features from the history that distinguish benign thunderclap headache from SAH. Exceptionally, bacterial meningitis can present with SAH.

Signs of global or focal dysfunction may be found depending on the severity and location of SAH. Consciousness is frequently altered, with confusion and lethargy in 30%, transient loss of consciousness in one-third and coma in 17%. In these patients, a history of headache may be lacking. Signs of meningeal irritation are found in most but not all patients and it is a common error for these either not to be elicited or misinterpreted in patients with acute headache. Neurological abnormalities are seen in 64% of cases with focal signs such as hemiparesis, IIIrd or VIth nerve palsies in 21%. Focal deficits may be caused by intraparenchymal extension of blood or later by vasospasm with resultant ischaemia and infarction.

Symptoms do sometimes help to localize the aneurysm. Anterior communicating artery (ACOM) aneurysms may present with frontal symptoms (bilateral lower-limb weakness, bilateral extensor plantars, incontinence and abulia) and electrolyte disturbance is not uncommon. Both anterior choroidal (although uncommon) and MCA aneurysms may present with hemiparesis, aphasia or visuo-spatial neglect, while peri-callosal artery and distal ACA aneurysms present with a contralateral lower limb monoparesis. A IIIrd nerve palsy suggests an aneurysm of the PCOM artery (Figure 4.16), or less commonly of the superior cerebellar artery. A painful pupil-involving IIIrd nerve palsy is usually a warning of potential imminent rupture of a PCOM artery aneurysm and should be investigated without delay.

Retinal and preretinal (subhyaloid) haemorrhages are seen in 25% of SAH patients. There are three types of haemorrhage that can occur alone or in combination with SAH:

1 Retinal haemorrhages may surround the fovea;

2 Subhyaloid preretinal haemorrhages are seen in 11–33% of cases as bright-red blood near the optic disc;

3 Terson's syndrome, consisting of haemorrhage within the vitreous humour occurs in approximately 4% of SAH cases and usually bilaterally.

Subhyaloid and vitreous haemorrhages are associated with a high mortality rate. Terson's syndrome patients who survive should be followed for the long-term complications of raised intra-ocular pressure and for retinal detachment.

Many retrospective studies comment on unusual or acute headaches predating the definite SAH by several days to weeks.

These headaches have been thought to represent warning leaks, intramural haemorrhage or aneurysmal enlargement and are sometimes called sentinel headaches. This may occasionally be the case. An alternative explanation is recall bias. A prospective study examining 148 patients with sudden onset headaches of thunderclap type showed that only 25% went on to SAH. Of these SAH patients, only two could recall a similar headache previously.

SAH tends to be misdiagnosed – as migraine or benign acute headache syndrome – typically when the headache is not catastrophic in severity, but simply sudden. Some of these SAH cases remain ambulant – and in these low back pain and sciatica resulting from local irritation by blood products can develop within 4–10 days of the haemorrhage. At the other end of the spectrum a small proportion of SAH cases are found dead, or are seen to die rapidly, within minutes or hours from massive haemorrhage.

Investigation

CT is mandatory in those with suspected SAH, generally revealing diffuse blood of a symmetrical distribution around the basal cisterns, Sylvian fissures and cortical sulci (Figure 4.15). Modern generation CT will demonstrate the presence of blood in 95% of patients scanned within 48 hours. However, blood is rapidly cleared from the cerebrospinal fluid (CSF) and the CT pick-up rate gradually decreases to 80% at 3 days, 50% at 1 week and 30% at 2 weeks. When asymmetrical or localized, the distribution of blood may suggest the location of the aneurysm in up to 70%. This is particularly important in the 10–15% of patients who harbour multiple aneurysms, when it may help to guide intervention towards the aneurysm that has bled. Intraventricular haemorrhage is characteristic of ruptured ACOM artery aneurysms; intracerebral haemorrhage is most commonly seen with PCOM artery and MCA aneurysms. Head CT can also demonstrate hydrocephalus, cerebral ischaemia or infarction, midline shift or a rebleed.

If clinical suspicion is strong and the CT is normal, lumbar puncture preferably by an experienced operator should be performed assuming there are no contraindications. If clinically appropriate this should be delayed for 12 hours from the ictus to allow time for xanthochromia (yellow discoloration) to develop. Xanthochromia of the supernatant, which is positive in almost all SAH patients between 12 hours and 2 weeks, is diagnostic. This must be determined by spectrophotometry rather than visual inspection. Negative CSF is very helpful in excluding SAH but bloodstained CSF may result from a traumatic tap. A decrease in the number of red cells from bottles one to three is a very unreliable way of supporting a traumatic tap instead of SAH. It should be remembered that patients may have had both SAH and a traumatic tap.

Conventional MRI is not sensitive to acute haemorrhage as there is too little methaemoglobin for haemorrhage to be easily differentiated from CSF. Visualization of blood products by MRI improves over 4–7 days following SAH. MRI is therefore excellent for demonstrating subacute and previous SAH, when the diagnostic yield from CT falls.

In patients with either diagnostic CT and/or lumbar puncture, or when results of these tests are equivocal, some form of arterial

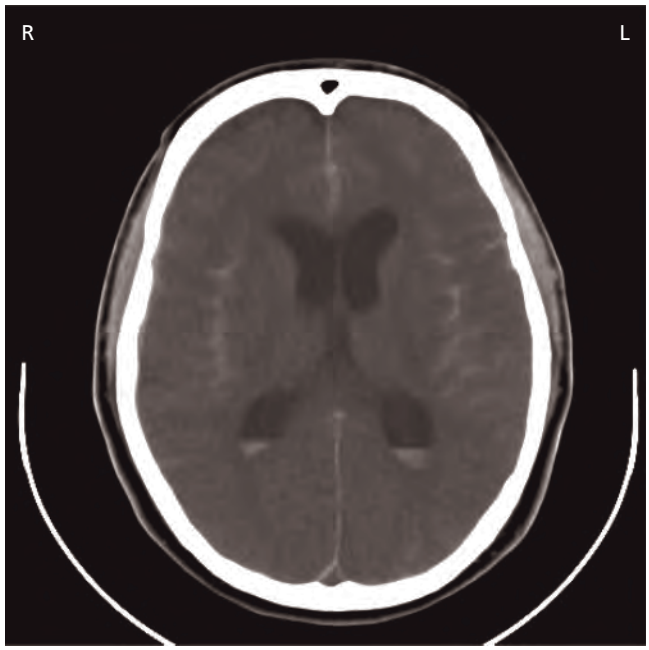

Figure 4.15 Diffuse subarachnoid and intraventricular blood (unenhanced CT).

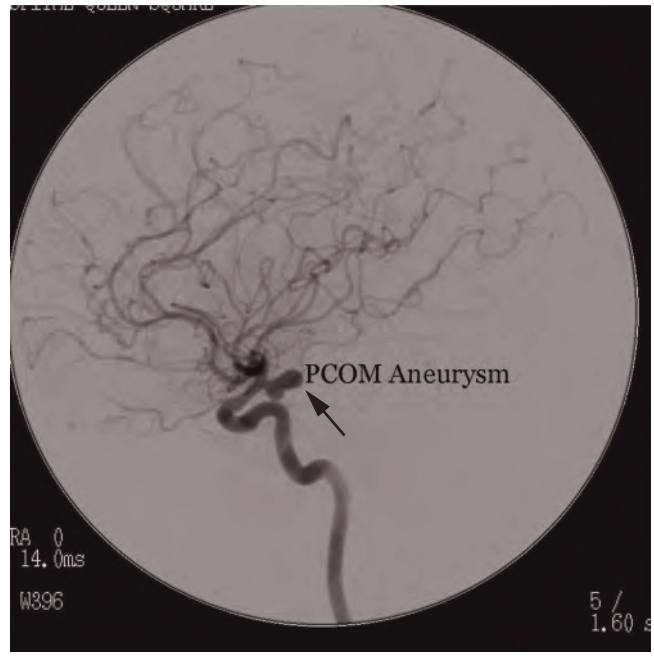

Figure 4.16 Large bi-lobed posterior communicating (PCOM) artery aneurysm (catheter angiogram).

imaging is necessary to search for a ruptured aneurysm or other lesion. Digital subtraction angiography (DSA) has been the gold standard investigation until recently, but non-invasive alternatives, including CT and MR angiography, are gaining popularity. DSA should demonstrate the aneurysmal site, type, size, orientation, neck intraluminal calcification and thrombus, the relationship between aneurysm and parent vessel, collateral flow through the circle of Willis, the presence of adjacent perforators and the state of the cerebral vasculature, including other aneurysms. In the case of multiple aneurysms, identification of the ruptured lesion may be difficult. The distribution of blood and location of any focal intraparenchymal haematoma on CT are more useful for identification. In situations where the CT reveals diffuse blood or the haemorrhage had been diagnosed on lumbar puncture, and multiple aneurysms are found subsequently, the aneurysm most likely to have ruptured is usually the largest, has greater irregularity, mass effect or associated local vasospasm.

Recent advances in three-dimensional CT angiography have meant that it now has a sensitivity and specificity approaching that of percutaneous arteriography (sensitivity 77–97% and specificity 87–100%). Imaging time is significantly reduced, allowing acquisition of the entire CT volume in 30–45 seconds during the first arterial pass of an intravenous contrast injection, with minimal patient movement artefact. Its non-invasive nature is likely to obviate the need for cerebral angiography with its inherent risks, at least as a first line investigation. MR angiography also reveals most aneurysms greater than 3 mm in diameter. The sensitivity of MR angiography for identification of aneurysms is 85–90%, with a specificity greater than 90% when compared with DSA as the gold standard, with an excellent intra-observer consistency and good-to-excellent inter-observer reproducibility. However, MRI times are significantly longer than CT. This is particularly relevant in this group of patients who are often in great pain and restless.

Despite thorough investigation, 10–15% of SAH cases have a normal angiogram. Of these, 65% will have a distinctive pattern of subarachnoid blood lying in the prepontine or perimesencephalic cisterns. These patients tend to be younger, non-hypertensive, of better clinical grade and more often male than SAH patients with angiograms positive for aneurysms. The aetiology of the SAH in these cases is unclear but the cause may be venous haemorrhage. The overall prognosis tends to be good, partly because rebleeding is rare and few patients develop delayed ischaemic deficit. However, the diagnosis should only be entertained with caution as 10% of vertebrobasilar aneurysms present with a similar distribution of blood. Repeat imaging should be considered carefully because these aneurysms can be obscured by vasospasm, hypoperfusion, poor angiographic technique or thrombosis. Such re-imaging at 2–4 weeks finds previously undetected aneurysms in 2–5% in these cases.

Initial management

General supportive care should be instituted. Stabilization of the patient, with optimization for aneurysm treatment, together with prevention of secondary cerebral insults is achieved by ensuring adequate ventilation and oxygenation, normovolaemia and haemodynamic stability and control of intracranial pressure. Frequent neurological examination is required in order to identify any neurological deterioration requiring further investigation or management.

Bed rest is generally recommended until aneurysm treatment is undertaken. Aspirin should be stopped, if it is being taken. Nimodipine, a calcium-channel antagonist has been shown to reduce the risk of cerebral infarction by 34% and as a result, poor outcome following SAH by 40%. A dosage of 60 mg 4-hourly is currently used. With a ruptured aneurysm prior to surgery or coiling, gentle volume expansion with slight haemodilution may help to return the circulating volume to normal and prevent or minimize the effects of vasospasm; however, hypertension should be avoided. Once the aneurysm has been secured, hypertension is allowed (see below), but there is no agreement on the safe range. Hyperglycaemia and hyperthermia are both associated with a poor outcome and should therefore be corrected. These problems are more often seen in poor grade patients, and their effect on outcome may therefore not be independent of presenting clinical condition. Analgesia is often required.

Aneurysm treatment

Currently, the two main treatment options for securing an aneurysm are microvascular neurosurgical clipping and endovascular coiling. Traditionally, craniotomy and clipping has been the method preferred, although the timing of surgery has been debated. The rebleeding rate from aneurysms is particularly high during the first 2 weeks, and then declines. This early high rebleed rate, which may have devastating complications, together with more recent improvements in microsurgical techniques, is the reason why early intervention is generally favoured. Securing the aneurysm will also facilitate the treatment of complications such as cerebral vasospasm. The Guglielmi Detachable Coil (GDC) has been available since 1991 and has been increasingly used in clinical practice. Detachable platinum coils are delivered endovascularly into the aneurysm. Once the correct position within the aneurysm has been achieved, the coil is detached from the wire. Multiple coils of various lengths and thicknesses are often packed into the aneurysm to exclude it from the circulation. The recently published results of the International Subarachnoid Aneurysm Trial (ISAT) suggest that patients treated by endovascular means have a 24% better chance of survival, free of disability, at 1 year than those treated surgically. The risk of epilepsy was substantially lower in patients who underwent endovascular coiling, but the risk of rebleeding was higher. Also, in patients who underwent cerebral angiography, the rate of complete occlusion of the aneurysm was greater with surgical clipping. ISAT was a landmark study that validated the technique of endovascular coiling in patients suitable for either treatment method. However, many aneurysms are not equally suitable for either microsurgical clipping or endovascular coiling. In individual cases, several factors – such as patient's age, and overall medical condition and the

aneurysm's location, size, morphology and relationship to adjacent vessels – need to be analysed by a multidisciplinary team to decide on the most appropriate treatment.

Management of complications

Neurological complications are common and include symptomatic vasospasm (46%), hydrocephalus (20%) and rebleeding (7%).

Untreated, 15–20% of patients will rebleed in the first 2 weeks, carrying with it a significant mortality (50–75%) and risk of permanent neurological disability. There is an initial peak of rebleeding in the first 48 hours of approximately 4%, which rapidly plateaus to 1–2% per day until 40 days post-haemorrhage. After 6 months there is a long-term risk of further haemorrhage of 3% per year in patients whose aneurysm has not been excluded from the circulation. The risk of rebleed is increased with poor clinical grade, posterior circulation lesions, hypertension, elderly patients and abnormal clotting.

Cerebral vasospasm is multi-factorial in origin. The mechanisms include the liberation of spasmogenic metabolites during clot lysis in the basal cisterns and impairment of cerebral vasodilatation related to endothelial dysfunction and structural changes within the arterial wall. Symptomatic vasospasm, often leading to delayed ischaemic deficit, occurs in 20–30% of patients and is at its worst 3–14 days following the haemorrhage. The severity and distribution of vasospasm are related to the amount and site of subarachnoid blood. Basal subarachnoid blood tends to be a more important risk factor for vasospasm than intraventricular blood or diffuse blood over the cortex. Other predisposing factors include increasing age of the patient, high systolic blood pressure, poor clinical grade, decreased conscious level, the presence of a motor deficit or hydrocephalus, while patients with vertebral aneurysms, predominantly intraventricular haemorrhage or a negative CT, have a lower risk of developing symptomatic vasospasm. Diagnosis of vasospasm can be difficult and is often made after exclusion of other causes of neurological deterioration such as hydrocephalus, electrolyte disturbance, seizures or a rebleed. Elevated velocities on transcranial Doppler can be useful in confirming clinical suspicion. Once identified, patients are treated with hypervolaemia and induced hypertension in an attempt to improve cerebral blood flow. In those patients refractory to medical treatment, transluminal balloon angioplasty at the site of the most severe vasospasm, or vasodilator infusion (e.g. papaverine) can be used to improve both angiographic appearances and the patient's clinical condition.

Symptomatic hydrocephalus caused by diminished CSF absorption is seen in 10–35% of patients. Acutely, hydrocephalus is treated by a period of external ventricular drainage but in the longer term, 10–15% of patients will require a permanent ventriculo-peritoneal shunt.

The highest risk of seizures is within the first 24 hours of initial bleeding, occurring at presentation in 3–18% of individuals. Epilepsy persists in 6–15% of survivors and is associated with intraparenchymal haematoma, vasospasm, MCA aneurysms, poor clinical grade, systemic hypertension, peri-operative complications, rebleed, early seizures, shunt-dependent hydrocephalus, neurological deficit and blood load.

The most common medical complications of SAH include pulmonary oedema in 23% (either cardiogenic or neurogenic), cardiac arrhythmias in 35% and electrolyte disturbances in 28% of patients. Hyponatraemia (Chapters 19, 25), is caused either by cerebral salt-wasting, with low-intravascular volume, or the syndrome of inappropriate anti-diuretic hormone (SIADH), with normal or increased intravascular volume; both, if left untreated, have a high morbidity and mortality. The distinction is important because cerebral salt-wasting is treated by aggressive fluid administration and sodium supplements, while treatment of SIADH involves fluid restriction. Fluid restriction of patients with cerebral salt wasting will worsen their hypovolaemia and will predispose them to vasospasm.

Outcome

Pre-hospital mortality is 3–26%, with an overall mortality of 45–60% in the first 30 days following SAH. Overall morbidity is some 25–33%, caused in the majority of patients by vasospasm, although initial deficits and intervention also contribute. The major predictive factors for a poor outcome are level of consciousness on admission, age and amount of blood on presenting CT. More than 50% of survivors report problems with memory, mood or neuropsychological function. Despite this, half to two-thirds of patients surviving SAH are able to return to work 1 year after presentation. Prompt physical and neuropsychological assessment for rehabilitation are important.

Arteriovenous malformations

Arteriovenous malformations (AVMs) form part of the larger group of structural cerebral vascular malformations (CVMs). Also included within this group of developmental vascular anomalies of the central nervous system are cavernous malformations, developmental venous anomalies and capillary telangiectasia. AVMs are characterized by a complex tangle of abnormal arteries and veins that lack a capillary bed but are linked either by one or more direct fistulas creating an arteriovenous shunt, or through a mass of dysplastic vessels within the nidus. Although considerably less common than intracranial aneurysms, with a prevalence of 0.14–0.5%, AVMs are an important cause of haemorrhage in patients under 40 years old. They are thought to arise from developmental derangements of the cerebral vascular system during the 40–80 mm stage of embryogenesis.

Presentation

Some 65% of individuals with AVMs present with haemorrhage at a peak age of 25–40 years. These figures may under-represent the true incidence of haemorrhage as clinically silent haemorrhage is diagnosed by imaging or at surgery in as many as 10% of patients: haemosiderin staining is seen surrounding the lesion.

It has been postulated that episodes of acute headache, seizures or other acute neurological symptoms may also represent episodes of otherwise silent haemorrhages. Risk factors for haemorrhage include increasing age, previous haemorrhage (particularly in the preceding 12 months), deep site (basal ganglia and posterior fossa especially), small size, diffuse nidus, deep venous drainage, a single draining vein and associated aneurysms. Haemorrhage may be intracerebral, subarachnoid or intraventricular. Most supratentorial haemorrhages are lobar in location, but they also occur in the basal ganglia or thalamus. In the posterior fossa, AVMs are the cause of most cerebellar haemorrhages in normotensive patients less than 40 years old. Pial-based AVMs may cause direct SAH. In most instances, however, SAH results from the rupture of an intraparenchymal bleed through the pial surface. In contrast to aneurysms, SAH from an AVM is rarely associated with vasospasm and recurrent haemorrhage within the first 2 weeks of AVM rupture occurs in only 1% of patients.

Alternative presenting symptoms in patients with AVMs include seizures in 20–30%, particularly if the lesion is large, involves the cortical surface or temporal lobe or there has been previous haemorrhage or surgery. Frontal lobe AVMs commonly present with generalized seizures, motor strip AVMs can cause Jacksonian seizures and medial temporal lobe AVMs are often associated with complex partial seizures. Patients may also present with non-haemorrhagic focal neurological symptoms. Most commonly seen in lesions within the MCA distribution, the focal symptoms are dependant on the location of the AVM. Large basal ganglia lesions may present with slowly progressive dementia, hemiparesis or visual field defect, while occasionally brainstem AVMs produce motor or sensory deficit with or without cranial nerve involvement, sometimes with patterns resembling multiple sclerosis. The cause of neurological deficit is often uncertain: recurrent haemorrhages, multiple micro-infarcts, decreased perfusion because of arterial stenoses, venous hypertension and steal phenomena have all been noted as mechanisms. Patients with AVMs often complain of headaches although, as a primary presentation, they are unusual (12%). Pain tends to be well localized, unilateral and throbbing and is often difficult to distinguish from other types of vascular headache or migraine. Headaches occur more frequently in AVMs that have a significant dural or pial component and despite treatment of the lesion, they often persist following treatment. Cranial bruits are present in as many as 25% of cases and again are more common with dural AVMs. With widespread MRI, many asymptomatic AVMs are now discovered coincidentally.

Natural history

Knowledge of the natural history of a disease is a prerequisite for evaluating the influence of any treatment on the course of that disease. This is especially true when the risks of therapy may be profound. Advances in treatment for AVMs are developing more rapidly than advances in our knowledge of their natural history. It has become increasingly difficult to identify large groups of untreated patients with AVMs for prospective study because of the availability of so many treatment options. Although it is possible to quote expected mortality and morbidity figures for AVMs on the basis of size, location and angioarchitecture, estimating the risks associated with a specific AVM is much more difficult. It is therefore important that the management of any patient with an AVM should be evaluated and planned carefully by an experienced multidisciplinary team of neurosurgeons, neuroradiologists and neurologists.

The treatment of AVMs is primarily intended to eradicate or lessen the risk of future haemorrhage. Untreated AVMs do have a significant risk of mortality and morbidity, most commonly associated with haemorrhage. In one prospective study, the annual mortality rate was 1% and that of severe morbidity 1.7%, these rates being constant over some 24 years. The long-term risk of AVM rupture for patients with symptomatic AVMs is estimated to be 2–3% per year. The risk appears higher in children and probably in those patients who have had a previous haemorrhage. Factors associated with AVM haemorrhage include small size, deep location, intranidal aneurysms, deep venous drainage and draining vein stenosis. A single haemorrhage is associated with 10–13% mortality and 30% serious morbidity. There is controversy whether or not treatment of high risk components within an incurable AVM, e.g. venous aneurysms, modifies the bleeding risk.

Management

In any patient where treatment is considered, MRI and formal angiography in expert hands is performed to define this angioarchitecture and to give precise anatomical localization (Figure 4.17). This allows the risks of treatment or conservative

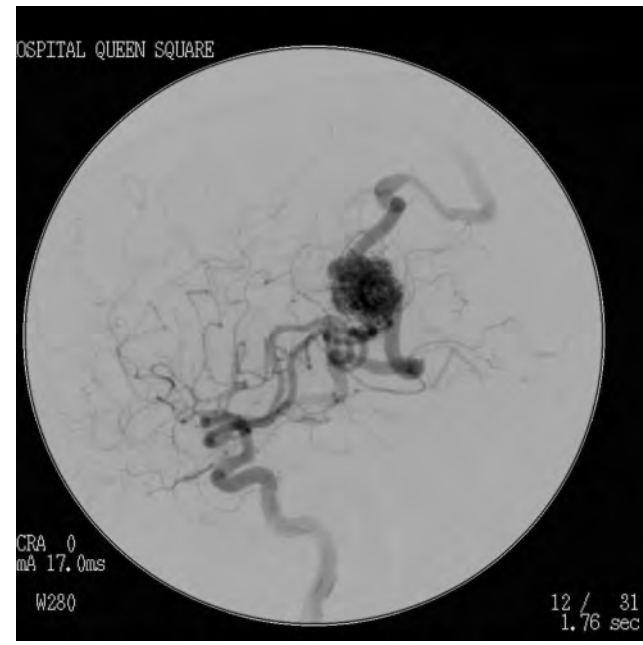

Figure 4.17 Parietal AVM (catheter angiogram).

Table 4.12 Example of surgical risks according to Spetzler–Martin grade.

Grade	No deficit (%)	Minor deficit (%)	Major deficit (%)
I	100	0	0
II	95	5	0
III	84	12	4
IV	73	20	7
V	69	19	12

management to be defined as accurately as possible. A variety of anatomical and physiological factors such as AVM size and location, number and distribution of arterial feeders, pattern of venous drainage and flow through the AVM nidus influence the technical difficulty and consequent risk of surgical, endovascular or radiosurgical treatment. The Spetzler–Martin AVM grading is commonly used (Table 4.12). This stratifies surgical risk specifically in association to the size, venous drainage and eloquence of surrounding brain and is frequently used in this decision-making process.

Many factors influence whether or how an AVM should be treated including age and co-morbidity, presentation, AVM location, size, morphology and complexity, expected natural history and treatment risks. Management plans for these lesions should only be made by a multidisciplinary team that can balance risk of treatment against expected natural history. Following rupture of an AVM, the risk of early rebleeding is significantly lower than that observed in aneurysmal rupture. Consequently, AVM treatment can be considered carefully and can often be delayed to allow the patient to recover and undergo treatment under optimal conditions.

Treatment modalities include operative resection, endo--vascular embolization and stereotactic radiosurgery, either alone or in combination. Surgical removal of an AVM is the most definitive treatment offering the best chance of lasting cure. Surgery for accessible lesions, particularly if small with single arterial supply and venous drainage, is the treatment of choice. Nevertheless, surgery carries significant mortality and morbidity. Patients should be carefully selected. Complete surgical resection should be confirmed by formal angiography postoperatively.

Endovascular embolization of AVMs is a rapidly evolving technique. The present agent of choice is *N*-butyl cyano-acrylate (NCBA). It is successful in eradicating approximately 20% of lesions. Procedural risk can be high. Between 2% and 17% have major or minor morbidity and mortality is 1–4%. The overall risk of an ischaemic complication per procedure is around 10%. Inadvertent glue deposition in normal cerebral vessels can cause infarction. Catastrophic AVM rupture from glue placement in a draining vein (raising intranidal pressure) is also a significant complication. However, endovascular treatment can be an extremely useful adjunct to surgery and radiosurgery, by reducing blood flow and eliminating surgically inaccessible arterial feeders pre-operatively. Sequential endovascular treatments can incrementally reduce the size of an AVM, making it amenable to definitive surgical or radiosurgical treatment. In some patients, endovascular treatment is useful in palliation, particularly for refractory headaches or progressive neurological deficit. However, recanalization of previously embolized segments can certainly occur in the long-term.

Stereotactic radiotherapy (Chapter 20), in particular LINAC or gamma knife radiosurgery can be used in selected patients to provide a single high dose of stereotactically localized radiation to the AVM nidus. The usual radiation dose is 20 Gy. This is administered to the margin of the nidus. This radiation causes endothelial damage, smooth muscle cell proliferation, progressive sclerosis and subsequent thrombosis of nidal vessels over time. The success of stereotactic radiosurgery depends on AVM size and radiation dose delivered. Several studies have demonstrated AVM obliteration in 80% with nidal size less than 2–3 cm diameter or 10 mL volume by 2 years. A small percentage will go on to thrombose between 24 and 36 months. The patient remains at risk of haemorrhage during this time. Delayed radiation injury, such as radiation necrosis of cortical tissue or cranial nerve palsy, is related to the radiation dose, volume treated, patient age and AVM flow characteristics. Radiation-induced tumours are very rare and generally occur many years after treatment. Radiation-related complications are correlated with the volume of normal brain tissue that receives greater than 12 Gy.

Conservative management, i.e. no intervention whatever, may be the best option in those patients with a low life-long risk of haemorrhage, e.g. asymptomatic older patients, given that all available treatment modalities have risks and the uncertainty about their benefits. Younger patients with a history of haemorrhage are now almost always offered some form of treatment. AVM cases should probably not take aspirin, nor probably non-steriodal anti-inflammatory drugs unless there is good reason.

Cavernous malformations

Cavernous malformation (CM), also called cavernous angiomas, cavernomas or cavernous haemangiomas, have a prevalence around 0.5% in the population. A retrospective review of MRI scans reported a detection rate of 0.4–0.9%. They are uncommon in children and have a peak incidence in the fourth and fifth decades of life. Overall, they account for 10% of all symptomatic intracranial vascular abnormalities. They can be familial and are often multiple.

Grossly, CMs are well-circumscribed, lobulated, raspberry-like lesions that vary from a few millimetres to several centimetres in diameter. Microscopically, they consist of a tangle of intertwined cluster of sinusoidal vascular channels that have one layer of endothelial lining and a variable layer of fibrous adventitia. Radiological evidence of previous haemorrhage, usually silent, is common, and there is often thrombosis within the dilated venules.

CMs are commonly asymptomatic but they may present with seizures or haemorrhage. Occasionally there is a progressive development of a neurological deficit, most likely to be caused by recurrent small bleeds. The frequency of haemorrhage among those who present either incidentally or with seizures is 0.4–2% per year. Among those presenting with symptomatic haemorrhage, the annual recurrent risk of haemorrhage is higher: 4–5% in the subsequent year. The risk of haemorrhage does appear to be dependent on location; there is a higher risk associated with deep lesions – brainstem, cerebellum, thalamus and basal ganglia. CMs are most readily seen on MRI as a combination of high and low T1 and T2 signal with surrounding haemosiderin (Figure 4.18). They are angiographically occult.

Surgery is usually considered in patients with multiple haemorrhagic episodes and sometimes in those with poorly controlled seizures. Most surgeons have a high threshold for advising surgery for CMs; but excision, even for those CMs in critical locations, often has an unacceptable morbidity. Radiosurgery has also been carried out but it is unclear whether it alters the natural history. The concept that CMs tend to bleed in clusters supports the decision to treat CMs with stereotactic radiosurgery. Some studies suggest a reduced haemorrhage rate, usually after a 1–3 year latent period.

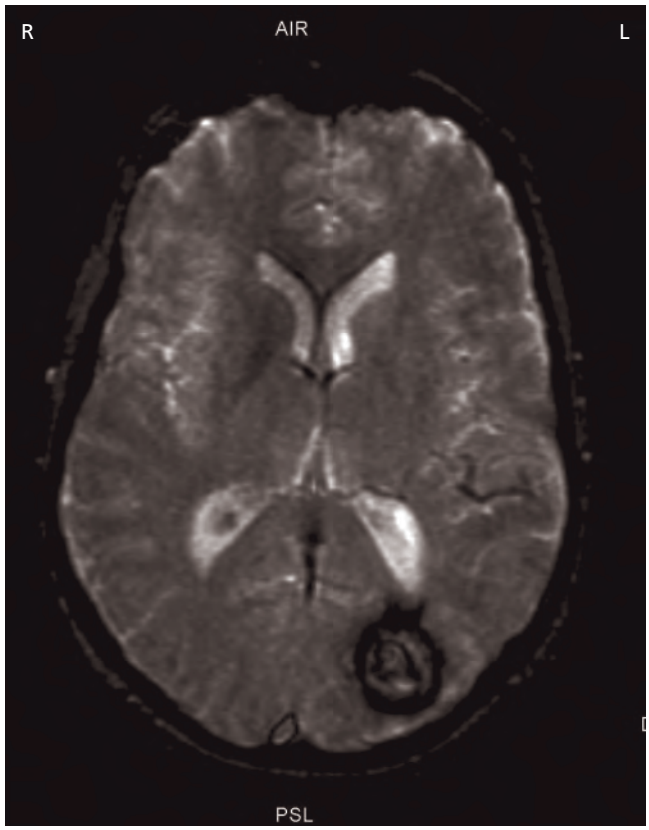

Figure 4.18 Occipital cavernoma (MRI T2*).

Dural fistulae

Dural arteriovenous fistulae (DAVF) are rare and can be found from adolescence to old age. They are most common in young adult women. They consist of an arteriovenous fistula with multiple arteries converging on a single venous structure. They are primarily fed by dural arteries but high-flow lesions can recruit pial branches. Different patterns of venous drainage are seen, e.g. drainage into a sinus with or without flow restriction or drainage into cortical veins either directly or by reflux from a venous sinus.

DAVFs are thought to be acquired lesions probably a result of venous thrombosis, usually silent, with development of collaterals. They may be located anywhere within the intracranial dura, although most are found adjacent to major dural venous sinuses, particularly the transverse sinus. Symptoms and signs differ greatly but are in the main caused by the pattern of venous drainage. Significant symptoms include haemorrhage, neurological deficit and intracranial hypertension. The overall risk of haemorrhage is approximately 2% per year; much depends on site and haemodynamics of the lesion. Rather than bleeding, common features are audible bruits, cranial nerve palsies and ocular signs such as papilloedema.

Head CT rarely detects a DAVF, although dilated veins may suggest its presence. MRI may demonstrate dilated feeding vessels and veins but is neither sensitive nor specific. Six vessel angiography, i.e. including the external carotid arteries, is necessary to detect and delineate a fistula accurately and is the optimal investigation.

Treatment of DAVFs has evolved over the last three decades. Cortical venous drainage is a risk factor for haemorrhage. Action is required in these cases. Patients without cortical venous drainage and without threat of visual loss from papilloedema have a benign natural history and may require no therapy. Treatment of these patients is justified only if the risk of complication is low. Sometimes palliation is necessary. The primary treatment has been surgical disconnection of the fistula and resection of the dural segment and venous sinus. Not surprisingly, this carries a high risk of substantial blood loss and morbidity. Recently, there has been less emphasis on resection of the venous sinus. This has proved as effective as sinus resection and the risk of venous infarction is lower. Therapeutic embolization can be used for either palliation or attempted cure. This can be achieved via transarterial and/and transvenous routes. DAVFs can also be treated with stereotactic radiosurgery with or without endovascular embolization of accessible feeding vessels. Partial prior endovascular treatment aims to reduce the risk of haemorrhage prior to the later obliteration of the DAVF by stereotactic radiosurgery.

Investigation of stroke and TIAs

Stroke investigation is aimed at identifying risk factors and confirming or refuting the clinical diagnosis. Investigation nearly always improves the clinician's understanding of the

pathophysiology of the stroke or transient ischaemic syndrome. This then guides acute treatment and secondary preventative measures. It is facile to separate completed stroke from TIAs when considering appropriate investigation. The aetiologic spectrum is identical, although management may be very different.

Basic investigations for all

Simple tests

In all patients, basic blood screening should include full blood count to look for anaemia, polycythaemia, thrombocythaemia and thrombocytopenia. Anaemia of chronic disease may be a marker for endocarditis. Exceptionally, haematological malignancies may be complicated by stroke. Basic coagulation analysis should be undertaken in patients with haemorrhage and is especially important in those receiving anticoagulants or any other medication. Urea and electrolytes guide homeostatic management in the acute phase and may also reveal end-organ damage from hypertension. Patients with significant electrolyte disturbance may present with global or focal dysfunction. Plasma glucose is an essential triage test; diabetes is common and hypoglycaemia can cause focal signs. Hyperglycaemia is also associated with severe stroke. Rarely, hyperosmolar non-ketotic diabetic coma presents as a stroke. Basic lipid analysis for cholesterol and fasting triglycerides should be performed in all. Syphilis serology should be performed if the patient has been at risk at any time. Erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) are non-specific screening tests for inflammatory arterial disease and endocarditis. Blood cultures and repeated urine examinations should be carried out if there any question of endocarditis. Thyroid function tests should be performed in all patients especially those with atrial fibrillation. In all patients, chest X-ray and electrocardiography (ECG) should also be carried out. The principal point of chest radiology is to establish the presence of a normal cardiac silhouette and look for consolidation. The ECG changes of note are left ventricular hypertrophy secondary to hypertension, previous or acute MI (possible cardiogenic embolus) and most importantly atrial fibrillation or other unsuspected dysrhythmia.

Imaging

Neuroimaging is essential. Although MRI is greatly superior to CT, it is not currently widely available as a routine acute investigation. Initial CT is performed to distinguish infarction from haemorrhage or reveal mimics of the stroke syndrome such as tumour or subdural haematoma. In the early stages depending partly on time interval, the size of infarction and the skill of the radiologist, CT may be negative. Only 50–70% of infarcts are ever visible with CT. It has become generally accepted that CT can diagnose a haemorrhage >0.5 cm accurately, i.e. exclude it, and indeed it is preferable to conventional MRI in the acute phase. However, patients with microhaemorrhage on gradient echo MRI may present with minimal impairments when CT and conventional MRI are normal. The very early CT changes of stroke are subtle, but the ability to read these is crucial in making decisions about the suitability of a patient for thrombolysis. The very early stages of cytotoxic oedema in the MCA territory are indicated by loss of the insular ribbon, and effacement of the sulci with obscuration of the lentiform nucleus, shown in Figure 4.19.

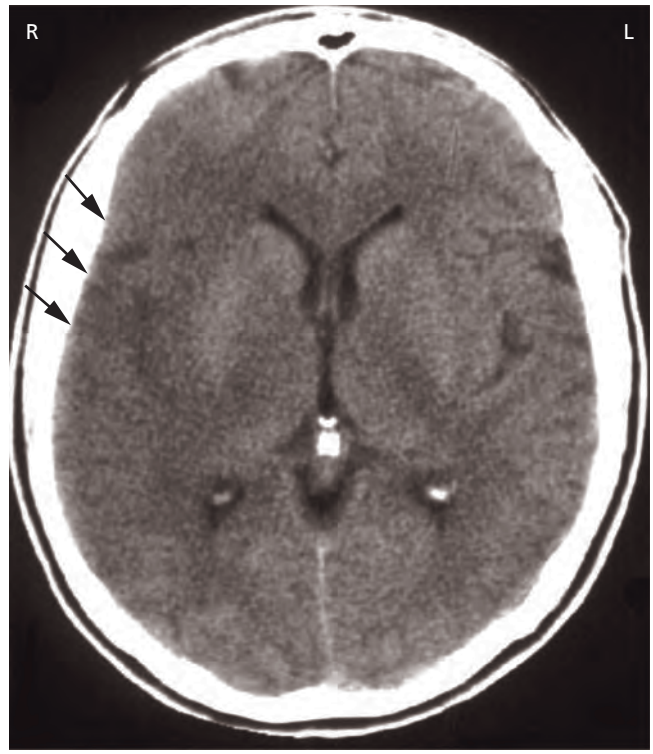

Figure 4.19 Early partial right hemisphere infarction following MCA occlusion. There is effacement of right temporal sulci, obliteration of the Sylvian fissure, with slight hypo-attenuation of the cortex, right temporal lobe and of the insula (unenhanced CT).

CT can indicate clearly large vessel occlusions (e.g. a dense outline of the MCA), pointing to a central cause for embolism, or multiple haematomas suggestive of amyloid angiopathy or vasculitis. The size of the infarct or haemorrhage will provide useful information relating to prognosis and the presence or likelihood of subsequent brain swelling. A small infarct in the territory of a lenticulo-striate penetrating vessel suggests a completed vascular syndrome, but if the anatomy suggested a more proximal MCA source then this would indicate the whole MCA territory is at risk. The role of CT in the diagnosis of SAH is discussed above.

MRI is a far more sensitive investigation than CT for both stroke and non-stroke pathology. It is especially superior in the posterior fossa and for revealing small areas of infarction secondary to penetrating vessel occlusion. Sophisticated multimodal imaging can also be used to distinguish acute from chronic infarction and may demonstrate microhaemorrhage. These techniques are likely to become critical to deliver safely hyperacute treatments such as thrombolysis. MRI has high sensitivity to detect

cerebral venous thrombosis and can be used in conjunction with MR angiography to detect dissections of the carotid and vertebral arteries. The two most useful newer MR sequences are diffusion weighted imaging and susceptibility T2* sequences. Diffusion weighted imaging (DWI) maps the constant diffusion of water. This rapidly becomes abnormal after ischaemia returning a 'light bulb signal' indicative of restricted diffusion resulting from cytotoxic oedema. This usually indicates completed infarction but this is not absolute; some reversible diffusion changes have been demonstrated. Older infarcts may also appear bright on DWI ('T2 shine-through'), but these can be distinguished from acute infarcts by examining the Apparent Diffusion Coefficient (ADC) images that show acute infarcts as dark. DWI can be matched with clinical examination, MR perfusion imaging and MR angiography to ascertain whether there are salvageable areas of brain. In addition, DWI commonly refines the pathophysiological diagnosis of stroke, by separating into time intervals different areas of infarction and demonstrating acute multi-territory changes suggestive of cardiac embolus, not apparent on conventional MRI.

MR T2* sequences help demonstrate areas of microhaemorrhage not visible on conventional MR or CT. The distribution of these microhaemorrhages may point to amyloid (superficial location) or severe hypertensive arteriopathy (deep location). Patients with microhaemorrhage are at higher risk of primary intracerebral haemorrhage and have a more severe form of small vessel disease than those without haemorrhage.

In patients with haemorrhage in whom a non-hypertensive aetiology is suspected, it is necessary to exclude an AVM. In some this can be adequately achieved with MRI and/or MR angiography delayed until resolution of the haematoma. However, many such patients will require catheter angiography.

Conventional MR sequences are also useful in the diagnosis of cervical artery dissection (see below). MRI is sensitive and specific when used to image in cross-section the carotid artery from the bifurcation to the skull base. The vertebral artery is harder to image accurately and false positives are common and secondary to the vertebral venous plexus returning a 'dissection type' signal. MR angiography is also helpful here.

Whatever imaging modality is available, information derived should be used to build up the pathophysiological profile and to guide management. Most importantly, the imaging abnormalities must be concordant with the clinical picture. For example, the presence of acute or old infarction in non-symptomatic vascular territories should focus further investigation toward a central embolic source. Also, extensive asymptomatic small vessel disease is a risk factor for cerebral haemorrhage and help refine a decision away from anticoagulation in a patient in atrial fibrillation.

Imaging also has a critical role in managing patients with stroke who may benefit from neurosurgical intervention.

The recommendations published in 2004 by the UK Royal College of Physicians is that brain imaging should be undertaken as soon as possible in all patients within 24 hours of onset at the most, unless there are good clinical reasons for not doing so. It is likely that this guideline will be shortened to 3 hours given recent evidence that immediate scanning of suspected stroke is the most cost-effective strategy. Urgent (i.e. at 3 AM) imaging is recommended in a number of circumstances (Table 4.13).

Table 4.13 Recommendations for urgent imaging in stroke based on the Royal College of Physicians National Clinical Guidelines.

If thrombolysis or immediate anticoagulation is contemplated
If clinical deterioration or fluctuation occurs
If there is severe headache at onset or subarachnoid haemorrhage is suspected
If hydrocephalus secondary to intracerebral haemorrhage is suspected
If trauma is suspected
In patients on anticoagulants or with a known bleeding tendency
If the diagnosis is in doubt
If there is depressed consciousness, papilloedema, neck stiffness or fever
If there are unexplained progressive signs.

Many of these recommendations relate to the simple yet important principle that any patient with a depressed level of consciousness may need urgent neurosurgical intervention. One of the most important recommendations is that patients on anticoagulants should be imaged immediately.

Guided investigations following basic profile

Imaging, simple tests and the clinical profile should build up the pathophysiological diagnosis sufficiently to direct further investigation. Ischaemic stroke within the carotid territory should prompt the search for carotid stenosis. This is obviously essential in those in whom secondary preventative surgery would be considered. The emphasis is on non-invasive imaging, in preference to invasive techniques such as catheter angiography. Both MR angiography and duplex imaging are useful. If either is completely normal then the screen is adequate. If either suggests carotid stenosis greater than 50% or occlusion then it is very useful to carry out both tests. If they are concordant one can assume that the information is accurate. In patients in whom the information is non-concordant it may be necessary to perform contrast-enhanced MR angiography or formal catheter angiography. It should be appreciated that catheter angiography carries the risk of causing stroke, fatal or severely debilitating, especially in those with severe atherosclerosis, and it has other hazards (see below).

Ultrasound of the neck vessels in real time mode provides images in several arterial planes. It is accurate in experienced hands, at the carotid bifurcation, the major area of interest in most cases. It has a good sensitivity and specificity for occlusive lesions, but has limitations. Sometimes, the vertebral origin is difficult to image and small clots and ulcers are difficult to image at any site. Calcification may obscure the visualization of a stenosis. Arteries may be misidentified. For example, a carotid occlusion may be reported as trickle flow by mistaking a small cervical artery for the carotid. When real time mode is combined

with Doppler the system is called duplex. The Doppler analyses flow patterns (average velocity of blood moving through a vessel) and the B mode the anatomy – the combination is better than either alone. Stenosis of an artery above a certain threshold increases peak systolic and diastolic blood flow velocity. Duplex is widely available and non-invasive but there are some difficulties. It is operator dependent and requires considerable experience. It is not completely sensitive or specific for high-grade stenosis.

Doppler can also be applied transcranially (TCD) and has significantly advanced the study of stroke. TCD can accurately detect atherosclerotic lesions in the intracranial ICA, MCA, intracranial vertebral artery the mid and proximal basilar. TCD may be used to detect emboli, acutely image intracranial vessel thrombosis and in some centres it has been used in combination with thrombolysis as a mechanical aid to clot dissolution. TCD may also be used to detect systemic right to left shunts, e.g. through a PFO. Agitated saline can be injected into a vein and the MCA insonated for arrival of small bubbles with a Valsalva manoeuvre.

Another safe sensitive non-invasive technique is MR angiography. MR angiography can accurately visualize the carotid bifurcation but may overestimate the degree of stenosis. MR angiography of the vertebral origin from the subclavian is disappointing in most cases, but the portions of the vertebral artery within the neck and within the intravertebral foramina are well shown. MR angiography (MRA) of the intracranial circulation is providing a useful screening tool both for aneurysms and occlusive disease.

The advent of MRA and duplex has led to a steady decrease in the indications for catheter angiography but this technique is still useful in selected circumstances. Intra-arterial angiography carries a small but definite risk of causing a stroke. The commonly quoted figure is 1% but inexperienced operators have a higher risk. The catheter or contrast can dissect the femoral artery and/or cause 'trash foot' as a result of dislodging aortic or arterial atheroma. Contrast medium can occasionally precipitate renal failure and provoke allergic reactions. Some patients develop alarming, but usually temporary blindness after vertebral injections. The decision for angiography should be made carefully in a multi-disciplinary setting. The non-invasive tests must have been carried out first and usually a therapeutic decision must follow catheter angiography if this is to be performed. It is necessary to perform angiography in a number of vascular situations. In occlusive carotid disease, angiography may clarify discordant results from non-invasive tests, e.g. MRA suggests a 90% stenosis but duplex 50%. It may clarify sites not visible on non-invasive testing or subject to artefact (Figure 4.20). Catheter angiography is able to detect smaller aneurysms than MRA and is necessary following SAH when MRA is negative. It can be used to screen for underlying vascular malformations when MRI and MRA are normal and is often the only way of detecting dural fistulae. Despite the sophistication of MR venography, the venous phase of a catheter angiogram is superior and can clarify anatomic

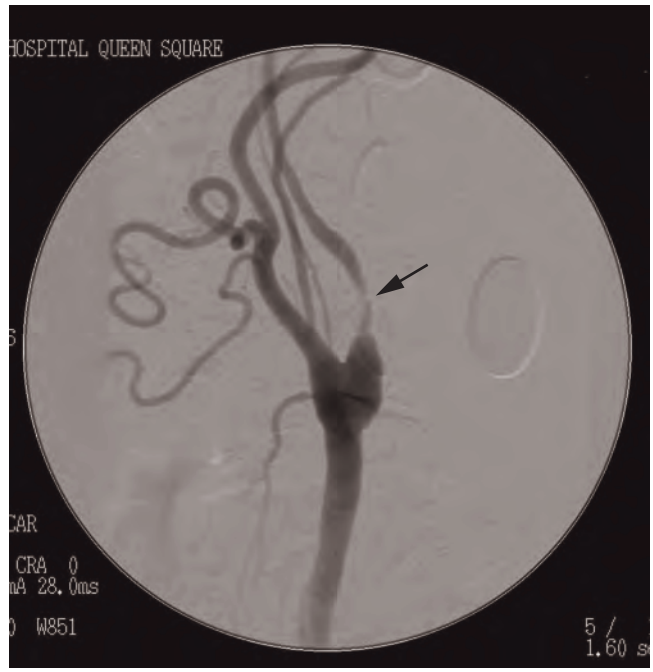

Figure 4.20 Severe left internal carotid artery stenosis (catheter angiogram).

variants less clearly interpretable on MR. Currently, three-dimensional CT angiography is also improving and is likely to take over from catheter angiography in many cases.

The degree of carotid stenosis is defined currently by three different methods other than angiography. It is important to know which method is being discussed as the values differ; so does the evidence on which intervention is based. All three methods measure the diameter of the stenosis at the site of the maximal narrowing of the artery but the proportional stenosis that they produce is then calculated from different estimates of what the normal artery should have measured at that point, as the denominator. The European Carotid Surgery Trial (ECST) method used an estimate of the normal luminal diameter at the site of stenosis. In the North American Symptomatic Carotid Endarterectomy Trial (NASCET) it is based on the distal carotid artery diameter. In the common carotid method, it is based on the common carotid diameter. These produce different measurements. The NASCET method produces a lower percentage stenosis than the ECST or common carotid methods for the same lesion at the carotid bifurcation.

Cardiac investigations

In patients with suspected cardiogenic embolus, transthoracic echocardiography can define wall motion abnormalities or the presence of atrial or ventricular thrombus. In selected patients with prosthetic valves, suspected aortic root disease and right to left shunts TOE provides better visualization than the transthoracic mode. If cardiogenic embolus is still strongly suspected despite normal chest X-ray, ECG and echocardiogram then

sometimes Holter monitoring may be useful to reveal paroxysmal atrial fibrillation; monitoring may need to be prolonged. Echocardiography has a high yield in patients with known cardiac disease, with systemic embolic phenomena and when the stroke pathophysiology points to cardiac embolism (e.g. PCA occlusion). TOE is undoubtedly superior to transthoracic insonation, particularly as the left atrium is directly anterior to the oesophagus. TOE also visualizes the proximal aorta, e.g. for atherosclerosis. If previous blood cultures have been negative, consider repeating them.

Special investigations

Thrombophilia assessment is rarely useful in arterial stroke with the exception of antiphospholipid antibodies. It should be noted that antiphospholipid antibodies can be associated with many sorts of vasculopathy and they are not uncommonly seen coincidentally in patients with atherosclerosis. Venous thrombophilia may be relevant in the rare circumstance of a positive family history of thrombosis associated with embolic stroke through a PFO. Autoantibodies may mark a systemic vasculitis. In appropriate circumstances, screening for common mitochondrial and NOTCH III (CADASIL) mutations, leucocyte galactosidase A for Fabry's disease, homocysteine, syphilis and HIV serology should be carried out. Very occasionally, if an infective aetiology is suspected it will be necessary to examine the CSF. Drug screening should be carried out if drug abuse is suspected.

Management of acute stroke

Over the last two decades, stroke has changed from being seen as untreatable, to a condition where there is now a range of options for acute interventions, shown conclusively to improve outcome. In the first few hours after stroke, measures are designed to restore blood flow (reperfusion), preserve the ischaemic penumbra (neuroprotection) and prevent early recurrence (aspirin treatment). Admission to a stroke unit and multidisciplinary rehabilitation are vitally important and are complementary to medical treatments. It is now well-recognized that rehabilitation should start as soon as possible after onset of stroke (Chapter 17), aiming to optimize recovery, enhance neural plasticity and facilitate functional adaptation to any residual impairments as far as possible. Active rehabilitation consists of measures designed to facilitate and enhance recovery from impairments, such as physiotherapy training and measures to improve function, e.g. the provision of aids such as a walking cane, wheelchair or modified utensils. Part of successful rehabilitation requires the setting of goals. Successful stroke unit care also pays attention to the prevention of complications and the prevention of recurrent stroke, as described below.

An early accurate diagnosis of the underlying pathological cause and mechanism of stroke should have been made to guide appropriate therapy. In particular, it is essential to distinguish between haemorrhage and infarction by brain scanning. Ideally, a CT or MRI scan should be performed as soon as the patient is admitted to hospital. Most initial treatments are given without clear knowledge of the underlying pathology, apart from the distinction between haemorrhage and infarction, but it should be borne in mind that treatments such as thrombolysis, designed to lyse a clot, are unlikely to be effective if the cause of ischaemia is arterial occlusion by atheromatous debris or a dissecting haematoma. On the other hand, identification of the mechanism of stroke may lead to specific therapies, e.g. antibiotics for bacterial endocarditis, in addition to more generic treatments.

Organized care in a stroke unit

One of the most important aspects of stroke treatment is quite simple. It is to treat patients in an organized stroke unit. The trials of stroke unit care show that about 1 in 12 patients are saved from death or being dependent by being cared for on an organized stroke unit rather than in a general medical ward. The same benefits cannot be achieved by providing a mobile stroke team visiting general medical wards in hospital, nor by visiting patients in their own homes. More patients are discharged from stroke units to their own homes without increasing average length of stay. The benefits of stroke unit care appear to apply equally to elderly and young patients, to both genders and irrespective of whether the stroke is mild, moderate or severe. All patients should therefore be admitted to an acute stroke unit as soon as possible after onset, irrespective of age, gender or clinical severity, for multidisciplinary assessment and treatment. It is likely that all patients benefit from the provision of information, the positive attitudes to stroke and the organized provision of care on an organized stroke unit. From a public health perspective, the benefits of stroke unit care arising from the overall prevention of death, reduction in disability and need for institutional care are considerable when compared with individual pharmacological treatments. Also, organized stroke care is unlikely to harm anyone.

The reasons why organized stroke care benefits patients are complex. Factors identified that characterize stroke unit as opposed to general medical ward care (e.g. a discrete geographical area, multidisciplinary team meetings) are to some extent epiphenomena of a more fundamental difference. This simply is having an effective team that has ownership of the patient's problems and a responsibility to address them. The complex problems of patients with stroke go far beyond the strict medical issues and cannot be effectively addressed by a disjointed approach. It is likely that the benefits from organized care result first from better care of the acute patient (e.g. accurate diagnosis, appropriate use of drugs, prevention of swallowing complications/hypoxia/hypovolaemia, appropriate treatment of pyrexia, hyperglycaemia) leading to less secondary brain damage. Secondly, coordinated goal-orientated rehabilitation and discharge planning is a totally different proposition to more fragmented delivery of rehabilitation. Patients with intracerebral haematomas often gain considerably and as much from organized care as patients with ischaemic stroke. In contrast to ischaemic stroke, they take much

longer to start to recover and need careful supportive care during this time.

The benefits of stroke unit care in the randomized trials were maximal when patients were admitted within a week of onset. The benefits are likely to be even greater where patients are admitted acutely for monitoring and provision of acute treatment such as thrombolysis. There are strong arguments for patients to be admitted to an acute stroke unit directly from the community or from the A&E department. Several models of service delivery of acute stroke care exist, depending on local circumstances. Some acute stroke units keep patients for 2–7 days before discharging those who require further therapy to a rehabilitation stroke unit. Other units combine acute and early rehabilitation care on one ward, keeping patients for up to 6 weeks before discharging them home or to alternative rehabilitation facilities. These facilities include community rehabilitation centres, community stroke teams providing treatment at home, rehabilitation facilities for care of the elderly and specialized neurological rehabilitation units.

Specific treatments for acute stroke

Thrombolysis

Thrombolysis is one of the most exciting, controversial and complex recent developments in stroke medicine. The first thrombolytic agent to be tried in acute ischaemic stroke in the 1980s was streptokinase, but this agent was found to cause an unacceptable incidence of cerebral haemorrhage and was abandoned. Later trials showed that alteplase, a recombinant tissue plasminogen activator, was far safer. The most convincing benefits of intravenous alteplase were shown in the National Institute of Neurological Disease and Stroke (NINDS) study, which randomized patients within 3 hours of onset of ischaemic stroke, half within 90 minutes of onset. The trial required a CT before treatment, and blood pressure was carefully controlled in those with raised readings, using intravenous drugs if necessary. One in 8 patients treated benefited in terms of making a full, or nearly full, recovery and the proportion of patients achieving a Rankin Grade 0 or 1 score at 3 months follow-up was 39% after alteplase treatment, compared to 26% after placebo. This benefit was accompanied by a significant risk of symptomatic intracranial haemorrhage after alteplase of 6%, compared to 1% in the placebo group. There was no significant difference in mortality rates between the two groups.

Subsequent trials of alteplase randomized patients up to 6 hours after onset of ischaemic stroke, but failed to show the striking benefits of the NINDS 3 hour study. Subsequent meta-analysis, combining the results of all previous major trials of intravenous thrombolysis with alteplase, has shown that there is a linear relationship between the time to treatment and the chances of benefit: the earlier patients are treated the better. These results led to alteplase receiving a licence for use in North America, Europe and elsewhere. The European Union licence has strict conditions, including limiting use to 3 hours from onset of stroke and insists that only experienced teams with neurological training should administer the drug. Beyond 3 hours from onset, the benefit remains uncertain. Further randomized trials are in progress to see whether the time window can be extended beyond 3 hours and to determine whether there are subgroups who benefit more or less from treatment within 3 hours.

Intravenous thrombolysis should only be offered to patients according to established protocols if they satisfy the inclusion criteria (Table 4.14). Patients treated with thrombolysis outside

Table 4.14 Guidelines for intravenous alteplase in acute ischaemic stroke.

Eligibility
Age 18 years or older
Clinical diagnosis of acute ischaemic stroke
Assessed by experienced team
Measurable neurological deficit
Glasgow Coma Score >8
Timing of symptom onset well established
CT or MRI and blood tests results available
CT or MRI consistent with diagnosis
Time since onset <3 hours at start of infusion
Exclusion criteria
Symptoms only minor or rapidly improving
Haemorrhage on pre-treatment CT (or MRI)
Suspected subarachnoid haemorrhage
Active bleeding from any site
Recent gastro-intestinal or urinary tract haemorrhage within 21 days
Platelet count less than 100×10^9/L
Recent treatment with heparin and APTT above normal
Recent treatment with warfarin and INR elevated
Recent major surgery or trauma within the previous 14 days
Recent post-myocardial infarction pericarditis
Neurosurgery, serious head trauma or previous stroke within 3 months
History of intracranial haemorrhage (ever)
Known arteriovenous malformation or aneurysm
Recent arterial puncture at non-compressible site
Recent lumbar puncture
Blood pressure consistently above 185/110 mmHg
Abnormal blood glucose (<3 or >20 mmol/L)
Suspected or known pregnancy
Active pancreatitis
Epileptic seizure at stroke onset
Cautions and limitations
Age >80 years
Severe neurological deficit (NIHSS >22)
Visible changes on pre-treatment CT of infarction > one-third of MCA territory
Diabetic retinopathy

APTT, activated partial thromboplastin time; CT, computerized tomography; INR, international normalized ratio; MCA, middle cerebral artery; MRI, magnetic resonance imaging; NIHSS, National Institutes of Health Stroke Scale.

the strict protocol have an unacceptable rate of complications, especially intracranial haemorrhage. Training and experience are required to diagnose stroke, exclude stroke mimics and interpret CT appearances in acute ischaemic stroke. Established infarction shows on the CT as a well-defined area of low attenuation. However, the early changes of infarction are often subtle. In MCA territory infarction, these include loss of distinction of the internal capsule and insular ribbon cortex, loss of cortical definition between grey and white matter, and effacement of the sulci (Figure 4.19). Although not part of the NINDS protocol, most experts would exclude patients with early signs of infarction involving a large proportion of the MCA territory, because such signs imply that ischaemia has already progressed to irreversible infarction. Patients and relatives need to accept that although thrombolysis provides a chance of some real benefit, there is also a risk of harm from cerebral haemorrhage. Patients should not be denied thrombolysis if consent cannot be obtained, e.g. because of aphasia. It is essential that the timing of symptom onset should be well established, so that patients are only treated within the guidelines, currently within 3 hours of onset. For example, patients who wake from sleep with deficit from an ischaemic stroke are not eligible for thrombolysis with alteplase.

Only a proportion of patients will be suitable for thrombolysis, especially because many patients will not reach hospital within 3 hours of onset. Nevertheless, changes in service delivery are required to institute thrombolysis, e.g. development of acute stroke teams and protocols to ensure that patients are scanned with alacrity. The proportion of patients reaching hospital in a timely fashion can be increased by joint hospital and ambulance service protocols, involving training of ambulance personnel in the recognition of stroke, so that patients with suspected stroke are taken directly to an acute stroke centre. Education of the public to recognize stroke symptoms and to summon emergency ambulance services immediately is also required.

In the future, selection of patients with persisting penumbra may play a part in selecting cases for thrombolysis. For example, a mismatch between a small area of infarction shown on DWI and of impaired cerebral blood flow shown on perfusion MRI may be an indication of salvageable penumbra, and this could allow the extension of the window for thrombolysis beyond 3 hours in patients who arrive late and have persistent mismatch. Alternative thrombolytic agents may also allow the time window to be prolonged. For example, desmoteplase shows promise as an intravenous thrombolytic agent when administered within 3–9 hours of ischaemic onset in patients with MRI perfusion–diffusion mismatch, but the agent needs to be tested in larger randomized trials. CT perfusion imaging is an alternative to perfusion MRI that may become more widely applicable in the future.

Another experimental approach to improving the effectiveness of thrombolysis is to combine intravenous alteplase with therapeutic transcranial ultrasound applied to the skull and focused on the site of arterial occlusion. Experimental studies have shown that ultrasound improves the activity of clot lysis, presumably by facilitating access of the thrombolytic drug to the core of the thrombus. Clinical trials have suggested an improvement in recanalization rates with continuous transcranial Doppler ultrasound given for a 2-hour period after administration of intravenous alteplase. Again, larger trials are required to demonstrate the benefit of this approach.

The majority of evidence in favour of thrombolysis relates to the intravenous route of administration. This reflects the ease and rapidity with which an intravenous transfusion can be administered. On the other hand, local arterial infusion of thrombolytic agents has the advantage that a preliminary angiogram can be performed to confirm arterial occlusion, and that the agent can be infused exactly where it is needed. Case series and the PROACT II randomized trial suggest that intra-arterial thrombolysis can be highly effective, even up to 6 hours after onset in selected patients. However, intra-arterial thrombolysis requires specialized facilities and experienced neuroradiologists, limiting its widespread applicability. Moreover, the need to establish arterial access increases the delay to treatment compared with the intravenous route. There are therefore studies in progress investigating the benefits of arterial thrombolysis following an initial intravenous dose of alteplase, to determine if this combination results in superior outcomes in patients who do not initially benefit from an intravenous agent. Intra-arterial thrombolysis may also have a particular role in patients with basilar artery thrombosis, possibly up to 12 hours after onset, particularly if infarction in the posterior circulation has not yet developed.

Mechanical recanalization

A number of devices are being developed to extract or break up thrombus occluding the larger intracranial blood vessels following acute ischaemic stroke, using microcatheters inserted via an endovascular approach. The use of mechanical devices will require specialized facilities and experienced operators, but in appropriate centres, the technique may provide an alternative to thrombolysis or an additional therapy for patients in whom thrombolysis has failed to achieve effective reperfusion.

Antiplatelet therapy in acute stroke

Two very large randomized trials have shown that aspirin, given within 48 hours of onset, has a small but significant benefit in reducing the rate of recurrent ischaemic stroke. About 1/100 patients treated with aspirin avoid death or disability without a significant increase in the risk of symptomatic cerebral haemorrhage. Although this benefit seems small, it translates into a substantial cost effectiveness, given the commonness of stroke and the low cost of aspirin. For example, in the UK it is estimated that if everyone with stroke were given aspirin within 48 hours of onset, preferably after a CT scan to exclude cerebral haemorrhage, then more than 1000 patients would be saved from death or disability every year. Aspirin has not been extensively studied in patients with cerebral haemorrhage, but the majority of experts and emergency physicians consider aspirin contraindicated in any cerebral haemorrhage or if there is substantial haemorrhagic transformation within an ischaemic stroke.

Currently, there are no randomized trials of antiplatelet agents other than aspirin, to establish their safety within the first week or so after the onset of stroke. Aspirin therefore remains the agent of choice in acute ischaemic stroke. We recommend a loading dose of aspirin 300 mg, followed by 75 mg daily. We would only use an alternative antiplatelet agent within the first week after onset in patients allergic or intolerant of aspirin. Antiplatelet therapy for longer term prevention is discussed below.

Anticoagulation in thrombo-embolic stroke

A large number of randomized trials have failed to demonstrate any overall benefit of early anticoagulation with standard heparin, or with low molecular weight heparins, either routinely in acute stroke or in patients with progressive stroke or acute cardio-embolic stroke associated with atrial fibrillation. The latter is in contrast to the clear benefit of warfarin in the long-term prevention of stroke from atrial fibrillation. In the acute stroke trials, any reduction in the rate of recurrent ischaemic stroke related to anticoagulation was matched by an increased rate of symptomatic intracranial haemorrhage. The evidence shows that there is no place for the routine use of anticoagulation or subcutaneous heparin in acute stroke. However, given that the risk and benefits appear to be balanced overall, prophylactic low-dose subcutaneous heparin can be used in patients who are thought to be at high risk of deep vein thrombosis, e.g. immobile patients with a previous history of deep vein thrombosis. We recommend the routine use of anti-embolism stockings for all cases. Stockings are currently being tested in a randomized trial. Early mobilization, e.g. sitting the patient up the day after stroke, and active physiotherapy play an important part in limiting deep vein thrombosis.

There may also be a role for the use of intravenous heparin in selected patients who are thought to be at high risk of early stroke recurrence. We use heparin in patients with demonstrated thrombus in the heart, or those with acute vertebral or carotid artery occlusion, so long as the patient does not have a large infarct (more than one-third of MCA territory by volume). In these latter cases the risk of symptomatic haemorrhagic transformation may be increased. Anticoagulation is often recommended in patients with carotid and vertebral artery dissection (see below), so long as the dissection is limited to the extracranial portions of the artery, but the benefits and risks of this treatment have not yet been shown in randomized trials. In patients in whom there is a good indication for long-term anticoagulation, e.g. atrial fibrillation, we delay anticoagulation for 2 weeks if the infarct is large.

Neuroprotection

Many neuroprotective drugs, designed to block various components of the biochemical cascade leading to cell death after an ischaemic insult, have been shown to reduce the size of infarction in animal models of ischaemic stroke. To date, none of these agents has fulfilled their promise in randomized trials in human stroke. A number of factors may be responsible for this failure to translate animal research to the bedside, including inability in clinical trials to replicate experimental conditions and inclusion of patients too late – up to 24 hours after onset of stroke. In animal studies of neuroprotection, agents are usually only effective if given within an hour or two after induction of ischaemia. Nevertheless, a free-radical trapping agent, known at present as NXY-059, looks promising. This was tested after initiation within 6 hours of onset in acute ischaemic stroke patients in the SAINT-1 Study. The drug resulted in significantly improved Rankin scores at 90 days in about 1 in 20 patients treated. Patients who received thrombolysis with alteplase and NXY-059 also had a lower rate of symptomatic haemorrhagic transformation. However, other measures of outcome, including a neurological impairment score, did not improve. Benefits were not found in the larger SAINT-2 Study.

The only licensed drug with an apparent protective benefit is nimodipine, given after recent SAH. In the British Aneurysm Trial, nimodipine reduced the incidence of cerebral infarction and the proportion of patients with a poor outcome by about 10%. Nimodipine has been shown to have no effect, or even to be harmful, in patients with ischaemic stroke and it is therefore possible that the benefits in patients with SAH arose because the patients can be pre-treated before the onset of ischaemia from vasospasm, or because nimodipine reduces severity of vasospasm.

Maintenance of homeostasis

Although drug therapy to protect the brain against the effects of ischaemia may not be beneficial, it is still logical to maintain the brain's physiological and biochemical environment in normal homeostatic balance, to preserve the penumbra and take all steps to prevent secondary deterioration. However, there is no trial evidence that the measures we recommend below to maintain homeostasis improve final outcome. Oxygen saturation should be monitored routinely and hypoxaemia treated appropriately.

Blood sugar levels are elevated in about one-quarter of all stroke admissions. This includes patients with known and undiagnosed diabetes, and patients in whom elevation in blood glucose appears as a stress response. Mortality, poor outcome and infarct size are increased in patients with raised blood glucose, but whether the larger size of infarction contributes to the high blood glucose, or vice versa, is uncertain. Nevertheless, we recommend avoiding administering intravenous glucose in patients with acute stroke, and we institute insulin therapy on a graded scale when the blood glucose is >10 mmol/L, to maintain optimal levels within 6–9 mmol/L. Equally, hypoglycaemia should be avoided.

The majority of patients with acute stroke have raised blood pressure on admission, often because of pre-existing hypertension and an invariable hormonal or autonomic response to the stroke itself. The blood pressure readings usually fall over the course of the first week. It is not clear whether hypertension in the acute stage is harmful or even beneficial. Trials are therefore in progress, raising or lowering high blood pressure

in acute stroke. Until the results of these trials are available, we recommend continuing any previously prescribed antihypertensive agents, but do not intervene to lower blood pressure unless the patient is a candidate for thrombolysis, has hypertensive encephalopathy, malignant hypertension or the blood pressure readings are above an arbitrary threshold of 200/120 mmHg. Over-vigorous lowering of blood pressure in acute stroke can certainly lead to extension of the infarct. In most cases, blood pressure should therefore be lowered using oral agents, although in patients in whom thrombolysis is appropriate, intravenous medication with labetalol is used. This should be given at a dose titrated against the blood pressure. The latter should be closely monitored in any patient receiving hypotensive therapy to avoid precipitous falls in blood pressure, aiming for systolic readings of 150–185 mmHg. Intramuscular agents should be avoided because of their unpredictable effect on blood pressure. In other cases, we would recommend that the institution of medication to treat hypertension should be delayed for 48 hours or more after onset.

Spontaneous hypotension after stroke is rare, but may occur if the patient develops cardiac problems or becomes dehydrated. Hypotension should be corrected promptly by raising the foot of the bed, fluid replacement and stopping hypotensive medication. Occasionally, inotropic medication may be required.

Pyrexia is associated with poor outcome of stroke, while animal studies show that even a small fall in body temperature is associated with smaller infarct volumes. Hence, we recommend that all patients should have fever treated vigorously, e.g. with paracetamol, and infections should be treated promptly with antibiotics. In clinical practice, therapeutic hypothermia is difficult to achieve, requires intensive care and is associated with significant complications on rewarming, and has therefore not entered routine clinical practice.

Treatment of cerebral oedema

Cerebral infarction is associated with failure of membrane pumps and influx of water into the cells. Cytotoxic oedema is therefore an inevitable consequence of cerebral infarction, and it is this feature that allows infarcts to be seen on CT. All infarcts are associated with a degree of swelling of the ischaemic tissue, which is manifest in larger infarcts on imaging by compression of the sulci and ventricles. The swelling of the infarct may last up to 4 weeks before the oedema resolves. In large hemispheric infarcts, this mass effect can cause transtentorial herniation with compression of the brainstem and is the most common cause of death in the first week after cerebral infarction. Typically, in patients with symptomatic cerebral oedema, the patient appears stable after the onset of symptoms for the first 24–48 hours, and then deteriorates on the second or third day, with progressive impairment of consciousness, coma and respiratory failure. This most often occurs in a patient with a large infarct caused by MCA occlusion, which is then sometimes known as malignant MCA infarction. Direct brainstem compression may also occur in patients with large cerebellar infarcts.

Cytotoxic cerebral oedema secondary to infarction tends to be unresponsive to steroids, but mannitol may provide a temporary respite pending surgical treatment. Paralysis and hyperventilation are rarely of benefit. Instead, decompressive neurosurgery with a large craniectomy should be considered, particularly in younger patients with non-dominant malignant MCA infarction, and in patients with brainstem progression secondary to cerebellar infarction. Craniectomy may be life-saving, and surprisingly good outcomes obtained in selected patients.

Patients with cerebral haemorrhage may also deteriorate because of oedema and transtentorial herniation, or direct brainstem compression. Occasionally, cerebral infarction, usually in the cerebellum, is associated with the development of hydrocephalus from compression of the aqueduct, although this is much more common following intracranial haemorrhage. Hydrocephalus may require shunting, or evacuation of the infarct or haemorrhage (see above).

Management of progressive stroke

About one-third of patients with ischaemic stroke progress in the first day after onset. Acute progression is even more common in patients with cerebral haemorrhage because of continued bleeding and enlargement of the haematoma. In ischaemic stroke, the causes of early progression are often unclear, but may include extension of the area of ischaemia from thrombus propagation, recurrent embolism, failure of initially adequate collaterals or enlargement of the penumbra from release of cytotoxic chemicals and the local effects of cytotoxic oedema. In patients who deteriorate after a period of stability, a number of causes need to be considered:

- Metabolic disturbances, e.g. low or high blood sugar, or hyponatraemia;
- Hypotension, or severe hypertension;
- Cardiac arrhythmias or myocardial infarction;
- Pyrexia and infections;
- Dehydration;
- Hypoxia, e.g. from aspiration, infection or silent pulmonary embolism;
- Cerebral oedema or hydrocephalus;
- Haemorrhagic transformation of infarction;
- Vasospasm after subarachnoid haemorrhage; and
- New infarction (often from cardiac embolism) or haemorrhage in a new location.

Patients who deteriorate should therefore be investigated for these possibilities by repeat CT or MRI, chest imaging and appropriate blood tests. Management will depend on the findings.

Common medical complications of stroke

Frank dysphagia, or an unsafe swallow with the risk of aspiration, is very common and occurs in about one-third of patients with hemispheric stroke and two-thirds of those with brainstem stroke. This can easily cause aspiration pneumonia, leading to hypoxia and stroke progression. All acute stroke patients should therefore

have their swallowing assessed as soon as possible, using an agreed protocol. They should be kept nil-by-mouth until their swallowing has been assessed as safe. It is very likely that dehydration and starvation are harmful in the acute stages of stroke and fluid replacement should commence as soon as the patient is admitted if swallowing is not safe. It also makes sense to start feeding patients immediately. Even if a patient can swallow safely, the spontaneous intake of food and liquid is often inadequate because of poor appetite, cognitive impairment, neglect or physical difficulties in feeding. Nurses and carers should therefore have adequate time to help a patient to eat and drink sufficiently. When the oral route is not safe or practical, it is essential to establish other routes. In the short term, it is often convenient to replace fluids via an intravenous line, but this has the disadvantage of immobilizing the patient. A nasogastric tube is therefore preferred, with the advantage of allowing feeding as well as fluid replacement, with less risk of cardiac overload or line infection. If nasogastric tube feeding is likely to be required for more than 2 weeks, consideration should be given to inserting a percutaneous endoscopic gastrostomy (PEG) tube. This is usually preferred by patients and has the advantage that a large tube can be used. However, there are some risks of tube insertion, including peritonitis. Overall, there is little difference to the outcome after early PEG feeding compared with a nasogastric tube. It should be borne in mind that nasogastric tubes may increase the risk of gastrointestinal haemorrhage.

Deep vein thrombosis is usually seen in severely hemiparetic limbs and is very common on radiographic studies. Pulmonary embolus is a rare but important cause of death after stroke. The prevention of deep venous thrombosis is discussed above in the section on anticoagulation.

Pressure sores should be vanishingly rare and can be avoided by frequent turning of immobilized patients and the use of special bedding, e.g. air mattresses. Early mobilization and sitting the patient out of bed as soon as possible after onset also play a part in preventing pressure sores and other complications of immobility.

Shoulder pain is a common complication of stroke, largely preventable by good positioning of the shoulder and early physiotherapy. In particular, a paralysed upper limb should not be allowed to hang unsupported at the side of the patient, because the weight of the limb leads to subluxation of the shoulder joint and subsequently a painful frozen shoulder. The correct position of a patient in a bed or chair, with the weak limb supported at all times by a comfortable pillow or similar support, is essential. Patients who do experience shoulder pain may benefit from standard rheumatological treatments, including local steroid injections. The paralysed upper limb must never be neglected from motor therapy as it will contract and become dysfunctional and painful.

Limb swelling of the hand or foot of a hemiparetic limb is common and is partly explained by excessive sympathetic activity. The patient often complains that the limb is cold, because vasodilatation results in heat loss, even though the limb may feel warm to touch. This type of oedema should be distinguished from oedema secondary to a deep venous thrombosis. Elevation of the limb may help. Diuretics are not indicated.

Spasticity is a common but not universal feature of the upper motor neurone lesion resulting from infarction or haemorrhage. The increase in tone often develops several days or weeks after the onset of stroke. In the upper limb, the pattern of spasticity usually leads to flexion at each joint, and in the lower limb to extension. Early mobilization and appropriate physiotherapy probably play an important part in limiting the development of severe spasticity, and particularly the development of contractures. Oral drug treatment has a limited role in treating spasticity in stroke. The problem is that drug treatment often results in generalized muscle weakness and function is rarely improved. However, local injections of botulinum toxin into individual muscles may benefit patients in whom spasticity is causing focal problems.

Depression is very common after stroke and may reflect a direct neurophysiological cause, as well as reaction to the illness and persistent disability. Depression is associated with poor outcomes and should therefore be treated vigorously and expert psychiatric advice sought if necessary.

Post-stroke pain (Chapter 22) is characteristically associated with infarction in the thalamus and often develops weeks or even months after the onset of stroke. The pain is often described as a deep burning pain throughout one side of the body, which limits the patient's activities and may lead to severe depression. Standard analgesics are often ineffective, but relief may be obtained with tricyclic antidepressants, particularly amitriptyline taken at night, or anticonvulsants, e.g. gabapentin. Occasionally, transcutaneous nerve stimulation is helpful.

Dystonia is a rare complication of stroke involving the basal ganglia and usually develops some months after the initial event. Chorea appears to be particularly common in patients with the Moyamoya syndrome (see below).

Secondary prevention

Secondary prevention implies specific evidence-based measures that improve the prognosis following a defined clinical event. In the case of TIA, this implies preventing, to some degree, the risk of subsequent stroke. Following a stroke, secondary prevention means recommending and/or adopting measures that have been shown to prevent a further stroke. Advice that is not based upon evidence, nor widely agreed, is frequently given to patients in these clinical settings. Much of the evidence related to primary prevention, such as the control of hypertension, also applies to secondary prevention.

Secondary prevention after TIA and stroke

Patients who have had a TIA are at high risk of stroke and those who have had a stroke are at high risk of recurrent stroke. Both are at risk of MI. As a general figure, following either of these

events, the risks of stroke or a recurrent stroke are about 5% per annum, but can be as high as 30% in patients with severe carotid stenosis. In general, the older the patient, and the more risk factors present, the greater the risk of recurrence. There is therefore much to be saved by effective measures to prevent recurrence. Treatment should be based on addressing risk factors and the results of investigations, together with an assessment of the degree of risk and benefits of treatment in individual patients. Targets for preventive measures include the following:

- Lifestyle risk factors;
- Lowering blood pressure;
- Lowering cholesterol by statin therapy and diet;
- Optimizing treatment of other conditions that promote vascular disease, e.g. diabetes;
- Prevention of cardiac embolism, e.g. valve surgery or anticoagulation;
- Targeted treatment for atherosclerotic stenosis by endarterectomy or stenting; and
- Inhibition of platelet aggregation with antiplatelet agents.

In patients with a history of cerebral haemorrhage, prevention should be targeted only at the first four issues and, in general, antiplatelet therapy and anticoagulation are contraindicated. Sources of cerebral haemorrhage, particularly aneurysms and AVMs may require specific treatment as previously described.

Following thrombo-embolism, treatment to prevent recurrence should start immediately after a TIA or recovery from a minor stroke, and in patients with more severe stroke, specific measures to prevent recurrence should be routinely considered and therapy started at around 2 weeks after onset. In patients who are very disabled, some preventive measures may need to be delayed, e.g. carotid endarterectomy, until the patient has recovered sufficiently. Anticoagulants and antiplatelet therapy have a rapid effect at reducing risk in appropriate patients. However, lowering of blood pressure appears to take several months to be effective at reducing risk, and the maximum benefits are not achieved for up to 2 years. Lowering cholesterol by statins also appears to take a year for benefit to be evident.

There is much to be gained by effective secondary prevention of stroke. The patient who stops smoking will halve their risk of stroke, a patient with atrial fibrillation taking warfarin will reduce their risk of stroke by two-thirds, and a patient taking simvastatin 40 mg/day and a combination of aspirin with an extended release form of dipyridamole will have their stroke risk reduced by 30% for each of these measures. Carotid endarterectomy in patients with recent symptoms and severe carotid stenosis may reduce the risk of recurrence by as much as 80%. Each of these treatment modalities acts independently. Thus, patients with multiple risk factors stand to benefit considerably from multiple manoevres.

Lifestyle modification

Patients with the relevant risk factors should be strongly advised to stop smoking, eat healthily to reach and maintain a normal weight, to take regular exercise and to reduce excessive alcohol consumption.

Lowering blood pressure

Epidemiological studies have established clearly that the lower an individual's blood pressure, the lower the risk of stroke, even within the normal range. In patients with hypertension, it is therefore likely that the lower the blood pressure is reduced with treatment the better, so long as the patient does not develop unwanted effects. Thus, we suggest that if the patient is at any risk of recurrence and can tolerate the medication, the British Hypertension Society (BHS) guidelines (optimum targets: below 140/85 mmHg in general and below 140/80 mmHg for patients with diabetes) should be followed closely, i.e. the blood pressure maintained at levels lower than these. This may require the use of three or four antihypertensive agents. At one time, there was concern that lowering the blood pressure in patients with prior stroke might be harmful, but the PROGRESS trial established that even patients with a relatively normal blood pressure after a stroke (often achieved with prior medication), benefited from further reduction in their blood pressure using a combination of an angiotensin converting enzyme (ACE) inhibitor and a diuretic.

Most experts believe that the benefits of lowering blood pressure in preventing stroke are related to the degree in reduction of blood pressure, not the drug class used to lower it. However, there is some evidence that β-blockers are less effective than other classes of antihypertensive agent. The authors usually start treatment with a thiazide diuretic and then add an ACE inhibitor, e.g. perindopril or ramipril. If further reduction in blood pressure is required, calcium antagonists can be added. The target of treatment should be to lower the blood pressure as low as tolerated, and certainly to ensure readings below the British Hypertension Society guideline figures.

Diabetes mellitus

Both Type I and Type II diabetes are well-recognized risk factors for stroke, probably because of the association of atherosclerosis and hypertension with diabetes. In keeping with this assumption, vigorous control of hypertension has more benefit in reducing the incidence of stroke in patients with diabetes than tight control of blood sugar levels. However, it is important to maintain HbAc1 levels at less than 7% if this feasible.

Lowering cholesterol

There is now convincing evidence from the Heart Protection Studies and the SPARCL study that lowering cholesterol with a statin after ischaemic stroke dramatically reduces the risk of recurrent stroke and MI. The lower the achieved level of cholesterol the lower the risk, with an approximately 25% reduction in the risk of recurrent ischaemic stroke and MI associated with a reduction in LDL cholesterol of 1.0 mmol/L. The benefits of statin therapy are therefore greater than those of antiplatelet therapy. All patients with stroke and TIA should therefore be considered for statin therapy, unless they have a cholesterol of <3.5 mmol/L or unlikely to have atherosclerosis (e.g. patients under the age of 40).

Anticoagulation

Anticoagulation in acute stroke has been discussed above. In contrast to the lack of benefit of heparins in acute stroke, there is good evidence that anticoagulation with warfarin prevents recurrent stroke in patients with cardio-embolic sources of thrombus (Table 4.15). The evidence is best for atrial fibrillation (AF), which is associated with a very high rate of recurrent stroke. In the European Atrial Fibrillation Trial, warfarin reduced the rate of recurrent TIA and stroke from 12% per annum down to 4% per annum, a two-thirds reduction in risk. In contrast, aspirin was much less effective, reducing the rate of recurrence by only about one-sixth. It is likely that warfarin works more effectively than aspirin because it affects the formation of thrombin-based clots in the heart, whereas antiplatelet agents are more effective at preventing thrombus starting with platelet aggregation on atheromatous clots. Thus, warfarin is the treatment of choice in patients with AF following stroke or TIA to prevent recurrence. In the elderly, the risks of intrcranial haemorrhage (including subdural haematoma), the need for regular monitoring and the issue of compliance, especially if there is cognitive impairment, need to be considered. In patients with contraindications to warfarin therapy, aspirin should be prescribed, bearing in mind that it is likely to be much less effective. Other antiplatelet agents have not yet been shown to be more effective than aspirin in patients with atrial fibrillation, but should be used in patients unable to take warfarin or aspirin. Fixed or low dose warfarin therapy is not effective in preventing embolism in patients with atrial fibrillation. In the future, it is possible that fixed doses of an oral direct thrombin inhibitor will provide a more convenient alternative to warfarin therapy, depending on the results of current randomized trials.

Table 4.15 Indications for anticoagulation in secondary stroke prevention.

Established indications
Cardiac embolism
• Atrial fibrillation
• Mechanical valve prosthesis
• Recent myocardial infarction
• Left ventricular aneurysm
• Dilated cardiomyopathy
Cerebral venous and venous sinus thrombosis
Possible indications
Recent major vessel occlusion
• Internal carotid artery occlusion
• Basilar artery occlusion
Recent extracranial cervical arterial dissection
Severe carotid stenosis prior to surgery or stenting
Crescendo TIAs despite antiplatelet therapy
Thrombophilia and prothrombotic states
Paradoxical embolism

Anticoagulation is indicated as a life-long treatment for patients who have had heart valves replaced with mechanical prostheses. If such patients have a cerebral haemorrhage while on warfarin, the treatment can be relatively safely stopped empirically, but should be restarted after 2 weeks. Other cardiac conditions associated with a high likelihood of the development of cardiac embolism listed in Table 4.15 should be considered for anticoagulation.

Possible indications for anticoagulation after stroke are also listed in the Table 4.15. Evidence that anticoagulation is superior to aspirin in all these disorders is lacking. It needs to be borne in mind that there are significant long-term risks of warfarin therapy, including a risk of 1–2% of intracranial haemorrhage per annum. We therefore usually only recommend anticoagulation for short periods in patients with uncertain indications to cover the period of time when their risk of recurrence is highest, e.g. for a maximum of 6 months after an acute ischaemic event.

The usual target International Normalized Ratio (INR) for the treatment of atrial fibrillation is 2.5 (range 2.0–3.0). For patients with mechanical prosthetic valves, a higher INR target to 3.5 (range 3.0–4.0) is usually chosen. A target INR of 2.5 is appropriate for most other indications. Analysis of the Atrial Fibrillation Trials suggests that an INR of 2.0 or less is insufficient to prevent thrombo-embolism, while the risk of haemorrhage rises substantially with an INR of above 4.0. It is important that anticoagulant clinics, and the patients themselves, are aware of these recommended levels.

The management of patients who are found to have a PFO, in association with TIA or stroke, remains controversial. There appears to be an association between PFO and cryptogenic stroke, i.e. those patients in whom no other cause is evident after full investigations. However, whether the mechanism of stroke in these patients is paradoxical embolism from cryptic deep vein thrombosis, embolism of thrombus formed in the PFO itself, or some unrelated mechanism, is not clear. Nevertheless, careful observational studies have suggested that the rate of recurrent stroke in patients with PFO treated with aspirin alone is as low, as the rate in patients with cryptogenic stroke without PFO, except if the PFO is associated with atrial septal aneurysm, when the risk may be increased. There appears to be little consistent relationship between the risk of stroke treated with aspirin and the size of the PFO. In patients where the PFO is thought to be relevant to the mechanism of their stroke, the PFO can be closed using percutaneous techniques and mechanical devices. The risks of this treatment are low, but not zero, and the long-term consequences of having a prosthesis in the heart are uncertain. We therefore favour treatment with aspirin in the majority of cases. The evidence suggests that warfarin is no more effective than aspirin in these patients.

For non-cardioembolic stroke, a number of randomized trials have shown that warfarin is no more effective than aspirin in preventing recurrent stroke in patients who have had TIA or stroke that has not been attributed to atrial fibrillation or a cardiogenic source, i.e. patients with stroke attributable to

atherosclerosis, small vessel disease or cryptogenic mechanisms. Antiplatelet therapy is therefore preferred to anticoagulation in patients with this type of stroke, sometimes known as atherothrombotic stroke. The danger of warfarin therapy in this group of patients was emphasized by the results of the Stroke Prevention in Reversible Ischaemia Trial (SPIRIT), which was stopped prematurely because of an excess of brain haemorrhage in patients randomized to warfarin, compared with those randomized to aspirin after a recent TIA or stroke – in patients who did not have atrial fibrillation or cardiac embolism. Most of the haemorrhages occurred in patients over the age of 75 and in those who had moderate or severe small vessel disease (leuco-araiosis) on CT. This trial used a high target range for INR of 3.0–4.0, which may have increased the risk of cerebral haemorrhage; nevertheless, extensive leuco-araiosis should be considered a relative contraindication to warfarin therapy.

There is no evidence that patients with recurrent stroke or TIA symptoms on antiplatelet therapy benefit from anticoagulation, but we do regard recurrent symptoms as an indication to repeat or extend investigations, e.g. TOE, and prolonged Holter to exclude a cardiac source of embolism. In patients who have recurrent symptoms on warfarin, it is also important to review the diagnosis, and if the symptoms are likely to be the result of cardiac embolism, and the INR is in the target range at the time the patient has recurrent symptoms, consideration can be given to adding an antiplatelet agent, e.g. low dose aspirin 75 mg/day. However, the evidence suggests that the combination of aspirin and warfarin significantly increases the risk of gastrointestinal haemorrhage, and we are cautious about prescribing the combination.

Antiplatelet therapy

Aspirin has been the mainstay of treatment to prevent recurrent stroke for many years in patients who are not anticoagulated, and has the advantage of being very cheap. However, it should be borne in mind that antiplatelet therapy has less relative benefit in reducing the risk of vascular events than lowering blood pressure or lowering cholesterol. In a meta-analysis looking at the overall benefit of aspirin after stroke or TIA, the overall relative risk reduction in the combined outcome of stroke, MI or vascular death in different trials was only 13%. Aspirin also has the disadvantage of frequent side effects, particularly at high doses, including gastrointestinal haemorrhage and intracranial haemorrhage, which have incidences of approximately 27 and 5 per 1000 patients per year, respectively. The most common side effect is gastrointestinal irritation, and as many as 25% of patients discontinue aspirin treatment within a year or so of starting. Gastrointestinal side effects are less troublesome at lower doses. There is little evidence for a significant difference in effectiveness at any dose above 30 mg/day, and we therefore recommend using the lowest easily available convenient dose, which in the UK is 75 mg once daily.

There has been considerable interest in developing alternative, more effective antiplatelet agents than aspirin. The first widely used alternative to aspirin was dipyridamole. Initially, there was doubt about the effectiveness of dipyridamole in preventing stroke, but the Second European Stroke Cooperative Study (ESCS-2) showed that dipyridamole in a modified released preparation at a dosage of 400 mg/day had a similar effectiveness to aspirin in preventing recurrent stroke in patients with recent stroke or TIA. The combination of low dose aspirin and dipyridamole was significantly superior to aspirin or dipyridamole alone, with a relative reduction in stroke recurrence, compared with placebo, of 37%. These results have recently been confirmed by the ESPRIT trial. Dipyridamole is a very safe antiplatelet agent, and does not appear to significantly increase the risk of bleeding, even when combined with aspirin. However, it is not well tolerated by a significant proportion of patients because of side effects, particularly headache. These side effects may be minimized by starting with a low dose of dipyridamole and increasing the dose gradually, and may work in some patients over a few weeks, if they persist in taking the tablets. In ESCS-2, nearly 30% of patients discontinued combination therapy because of side effects.

The National Institute of Clinical Excellence (NICE) in England, in its 2004 appraisal of antiplatelet agents for the prevention of thrombosis in patients with stroke, recommended that all patients with recent stroke and TIA should be started on the combination of aspirin and dipyridamole, and that the medication should be continued for 2 years. Thereafter, NICE recommended that patients should be treated with aspirin alone.

Clopidogrel is an antiplatelet agent that was developed as a replacement for ticlopidine, an older antiplatelet agent that had the disadvantage of a 1% incidence of neutropenia. Clopidogrel 75 mg/day was compared with aspirin in the CAPRIE trial, and was shown to be slightly better than aspirin in the prevention of the combined outcome of all vascular events in patients with recent stroke, MI or peripheral vascular disease. However, the absolute reduction in vascular events attributed to clopidogrel over and above the benefit of aspirin alone was only 0.5%, i.e. the number needed to prevent one additional event was 200 patients over 2 years. Clopidogrel is considerably more expensive than aspirin, and slightly more expensive than dipyridamole. Moreover, CAPRIE was not powered to demonstrate effectiveness in the subgroup of patients randomized after stroke. Hence, NICE concluded that it was not cost effective as a first line treatment for stroke and TIA patients. Nevertheless, clopidogrel provides a good alternative for patients unable to tolerate aspirin or dipyridamole. NICE recommended that patients who are hypersensitive or unable to tolerate aspirin should be treated with clopidogrel. Although widely used as a substitute for aspirin in patients with recurrent symptoms while taking aspirin, or aspirin and dipyridamole (often known as aspirin failures), there is no evidence that this approach is effective. Clopidogrel is slightly better tolerated than aspirin in terms of gastrointestinal symptoms, but has a slightly higher rate of rash and diarrhoea as side effects. The rate of haemorrhage associated with clopidogrel is similar to that of aspirin.

The combination of clopidogrel and aspirin is no more effective than either drug alone in preventing recurrent stroke. In the MATCH trial, clopidogrel plus aspirin was compared with clopidogrel alone in patients with recent stroke considered at a high risk of recurrence. In this trial, there was a significant increase in the risk of cerebral haemorrhage in patients treated with the combination, without any significant reduction in the rate of ischaemic stroke. Thus, the combination of aspirin and clopidogrel cannot be recommended for the prevention of stroke, except in specific situations, e.g. in patients being treated following carotid stenting.

Management of carotid stenosis

Symptomatic carotid stenosis

The large randomized trials comparing carotid endarterectomy with medical treatment alone have demonstrated that patients with recent ipsilateral TIA or stroke, who are fit for surgery and have significant carotid stenosis, benefit from carotid endarterectomy to remove the stenosis (Table 4.16). The benefit of surgery is strongly related to the severity of the stenosis and the recentness of symptoms. The risk of recurrent stroke in patients with recent TIA who do not have carotid endarterectomy and are treated medically increases substantially above 50% stenosis with increasing deciles of stenosis over the next 5 years. Carotid endarterectomy has a risk of causing a stroke or death at the time of the surgery, in good hands, of about 6% in recently symptomatic patients, but thereafter removing the stenosis surgically almost abolishes the risk of ipsilateral recurrence, with a subsequent annual rate of stroke of only about 1%. The risks of surgery bear little relationship to the severity of internal carotid artery stenosis. Hence, the benefits of surgery increase with increasing degrees of stenosis above 50% or so, in patients with recently symptomatic stenosis (Figure 4.21). However, patients with very severe stenosis in which the distal internal carotid artery has collapsed (an appearance referred to as pseudo-occlusion or near occlusion on angiography) have a low risk of recurrent stroke and do not benefit from surgery. Patients with complete carotid occlusion were not included in the endarterectomy trials, but previous studies suggested that surgery for carotid occlusion was hazardous.

Table 4.16 Indications for carotid surgery.

History of ipsilateral carotid TIA or stroke with reasonable recovery
Severe stenosis (≥70%, NASCET method, excluding near-occlusion) and symptoms within 6 months
Moderate stenosis (50–69%, NASCET method) and symptoms within 2 months and male gender
Patients must be fit for surgery and an experienced, skilled surgical team available

NASCET, North American Symptomatic Carotid Endarterectomy Trial.

The benefits of surgery for carotid stenosis decline with time from symptoms to the operation. Patients with moderate degrees of stenosis (50–69%, measured using the NASCET method) benefit from surgery if it is performed within the first few weeks after recent symptoms, especially if they are male, but not thereafter. Patients with more severe stenosis may benefit from surgery performed up to 6 months after symptoms, but any delay in surgery in these patients will mean that some patients will already have had a stroke while awaiting surgery. It is therefore essential that patients should be referred as soon as possible after TIA and stroke for carotid investigations, and operated on as soon as possible if significant stenosis is detected. In patients with large acute infarcts, there may be a risk of causing reperfusion haemorrhage if the artery is operated on immediately, and it may be wise to wait 2 weeks or more before operating on these patients.

The main hazard of carotid endarterectomy is stroke during the procedure itself. There is also a small incidence of stroke in the first 2 weeks after endarterectomy, probably resulting mostly from a thrombus formed on the endarterectomy site. Surgery also risks MI, pulmonary embolism and the development of a haematoma at the wound site. Up to 10% of patients develop a cranial nerve palsy, usually a unilateral hypoglossal nerve palsy, but these usually recover and only rarely cause disability (Chapter 12). Performing the operation under local anaesthesia, rather than general anaesthesia, may avoid some of the complications of carotid endarterectomy, but this remains to be proven by ongoing trials. About 1% of patients develop hyperperfusion syndrome, which usually follows endarterectomy (or stenting)

Figure 4.21 Stented left ICA stenosis; stent passes from common carotid artery (CCA) into internal carotid artery (ICA) (catheter angiogram).

for a very tight stenosis, and may be more common in patients who develop postoperative hypertension. Patients with hyperperfusion syndrome complain of headache and may develop seizures, and/or cerebral haemorrhage. Treatment of the hyperperfusion syndrome includes the urgent lowering of blood pressure.

Asymptomatic carotid stenosis

Patients investigated for TIA, stroke or other vascular conditions may be found to have a stenosis of one or more internal carotid arteries that is asymptomatic. A number of randomized trials have established that patients found to have carotid stenosis who have never had ipsilateral symptoms, or have had symptoms more than 6 months prior to randomization, have a very low rate of ipsilateral stroke during follow-up of around 2% per annum. Carotid endarterectomy for asymptomatic carotid stenosis is less hazardous than in symptomatic patients, but still carries a risk, in good hands, of around 3% within 30 days of the operation. Surgery then reduces the risk of ipsilateral stroke to about 1% per annum. The 5-year risk of any stroke or surgical death in the Asymptomatic Carotid Surgery Trial (ACST) fell from about 12% in patients in whom surgery was deferred until a more definite indication appeared (e.g. the stenosis became symptomatic), down to 6.4% in patients who had early endarterectomy. Subgroup analysis of ACST showed that patients over the age of 75 did not benefit from surgery, and the benefit in women was doubtful. The low rate of stroke in patients treated medically means that operating on asymptomatic carotid stenosis as a policy would result in a very large number of patients having unnecessary surgery, while some would be harmed from the operation, and only a small proportion (5%) would gain some benefit by avoiding stroke over the next 5 years. The majority of neurologists have concluded that this does not justify a policy of endarterectomy for asymptomatic stenosis, although exceptions may be made for young patients who are particularly anxious. The existing carotid endarterectomy trials did not incorporate state-of-the-art medical treatment. It is likely that in asymptomatic patients who are treated with high dose statins, have vigorous control of hypertension and stop smoking, the benefits of endarterectomy will be even less than those demonstrated in the trials. There is no benefit to following up asymptomatic stenosis with regular ultrasound examinations.

The benefits of carotid endarterectomy or stenting for patients with asymptomatic carotid stenosis who require major surgery, especially coronary artery bypass grafting (CABG), is uncertain. Severe carotid stenosis increases the risk of stroke during CABG, but the risk is not necessarily reduced by prior carotid endarterectomy or stenting, and the risk of stroke during treatment of the carotid artery are similar to the risk of stroke during CABG. Hence, a routine policy of screening and treatment of carotid stenosis prior to CABG is probably not justified. Patients who are symptomatic from both their carotid and coronary arteries should have the carotid treated prior to treatment of the coronary arteries.

Carotid stenting

Carotid stenting is rapidly developing as an alternative to carotid endarterectomy for the treatment of carotid stenosis. Carotid stenting has the advantage of avoiding any incision in the neck and is always performed under local anaesthesia. It appears less invasive and is therefore often preferred by patients to carotid endarterectomy, given the choice. However, the safety of carotid stenting compared to endarterectomy has not yet been established. The first trial of endovascular treatment for carotid stenosis compared to endarterectomy, the Carotid and Vertebral Artery Transluminal Angioplasty Study (CAVATAS) showed almost identical risk and long-term effectiveness of endovascular treatment compared with surgery, but did not include enough patients to form firm conclusions. Long-term follow-up from CAVATAS also showed a higher rate of restenosis in patients who received endovascular treatment compared to surgery, but this was not associated with a significant increase in the risk of stroke. Three other trials of carotid stenting have been stopped early because of poor results in stented patients, but this may reflect inexperience of the procedure in comparison to surgical skills in carotid endarterectomy, which have been developed over the last 50 years. Further randomized trials are in progress to compare carotid stenting with surgery, and until these are completed carotid endarterectomy should remain the treatment of choice for carotid stenosis, except in the context of clinical trials, or possibly in patients who have good indications for treating the carotid but are not fit for surgery, e.g. 'hostile neck' secondary to previous radiotherapy.

Vertebral stenosis

Vertebral artery stenosis is rarely treated by surgical methods because of difficulty with access. Stenting provides an alternative method of treating vertebral stenosis; this appears to be effective in preventing recurrent symptoms but is frequently associated with restenosis requiring further stenting or angioplasty. The benefits of vertebral stenting compared to medical treatment have not been established in clinical trials. We therefore reserve stenting for patients with vertebro-basilar symptoms associated with vertebral stenosis in the extracranial vertebral artery who have recurrent symptoms despite optimal medical treatment. Angioplasty and stenting are occasionally used to treat intracranial, vertebro-basilar and MCA stenosis, but treatment at this site has considerable hazards and is usually regarded as a last resort for patients with severe stenosis and recurrent symptoms unresponsive to other treatments.

Non-atherosclerotic vascular disease, and other rarer causes of stroke

Although the majority of patients with ischaemic arterial stroke and primary intraparenchymal haemorrhage have atherosclerosis, there are several important non-atherosclerotic vasculopathies, including extracranial arterial dissection and conditions associated with vasculitis.

Carotid and vertebral artery dissection

Cervicocephalic dissections should be especially considered in young patients. Although many disease processes that may be associated with dissection (e.g. Marfan's syndrome, Ehlers–Danlos syndrome and fibromuscular dysplasia), the vast majority occur in apparently normal subjects after trivial neck trauma, e.g. minor whiplash injuries or manipulation, or apparently spontaneously. New evidence is emerging that these people probably have subtle underlying collagen defects. These patients may have fragments of Marfanism. For example, they may be entirely double-jointed, or they may have a relative with Marfan's syndrome.

Fibromuscular dysplasia can affect many systemic arteries and is a non-atheromatous condition that may involve all three arterial wall layers. It is most commonly described in middle-aged women. Bilateral ICA involvement is common, sparing the bifurcation and intracranial carotid artery. In fibromuscular dysplasia, dysplastic fibrous tissue and proliferating smooth muscle cause constricting areas interspersed with areas of dilation. This is responsible for the characteristic sign on angiography – the 'string of beads' sign. Many of these lesions are benign or present with benign symptoms (e.g. pulsatile tinnitus) but stroke may occur from embolism or occlusion. The recurrence rate of stroke is low. In addition, patients with fibromuscular dysplasia have a high incidence of intracranial aneurysms and SAH.

In apparently spontaneous dissection, hyperextension of the neck during hairwashing in the salon or when painting a ceiling are common preceding events. Dissection is produced by the subintimal penetration of blood and subsequent extension between the vessel layers. This may lead to occlusion of the vessel but more often exposes a thrombogenic surface on which intraluminal haematoma develops. This haematoma may then embolize and produce stroke. The vast majority of cases affect the extracranial carotid and vertebral arteries. Intracranial dissection is much rarer but usually leads to SAH which is sometimes catastrophic. Occasionally, intracranial dissection cuts through perforating vessels and present as stroke.

The classic clinical scenario is of the precipitating event to be followed shortly by the development of neck pain and headache. There maybe a delay of several days, sometimes weeks before embolization causes stroke. Patients more often present when stroke has occurred. In some, dissection may never give rise to symptomatic embolization but in others dissection may be instantly associated with devastating cerebral infarction. Although any stroke syndrome may occur as a complication of dissection, the presence of a Horner's syndrome may be particularly alerting. In the carotid circulation, this will be caused by involvement of the ascending sympathetic fibres surrounding the ICA in the neck. In the vertebro-basilar circulation this may result from embolic occlusion of the posterior inferior cerebellar artery with resultant infarction of the dorsolateral medulla where the descending sympathetic tracts lie (lateral medullary syndrome). Some patients present with a painful Horner's syndrome alone brought about by carotid dissection. Occasionally, carotid dissection causes compression of a lower cranial nerve or nerves within the jugular foramen, e.g. a unilateral XIIth nerve lesion causing deviation of the tongue. MRI provides a sensitive and non-invasive means to confirm dissection. Fine-cut axial imaging through the neck may reveal the characteristic cresentic vessel wall haematoma and flow-related MRI (Figure 4.22). Catheter angiography may show tapering luminal compromise or, rarely, an intimal flap. Carotid imaging is far easier to interpret than vertebral imaging; as the vertebral artery is wrapped at some points in a venous plexus this sometimes give the artificial appearance of cresentic haematoma. The dissection should be followed on MRI as rarely a false aneurysm develops. These are usually asymptomatic but rarely may expand resulting in a retropharyngeal mass effect. Carotid ultrasound may show characteristic appearances, but is not as sensitive as other techniques.

Figure 4.22 Bilateral internal carotid artery (ICA) dissection. Flow voids indicate patency of each arterial lumen; the crescent-shaped hyperintensity is the intramural thrombus on each side. (MRI T2W.)

The accepted management of dissection is anticoagulation with heparin, followed by warfarin for at least 3 months. The rationale is that anticoagulation will lower the risk of embolization. There is no clinical trial that provides solid evidence for this practice, but longitudinal studies show that stroke is rare following anticoagulation. There have been no randomized controlled trials comparing anticoagulation with antiplatelet therapy. There is no evidence that anticoagulation worsens intramural haematoma. In patients with false aneurysm formation, follow-up to

ensure stability with MR angiography or ultrasound is recommended for 2 years. Expansions may need stenting.

Vasculitis

Vasculitis is beloved by some in the differential diagnosis of stroke. Although vasculitis may result in stroke (usually from uncontrolled hypertension), it is exceedingly rare for vasculitis to present simply as stroke. Vasculitis may be of infective origin, necrotizing, associated with collagen vascular disease, other systemic disease, hypersensitivity, giant cell or miscellaneous. Neurological investigations, other than the occasional cerebral biopsy, are not particularly helpful in the diagnosis of cerebral vasculitis. If MRI is requested with the words: 'Stroke – ? vasculitis', the report is likely to indicate: 'Vasculitis cannot be excluded'. In systemic and other vasculitides, the diagnosis is based on the extracranial features and typical serology. It is only when the vasculitis is confined to the nervous system (isolated angiitis) that the diagnosis will require more detailed investigation (see also Chapters 8, 25).

Infective vasculitis

Infective vasculitis associated with meningitis can occur acutely in the appropriate setting of severe bacterial, fungal, tuberculous or herpes zoster infection. There is nearly always an appropriate proceeding history suggestive of a menigo-encephalitis syndrome. After primary syphilis infection an obliterative endarteritis affecting the small vessels of the brain may occur with a usual latency of 7 years. Headache and encephalopathy predominate in the prodrome before stroke occurs. Evidence of previous infection is easy to screen for in the blood and those with neurological involvement usually have pleocytosis and positive serology in the CSF (Chapter 8). Enhanced MRI may show chronic syphilitic pachymeningitis with thickening of the meninges. Lyme borreliosis can mimic syphilis.

Viral infection may well be responsible for some cases of vasculitis previously considered idiopathic. Hepatitis B and C and herpes zoster are proven examples. Zoster is the most well-described form of viral arteritis to affect the CNS. The classic scenario is of V_1 shingles followed by brain infarction several weeks later. The infarct is usually ipsilateral to the rash and some patients may have encephalitis. The carotid territory is most commonly involved with occlusion at the siphon or MCA. In children, stroke may follow primary zoster infection (chickenpox). Patients with HIV have higher rates of cerebrovascular disease but there are many mechanisms underpinning this, including hypercoagulability.

Parasites may also be associated with endarteritis. Cysticercosis may be complicated by stroke when cysts lodge in the subarachnoid space leading to meningeal inflammation. The major basal arteries may be affected by this process and asymptomatic angiographic stenosis is more common than stroke.

In cerebral malaria caused by *Plasmodium falciparum*, haemorrhagic stroke may accompany the diffuse brain injury, particularly in children.

Systemic vasculitides

Systemic vasculitis has been classified immunopathologically, by the nature of the vessel involved or clinically. Most strokes associated with systemic vasculitis are brought about by uncontrolled hypertension, not cerebral involvement, and patients have usually been unwell for a considerable time. When looking at vasculitis through stroke spectacles, vessel size is a good starting point. Issues relevant to stroke are discussed here.

Large vessel vasculitis

These are Takayasu and giant cell arteritis. Both are granulomatous vasculitides. In giant cell arteritis (Chapter 25), the internal elastic lamina of the extracranial medium sized arteries becomes fragmented and invaded by inflammatory cells. It virtually always occurs in those aged over 50 and in 90% is accompanied by an elevated ESR. Patients complain of headache with scalp tenderness associated with malaise, depression, myalgia and sometimes claudication of the jaw muscles while eating. Examination usually reveals thickened tender temporal arteries. Stroke is a very rare complication of the disease but may occur from involvement of the extradural vertebral artery leading to brainstem infarction. A far more common complication without treatment, or at presentation, is anterior ischaemic optic neuropathy (Chapter 13). Diagnosis is established by temporal artery biopsy. Treatment is with high dose prednisolone, and if the diagnosis is correct the response of the systemic symptoms is dramatic and usually occurs within 1 day. Occasionally, the intracranial ICA may be involved.

Takayasu's arteritis was originally described in Japanese girls and women and is often called pulseless disease. There may be a prodromal phase associated with anaemia and raised ESR followed by severe occlusive disease of the aortic arch and branches, leading to absent neck and limb pulses. Stroke is not a common feature but headache, dizziness and syncope are more frequent. The diagnosis of Takayasu's arteritis may be made by ultrasound showing occluded or stenotic large vessels at the origin with thickened walls. Characteristic sites of involvement include the proximal common carotid artery (CCA), subclavian artery and innominate.

Medium vessel vasculitis

Polyarteritis nodosa (PAN) is the principle medium vessel vasculitis. It is important to remember that PAN is usually ANCA negative. PAN affects medium and small arteries and the most common neurological feature is mononeuritis. CNS involvement may occur in 20%, but it is often late in the disease. Presenting features include cerebral infarction, cerebral haemorrhage and SAH.

Small vessel vasculitis

Microscopic polyarteritis is usually ANCA positive and affects small vessels, as do Wegener's granulomatosis and Churg–Strauss syndrome. Encephalopathy and peripheral manifestations are common but stroke rare. Exceptional patients have presented with SAH as the first sign of vasculitis.

Collagen vascular disease

SLE commonly cause neurological problems. These are often neuropsychiatry and rarely caused by vasculitis. Encephalopathy, psychosis, seizures, stroke-like focal deficits, myelopathy and neuropathy are all encountered. At pathological examination the histology is often one of non-specific gliosis although thrombosis may be observed especially in those with antiphospholipid antibodies. Echocardiography shows a high frequency of valvular disease in SLE, particularly Libman–Sacks endocarditis, which may lead to cerebral embolism. Myocarditis is also a feature of SLE. Response to immunosupression of florid neurological involvement is often poor. Lupus may also cause a terminal carotid occlusive syndrome leading to a Moyamoya scenario.

Other vasculitis

Very rarely, true necrotizing arteritis can be seen in association with rheumatoid resulting in encephalopathy or small infarcts. Brain infarcts have also been reported in systemic sclerosis along with SAH, but there is a high incidence of hypertension in systemic sclerosis. Sarcoid may occasionally cause a cerebral vasculitis or focal infarction, usually in association with meningeal involvement.

Isolated angiitis of the central nervous system

This rare condition affects small and medium sized intracranial vessels. It may cause a combination of infarcts and haemorrhages. Presentation is usually chronic with prominent headache, leading to encephalopathy and then stroke-like focal dysfunction. Any age may be affected and there is a male predominance. The disorder may be acute over weeks or subacute. Angiography may reveal segmental narrowing of intracranial vessels but this is neither sensitive nor specific. Many patients have normal angiography. The CSF often shows a pleocytosis with oligoclonal immunoglobulin on electrophoresis. Brain imaging may show multiple small vessel infarcts and sometimes haemorrhages, if advanced. Diagnosis is by meningeal and brain biopsy, which typically shows a granulomatous vasculitis. If patients have neither headache nor CSF pleocytosis then biopsy rarely shows vasculitis. Treatment is with steroids and cyclophosphamide.

Thrombotic thrombocytopenic purpura

This is characterized by microangiopathic haemolytic anaemia, thrombocytopenia and systemic microinfarction from platelet-rich thrombi. Renal failure, fever and transient neurological signs, or diffuse encephalopathy are common. Large vessel infarction may also occur and cerebral haemorrhage. Posterior leucoencephalopathy has been described. The mainstay of treatment is plasma exchange but anticoagulation is sometimes necessary and the decision to do this has to be finely balanced against the risk of haemorrhage.

Behçet's disease

The common neurological manifestations of Behçet's disease are meningitis, encephalitis with multifocal signs, stroke-like events and dural sinus thrombosis. The lesions of Behçet's disease do not conform to arterial territories, suggesting a venous origin, and usually angiography shows no abnormalities. The brainstem is frequently involved.

Susac's syndrome

Susac termed this condition a microangiopathy of the brain and retina. The cochlea is also involved. There is always obliteration of the large retinal arteries causing severe progressive visual loss. Tinnitus and sudden hearing loss are common and the principle neurological features are dementia, pyramidal and cerebellar dysfunction. The disorder usually affects young women.

Sneddon's syndrome

This is characterized by chronic skin lesions, livedo reticularis and stroke. The most important feature is the livedo. Skin biopsy may show distinctive abnormalities in small and medium arteries. Cerebral angiography may show branch intracranial occlusions. APAS needs to be excluded.

Mitochondrial disease

MELAS syndrome (mitochondrial myopathy, encephalopathy, lactic acidosis and stroke-like episodes) is sometimes considered as a differential diagnosis under the young stroke umbrella. Imaging may show multifocal abnormalities most often in the parieto-occipital and temporal lobes. Although the ischaemic lesions affect cortex and underlying white matter, these often cross arterial territories and the arteries supplying these areas are normal on investigation. Other features of a mitochondrial cytopathy are usually present (Chapter 9).

Fabry's disease

Fabry's disease is an X-linked lyposomal disorder in which there is deficiency of α galactosidase A. Typical clinical manifestations include painful neuropathy, stroke and renal failure, but young stroke may be the presenting feature. Angiography shows branch artery occlusion caused by the diffuse arteriopathy associated with sphingolipid accumulation. Imaging usually shows features of small vessel disease.

CADASIL

Of the rare conditions this actually does crop up from time to time in vascular clinics. Cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy (CADASIL) is a dominant condition characterized by migraine headache often with aura and extensive white matter abnormalities and lacunar infarction. Patients may present with depression, migraine, dementia and/or progressive gait difficulty. MRI often shows characteristic involvement of the temporal white matter. The diagnosis may be obtained through skin biopsy and genetic testing for the underlying mutation of the NOTCH III gene (Chapter 7).

Hypertensive encephalopathy

This condition, which is now rare, develops if systemic blood pressure exceeds the upper limit of cerebral autoregulation.

Oedema develops in the hyperperfused intracerebral circulation. Patients present with headache, fits, focal TIA-like events, stroke and depressed consciousness. Examination may reveal optic disc swelling in addition. The blood pressure is usually very high, e.g. 250/150 mmHg, but may be lower. In these patients the rate of blood pressure elevation has often been rapid and brought about by renal disease. Slower elevation allows autoregulatory mechanisms to compensate to some extent. Brain imaging may show a reversible posterior leuco-encephalopathy, as well as focal infarcts or haemorrhage. Eclampsia, in pregnancy and the puerperium, has similar features.

Migraine and stroke

There is a small but definite increase in stroke incidence in patients with migraine. However, this needs to be interpreted with caution as vascular disease predisposes to migraine headaches and aura. In particular, carotid artery dissection may precipitate a classic migraine attack with visual aura. There are links between antiphospholipid syndrome, sickle cell disease and possibly PFO with migraine, all of which can cause stroke. Other associations include mitochondrial disease and CADASIL. There remain very rare patients who develop infarction at the peak of a typical migraine attack, for which no other reason can be found. The symptoms of these migrainous strokes mimic the features of the patient's aura, and the associated infarction usually involves the occipital cortex. Hemiplegic migraine is a very rare familial channelopathy. Almost all young patients with migraine-like headache who suffer a hemiplegia have had the stroke from a cause unrelated to migraine. Migraine without aura, and more so migraine with aura, are both very slight independent risk factors for stroke (Chapter 11).

Moyamoya angiopathy

The term Moyamoya ('puff of smoke') angiopathy refers to an angiographic appearance in which terminal carotid occlusion is associated with the development of a fine and friable network of basal collateral vessels. Moyamoya disease is a distinct condition, prevalent in Japan but also occasionally seen in the West, in which a symmetric progressive and obliterative intracranial arteriopathy develops, affecting the basal vessels, usually the termination of both internal carotid arteries. The term Moyamoya syndrome is used when similar appearances, often with unilateral carotid occlusion, occurs from identifiable causes such as radiotherapy and sickle cell disease. Moyamoya disease presents most often in children as TIAs, stroke, chorea, headache or seizures. Adults more commonly present with ICH from rupture of the friable collaterals. Some patients appear to stabilize clinically in late adolescence, although long-term follow-up studies are lacking. Treatment options include surgical revascularization, either extracranial–intracranial bypass or synangiosis, a procedure in which vascularized omentum or muscle is juxtaposed to the brain. Children are usually prescribed aspirin, but this should be stopped in adults because of the risk of haemorrhage.

Cerebral venous thrombosis

Cerebral venous thrombosis is often considered under the umbrella of stroke but is a condition with diverse manifestations that mimic many other neurological disorders. It is increasingly recognized because of enhanced awareness and the use of MRI. Venous thrombosis may be septic or non-septic. Septic causes are increasingly rare but cavernous sinus thrombosis secondary to facial cellulitis and lateral sinus thrombosis secondary to purulent otitis media or mastoiditis are still seen. Septic thrombo-phlebitis of the cortical veins may also be associated with severe bacterial meningitis.

Aseptic thrombosis can affect the cortical veins, dural sinuses and deep veins. There are numerous potential causes. The most common are raised oestrogen levels in women, associated with pregnancy, the pueperium and the contraceptive pill. There are no reliable estimates of incidence although venous thrombosis may complicate 11/100,000 deliveries. Other factors include dehydration in association with systemic disease, thrombophilia (particularly the factor V Leiden polymorphism), activated protein C resistance and Behçet's syndrome. It has become clear that such external factors pose far more significant risk for recurrent thrombosis than inherited thrombophilias. In 20% of cases of venous thrombosis no aetiology is uncovered.

The clinical syndrome that manifests from cerebral venous thrombosis may be acute or subacute. The most frequent manifestations are headaches, seizures, altered consciousness, focal signs and optic disc swelling. Hence, cerebral venous thrombosis should be considered in the differential diagnosis of patients presenting with severe headache, seizure disorders, coma, stroke, acute meningo-encephalitis syndromes or isolated intracranial hypertension, mimicking idiopathic intracranial hypertension. Venous sinus thrombosis can cause headache, sometimes thunderclap, as the only feature. Only 50% of patients have papilloedema.

Venous thrombosis results in venous hypertension that leads to raised intracranial pressure. This may give rise to a syndrome of headache with papilloedema and normal CT imaging, initially identical to idiopathic intracranial hypertension. However, as the venous pressure rises, forced local arterial hypertension can lead to cerebral haemorrhage. Alternatively, or in addition, spread of the thrombus to cortical veins results in venous infarction, which is often haemorrhagic and results in focal neurological deficit and depression of consciousness.

Patients with venous sinus thrombosis may be severely ill and such patients often present to neurosurgeons as cases of primary intracerebral haemorrhage in coma. However, the radiological findings are usually distinct from both arterial ischaemic stroke and intracerebral haemorrhage. Venous infarction is characterized on imaging by vasogenic as opposed to cytotoxic oedema. These areas do not confine themselves to vascular territories and are often haemorrhagic. The thrombus in the venous sinuses may be visible on plain MRI although false negatives occur in the

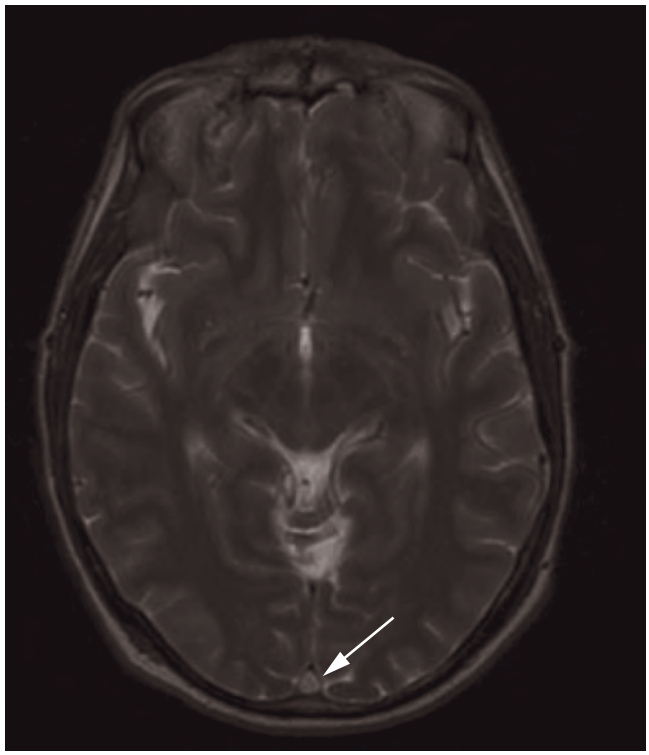

Figure 4.23 Absence of flow in the superior sagittal sinus caused by thrombus (MRI T2W). Arrow indicates thrombosed sagittal sinus.

Figure 4.24 Parieto-occipital haemorrhage and multiple venous infarction (MRI T2W).

hyperacute (first few days) and chronic phases (1–2 months) necessitating flow-related imaging (Figure 4.23). Sometimes, the flow-related imaging can be difficult to interpret, especially whether the transverse sinus on the left is hypoplastic (a common variant) or thrombosed. If sufficient clinical suspicion exists and MR/MRV are negative, we recommend CT angiography or, if necessary, catheter angiography. Depending on local practice, CT angiography may be the investigation of choice. Rarely, venous sinus thrombosis is the result or the cause of dural fistulae and this often needs full intra- and extracranial angiography to diagnose.

The most common sinus involved is the sagittal sinus, followed by the lateral sinuses. Cortical veins may rarely be involved in isolation (Figure 4.24). Imaging proof of isolated cortical venous thrombosis is difficult. Often one has to embark on treament on the basis of the clinical presentation and MRI of a presumed venous infarct. Thrombosis of the deep venous system is rare in adults and gives rise to thalamic venous infarction with prolonged coma.

Cavernous sinus thrombosis should be considered a separate entity as it is most commonly caused by local sepsis rather than primary or secondary non-septic hypercoagulable states. It is a serious disease with a high mortality. The veins draining the face are the common portals, hence the view that facial cellulitis is a very serious condition. The early symptoms are pain, headache, fever, facial oedema then proptosis and ophthalmoplegia (Chapter 13). The principal treatment is antibiotics. Non-septic cavernous sinus thrombosis may follow head injury and thrombosis within dural cavernous arteriovenous fistulae. Cavernous sinus thrombosis rarely presents to stroke neurologists, but is seen more commonly in ophthalmological and emergency medical practice.

The accepted treatment of intracranial venous thrombosis is anticoagulation, whether haemorrhage is present or not. The evidence for this is controversial. Anticoagulants were first given to prevent pulmonary embolism from intracranial thrombosis. Early studies suggested that patients treated with anticoagulants had a 7% mortality as opposed to 37% untreated. A small prospective trial and retrospective analysis also suggested a significant survival benefit with anticoagulation and also the safety of heparin in the presence of haemorrhage. Later studies have suggested no advantage to heparin but were weighted toward less sick patients with indolent intracranial hypertension presentations, and better than expected outcomes in the placebo arm. It is the general view from clinical practice that anticoagulation is an essential treatment for these patients. The favoured method is subcutaneous low molecular weight heparin as opposed to intravenous heparin unless surgery is contemplated. The literature supports the safety of heparin in haemorrhage. In addition to anticoagulation, sepsis must be identified and treated with antibiotics and drainage where appropriate (e.g. mastoiditis). Patients with significant intracranial pressure will need ventilation and occasionally consideration for craniotomy. Our policy following

venous thrombosis is to anticoagulate for 6 months, or for longer terms if a persisting reason for hypercoagulability persists. In patients with disc swelling vision should be monitored using a visual field screen (e.g. Goldmann) at regular intervals. Visual obscuration (Chapter 13) is a sign of incipient optic nerve infarction. Optic nerve fenestration, therapeutic lumbar puncture, lumbo-peritoneal shunting and acetazolamide all have their place in management. Recently, thrombolytic agents delivered by a transvenous endovascular route have been used to treat patients with sinus thrombosis and may be safe with haemorrhage. Early studies show promising results, but our current policy is to reserve this for patients not responding to, or worsening on, heparin.

The outcome of venous thrombosis tends to be polarized. Usually, patients either make a good recovery or die. Good outcome may be seen in up to 85%, death in 12%, and the remainder have an intermediate outcome. Mortality is higher with age and in association with infection or cancer. Seizures occurring during the acute phase have a good long-term prognosis with low rate of recurrence. Recurrent thrombosis may be seen in 10–20%, usually in the first year. The necessity for long-term anticoagulation after the first thrombosis is based on identifying ongoing active risk factors and the strategy is identical to that applied to limb venous thrombosis.

Vascular disease of the spinal cord

The spinal cord is most often affected by occlusion of the anterior spinal artery which supplies the anterior two-thirds of the cord. The blood supply is most tenuous in the upper thoracic region of the cord, which is a border-zone region. Although the anterior spinal artery is vulnerable to aortic dissection, most patients with anterior spinal artery occlusion presenting to a neurologist have atherosclerosis secondary to multiple risk factors, especially hypertension and diabetes. The dorsal columns are spared (because of a rich plexal supply) after the anterior spinal artery occludes. The resultant clinical picture is that of acute areflexic paraplegia characterized by dissociated sensory loss, with striking preservation of joint position and vibration sense but marked loss of pinprick and temperature sensation. Paraplegia is also well recognized following aortic surgery. There is a vogue still for anticoagulation of these patients but little evidence to support this measure.

The spine can also be affected by AVMs and dural fistulae. Dural fistulae present with symptoms resulting from venous hypertension and cord ischemia. Bleeding does not occur from spinal dural fistulae, unlike their cranial counterparts. They often present in elderly men with stepwise cauda equina symptoms with prominent exercise exacerbation. MRI virtually always shows dilated draining veins and treatment may be possible with embolization or surgery. The remainder of spinal AVMs are mostly intramedullary; they present in younger men with cord syndromes, cord or epidural bleeding. Treatment is often difficult, and unsatisfactory. Other features of vascular cord disease are discussed in Chapter 15.

5 Movement Disorders

Niall Quinn, Kailash Bhatia, Peter Brown, Carla Cordivari, Marwan Hariz, Andrew Lees, Patricia Limousin, Mary Robertson, Anette Schrag, Sarah Tabrizi

Movement disorders are common causes of disability, especially in older people. They either cause poverty of movement, typical of akinetic-rigid disorders, or unwanted, involuntary movements – the hyperkinetic disorders, or dyskinesias.

Much early work in the field was pioneered by Dr Kinnier Wilson and Dr Purdon Martin at The National Hospital, and many others elsewhere. Professor David Marsden, in London and Professor Stanley Fahn (the Neurological Institute, New York) founded the Movement Disorder Society and its journal *Movement Disorders*.

Akinetic-rigid syndromes

Cardinal motor features of parkinsonism

Akinesia is the defining, obligatory and principal disabling feature of parkinsonism (Table 5.1). It is a symptom complex, comprising slowness of movement (bradykinesia), poverty of movement and small amplitude of movements (hypokinesia), difficulty initiating movement or with simultaneous motor acts and, most specifically, fatiguing and decrementing amplitude of repetitive alternating movements, which distinguish true akinesia from pyramidal or cerebellar slowing.

Almost all individuals with parkinsonism also display muscular rigidity to passive movement across a joint. Unlike spasticity, it is fairly equal in flexors and extensors, and may feel like bending a lead pipe; the presence of additional tremor (which may not be visibly evident) can add a ratchety 'cogwheel' feel to the rigidity (tremor alone can cause cogwheeling, but without rigidity).

Tremor is an optional extra for parkinsonism, and indeed for Parkinson's disease (PD) itself, although up to 80% of PD patients will display a tremor at some stage. This is usually in the form of a 4–6 Hz classic rest tremor which, in the hand, is 'pill-rolling' with flexion of the thumb. It typically subsides or lessens with movement, to reappear after an interval when a new position of rest (e.g. arms outstretched) is achieved ('re-emergent tremor'). A number of patients may additionally, or instead, display a faster postural tremor. A classic rest tremor, particularly if accompanied by a jaw tremor, is a strong pointer to PD or drug-induced parkinsonism, but this combination can also be seen in dystonic tremor (see tremor below). Classic rest tremor is uncommon, and jaw tremor rare, in other degenerative forms of parkinsonism.

To the above triad a fourth 'cardinal' motor feature of parkinsonism is sometimes added – postural abnormality. Flexed posture may or may not be evident early in the disease, and postural instability is typically a late feature in PD, so this item is not useful for detecting PD, although if present early on may point to alternative causes of the syndrome.

(Idiopathic) Parkinson's disease

Traditionally, PD has been defined as a clinico-pathological entity, in which progressive levodopa-responsive parkinsonism, without atypical features (see below), is associated, at autopsy, with neuronal loss and the presence of eosinophilic intracytoplasmic Lewy bodies in specific central and autonomic nervous structures. These include particularly the pigmented brainstem monoaminergic nuclei, the substantia nigra (dopaminergic) and locus caeruleus (noradrenergic). However, the pathology is usually much more widespread, also involving serotonergic raphe nuclei, dopaminergic mesolimbic, mesocortical and tubero-infundibular pathways, the cholinergic nucleus basalis of Meynert (NBM), cerebral cortex, the hypothalamus, the dorsal motor nucleus of vagus, the olfactory tract and sympathetic ganglia.

Clinical heterogeneity has long been recognized within 'PD', and the definition of PD has been turned upside down with the isolation (thus far) of two genes (*alpha-synuclein* and *LRKK2*), mutations in which (or, in the case of *alpha-synuclein*, duplications or triplications of which) can cause dominantly inherited or sporadic parkinsonism accompanied by Lewy bodies, and also

Neurology: A Queen Square Textbook Edited by Charles Clarke, Robin Howard, Martin Rossor and Simon Shorvon
ISBN: 978-1-405-13443-9

Table 5.1 UK PDS Brain Bank diagnostic criteria for Parkinson's disease.

STEP 1. Diagnosis of a parkinsonian syndrome

Bradykinesia (slowness of initiation of voluntary movement with progressive reduction in speed and amplitude of repetitive actions) – obligatory

And at least one of the following:

- Muscular rigidity
- 4–6 Hz rest tremor
- Postural instability not caused by primary visual, vestibular, cerebellar or proprioceptive dysfunction

STEP 2. Exclusion criteria for Parkinson's disease

History of repeated strokes with stepwise progression of parkinsonian features
History of repeated head injury
History of definite encephalitis
Oculogyric crises
Neuroleptic treatment at onset of symptoms
More than one affected relative
Sustained remission
Strictly unilateral features after 3 years
Supranuclear gaze palsy
Cerebellar signs
Early severe autonomic involvement
Early severe dementia with disturbances of memory, language and praxis
Babinski sign
Imaging evidence of a cerebral tumour or communicating hydrocephalus
Negative response to large doses of levodopa if malabsorption excluded.
MPTP exposure

STEP 3. Supportive prospective positive criteria for Parkinson's disease

(Three or more required for diagnosis of definite Parkinson's disease)
Unilateral onset
Rest tremor present
Progressive disorder
Persistent asymmetry affecting the side of onset most
Excellent response (70–100%) to levodopa
Severe levodopa-induced chorea
Levodopa response for 5 years or more
Clinical course of 10 years or more

three recessive genes (*parkin*, *DJ1* and *PINK1*), mutations of which can cause parkinsonism, typically without Lewy bodies, mainly in younger individuals. Thus, there are at least six 'PDs' so far, with perhaps a dozen or more yet to identify. How many of these should still be called Parkinson's disease is a moot point. The phenotypes of these monogeneic 'PDs', especially of *LRKK2* cases, can be indistinguishable from typical sporadic PD. However, patients with *alpha-synuclein* mutations or triplications have somewhat younger onset, shorter survival and a higher incidence of dementia. The recessive forms have younger onset, slower disease progression and present with leg tremor more often than sporadic PD.

Molecular advances have introduced alternative schemata for classifying the principal degenerative parkinsonisms into alpha-synucleinopathies (Lewy body diseases and multiple system atrophy [MSA]), tauopathies (including progressive supranuclear palsy [PSP] and cortico-basal degeneration [CBD]), and others (e.g. cases with parkin mutations). Classification is therefore currently back in the 'melting pot'. Table 5.2 gives causes of parkinsonism and other conditions sometimes confused with PD.

Table 5.2 Causes of parkinsonism and other conditions sometimes confused with Parkinson's disease.

Idiopathic Parkinson's disease (including DLB)

Genetically determined 'Parkinson's diseases'

Dominant

- *Alpha-synuclein* mutations (PARK1) or gene duplications/ triplications (PARK4)
- *LRKK2*/dardarin mutations (PARK8)

Recessive

- *Parkin* mutations (PARK2)
- *DJ1* mutations (PARK7)
- *PINK1* mutations (PARK6)

Other neurodegenerative diseases

Classically sporadic

- Multiple system atrophy (MSA)
- Progressive supranuclear palsy (PSP)
- Cortico-basal degeneration (CBD)

Genetic

- Dominant
  - Huntington's disease (HD, Westphal variant)
  - Spinocerebellar ataxia type 2 (SCA2)
  - SCA3
  - Frontotemporal dementia with parkinsonism related to chromosome 17 (FTDP-17)
- Recessive
  - Wilson's disease (WD)
  - Neurodegeneration with brain iron accumulation (NBIA) type 1 (formerly Hallervorden–Spatz disease)
- Uncertain
  - Parkinsonism–dementia–ALS complex of Guam
  - PSP-like atypical parkinsonism in Guadeloupe
- Other genetic
  - Dopa-responsive dystonia (DYT5, Segawa disease – older patients) – dominant with incomplete penetrance
  - Dystonia-parkinsonism in Filipinos (DYT3, XDP,Lubag) – X-linked
  - Rapid onset dystonia-parkinsonism (DYT12) – dominant
- Reversible drug-induced secondary to dopamine receptor blocking or dopamine depleting drugs
- Toxic, due to MPTP/CO/methanol/manganese
- Post-encephalitic due to encephalitis lethargica/post-strep/Japanese B encephalitis
- Dementia with Lewy bodies (DLB)
- Vascular parkinsonism/pseudoparkinsonism*
- Post-traumatic due to repeated head trauma ('punch-drunk syndrome') or midbrain compression
- Essential tremor*
- Dystonic tremor*

* Often misdiagnosed as Parkinson's disease even though fatiguing/decrement of repetitive movements not present.

The prevalence of PD in most countries is around 180/100,000. Different genetic causes vary in frequency in different populations (e.g. *LRKK2*-related parkinsonism is particularly common in Askenazi Jews and in North Africans). Overall, incidence rises steadily with age, although recessive forms become less frequent with age. Average age at onset is about 60 years, with fewer than 5% of cases starting before age 40. Despite modern treatment, life expectancy is still reduced, with a standardized mortality ratio of about 1.9.

The most widely used clinical diagnostic criteria for PD are still those elaborated in 1988 by the UK Parkinson's Disease Society Brain Bank (Table 5.1).

PD has been traditionally defined as a motor disorder, but the frequency and importance of premotor and non-motor features is increasingly recognized.

Premotor features

All neuronal systems have built-in reserves in terms of tolerating a degree of neuronal loss, and compensating for this by up-regulation of surviving neuronal function before a threshold symptomatic deficit is reached. Thus, 60–80% of nigro-striatal dopaminergic reserve is lost before the motor features of parkinsonism emerge. Brains with 'subclinical' nigral Lewy bodies have been called 'incidental Lewy body disease'. Sequential fluorodopa positron emission tomography (PET) scans have been used to estimate, by back-extrapolation, the duration of the 'presymptomatic' phase of PD, with estimates varying between 3 and 6 years. However, a number of pathological and clinical observations have questioned this. Thus, in 2006, Braak *et al*., based on examination of Lewy body pathology in a large number of brains of individuals with and without clinical parkinsonism in life, postulated 6 'stages' of PD. In stages 1 and 2, Lewy bodies are restricted to the medulla, pontine tegmentum and anterior olfactory structures, and it is only in stage 3 that the nigro-striatal tract is first involved. Thus, back-extrapolation from fluorodopa PET scans can only, at best, tell us when stage 3 might begin. Clinically, constipation, dysphagia, olfactory impairment, cardiovascular autonomic involvement and REM sleep behaviour disorder (RBD) can precede, by many more years, the appearance of the motor disorder in PD. In RBD there is loss of the usual somatic atonia that accompanies dreaming, such that the individual is able to 'act out' usually frightening dreams, often striking or injuring their bed-partner, and often with vocalizations. In one sleep laboratory study, 38% of 29 men with (at that time idiopathic) RBD went on to be diagnosed with a parkinsonian disorder an average of 3.7 years after the diagnosis and 12.7 years after the onset of their RBD.

When candidate neuroprotective agents do appear, if they are to be applied to greatest effect they will need to be given as early in the disease process as possible, hence the considerable current efforts to develop a reliable battery of tests to screen for subjects in the earliest stages of disease, or with a particularly high risk.

Other non-motor features

A host of other non-motor features occur in, and can be the most disabling features of PD:

- Sialorrhoea is particularly a problem in later disease; only a few patients can tolerate centrally acting anticholinergics such as scopolamine because of the risk of confusion, but some can be helped by peripherally acting drugs, or botulinum toxin injections or radiotherapy to salivary glands.
- Drenching sweats usually occur in drug-treated patients, but are poorly understood and no effective pharmacological treatment exists.
- Urinary urgency and frequency are common, as a result of detrusor hyper-reflexia in PD, and can be helped by a peripherally acting anticholinergic such as trospium.
- Depression, usually minor rather than major, affects about 40% of patients before, at or after diagnosis. The symptomatology of this minor depression overlaps with abulia, and lack of initiative and drive, which is also common in PD. Clinical depression is probably best treated with a selective serotonin re-uptake inhibitor (SSRI) rather than a tricyclic. In numerous studies, depression has been shown to be the most important factor correlating with impaired quality of life, so it should be actively sought, and treated if found.
- Anxiety, and sometimes panic, can also be a major problem for many patients, and again is poorly understood.
- Pain is also common in PD. It may be a presenting feature or may arise in established disease.

Any or all of the features described here may occur not on a sustained basis, but appear at times when the patient is 'off' or wearing off in the context of levodopa-related motor fluctuations – indeed, such *non*-motor fluctuations can represent the patient's biggest problem. Pain is typically lateralized to the side more affected by PD. Appropriate management in these patients may take the form of measures to minimize time 'off', e.g. by appropriately timed injections of apomorphine, rather than necessarily resorting to antidepressants or analgesics.

A whole range of neuropsychiatric disturbances resulting from the disease or its treatment can also occur (see below).

The 'typical' motor presentation of PD

PD is classically an asymmetric disease, remaining so throughout its course. It more commonly starts in the arm, with impaired dexterity on fine tasks, and often with a tremor at rest, e.g. holding a newspaper. Other patients present with a tendency to drag one leg or shuffle. The spouse may have noticed a general slowing down, a change in facial expression or impaired arm swing. Direct questioning may reveal a change in voice or micrographia, but speech difficulty or micrographia as presenting complaints are less common, raising the possibility of atypical disease. The patient may admit to aching or sometimes pain in the affected limb, and presentation with or development of a frozen shoulder or worsening back discomfort is well recognized.

Examination will reveal akinesia, usually with rigidity and often tremor, which may be difficult to bring out. The patient

should be asked to dangle the wrists over the arms of a chair, and stressed by being asked to count backwards with the eyes closed, again with the arms outstretched, then with the fingers in front of the nose. Often the earliest tremor to be observed may be an adduction–abduction tremor of the fingers. Sometimes, the only time a rest tremor is observed is on walking, when reduced arm swing, flexed posture (initially of one arm) and gait abnormality may be seen.

Atypical features should also be sought. The 'bedside' examination of eye movements should be normal (except for some limitation of convergence or of up-gaze with normal saccadic velocity), and there should be no evidence of limb or gait ataxia or dysdiadochokinesis, no apraxia and no pyramidal signs. The so-called 'striatal toe' can mimic a Babinski response, but is often present spontaneously or on walking and is not accompanied by other pyramidal features. Sometimes (particularly younger) patients may present with 'dystonic claudication' (exercise-induced leg dystonia) on prolonged walking. Early postural stability or freezing of gait, although sometimes seen in PD, should raise other possibilities. Of note, patients who are unsteady for whatever reason may not swing their arms, and abnormal arm swing is also common in patients with dystonia.

Evolution of disease

Unilateral PD (stage 1 on the non-linear Hoehn and Yahr scale) always progresses, through stage 2 (bilateral), which typically lasts for 5–10 years, until postural instability (stage 3) appears. Over time, fully developed disease (stage 4) develops, and after many years the patient may eventually become chair- or even bed-bound (stage 5). However, this progression is influenced by treatment, so that a patient on chronic levodopa treatment may fluctuate between stage 4 or even 5 when 'off', to stage 2 or 3 when 'on'. Freezing of gait is usually a late feature.

Ancillary investigations

Young onset (less than 40 years) patients should always be screened for Wilson's disease with serum copper and coeruloplasmin and slit-lamp examination. Routine magnetic resonance imaging (MRI) of the brain is normal in PD and not necessary in typical cases. A dopamine transporter (DaT) single photon emission computerized tomography (SPECT) scan can sometimes be useful to confirm a nigro-striatal lesion (see further details below) but in a typical case of PD is unnecessary and expensive.

Treatment

Discussion of treatment options is influenced by what is known about the course of PD on chronic treatment with levodopa preparations, so levodopa will be dealt with first, 'out of turn', in order to inform about alternative treatments early in the disease course.

Levodopa

Preparations of levodopa combined with the peripheral decarboxylase inhibitors (PDIs) carbidopa or benserazide (co-careldopa, Sinemet; co-beneldopa, Madopar) are still the most potent and effective symptomatic treatment for PD, and remain the 'gold standard'. Levodopa, in common with other large neutral amino acids, is transferred across the wall of the proximal small bowel, and again across the blood–brain barrier, by a competitive active transport system. Some patients find that protein in meals impairs the effect of a dose of levodopa close to meals, so that timing or size of the dose, or the protein intake, may need adjustment.

Once in the brain, no longer protected from the peripheral decarboxylase inhibitor that cannot follow it, levodopa is metabolized to dopamine, which then stimulates available dopamine receptors in striatum (but also elsewhere in the brain).

It is usual to start with half a tablet of 25/100 (PDI/levodopa) strength b.d. or t.d.s. for a couple of weeks, then doubling the dose and waiting to judge the effect. If ineffective or insufficiently effective, the dosage may then be increased to 1½ or 2 tablets t.d.s., although the ELLDOPA trial showed increasing rates of dyskinesia and wearing-off, particularly as the dose increased from levodopa 300 to 600 mg/day. Almost all PD patients will show marked improvement at this dose but, if ineffective, the total daily dosage of levodopa should be further increased to 1–1.5 g/day (if tolerated) before deciding it is not going to benefit a given patient. One should note that there are long duration effects of levodopa such that a treatment change can take at least 2 weeks for its effect to equilibrate in the brain, and similarly one can see late deterioration up to 2 weeks after discontinuing or reducing the dosage. Initially, benefit is smooth throughout the day, even if a dose is late or missed – the so-called 'honeymoon period'. Over time, however, patients start to notice early morning akinesia, or wearing off of their doses, and around the same time develop an 'overshoot' from akinesia to dyskinesia when the dose is working. A very rough rule of thumb is that these problems (the long-term levodopa syndrome) develop in 10% of patients per year of treatment, so that after 5 years about 50% of patients will have them, and after 10 years all patients will ultimately experience them, to a greater or lesser degree. In general, younger onset patients develop them earlier and to a more severe degree. Rates reported from clinic-based series are higher than those in community-based studies.

Gradually a 'threshold' level of dopaminergic transmission in the striatum develops, so that the doses work in an all-or-none fashion, and the patients fluctuate, sometimes over minutes or even seconds, from mobile dyskinetic 'on' to akinetic 'off'. Fractionation of doses to give smaller amounts more frequently may lead to dose failure, or unpredictability of effect. This may also occur with controlled release (CR) preparations because, relative to standard preparations, bioavailability of CR levodopa is only 70%; moreover, although providing a longer tail at the end of the dose, CR is absorbed more slowly than standard, leading to delayed 'on' and sometimes only a short 'on' period because the threshold is only briefly exceeded. CR formulations have been disappointing in managing daytime fluctuations, but useful at bedtime to improve nights. A (very expensive) levodopa-carbidopa gel (Duodopa) delivered continuously into proximal jejunum via a

gastrostomy can give stable plasma levels and improve fluctuations in patients who are unsuitable for, or unable to tolerate, apomorphine or surgery.

Mobile dyskinesias can be peak dose (occurring mainly at the peak of action of each dose), square wave (occurring throughout the period of benefit) or diphasic (being much more severe at the beginning or at the end of action of a dose of levodopa). Most 'on' period dyskinesias are usually a mixture of chorea and dystonia, but when diphasic (usually in young onset patients) they can be violent and disabling stereotyped or ballistic movements.

Some patients develop 'off' period dystonia, which is relatively fixed, usually painful, most commonly affects one leg and relates to falling, low or intermediate levels of dopaminergic stimulation; paradoxically, they are both caused and relieved by levodopa, disappearing when the patient turns 'on'. Levodopa-induced dyskinesias in PD typically involve limbs more than neck and face, and are more severe on the initially, and more, affected side.

Other side effects of levodopa

Levodopa can also cause nausea or vomiting, mainly by stimulating dopamine receptors in the chemoreceptor trigger zone in the area postrema in the floor of the fourth ventricle, functionally outside the blood–brain barrier, which can be prevented or reduced by giving domperidone, a peripheral dopamine antagonist that does not follow levodopa into the brain. Levodopa can also cause or aggravate postural hypotension, mainly through a central action. It can also cause a wide range of neuropsychiatric disturbances in susceptible individuals.

There is no evidence that levodopa kills nigral dopaminergic neurones in patients with PD. However, concerns about the development of the long-term levodopa syndrome have led many physicians to try to delay the introduction of levodopa, if possible, at least in younger patients, by using a variety of medications that do not cause this problem, although at the expense of having a less potent therapeutic effect and more psychiatric adverse effects.

When to start treatment

No drug has so far been proven to be neuroprotective in PD. When the patient is first diagnosed they may not feel in need of symptomatic treatment, and the doctor may not wish to rush into treatment at the first visit. There have been recent suggestions that early initiation of treatment might improve subsequent response, even without a neuroprotective action, but this is unproven. Today, most physicians still wait until the patient's symptoms are beginning to affect their daily life before starting symptomatic treatment.

How to start treatment

There is little to be gained in elderly PD patients, especially if cognitively impaired, in using alternative medications to delay the introduction of levodopa, because in this group it has the best therapeutic index – other drugs, and polypharmacy, are more likely to produce confusion or hallucinations, while also being clinically less effective.

In contrast, in younger patients there are several possible options.

Catechol-O-methyl transferase (COMT) inhibitors

Entacapone (peripheral) and tolcapone (peripheral and central COMT inhibitor) block the conversion of levodopa to 3-O-methyldopa, its principal metabolite. They both extend the elimination half-life of levodopa, and thereby often extend the duration of action of individual doses. Tolcapone is generally the more effective of the two, but is only used as a second-line treatment because of a (low) risk of potentially fatal hepatotoxicity, necessitating frequent liver function test monitoring. Both drugs can cause gastrointestinal upset, particularly diarrhoea, and a harmless orange discoloration of the urine. A combined tablet containing levodopa, carbidopa and entacapone (Stalevo) is available.

Monoamine oxidase B (MAO-B) inhibitors

Selegiline and rasagiline are 'suicide' inhibitors of MAO-B, the iso-enzyme responsible for catabolizing dopamine to homovanillic acid (HVA). Unlike MAO-A inhibitors, they can safely be given together with levodopa. Used alone in early disease, these drugs can, probably through a mild sympathomimetic effect, delay the need for levodopa. Oral selegiline is partly metabolized to metamphetamine, so should be given in the morning to avoid insomnia. Zelapar, a buccally absorbed preparation of selegiline, avoids first-pass metabolism and hence this problem. Otherwise these drugs have very few side effects when given alone, but can potentiate any of the symptomatic side effects of levodopa.

Anticholinergics

Anticholinergics were the first drugs used to treat PD. They usually have only a mild symptomatic effect, often restricted to reducing tremor, although when abruptly discontinued patients can dramatically worsen acutely. Because of cortical pathology, and the cholinergic deficit caused by NBM pathology, older PD patients are particularly susceptible to develop hallucinations and organic confusional states when given centrally acting anticholinergics, so these should be avoided in such cases, and restricted to younger, cognitively intact, usually tremor-dominant patients.

In the periphery, anticholinergics can cause blurred near vision because of mydriasis (so are contraindicated in narrow angle glaucoma), delayed gastric emptying and constipation. However, they can help sialorrhoea, and also reduce the detrusor hyperreflexia commonly responsible for frequency and urgency in PD, but can precipitate retention of urine if there is also an element of prostatic obstruction.

Amantadine

This drug has several actions: an amphetamine-like effect (releasing presynaptic dopamine stores); a mild anticholinergic effect; a mild dopamine re-uptake inhibition effect; finally, it is also an *N*-methyl-D-asparate (NMDA) glutamate receptor antagonist.

Traditionally, amantadine was used as a mild early treatment. Often the effect would wane, at least in part, after 6 weeks or so. The drug commonly causes ankle oedema and livedo reticularis,

and lowers seizure threshold. It can cause hallucinations or confusion, and is excreted by the kidneys, so should be used with caution in renal failure. More recently, amantadine has been recognized to have a (sometimes dramatic) antidyskinetic effect in at least some patients on levodopa, without worsening parkinsonism, presumed to be mediated by its NMDA antagonist property. It can also help freezing, even 'on' freezing, in a minority of patients.

Dopamine agonists

Dopamine agonists stimulate dopamine receptors directly. Six oral agonists (four ergoline: bromocriptine, lisuride, pergolide and cabergoline; and two non-ergoline: ropinirole and pramipexole) and one transdermal non-ergoline agonist (rotigotine) are available. Given before levodopa is introduced, these drugs cause fluctuations and dyskinesias much less frequently, but have a weaker antiparkinsonian effect. However, they can cause dyskinesias in patients who have already developed them on chronic levodopa treatment. The intensity of dyskinesias in levodopa-treated patients can often be lessened by partially replacing levodopa with an agonist.

Adverse effects

Dopamine agonists stimulate both peripheral and central dopamine receptors. The risk of nausea and vomiting can be reduced by the peripherally acting dopamine receptor antagonist domperidone, which does not cross the blood–brain barrier. Other antiemetics that do not block dopamine receptors are cyclizine, promethazine and ondansetron. Tolerance to nausea usually develops rapidly over 10 days or so, and there is cross-tolerance between levodopa and agonists, and between different agonists. Covering the introduction of an agonist is therefore most important with *de novo* treatment, optional when adding an agonist to levodopa, and unnecessary when switching between agonists (except to switch to apomorphine).

Agonists can cause postural hypotension and aggravate active cardiac disease or peptic ulceration. Any antiparkinsonian medication can cause neuropsychiatric adverse effects, but the oral agonists definitely cause more problems than levodopa. At the milder end of the spectrum, they can cause vivid dreams or nightmares, illusions, extracampine hallucinations (delusions of presence) or (typically visual) pseudohallucinations (with retained insight), of animals or people, sometimes Lilliputian, often non-threatening. More problematic are true hallucinations (with loss of insight) and other delusions (often paranoid, sometimes involving morbid jealousy); and hypersexuality, exhibitionism or paraphilia and pathological gambling and shopping (sometimes isolated, but sometimes in the context of hypomanic-like symptoms), and 'punding' (defined as repeated stereotyped pointless complex behaviours), often grouped together under the heading of impulse control disorders or dopamine dysregulation syndrome.

All agonists can cause ankle swelling, sometimes extending to the knees or higher. In most cases the mechanism is unknown, but evidence of cardiac failure should always be sought. The ergot derivatives, particularly, can cause a tense angry erythematous rash called erythromelalgia.

It has long been recognized that some agonists can (rarely) cause lung fibrosis, pleuro-pulmonary effusions or (even more rarely) retroperitoneal fibrosis. More recently, they have also been found to cause fibrosis of heart valves (most commonly the tricuspid), analogous to what is seen with carcinoid tumours and fenfluramine treatment. This reaction is thought to be mediated by stimulation of 5HT2B receptors, and to be wholly, or mostly, restricted to ergoline agonists. The vast majority of patients found on echocardiography to be affected are asymptomatic, but because of these problems pergolide is being withdrawn by the manufacturers in the USA, and cabergoline might follow suit.

de novo use of dopamine agonists

Patients should be warned that at low dosage dopamine agonists can have a paradoxical effect of worsening parkinsonism. This is because the presynaptic dopamine D2 autoreceptors that shut down endogenous dopamine release are more sensitive to dopamine agonists than are the postsynaptic D2 receptors that mediate their beneficial motor effects. Agonists are often used in suboptimal dosage, often because the patient stops increasing the dosage at the end of a 'starter pack', and because of confusion about what is meant by 'minimum effective dose' – this may be construed as the dose that is effective, but is usually the minimum dose that has any useful effect.

If an agonist has not been effective, or not well tolerated, what should be done? This partly depends on the dosage reached. The authors' practice is that if a patient achieves up to two-thirds of the recommended dosage with absolutely no benefit, usually either levodopa is added or, less often, another agonist is used instead. If the patient benefits, but not sufficiently, upward titration towards the maximum dosage would be used, side effects permitting, before adding levodopa and later cutting back on the agonist dosage. If one oral agonist fails to have any useful effect at maximum dosage, there is usually little to be gained by switching to another. If one agonist is poorly tolerated because of somnolence, one may switch to another, although risking the same problem again. If an agonist is poorly tolerated because of hallucinations, delusions or confusion, there is a significant risk of the same with another agonist.

'Add-on' use of dopamine agonists

Dopamine agonists have longer clinical and pharmacological half-lives than levodopa. Hence, when added, they can help to minimize 'troughs' of dopaminergic stimulation and increase 'on' time. Dyskinesias will usually increase, unless the dose of levodopa is reduced to compensate. In general, the less a patient's dopaminergic stimulation is obtained from levodopa and the more from an agonist, the less severe their dyskinesias tend to be.

Apomorphine is the oldest and most effective agonist. Because of extensive first pass metabolism, it has to be given parenterally, by subcutaneous intermittent injection, to 'rescue' patients from 'off' periods, or by continuous infusion to reduce them. The effect of single injections (usually 3–5 mg) is rapid (within 10–15 minutes) and reliable. Infusions (usually 3–6 mg/hour) can be supplemented by on-demand boluses. Apomorphine causes more

drowsiness, particularly initially, and less psychiatric morbidity than oral agonists. It can rarely cause an autoimmune haemolytic anaemia, so periodic haemoglobin, reticulocytes and Coombs testing is mandatory. Patients may also develop tender, inflamed or infected subcutaneous nodules or panniculitis which may cause them to abandon treatment. Infusions are usually given for about 12 hours during the day, and any oral agonists can usually be tailed off and levodopa dosage often reduced. Dyskinesias usually diminish over weeks or months. Some patients use apomorphine infusions just at night, or 24 hours/day, with a lower rate at night. Occasional patients who are very sensitive to levodopa may end up on apomorphine monotherapy.

Surgery for PD

For some patients with advanced PD, with motor fluctuations and dyskinesias, or troublesome tremor, who are difficult to manage despite the combination of available drugs, functional neurosurgery can be an option. Lesioning procedures were applied for many years but have been largely replaced by deep brain stimulation (DBS) in most countries. DBS uses permanent implanted electrodes in the brain in conjunction with a pacemaker that delivers high-frequency electrical impulses. The three established brain targets for the treatment of PD with DBS are the ventrolateral thalamus, the internal pallidum (GPi) and the subthalamic nucleus (STN). DBS on each target improves a different range of symptoms.

Thalamic deep brain stimulation

Thalamic stimulation was developed in 1987 to treat tremor related to PD or essential tremor, initially contralaterally to a previous thalamotomy. In view of the benefits on tremor and the low rate of side effects, bilateral thalamic stimulation was then performed. However, thalamic DBS does not allow much reduction in drug dosage. Balance problems and dysarthria are possible side effects, especially after bilateral surgery. Patients are usually asked to stop the stimulation at night to reduce the risk of tolerance and rebound. Benefits on tremor can be maintained for more than 10 years. Nevertheless, some long-term studies have shown that in many patients other symptoms such as gait difficulty and dyskinesia progress and are not helped by thalamic DBS. This has lead to the search for other brain targets in which DBS may help those symptoms and there has been a decrease in the indications for thalamic DBS. Thalamic DBS still has a place for elderly patients with tremor dominant disease.

Subthalamic nucleus deep brain stimulation

Subthalamic nucleus deep brain stimulation (STN DBS) was developed in 1993, following basic research in the MPTP monkey model of PD. Hyperactivity of the STN was identified in their parkinsonian condition and an improvement of symptoms after STN lesions. In patients with PD, STN DBS can improve a large range of off-phase symptoms: limb bradykinesia, rigidity, tremor and gait difficulty including balance and freezing (if they are also dopa-sensitive). Levodopa-induced dyskinesias also improve over time, probably largely because of drug dosage reduction. 'Off' dystonia improves as well. Dopa-refractory symptoms are not helped and the effect on speech is variable, and in some patients intelligibility can deteriorate. Medications are usually reduced after STN DBS. In the early stage, stimulation is increased slowly in parallel with drug reduction to avoid increase of dyskinesias. After 5 years of STN DBS, although some of the benefits are maintained, the effect on axial features and the on-phase scores often declines. Side effects are not infrequent; they include speech problems, neuropsychiatric problems (in particular mood change), eyelid opening apraxia and dyskinesias induced by the stimulation.

Internal pallidum deep brain stimulation

Internal pallidum (GPi) DBS was developed in parallel with STN DBS but a smaller number of patients have received surgery because most teams opt for STN DBS. The effect on 'off' symptoms is more variable than with STN, the most reliable effect being against dyskinesia. Nevertheless, preliminary results of a comparative study have shown only a moderate difference between the results of GPi versus STN DBS. GPi DBS nevertheless has the advantage of a lower rate of side effects and remains useful particularly for older patients with severe dyskinesias who are at higher risk for adverse effects with STN DBS.

Patient selection for surgery

Patient selection aims at identifying those patients likely to benefit from surgery and unlikely to have severe adverse effects. Therefore, it is important to identify the disabling symptoms and assess if they are dopa-sensitive or dopa-induced and how they impact on the patient's daily life. A dopa challenge is very helpful to assess in detail 'off' symptoms, the response to medications and the severity and type of dyskinesias. Cognitive functions and mood should also be carefully assessed. Brain MRI is carried out to exclude contraindications such as severe atrophy, extensive white matter change and focal lesions. The patient's general condition has to be considered. Patients treated by platelet anti-aggregants or anticoagulants should be able to stop them for 2 weeks before and after surgery. Speech and swallowing have to be considered, because of the risk of deterioration. Patients and their family should be given detailed information about the procedure, its risks and potential benefits, as well as its limitations. Patient and family expectations have to be addressed. The choice of target depends on the profile of symptoms and the risk factors.

Surgery

Surgery is performed under stereotactic conditions. The implantation of the electrodes is usually carried out under local anesthesia. The target can be located using different imaging methods – brain MRI is now used for this by most surgeons. Brain atlases can also provide some guidance, in particular when the target cannot be visualized on MRI, e.g. the nuclei of the thalamus. During surgery different electrophysiological methods can be used. Microrecordings are used by many surgeons, although their safety is not entirely established. Intraoperative stimulation allows one to confirm the benefits and to observe side effects. The

pacemaker and the connectors are usually implanted under general anaesthesia. The general risk of surgery includes haemorrhage in 1–4% of patients according to the technique and the surgeon, and infection of the system in about 2% of patients.

Stimulator adjustment and long-term management

Patients implanted with DBS need long-term follow-up by a specialist team. Stimulation parameters have to be adjusted from time to time, as well as medication. Electrical parameters are similar for all targets: voltage is usually between 2 and 4 V, pulse width usually 60 μs, occasionally 90 μs, but tends to be higher in GPi, and frequency is typically 130 Hz or above. Monopolar stimulation is preferred unless side effects limit the increase in voltage. Adjustment of thalamic DBS is usually straightforward. Adjustment of STN DBS has to be progressive, in parallel with adjustment of medications. Adjustment of GPi DBS does not have the same immediate effect on the symptoms. The pacemaker has to be changed approximately every 4–7 years.

Some side effects, in particular neuropsychiatric problems such as depression, apathy and mania, can occur a long time after surgery. Infections can also occur late and patients should take prophylactic antibiotics in appropriate circumstances. Some medical equipment, in particular diathermy and monopolar coagulation, should not be used in DBS patients. Brain MRI after implantation can only be performed under very restricted conditions of energy delivery and using a receiver–transmitter head coil.

The future

Existing DBS procedures, although very helpful, have limitations. They only allow symptomatic improvement, they do not appear to change the progression of the disease and they are ineffective against dopa-refractory symptoms, with the exception of tremor. There is no real alternative at present, although preliminary reports of DBS in the area of the pedunculo-pontine nucleus have suggested that it might improve gait.

Dopaminergic cell transplants and intraputaminal delivery of glial derived neurotrophic factor (GDNF) have shown apparent improvement in a minority of patients, but these procedures are currently halted while some of their side effects are investigated further. Further development of potentially disease-modifying and restorative procedures is the challenge for the future.

Dementia in association with Lewy body pathology

It has long been recognized that patients with PD have a higher risk of developing dementia than age-matched individuals who do not have PD. Cross-sectional studies gave average prevalence rates for dementia in the PD population of 15–30%, but this had to be an underestimate of the true cumulative risk because such subjects died sooner than those without dementia, leaving fewer prevalent cases. The first longitudinal study found a rate of 42%, and a recent study in Norway with 8-year follow-up gave a cumulative dementia risk of 78%. Cases with more than 1 year of parkinsonism before developing dementia are arbitrarily called Parkinson's disease dementia (PD-D).

Another clinical pattern is the development of parkinsonism and dementia within 1 year of each other, or a similar type of dementia without spontaneous parkinsonism but with the presence of Lewy body pathology (usually accompanied by varying numbers of senile plaques and sometimes of both senile plaques and neurofibrillary tangles) in both cerebral cortex and brainstem. This is called dementia with Lewy bodies (DLB), and is the most common cause of dementia in the elderly after Alzheimer's disease (AD; see Chapter 7). Mean survival of both DLB and PD-D cases after the development of dementia is only 5 years.

Progressive disabling mental impairment is a mandatory requirement for both PD-D and DLB. For probable DLB two, and for possible DLB one of three core features are required:

1 Fluctuating cognition with pronounced variations in attention and alertness;
2 Recurrent visual hallucinations; and
3 Spontaneous features of parkinsonism.

Features suggestive of DLB are REM sleep behaviour disorder, severe neuroleptic sensitivity and impaired dopamine transporter uptake in striatum on PET or SPECT scanning.

The management of confusion and hallucinations and of cognitive impairment in PD, PD-D and DLB is challenging. Intercurrent illness should be sought and treated. The number of different psychoactive (mostly antiparkinsonian) drugs taken should be reduced, starting with anticholinergics, then dopamine agonists and amantadine, then MAOB inhibitors, then catechol-*O*-methyltransferase (COMT) inhibitors, leaving the patient on monotherapy with a levodopa preparation in the lowest dose possible. If hallucinations or delusions persist, an antipsychotic drug may be needed. Risperidone and olanzapine are not recommended. Quetiapine is well tolerated, but not of proven efficacy in this indication. The only drug with class 1 evidence of antipsychotic efficacy, while not worsening underlying parkinsonism, is clozapine. However, because of the risk of bone marrow suppression and the consequent stringent monitoring requirements, it is little used in the UK in this indication, for which it is often considered a second-line drug.

The cortical cholinergic deficit in demented, and even in non-demented, PD patients and in DLB, is greater than that in AD. Therefore, the cholinesterase inhibitors are also effective in these indications. However, they may be more likely to worsen urinary frequency and urgency because of the underlying detrusor hyperexcitability in Lewy body diseases.

Multiple system atrophy

This sporadically occurring alpha-synucleinopathy was also previously described as Shy–Drager syndrome, striato-nigral degeneration, or (some cases) sporadic olivo-ponto-cerebellar atrophy (sOPCA). It causes varying combinations of parkinsonism (MSA-P, usually poorly responsive to levodopa), cerebellar dysfunction (MSA-C), autonomic failure (orthostatic hypotension, male erectile dysfunction and urinary incontinence or incomplete bladder emptying) and pyramidal signs. Pathology involves varying combinations and locations of neuronal loss and oligo-

dendroglial pathology (ubiquitin and alpha-synuclein positive intracytoplasmic inclusions – GCIs) in striatum (especially posterior putamen), substantia nigra, locus caeruleus, inferior olives, pons and cerebellum, and in the intermediolateral cell columns and Onuf's nucleus of the spinal cord. Prevalence is about 4/100,000, mean age at onset is 57 years (never starting before age 30) and mean survival is about 7 (1–16) years. Often autonomic failure (AF) antedates the other neurology. If isolated AF persists for more than 5 years the term pure autonomic failure (PAF) is used – such patients usually have Lewy body pathology in autonomic ganglia, and also in nigra, but not enough to cause parkinsonism. Rare cases of MSA or of PD 'convert' from a label of PAF after the arbitrary 5-year period.

Other clinical features of MSA include RBD and sleep apnoea (also common, but less so, in PD), increased snoring, nocturnal or daytime stridor, emotional incontinence, myoclonic jerks of the fingers, impaired sweating and heat intolerance, Raynaud's phenomenon, cold dusky hands, disproportionate fixed antecollis, postural instability, dysphagia and a characteristic dysarthria – high-pitched, quivery, strained and hypophonic in MSA-P or slurring cerebellar-type in MSA-C. Frank dementia is rare, and an exclusion criterion for the diagnosis, because patients (usually more elderly) with the combination of dementia, parkinsonism and autonomic failure are much more likely to have Lewy body pathology. Consensus diagnostic criteria for MSA were recently revised (Gilman *et al*. 2008).

Progressive supranuclear palsy

Progressive supranuclear palsy (PSP) is a tauopathy, usually sporadic, rarely familial. It classically causes axial (hence symmetrical) akinesia and rigidity, early falls (classically backwards without warning), dysarthria (lower pitch, growling, with late groaning), dysphagia, personality change, frontal cognitive deficits and eye features. These include frontalis overactivity, levator inhibition, sometimes blepharospasm, and a characteristic supranuclear gaze palsy (or, more correctly, paresis) that is necessary for the clinical diagnosis and which gives the disease its name. Often the earliest feature is slowing of vertical voluntary saccades, followed by supranuclear limitation of up-gaze (non-specific) or down-gaze (always pathological), followed by similar abnormalities on horizontal saccades. The supranuclear cause of any limitation of voluntary gaze is identified when a complete range of automatic reflex eye movements is demonstrated by the oculocephalic, or doll's head, manoeuvre, such automatic–voluntary dissociation indicating that the oculomotor pathway from the nucleus distally is intact. The latency to initiate saccades is typically normal in PSP, in contrast to CBD (see below).

The pathology of PSP involves neuronal loss and gliosis, with straight neurofibrillary tangles and tufted astrocytes particularly in substantia nigra, dentate nucleus, pallidum, subthalamic nucleus and, to a variable degree, cerebral cortex.

The prevalence of PSP is about 5/100,000, mean age at onset is 63 years, never starting before 40, and mean survival is 7 years. Although about half of patients with pathologically proven PSP show the classic clinical picture (Richardson syndrome) with mean survival of 6 years, about one-third have a longer course averaging 9 years (PSP-P) with more PD-like features, including some levodopa response and resting tremor, with falls and gaze palsy developing later on. Other clinical features include emotional incontinence, frontal release signs, a memory retrieval deficit, palilalia and palilogia, other motor perseveration, sitting down 'en bloc' and prominent sialorrhoea. Despite severe postural instability, patients usually fail to widen their base which, combined with 'motor recklessness', causes frequent falls, with injury. Unlike MSA and PD, cardiovascular AF is not a feature of PSP. However, urinary disturbance is common. Currently used research diagnostic criteria are those of Litvan *et al*. (1996).

Cortico-basal degeneration

This tauopathy is also largely sporadic, with only very rare familial cases. Nevertheless, it shares with PSP over-representation of the H1/H1 tau haplotype, indicating some shared genetic susceptibility. Those with the disease classically present to movement disorder specialists with the asymmetric and progressive evolution, usually starting in one arm (but sometimes in a leg), of 'difficulty' using the limb, which progressively becomes useless because of a combination of akinesia, rigidity, fixed dystonia, myoclonus, jerky tremor, cortical sensory loss and, above all, apraxia. Sometimes there is an additional 'alien limb' phenomenon, when the limb wanders off 'with a mind of its own'. Progression is then to the opposite limb or the other limb on the same side, ultimately to all four limbs, and a supranuclear gaze palsy (paresis) gradually develops which classically is the 'mirror-image' of PSP. Thus, there is great difficulty initiating voluntary saccades, with prolonged latency, but when the eyes finally move they do so with normal velocity. The pathology of CBD involves swollen ('ballooned') cortical neurones predominantly in frontal and parietal areas.

The prevalence of CBD is unknown, but it is rarer than MSA or PSP. Mean age at onset is 63 years and mean survival is 8 years.

The classic clinical picture described above can be misleading. Thus, those with CBD may present to dementia specialists with apraxia or primary progressive aphasia, or disease may present symmetrically, or with falls. Other diseases can also present with a cortico-basal-like syndrome, including strokes and prion disease.

Ancillary investigations to distinguish between PD, MSA, PSP and CBD

MRI of brain in MSA may reveal, supratentorially, putaminal atrophy, a hyperintense slit-like lateral rim to the putamen, or posterior putaminal hypointensity (Plate 5.1). Infratentorially, pontine atrophy, a 'hot-cross bun' appearance of the pons in cross-section, hyperintensity of the middle cerebellar peduncles, or cerebellar atrophy may be seen.

In PSP one may see atrophy of the midbrain, as evidenced by the 'hummingbird sign' on sagittal cuts, and atrophy of the

superior cerebellar peduncles on axial cuts (best demonstrated with voxel-based morphometry). In CBD there may be asymmetrical or unilateral frontal and parietal atrophy.

F-dopa PET (FDG PET) or dopamine transporter SPECT scans only provide evidence of nigral pathology, so cannot reliably distinguish between these conditions. However, a normal scan can provide useful evidence in favour of psychogenic or drug-induced parkinsonism, or of essential or dystonic tremor, or in distinguishing between dopa-responsive dystonia (normal) and 'juvenile PD' (abnormal). FDG-PET may show a signal void in striatum in MSA (and PSP), and asymmetrical fronto-parietal hypometabolism in CBD. Cardiac ^{123}I meta-iodobenzyl guanidine (MIBG) scanning usually, but not always, reveals evidence of post-ganglionic cardiac denervation in PD, whereas such scans are typically, but again not always, normal in MSA, PSP and CBD.

Autonomic function tests can reveal evidence of autonomic failure, but not whether it is caused by Lewy body pathology or MSA.

Urethral or anal sphincter elctomyography (EMG) can show evidence of denervation and reinnervation (increased amplitude, duration and polyphasia) consequent on loss of anterior horn cells in Onuf's nucleus at S2–3. A normal result would argue against MSA, but abnormal results occur also in PD and PSP. The growth hormone response to clonidine infusion is abnormal in MSA, and in some patients with PD; the response to an arginine infusion may be a better discriminator.

Vascular parkinsonism

Subjects with multiple infarcts or, more commonly, multiple basal ganglia lacunes or deep white matter vascular changes, can present with what is often a poor mimic of PD or even of true parkinsonism. Typically, spontaneous movements and facial expression are good, posture upright, and while there may be pyramidal slowing of finger movements, there is no classic fatiguing or decrement, and no tremor. The gait may be wide-based or unsteady, and small-stepped (*marche à petits pas*) rather than shuffling. Start hesitation or gait initiation failure, freezing and some fatiguing of alternating ankle movements are often present, leading to terms such as lower body parkinsonism or parkinsonian ataxia. True parkinsonism involving upper as well as lower body, in the presence of cerebrovascular disease (CVD) is usually brought about by the co-occurrence of PD – the patient's upper body has levodopa-responsive parkinsonism while their lower half behaves differently, and gait problems and falls often appear or worsen suddenly or subacutely. However, some cases of apparent true parkinsonism resulting from CVD, with no Lewy body pathology, have been reported, and some of these have responded to levodopa, so that a trial of this drug is probably justified in all cases of CVD with 'parkinsonian' features.

Ethnic or region-specific parkinsonism

X-linked dystonia-parkinsonism ('Lubag') with striatal mosaicism is essentially limited to Filipinos. The parkinsonism–dementia–ALS complex in Guam, a disease characterized by tangle pathology rather than Lewy bodies, may be of environmental, rather than genetic, origin, as it is fast disappearing. Atypical parkinsonism on Guadeloupe may be heterogenous, and at least partly environmentally determined.

Other causes of parkinsonism

Other genetic causes include the Huntington's disease Westphal phenotype, mostly in juvenile onset cases; Wilson's disease; SCAs 1–3, in which tremor and levodopa-responsiveness may be seen; FTDP-17; and other rarer causes (Table 5.2).

Environmental causes include toxins (MPTP, CO, methanol and manganese) and drugs (dopamine receptor blockers, presynaptic dopamine depletors); post-infectious, particularly after Japanese B encephalitis and encephalitis lethargica (which still occurs rarely, with positive antibasal ganglia antibodies): post-traumatic, in boxers with punch drunk syndrome; hydrocephalus and tumour.

Tremor

Tremor is defined as rhythmic sinuisoidal alternating movement. It can be described in several ways: e.g. rest; postural; action or terminal; or intention. Tremor in PD, MSA and PSP has been discussed above.

Benign essential tremor

This is commonly inherited as an autosomal dominant trait. Most people with essential tremor (ET) have little or no disability, so never see a neurologist. Published community prevalence figures vary hugely, but an average of studies is 3–400/100,000. Typically, ET involves both arms first, fairly symmetrically, and to a greater degree than any other body parts (neck, legs, voice) which may be subsequently involved. The tremor is usually vertical (flexion–extension) rather than pronation–supination. It often worsens slowly over many years, but even then often does not cause marked functional impairment, although in some cases it does. It often improves after alcohol, and may be helped by β-blockers, primidone, gabapentin and topiramate in some cases.

Dystonic tremor

The authors' view of dystonic tremor is that it is poorly defined, under-recognized and often misdiagnosed as ET or as benign tremulous PD. This Queen Square view is controversial, and not yet generally accepted. The Movement Disorder Society Consensus Statement on Tremor restricts the term dystonic tremor to a tremor in a body part also displaying overt dystonia (e.g. tremulous torticollis). When someone with spasmodic torticollis, for example, also has a tremor of one or both arms, without overt dystonia in those limbs it is called tremor associated with dystonia. Such an arm tremor usually displays other characteristics: it may be unilateral or asymmetrical, relatively

slow ('myorhythmia'), pronation–supination, coming in 'flurries', jerky, position-specific or markedly worsened by certain tasks (e.g. attempting to write), and therefore more commonly disabling than ET; it can be associated with abnormal or reduced arm swing, or a jaw tremor, and about one-third of these patients also display a dominant family history (in taking a family history of tremor it is always useful to ask what shook [e.g. neck] as well as who shook). We would also call this tremor dystonic tremor. Where the patient has tremor with these characteristics, but (as yet) no evident dystonia, we currently label this as atypical tremor, whilst recognising that many of these subjects may later turn out to have dystonic tremor. Drug treatment is disappointing in older patients, but levodopa and anticholinergics are worth trying in younger subjects.

Both ET and dystonic tremor can be helped by botulinum toxin injections or, in severe cases, thalamic DBS or pallidal DBS (if dystonic).

Neuropathic tremor

Some neuropathies, particularly IgM dysgammaglobulinaemic neuropathy, can cause a postural (and if severe, even a resting) tremor. The severity of the tremor does not necessarily correlate with the severity of the neuropathy or the degree of deafferentation. In patients with unexplained tremor it is always important to search for any clinical evidence of neuropathy.

Fragile X tremor ataxia syndrome (FXTAS)

It has recently been recognized that individuals (usually males) with premutations (55–200 CGG repeats) in the fragile X mental retardation 1 (*FMR1*) gene may, as they get older, present with a relatively slowly (compared to MSA-C) progressive syndrome combining postural or action tremor and ataxia, sometimes with additional parkinsonism, peripheral neuropathy, cognitive impairment and dysautonomia. There may be a family history of, and an increased risk, especially to males, of mental retardation, and premature ovarian failure may occur in females. MRI commonly shows hyperintensity of the middle cerebellar peduncles or of subcortical white matter, and cerebellar atrophy.

Cerebellar (pathway) tremor

Intention tremor

This is caused by brainstem or cerebellar outflow pathway lesions, the most common cause being multiple sclerosis. The tremor is not just action or terminal (features common to many postural tremors), but worsens steadily throughout the whole trajectory of the movement. Symptomatic drug treatment is unhelpful. DBS may transiently help, but its benefits are usually overwhelmed by the progression of lesion load.

Holmes tremor

This form of tremor, previously called midbrain tremor or rubral tremor, is a tripartite tremor incorporating tremor at rest, postural tremor and intention tremor. It is caused by a combination of damage to the cerebello-rubrothalamic and nigro-striatal pathways.

Palatal tremor

This comprises rhythmic (1–2 Hz) contractions of the soft palate, presumably resulting from a dysfunction (essential palatal myoclonus [EPM]) or a lesion (symptomatic palatal myoclonus [SPM]) involving the connections between dentate nucleus, red nucleus and inferior olivary nuclei (the Guillain–Mollaret triangle). EPM consists of rhythmic contractions of the tensor veli palatini, innervated by the trigeminal nucleus; in SPM, the main muscle involved is the levator palatini, innervated by the facial nucleus and the nucleus ambiguus. EPM is typically associated with clicking, whereas SPM usually persists during sleep and is often associated with hypertrophy of the inferior olive. SPM is often associated with vertical ocular movements (oculopalatal myoclonus) or rhythmic and oscillatory limb movements at a rate of 1–3 Hz. Important causes of SPM include Wilson's disease, stroke and/or tumour and Alexander's disease. Oculomasticatory myorhythmia or oculo-facial-skeletal myorhythmia are said to be pathognomonic of Whipple's disease. Clonazepam sometimes helps.

Orthostatic tremor

This is a rare condition in which subjects feel unsteady, and often tremulous, while standing still, but not on walking, so that they like to either sit down or to keep moving (the 'white rabbit syndrome'). It is characterized by 16 Hz tremor of the leg muscles, easily recorded on surface EMG which can often be felt or auscultated, but not usually seen. Some cases have additional features of parkinsonism or restless legs. Clonazepam sometimes helps.

Drug and toxin-induced tremor

Tremor can be caused by a number of different drugs or toxins including dopamine-depleting or receptor-blocking drugs, cinnarazine, some calcium-channel blockers, e.g. diltiazem (mostly rest tremor), sodium valproate (rest or postural), or beta-agonists, theophylline, caffeine, nicotine, lithium, amiodarone, SSRIs and tricyclic antidepressants, ciclosporin, thyroxine excess, and intoxication with marijuana, cocaine, amphetamines or mercury (postural).

Psychogenic tremor

This is dealt with under other movement disorders.

Dystonia

Dystonia is a heterogeneous and common movement disorder typically characterized by involuntary muscle spasms leading to abnormal postures of the affected body part. Typically, the spasms in dystonia are mobile and this often leads to a slow writhing of the affected body part as described by the older term 'athetosis'. Co-contraction of agonist and antagonist muscles is the underlying reason for the abnormal posturing in dystonia, and this can be obvious clinically or more easily on simple EMG assessment. Dystonia can be variable in its presentation and in some cases

tremor or jerks may be the predominant feature with the abnormal postures being subtle. Dystonia can also often be task, or position-specific, e.g. present only on writing or playing a musical instrument but not with other tasks. Another characteristic feature of dystonia, particularly focal dystonia, is the presence of a sensory trick or 'geste antagoniste', whereby applying a sensory stimulus to a particular area will cause the abnormal posture to resolve.

Epidemiology

There have been few epidemiological studies of dystonia. Most studies have provided estimates based on few cases. A European prevalence study with pooled data from eight countries undertaken to provide more precise rates of dystonia found the crude annual period prevalence rate (1996–1997) for all primary dystonia was 152 per million, with focal dystonia having the highest rate of 117 per million (108–126) of which cervical dystonia was most common (57 per million), followed by blepharospasm (36 per million) and writer's cramp (14 per million). However, the authors pointed out that because of under-ascertainment of cases, these rates were probably an underestimate of the true prevalence of dystonia.

Classifying dystonia

Dystonia can be classified in a number of ways including by age of onset, by distribution and aetiology (Table 5.3). With regard to aetiology there have been major advances in the genetic causes of the dystonias and this list keeps growing. Clinically, however, the most important and useful division is classifying patients broadly into two categories: those with 'primary dystonia'; and those with 'secondary/heredodegenerative' dystonic conditions. Dystonia is the only clinical sign (with the exception of tremor) in primary dystonia, and there is no neurodegeneration. The age of onset (below or above age 28), and distribution (focal, segmental, generalized) can be very useful to decide whether the patient fits into the well-defined phenotypes of primary dystonia (see below), and for picking up patients with unusual phenotypes (e.g. an adult presenting with generalized dystonia, which would be incompatible with typical primary dystonia) and to investigate these patients further to find out the likely secondary/heredodegenerative cause. Clinical features or 'red flags' that should make one consider secondary dystonia rather than primary dystonia are listed in Table 5.4.

Psychogenic dystonia is dealt with later in this chapter (see Other movement disorders).

Primary dystonia

In patients with primary dystonia, age at onset appears to be very important in determining the clinical phenotype. Young onset dystonia (before the age of 28 years) most commonly manifests with limb onset dystonia, followed by subsequent generalization and was referred to in the older literature as dystonia musculorum deformans or Oppenheim's dystonia. It is now known that about 70% of patients presenting in this way will carry a single GAG deletion in the *DYT1* gene on chromosome 9. This condition is more common in Ashkenazi Jews, with a possible founder in Eastern Europe about 3 centuries ago. It has an autosomal dominant inheritance, but a very low phenotypic penetrance such that only 30–40% of gene carriers will ever develop dystonia, and in those who do this will almost always happen before the age of 30 years.

When dystonia appears in adult life, a focal or segmental distribution is commonly seen and the condition does not generalize. These presentations, in order of frequency of occurrence, include cervical dystonia (spasmodic torticollis), cranial dystonia (e.g. blepharospasm, Meige syndrome [blepharospasm and oromandibular dystonia]), writer's cramp, laryngeal dystonia (sometimes called spasmodic or, inappropriately, spastic dysphonia) and other task-specific dystonias. Cranio-cervical dystonia is more common in women than men, with the opposite pattern seen in task-specific writing dystonia. The adult onset focal dystonias are not a forme fruste of the early onset *DYT1* gene-related dystonia, and this gene has been excluded in these disorders, most of the patients being sporadic. However, three genetic loci

Table 5.3 Classification of dystonia.

By aetiology	By distribution	By age at onset
Primary (no neurodegeneration; dystonia only +/– tremor)	Focal	Young onset (<28 yrs)
	Segmental	Adult onset (>28 yrs)
Dystonia-plus syndromes	Multifocal	
Dopa-responsive dystonia	Hemidystonia	
Myoclonus dystonia		
Secondary		
Symptomatic		
Heredodegenerative		
Paroxysmal		

Table 5.4 Clinical clues in the history and examination suggesting a secondary cause of dystonia.

Abnormal birth/perinatal history
Developmental delay
Continued progression of symptoms
Unusual distribution of dystonia given age of onset (e.g. leg dystonia in an adult, hemidystonia)
Unusual nature of dystonia (e.g. fixed dystonic postures)
Prominent bulbar involvement by dystonia
Additional neurological symptoms (pyramidal signs, cerebellar signs, cognitive decline)
Seizures
Other systems affected (e.g. organomegaly)
Previous exposure to drugs, e.g. dopamine receptor blockers

Table 5.5 A list of the dystonia genetic conditions.

Name	Gene	Mode of inheritance	Clinical features
DYT1	*DYT1*	AD	Young onset primary generalized dystonia
DYT2	n.k.	AR	Recessive young onset primary dystonia in a single Spanish gypsy family
DYT3	Linkage to X13.1	XR	Dystonia parkinsonism in Filipino males
DYT4	n.k.	AD	Laryngeal dystonia (whispering dysphonia) +/– limb dystonia in a single Australian family
DYT5 (DRD)	*GTPCH1*	AD	Young onset dopa-responsive dystonia/parkinsonism
DYT6	Linkage to 8p21-p22	AD	Two Mennonite families with variable onset of primary craniocervical and limb dystonia
DYT7	Linkage to 18p	AD	Single(?) German family with primary craniocervical dystonia
DYT8 (PNKD)	*MR-1*	AD	Attacks of dystonia and chorea precipitated by coffee, alcohol and fatigue
DYT9	Linkage to 1p	AD	Episodic chorea and ataxia with progressive interictal spasticity
DYT10 (PKD)	Linkage to centromeric region of chromosome 16	AD	Episodes of chorea and dystonia precipitated by sudden movement
DYT11	ε-sarcoglycan gene	AD	Myoclonus and dystonia
DYT12	*ATP1A3*	AD	Rapid onset dystonia following infection/exercise
DYT13	Linkage to 1p36.13	AD	Single Italian family with primary cranio-cervical dystonia
DYT14	Linkage to 14q13 outside region for *GTPCH1* gene	n.k.	Dopa-responsive dystonia parkinsonism

AD, autosomal dominant; AR, autosomal recessive; XR, X-linked; n.k., not known; DRD, dopa-responsive dystonia; PKD, paroxysmal non-kinesigenic dyskinesias; PNKD, paroxysmal non-kinesigenic dyskinesias.

– *DYT6*, *DYT7* and *DYT13* – have been described in rare families with cranio-cervical segmental dystonia but the genes are yet to be discovered (Table 5.5) and the disorder is likely to be even more genetically heterogenous, as a number of autosomal dominant craniocervical dystonia families do not link to these three loci.

Dystonia-plus syndromes

This category refers to two diseases without evidence of neurodegeneration whose motor manifestations are restricted to dystonia, plus parkinsonism or myoclonus. Some would consider it reasonable to include them with *DYT1* under the heading of primary dystonias.

Dopa-responsive dystonia

Dopa-responsive dystonia (DRD; *DYT5*), previously also called Segawa disease, typically presents in childhood, purely with lower limb dystonia, and parkinsonism may rarely be associated, although the latter can be a presenting feature when onset is at an older age. A diurnal fluctuation in symptom severity with a gradual worsening of symptoms throughout the day was said to be typical of the condition, but is present in only 60% of cases. This condition is inherited in an autosomal dominant manner, with reduced penetrance, and is caused by mutations in the GTP cyclohydrolase 1 gene (*GTPCH1*; *DYT5*), a rate limiting step in the production of dopamine from tyrosine. Although rare, it is of critical importance to the practising neurologist as it is entirely treatable by small doses of levodopa. This typically leads to complete resolution of symptoms which is sustained, without the development of long-term complications as seen in PD.

It is increasingly recognized that DRD can present with unusual phenotypes such as spastic diplegia, writer's cramp and other focal dystonias including predominant cervical dystonia and even ataxia. In view of this, an adequate trial of levodopa (ideally up to 100–200 mg plus peripheral decarboxylase inhibitor t.d.s., according to age, for at least 2 months) is strongly recommended in all those with young onset dystonia, especially as genetic diagnosis is time-consuming and not generally available. A phenylalanine loading test and cerebrospinal fluid (CSF) pterin studies may be helpful. It is also important to differentiate patients with DRD from those with young onset Parkinson's disease, who may present with foot dystonia, and in whom the early use of levodopa is not recommended. A DaT SPECT or a fluorodopa PET scan (both normal in DRD) can be useful in this regard. Other inherited defects of the dopamine synthesis pathway, e.g. the recessively inherited tyrosine hydroxylase deficiency, can also cause DRD, but usually as part of a more severe neurological syndrome.

Myoclonus dystonia

Patients with myoclonus-dystonia (*DYT11*), caused by autosomal dominantly inherited mutations in the ε-sarcoglycan gene on chromosome 7q21, present with early onset dystonia in combination with myoclonic 'lightning' jerks. The jerks respond quite dramatically to alcohol. The condition typically starts in childhood, and is mostly inherited through the father because of maternal genomic imprinting. The myoclonus or dystonia mainly

affects the head, neck and arms, with the legs usually being spared. The myoclonus worsens during movement (action myoclonus) and is often more prominent than the dystonia. It had been suspected that hereditary essential myoclonus (when myoclonus is prominent) and dominantly inherited myoclonic dystonia, with lightning jerks and dramatic response to alcohol, might often be the same disease, and this has now been confirmed with the discovery of the causative mutations, although other broadly similar cases are mutation-negative. Psychiatric features such as anxiety, depression and obsessive-compulsive disorders are also a feature of the condition in a proportion of cases.

Symptomatic dystonia

Dystonia can be secondary to a number of environmental causes, many of which affect the basal ganglia. Dystonia is commonly seen following brain injury, e.g. perinatally (dystonic/dyskinetic/athetoid cerebral palsy) or following stroke. In such patients a static deficit is commonly seen, although onset can be delayed for months or even years after injury, and progression and late worsening of symptoms is sometimes seen.

Tardive dystonia is dealt with under Other movement disorders, below.

Heredodegenerative dystonias

Dystonia can be a feature of a wide range of neurodegenerative conditions, which can make selection and prioritization of the appropriate investigations and reaching the correct diagnosis a difficult task. One aspect of such conditions that can be helpful is that many have syndromic associations which can help guide the investigating clinician. For example, peripheral neuropathy in association with dystonia would make one think of neuro-acanthocytosis or metachromatic leuco-dystrophy as more likely diagnoses. Prominent facial dystonia or flapping tremor would make one consider Wilson's disease and associated ataxia may point to spino-cerebellar degenerations such as SCA2 or SCA3. Prominent bulbar or severe tongue involvement by dystonia is a strong pointer to secondary dystonia and would favour certain conditions including neurodegeneration with brain iron accumulation (NBIA; formerly known as Hallervorden–Spatz syndrome) and also neuro-acanthocytosis and Lesch–Nyhan syndrome. Appropriate investigation should be carried out. Brain MRI is very important as it may show characteristic changes, e.g. the 'eye of the tiger sign' characteristic of NBIA caused by mutations of the pantothenate kinase 2 gene (*PANK2*) (Figure 5.1). A list of some of these conditions, with their associated clinical symptoms, is given in Table 5.6, and the investigations to be carried out as suggested by the syndromic association are given in Table 5.7.

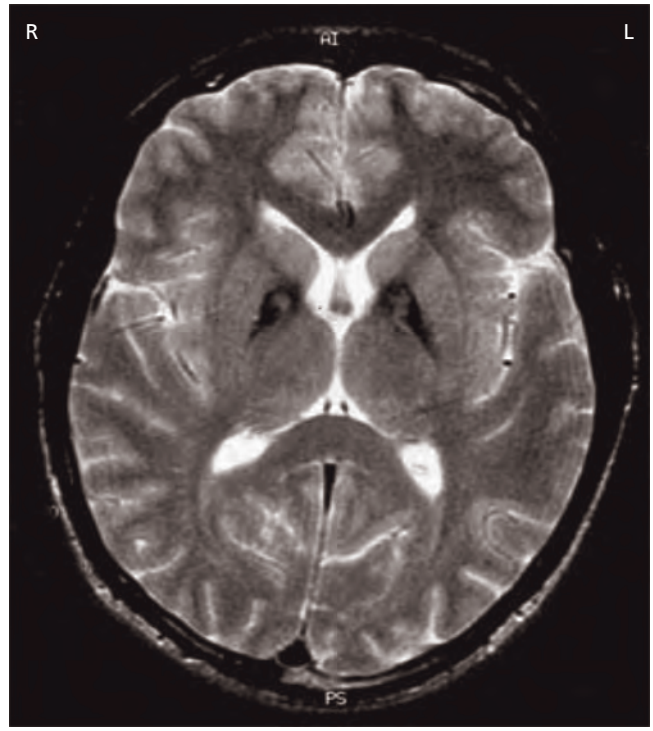

Figure 5.1 Classic 'eye of the tiger sign' (central hyperintensity with surrounding hypointensity in globus pallidus) in a patient with neurodegeneration with brain iron accumulation (NBIA) caused by a *PANK2* mutation (MRI T2W).

Table 5.6 Examples of common heredodegenerative causes of dystonia and associated syndromic clinical features.

Wilson's disease	Kayser–Fleischer rings, ataxia, cognitive decline
Neurodegeneration with brain iron accumulation (PANK2, Hallervorden–Spatz syndrome)	Retinal degeneration, pyramidal signs, oromandibular/bulbar involvement
Neuro-acanthocytosis	Peripheral neuropathy, oromandibular dystonia, epilepsy
Metachromatic leuco-dystrophy	Peripheral neuropathy, frontal dementia
GM1/GM2 gangliosidosis	Cognitive decline
Glutaric acidemia	Cognitive decline
Huntington's disease	Cognitive decline, personality change, depression, supranuclear eye movement abnormalities
Ataxia telangiectasia	Supranuclear eye movement abnormalities
Niemann–Pick Type C	Vertical gaze palsy, cognitive decline

Table 5.7 List of investigations in those suspected of secondary dystonia depending on syndromic associations in Table 5.6.

MRI brain/spine (structural lesions, leuco-dystrophies, 'eye of tiger' sign in NBIA)
Nerve conduction studies (neuro-acanthocytosis, metachromatic leuco-dystrophy)
Copper studies, slit-lamp, ?liver biopsy (Wilson's disease)
White cell enzymes (GM1, GM2, metachromatic leuco-dystrophy)
Alphafetoprotein, immunoglobulins (ataxia telangiectasia)
Lactate/pyruvate, mitochondrial mutations, muscle biopsy (mitochondrial disease)
Fresh thick blood smear for acanthocytes (neuro-acanthocytosis)
Plasma amino acids, urinary organic acids, aminoacids, oligosaccharides (glutaric academia, GM1, GM2)
Bone marrow biopsy/axillary skin biopsy (Niemann–Pick Type C, Kufs)
Phenylalanine loading test/CSF pterin assessments (DRD)
ERG, retinal examination, PANK2 gene test (positive in some cases of NBIA)
Huntington's disease gene test

DRD, dopa-responsive dystonia; ERG, electroretinogram; MRI, magnetic resonance imaging; NBIA, neurodegeneration with brain iron accumulation.

Wilson's disease

Of all the causes of heredodegenerative dystonia, Wilson's disease (WD) is the most important because it is treatable, but fatal if left untreated. It is an autosomal recessive disorder of copper metabolism that most commonly presents in the first two decades of life. It occurs worldwide with prevalence of 1–3/100,000. More than 300 different mutations have been identified distributed across the responsible gene, *ATP7B* on chromosome 13, which encodes a copper-dependent transmembrane protein P type ATPase. The most common in patients of European origin is the H1069Q mutation. The heterozygote carrier rate is 1%.

Clinical presentations

Patients may present with acute liver failure, chronic hepatitis or cirrhosis, most commonly in the first decade of life, and a few present with an acute haemolytic anaemia. Other features include joint and bone abnormalities, azure lunulae of the finger nails, aminoaciduria and cardiomyopathy.

Most cases of neurological WD present with slurred speech and a movement disorder in adolescence, often in association with behavioural disturbances. Approximately half of all cases present with neuropsychiatric symptoms, usually between 14 and 20 years of age.

The 'pseudosclerotic' neurological variant is perhaps the most common, with the onset of a Holmes or wing-beating tremor and some ataxia and dysarthria; in other patients dystonia or an akinetic-rigid syndrome may dominate. Early gait abnormalities are frequent and a mixed movement disorder is common, sometimes with associated risus sardonicus and pseudobulbar palsy. Dysarthria is the most common sign, whereas chorea and athetosis affect only about 10%. If left untreated, fronto-limbic cognitive dysfunction may develop and seizures, myoclonus and pyramidal signs have been reported. Cases presenting later than age 40 are exceptionally rare. Virtually every patient with WD presenting with neurological dysfunction has Kayser–Fleischer (K-F) rings on slit-lamp examination. These are caused by copper deposition on the inner surface of the cornea in Descemet's membrane and have a golden brown or greenish appearance. They can occur in other forms of chronic liver disease but in the context of a neurological presentation in adolescence can be considered pathognomonic for WD.

The histopathological findings in the brain include swollen glia and an increase in astrocytes within the grey matter, often with spongiform change.

Diagnosis

The emergence of parkinsonism, dystonia or a tremor in an adolescent or young adult with slurred speech should always raise the possibility of WD, particularly if there is a family history of hepatic, psychiatric or neurological disorder in childhood. Consanguinity should be enquired about. Suspected cases should be referred to an experienced ophthalmologist for slit-lamp examination.

The combination of a movement disorder with emotionalism, a risus sardonicus and a K-F ring makes the diagnosis highly likely but biochemical confirmation is required. Unfortunately, there is still no one single failsafe test.

A low serum caeruloplasmin level is consistent with WD and is diagnostic when K-F rings are present. Low levels of caeruloplasmin also occur in hereditary acaeruloplasminaemia and Menkes disease. Some WD heterozygotes have a reduced caeruloplasmin level, while a few WD patients with decompensated liver disease may have normal levels. In females, the oral contraceptive pill may raise an otherwise low level to within the normal range. In WD, a hepatic copper concentration greater than 250 μmg/gm dry weight is usual. Serum aminotransferase levels are also usually abnormal. However, a lower hepatic copper value does not absolutely exclude WD and long-standing cholestasis may also cause high copper levels. The biochemical results therefore need to be taken in the context of the clinical picture and the histological changes. Although genetic testing is not available as a routine service test, in ambiguous cases it may be extremely helpful to at least screen for the more common mutations. Urinary copper, derived from the free non-caeruloplasmin-bound copper circulating in plasma, is elevated in WD. An excretion rate greater than 100 μg/24 hours (0.6 mmol/L in 24 hours) is considered diagnostic but levels above 40 μg/24 hours may be significant in a neurological presentation. Wide-necked bottles with copper-free disposable polyethylene liners are recommended. Urinary copper excretion after penicillamine loading can be a useful ancillary test.

In neurological cases, brain MRI may show high signal abnormalities on T2 weighted images and low intensity lesions on T1 in the putamen, globus pallidus, thalamus, midbrain, pons and cerebellum. White matter abnormalities are also common and cortical atrophic changes may also occur. Proton density MRI sequences may be particularly sensitive. Once WD has been diagnosed, screening of all first degree relatives is essential.

Treatment

The first chelation treatment, parenterally administered British anti-Lewisite (BAL), was introduced in 1951. In 1956, John Walshe first reported clinical benefit with penicillamine and half a century of use has confirmed its efficacy in most cases. However, some patients cannot tolerate the drug and about 20% of patients with neurological presentations may deteriorate markedly on its introduction. Regular monitoring with a full blood count and renal function tests is recommended. Adverse events include fever, rash, lymph gland enlargement, neutropenia, thrombocytopenia and proteinuria. Nephrotoxicity, a lupus syndrome, bone marrow suppression, skin changes including elastosis perforans serpiginosa and a myaesthenic syndrome are late complications. Children and pregnant women should be given weekly pyridoxine.

In 1969, Walshe discovered another chelator, trientene, which has proved to be a well-tolerated alternative. It is still generally used as a second line drug, but some now recommend it as the initial treatment of choice in neurological cases, although deterioration can also occur on starting treatment. Pancytopenia has been reported and sideroblastic anaemia may occur if copper deficiency develops.

Oral elemental zinc, which induces intestinal metallothionein which binds copper within the enterocyte, has also been recommended, particularly for asymptomatic and presymptomatic patients and as maintenance therapy after a period of initial chelation.

Tetrathiomolybdate forms a complex with copper and protein and prevents copper absorption when given with food, and has been claimed to be highly effective, but remains investigational. Whichever drug is chosen, regular lifelong monitoring to ensure compliance is essential.

Chocolate, liver, nuts, mushrooms and shellfish contain high levels of copper, so are best avoided. Anticholinergics may modestly help dystonia and some patients with an akinetic-rigid syndrome may have some improvement with levodopa. In patients with hepatic disease who deteriorate despite optimum therapy, liver transplantation, which corrects the underlying pathophysiology, can be life-saving. For refractory or deteriorating neurological disability despite other treatments, a course of intramuscular BAL injections is worth trying. The use of liver transplantation for patients with progressive neurological impairment despite adequate chelation is controversial. Patients with WD surviving into middle age have an elevated risk of hepatic carcinoma.

Paroxysmal dyskinesias

Paroxysmal dyskinesias are defined as intermittent attacks of involuntary movements, usually dystonia, chorea or ballism, with normal neurological examination between attacks. Episodes are induced by trigger factors including sudden movements (paroxysmal kinesigenic dyskinesia [PKD]), prolonged exercise (paroxysmal exercise-induced dyskinesia [PED]) or alcohol and coffee (paroxysmal non-kinesigenic dyskinesia [PNKD]) or sleep (paroxysmal nocturnal dyskinesia [PND]). The duration can be seconds to hours. Recently, mutations in the myofibrillogenesis regulator gene (*MR-1*) on chromosome 2q33–35 have been identified in patients with PNKD. The encoded protein appears to have a role in the detoxification pathway of methylglyoxal, a compound present in coffee and alcoholic beverages, both of which can induce attacks. In PND, nicotinic acetylcholine receptor gene mutations occur and this is an example of a ligand-gated channelopathy. For the other forms, various loci have been proposed but genes have not yet been identified. Secondary paroxysmal dyskinesias have also been described and possible causes include demyelination, vasculopathy, infectious disease (HIV, cytomegalovirus), cerebral and peripheral trauma, neurodegenerative disease, hormonal and metabolic dysfunction, neoplasm and cerebral palsy. Anticonvulsants (first choice carbamazepine), benzodiazepines, barbiturates or acetazolamide can bring relief. Triggering factors should be avoided.

Investigation of dystonia

Following a careful history (in particular drug and family history) and examination, investigation of patients with dystonia should be tailored to the presentation of the patient, and in particular whether the clinical picture suggests primary or secondary dystonia. Common clinical situations are of children or adolescents presenting with a primary focal, segmental or generalized dystonia, or adults presenting with a primary focal or segmental dystonia. For the former category, investigations should include copper studies and slit-lamp to exclude WD, brain imaging (preferably MRI), the *DYT1* gene test and an adequate trial of levodopa. For adult onset primary dystonia, copper studies and slit-lamp to exclude WD may be performed if presentation is under 50 years of age; brain imaging is not generally required, but if there is fixed or painful cervical dystonia an MRI of the spine should be carried out to exclude structural lesions. More extensive investigations are needed in patients with presumed secondary dystonias (Table 5.4) but this list can be narrowed down by considering pertinent aetiological possibilities according to the presence of associated clinical features as shown in Table 5.6, and an outline of the investigations is given in Table 5.7.

Treatment of dystonia

Drug treatment of dystonia is most appropriate in those with younger onset generalized and/or segmental dystonia for whom botulinum toxin (see below) would be unlikely to control the full extent of the dystonia. First line treatment is with anticholinergics such as trihexyphenidyl. Slow introduction of the drug is very important to avoid side effects, but some, particularly younger, patients can ultimately tolerate very high doses (100 mg/day or more) with good effect. Clonazepam can be useful for the treatment of tremor, jerks and pain associated with dystonia. Other drugs that are sometimes useful include tetrabenazine, baclofen and even dopamine receptor blocking drugs. As mentioned above, all patients with young onset dystonia should receive an adequate trial of levodopa. The treatment of WD has been detailed above.

Botulinum toxin has revolutionized the treatment of patients with focal dystonia. Botulinum toxin cleaves specific proteins involved in vesicular fusion at the presynaptic terminal, thereby blocking the release of acetylcholine, the principal neurotransmitter at the neuromuscular junction. The affected nerve terminals do not degenerate, but the blockage of acetylcholine release is irreversible. Neuromuscular transmitter release recovers by sprouting of new nerve terminals and formation of new synaptic contacts, which takes about 3 months. Transmission is also inhibited at gamma neurones in muscle spindles, which may alter reflex overactivity.

A number of randomized double-blind clinical trials have established the efficacy of botulinum toxin injection treatment for focal dystonia. Treatment is required every 3–4 months, and is expensive, but a 70–80% improvement in symptoms is common in most patients, particularly those with blepharospasm and cervical dystonia. Treatment of those with limb dystonia, in particular writer's cramp, is often more difficult and benefit can be inconsistent. Main side effects of treatment are excessive weakness of the treated muscle or spread of effect to nearby muscles (e.g. paralysis of pharyngeal muscles following sternomastoid injections). Immune-mediated resistance to botulinum toxin is seen in a small proportion of chronically treated patients, particularly those who receive high doses, 'top-up' doses or injections more frequently than every 12 weeks. An alternative toxin, botulinum toxin type B, is available, but antibodies to the commonly used type A toxin can be cross-reactive with type B toxin, and, in addition, a primary immune response to type B toxin can also occur. Botulinum toxin can be helpful for those with generalized dystonia where a particular functional problem can be linked to dystonia in a single or a small group of muscles.

Surgery for dystonia

Although the primary treatment for dystonia is medical, a number of patients, particularly those with generalized dystonia, remain severely disabled and may benefit from surgery. Ventrolateral thalamotomies, and to a lesser degree pallidotomies, were performed from the 1950s for alleviation of dystonia. The results were not consistent and some patients had initial benefit that wore off over time, necessitating several operations. Complications, including dysarthria and dysphagia, were not uncommon, especially in bilaterally operated patients.

Concerns about potential side effects of bilateral lesions, and the beneficial effect of GPi DBS on dyskinesias in PD patients, led the group of Coubes in France to propose the use of GPi DBS in dystonia. Their early report of successful treatment has been confirmed in larger series of patients and multicentre controlled trials.

Primary generalized dystonia is recognized as being the indication giving the best results and both *DYT1* positive and negative patients can obtain a good effect – up to 70% improvement of the clinical score has been reported. The improvement is gradual and follows a complex time course; the mobile aspects of the dystonia tend to improve more rapidly than the fixed aspects that can take up to 6 months. In consequence it is difficult to adjust stimulation parameters according to acute changes of symptoms.

Beneficial effect on quality of life has also been reported, while there was little change on cognitive scores and neuropsychiatric measures, in particular on depression. The presence of fixed orthopaedic deformities limits the potential beneficial effect of DBS. Sudden interruption of the stimulation can lead to severe dystonic state in these patients, who may need urgent or prophylactic battery replacement.

Myoclonus dystonia (*DYT11*) can also benefit from GPi DBS. Some forms of secondary dystonia may benefit, but usually not to the same extent as primary dystonia. Pain is one aspect that often improves in those patients. Neuroleptic-induced tardive dystonia may show major benefit with GPi DBS.

The surgical procedure is similar to that used for PD and is usually carried out in one session under general anaesthesia. Side effects are rare and usually reversible by adjustment of electrical parameters.

In conclusion, the posteroventral sensorimotor pallidum is the primary brain target for surgical treatment of dystonia (although we successfully target thalamus in patients with dystonic tremor, with good results). DBS is the method of choice. Results for primary dystonia are better than for secondary; and mobile dystonia benefits more than fixed or tonic dystonia.

Chorea

Chorea is derived from the Greek word 'choreia' meaning a dance. Chorea is a state of excessive spontaneous movements, irregularly timed, randomly distributed and abrupt. Severity may range from restlessness with mild intermittent exaggeration of gesture and expression, fidgety movements of the hands or unstable dance-like gait to a continuous flow of disabling and violent movements. Chorea has many causes which can be simply divided into acquired and inherited. This section summarizes the assessment and investigation of the choreic patient and focuses on the important causes of chorea seen in clinical neurological practice (Table 5.8).

Assessment of chorea

Assessment of the choreic patient depends on directed history and examination (Figure 5.2, Table 5.9), which will determine the appropriate investigations to consider (Table 5.10). Onset and nature of progression are important features. Abrupt or subacute onset is more suggestive of acquired causes. It is important to take a detailed drug history (see below), to ask about recent throat infections (Sydenham's chorea or PANDAS), pregnancy (chorea gravidarum), rashes or joint aches (systemic lupus erythematosus [SLE]), and metabolic history (hyperthyroidism), and to note the symmetry of the chorea, as asymmetric onset suggests a structural or vascular lesion in the contralateral basal ganglia (Figure 5.3). Most inherited causes of chorea have a slow

Table 5.8 Inherited and acquired causes of chorea.

Inherited causes	Acquired causes
Huntington's disease*	Focal striatal pathology:
Neuro-acanthocytosis	Stroke
Macleod syndrome	Space-occupying lesions
Dentatorubro-pallidoluysian atrophy	Drug induced
Benign hereditary chorea	Chorea gravidarum
Spinocerebellar ataxia types 1, 2, 3 and 17	Thyrotoxicosis
Mitochondrial disorders	Systemic lupus erythematosus/ antiphospholipid syndrome
Inherited prion disease	Post-infective:
Huntington's disease-like 2	Sydenham's chorea (group A streptococcal infection)
Wilson's disease	Paediatric autoimmune disorders associated with streptococcal infections (PANDAS)
Friedreich's ataxia	Herpes simplex encephalitis
Neurodegeneration with brain iron accumulation type 1	Polycythaemia rubra vera
Ataxia telangiectasia	Infective:
Neuroferritinopathy	AIDS
Lysosomal storage disorders	New variant Creutzfeldt–Jakob disease
Amino acid disorders	
Tuberous sclerosis	

*The most common cause of inherited chorea – the remainder of these disorders are rare.

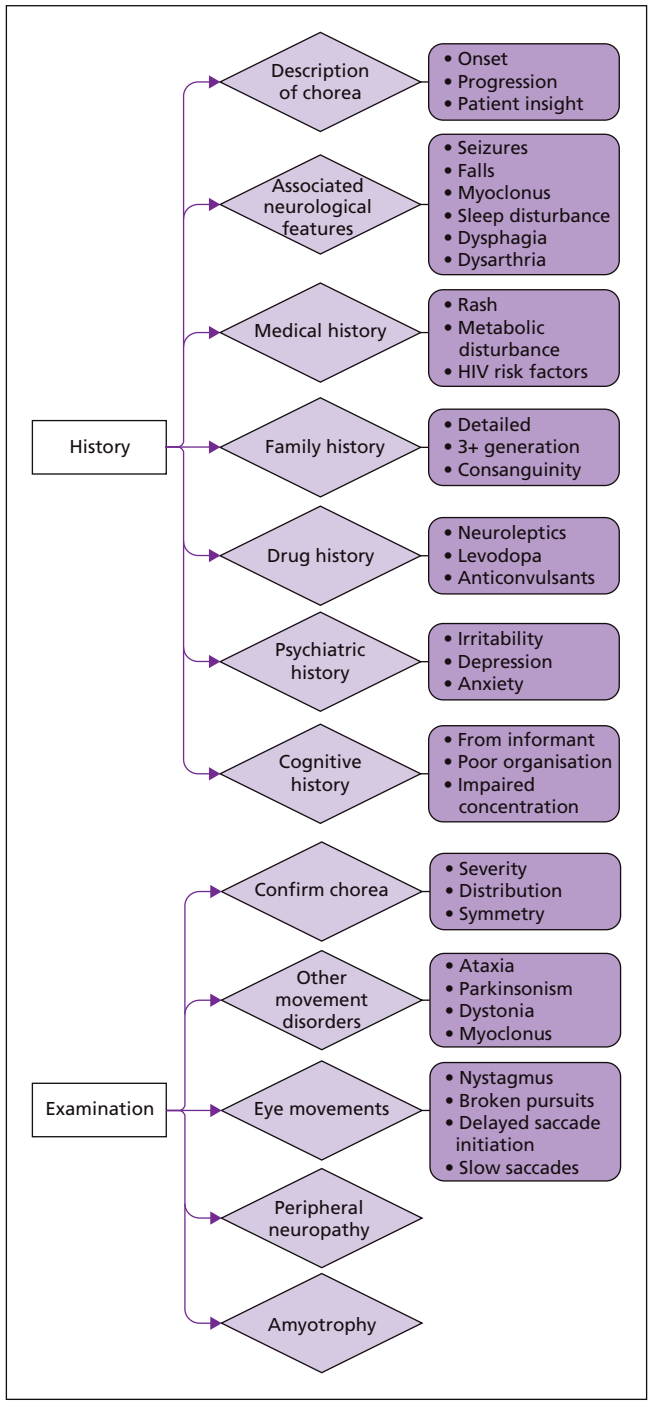

Figure 5.2 Clinical assessment of the choreic patient.

and insidious onset, most commonly noticed by friends or relatives rather than patients themselves. A detailed family history is crucial and particular attention should be paid to a parent who died at a relatively young age.

Huntington's disease

Huntington's disease (HD) is a slowly progressive autosomal dominant neurodegenerative disorder and the most important inherited cause of chorea. Onset is usually in adult life with a mean age of about 40 years, although juvenile and elderly onset are well described. It progresses inexorably, with death occurring 15–20 years from onset. Prevalence is 4–10/100,000 in populations of Western European descent, but HD has been described throughout the world. HD is named after George Huntington who originally described it in 1872. In 1993, the causative gene defect was identified as a CAG repeat expansion, encoding polyglutamine repeats within a novel protein *huntingtin*. This highly polymorphic CAG repeat is located in exon 1 and ranges between 10 and 28 copies on normal chromosomes, but is expanded to a range of 36–121 on HD chromosomes. Adult onset patients usually have 40–55 repeats, with juvenile onset patients having over 60. CAG repeats above 40 are fully penetrant, although there is a borderline repeat range between 36 and 39 repeats with reduced penetrance.

CAG repeat lengths vary from generation to generation, with both expansion and contraction, but there is a tendency for repeat lengths to increase, particularly when transmitted through the paternal lineage. The instability of the CAG expansion with the tendency to expand during transmission underlies the phenomenon of anticipation. Genetic anticipation describes increasing severity and earlier onset of an inherited disease during intergenerational transmission and is a hallmark of HD and the other trinucleotide repeat disorders. CAG repeat instability

Table 5.10 Investigations to consider in the choreic patient.

Test	Notes
MRI imaging	Stroke or other focal basal ganglia pathology
	T2* imaging abnormal in iron accumulation disorders
	FLAIR imaging abnormal in prion disease
	Deep brain T2 hyperintensities in Wilson's disease
Full blood count	Haematocrit may be elevated in PRV
Red cell mass	Sensitive test required for diagnosis of PRV
Blood film	3 × fresh thick blood films necessary to exclude neuro-acanthocytosis
Erythrocyte membrane chorein levels (western blot)	Neuro-acanthocytosis
Serum caeruloplasmin	Reduced in Wilson's disease
Urinary copper level	Elevated in Wilson's disease
Liver biopsy	Sometimes required to diagnose Wilson's disease
Pregnancy test	Chorea gravidarum in first trimester
HIV test	(Hemi) chorea/ballism may be presenting feature of AIDS
Erythrocyte sedimentation rate and antinuclear antibody	Sensitive tests to reveal SLE
Anti-dsDNA	Relatively specific to SLE
Anticardiolipin and lupus anticoagulant	Antiphospholipid syndrome is risk factor for chorea
Thyroid function tests	Thyrotoxicosis
Antistreptolysin O (ASO) titre	Recent streptococcal infection suggests Sydenham's chorea/PANDAS
Antibasal ganglia antibodies	Associated with post-infective chorea, chorea gravidarum and OCP-induced chorea
Muscle biopsy	Ragged red fibres or respiratory chain abnormalities in mitochondrial disease
Cerebrospinal fluid analysis	May reveal inflammatory/neoplastic causes

MRI, magnetic resonance imaging; PANDAS, paediatric autoimmune disorders associated with streptococcal infection; PRV, polycythaemia rubra vera; OCP, oral contraceptive pill; SLE, systemic lupus erythematosus.

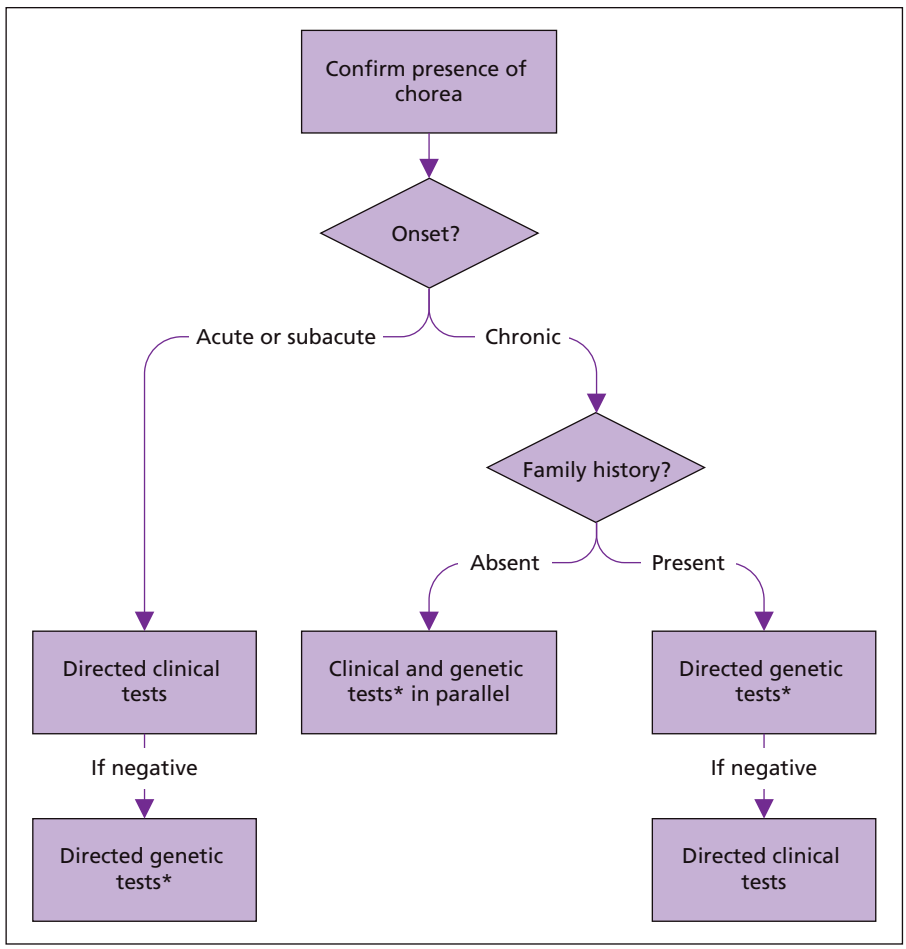

Figure 5.3 Approach to the investigation of the choreic patient. * Genetic testing must always be preceded by detailed expert genetic counselling.

during paternal transmission is important in the development of large expansions associated with juvenile HD: approximately 80% of juvenile HD patients inherit the HD gene from their father. There is a correlation between CAG repeat size and age at onset, such that the larger the repeat, the earlier the onset. Most individuals with more than 50 repeats develop the disease before the age of 30 years. CAG repeat number also appears to govern the development rate of neuropathological changes. However, CAG repeat length does not completely explain variations in age of onset, clinical phenotype or rate of clinical progression, so that other modifying genes obviously have an important role.

Neuropathologically, in the early stages of disease, the brain can look macroscopically normal, but later there is marked cortical atrophy with ventricular dilatation, severe atrophy of the caudate more than the putamen, with atrophy of the internal segment of the globus pallidus and substantia nigra pars reticulata.

Clinical features

HD can produce a varied clinical phenotype. It is important to realize that as the disease progresses, the signs and symptoms change, so disease duration can markedly modify the clinical presentation.

Motor features

The onset of HD is often difficult to discern clearly. Many patients report psychiatric problems or mild cognitive symptoms before developing any motor problems. However, the definitive diagnosis of HD is usually made when motor abnormalities are noted on examination. Subtle motor abnormalities seen early in the disease include general restlessness, abnormal eye movements, hyper-reflexia, impaired finger tapping, and fidgety movements of fingers, hands and toes during stress or when walking. Oculomotor abnormalities are a cardinal feature of the disease, and often the earliest motor sign. Saccadic abnormalities are characteristic and may include gaze impersistence and distractibility and delayed initiation or slowing of voluntary saccades (vertical worse than horizontal).

As the disease progresses, more obvious extrapyramidal signs develop; chorea is seen in 90% of adult onset patients but may decrease in the late stages, whereas dystonia, rigidity and parkinsonism may dominate the clinical picture in late disease. A key motor abnormality in HD is impaired voluntary motor function with clumsiness, motor impersistence and disturbances in fine motor control and motor speed. Gait disturbance is common, with impaired postural reflexes making patients more prone to falling. Dysarthria and dysphagia are common and should be asked about.

Cognitive features

Cognitive abnormalities are variable but universal in HD. The key cognitive abnormalities seen are impaired executive function with poor planning and judgement, impulsive behaviour, disorganized actions and difficulty coping with multiple tasks. Many patients exhibit psychomotor slowing with apathy, lack of self-care and loss of initiative which can make caring for them difficult. Patients often complain early on of visual and verbal memory problems, in addition to poor concentration and attention.

Psychiatric features

The combination of psychiatric and cognitive features causes the greatest disability, functional decline and distress to relatives and HD patients.

Psychiatric symptoms are common, particularly depression and anxiety. Irritability is also very common and some patients become aggressive. As the disease progresses, obsessions and compulsions often make life difficult for carers. Psychosis, despite being well-recognized, is relatively rare but the suicide rate is much higher than in the general population. Psychiatric symptoms often cause a great deal of distress to patients and relatives and should be actively managed with the same drugs used in standard psychiatric practice.

Juvenile Huntington's disease

Juvenile HD cases are defined as onset before age 20 years, usually associated with repeat lengths greater than 60. They have more severe disease and shorter life expectancy. The akinetic-rigid form of the disease (Westphal variant) is more common in juvenile HD: patients typically have little chorea and are predominantly rigid and dystonic. Juvenile HD patients also have a higher incidence of seizures and myoclonus than adult onset patients. Younger adult-onset patients with HD (<40 years) may also present with a predominantly parkinsonian phenotype similar to the juvenile HD cases.

Differential diagnosis of Huntington's disease

Huntington's disease phenocopies

Before the advent of genetic testing for HD, diagnosis was based on clinical evaluation and neuropathological examination. Now, genetic diagnosis allows definitive confirmation of the disease. Genotype–phenotype studies have increased our understanding of disorders that can present like HD (HD phenocopies) with similar cognitive, psychiatric and motor features, but are HD gene negative (Table 5.11). HD phenocopies occur in approximately 1% of large genetic screens of individuals with clinical signs of HD. An approach to genetic testing of HD phenocopies is suggested in Figure 5.4.

HDL2 (HD-like 2) is caused by a CAG/CTG expansion in the *Junctophilin-3* gene and is very rare, and moreover only reported so far in individuals with African ancestry. In one consanguineous family, a phenocopy syndrome (HDL3) was mapped to 4p15.3, but no causative mutation has been identified. Other dominantly inherited diseases mimicking HD are dentatorubropallidoluysian atrophy (DRPLA), another polyglutamine disorder caused by a CAG repeat expansion in the atrophin-1 gene, and spinocerebellar (SCA) 17 – also called HDL4 – caused by a CAG repeat expansion in the TATA-binding gene (*TBP*). SCA1

and SCA3 (Chapter 16) may also mimic HD. Inherited prion disease may cause HD phenocopies: one mutation causes HDL1, an early onset prion disease with prominent psychiatric features. Neuroferritinopathy, a very rare, dominantly inherited disorder, caused by mutations in the ferritin light chain, has clinical features overlapping with HD.

Neuro-acanthocytosis

There are several conditions (the neuro-acanthocytoses) in which chorea and other movement disorders are associated with the presence of acanthocytosis of the red blood cells in the peripheral blood. Autosomal recessive neuro-acanthocytosis is rare, and associated with mutations in the *CHAC* gene leading to production of a truncated protein termed chorein. Onset is typically in the fourth decade with a progressive movement disorder, psychiatric and cognitive changes which mimic HD. The movement disorder comprises chorea, dystonia and tics, with prominent eating dystonia, dystonic tongue protrusion and tongue and lip biting. Psychiatric and cognitive features are similar to HD. Unlike HD, seizures are seen in 50% of patients, and there is commonly a distal amyotrophy or axonal neuropathy with a high creatine kinase. Investigations include analysis of fresh blood films for >3% of acanthocytes. More than one blood film may be necessary to identify these. Genetic testing for mutations in the CHAC gene is difficult, so confirmation relies on demonstration of low erythrocyte membrane chorein levels in the blood.

Macleod syndrome is a very rare X-linked recessive disorder linked to mutations in the *XK* gene, which encodes the Kell antigen. It usually begins around the age of 45 years and is slowly progressive, with limb chorea and facial tics. Dystonia is less common than in chorea-acanthocytosis and subcortical dementia and psychiatric features tend to occur later in the disease. Axonal neuropathy, cardiomyopathy and haemolytic anaemia may be seen, CPK is often elevated, and acanthocytes are usually found in fresh thick peripheral blood films.

Acanthocytes have also been described in pantothenate kinase-associated neurodegeneration (PKAN, or NBIA type 1) and HDL2 and all these disorders are encompassed under 'core neuro-acanthocytosis syndromes'.

Table 5.11 Differential diagnosis of Huntington's disease (HD phenocopies).

Condition	Cause
HDL1	Octapeptide repeat insertion in gene encoding prion protein
HDL2	Triplet repeat expansion in gene encoding junctophilin-3
HDL3	Causative mutation unidentified
SCA17 (HDL4)	Triplet repeat expansion in gene encoding TATA-box binding protein
Inherited prion disease	Mutations in gene encoding prion protein
SCA1	Triplet repeat expansion in gene encoding ataxin-1
SCA3	Triplet repeat expansion in gene encoding ataxin-3
DRPLA	Triplet repeat expansion in gene encoding atrophin-1
Neuro-acanthocytosis	Mutation in gene encoding chorein
Neuroferritinopathy	Mutations in gene encoding ferritin light-chain
NBIA	Mutations in the *PANK2* gene

DRPLA, dentatorubro-pallidoluysian atrophy; NBIA, neurodegeneration with brain iron accumulation.

Post-streptococcal autoimmune disorders

Sydenham's chorea and PANDAS (paediatric autoimmune disorders associated with streptococcal infection) may both present with chorea and neuropsychiatric manifestations. Sydenham's chorea is one of the major manifestations of rheumatic fever. It occurs in children, mainly girls, between 5 and 15 years of age and is now rare in the developed world. Widespread chorea, behavioural disturbance and obsessive-compulsive symptoms are common. It is self-limiting and usually resolves within 6 months, with about 20% of cases being recurrent. Antibasal ganglia

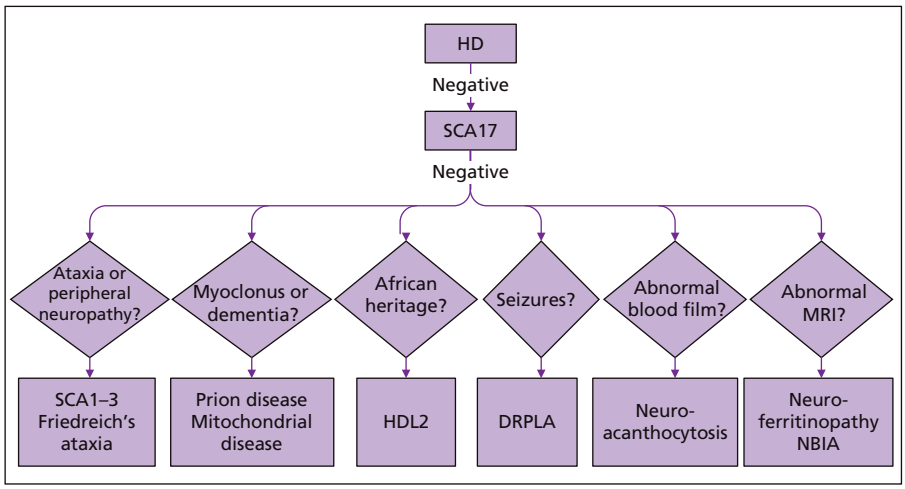

Figure 5.4 Suggested approach to genetic testing in chorea.

antibodies can be detected. The mechanism of damage is thought to be molecular mimicry with cross-reaction between antistreptococcal antibodies and neurones in the basal ganglia. PANDAS is also discussed under tics.

Benign hereditary chorea

Benign hereditary chorea (BHC) is a very rare, dominantly inherited disorder caused by mutations in the gene encoding thyroid transcription factor 1 (*TITF1*). It is usually of early onset and is characterized by very slowly progressive chorea without cognitive decline or other neurological features, but there is clinical heterogeneity within and between families. Some cases of BHC also display dystonia, myoclonic jerks, mild dysarthria, gait disturbances or low–average intelligence, and many cases may also have hypothyroidism or pulmonary abnormalities of varying degrees, leading to the recent application of the term 'brain–thyroid–lung syndrome'.

Drug-induced chorea

Many different medications can cause chorea. The main ones include neuroleptics (tardive dyskinesia), levodopa/dopamine agonists/anticholinergics (most often, but not exclusively, in patients being treated for parkinsonism), anticonvulsants (phenytoin, carbamazepine, valproate, gabapentin), CNS stimulants (amphetamines, methylphenidate, cocaine), benzodiazepines, oestrogens (oral contraceptive pill or, rarely, hormone replacement therapy) and lithium (although this more commonly causes myoclonus or jerky tremor).

Drug management of chorea

Chorea can cause cosmetic embarrassment to some patients but many do not notice the severity of their chorea. Indeed, it is often relatives, rather than patients, who request treatment. Best agreed practice is to use antichoreic medication sparingly as no drug is particularly efficacious, and a balance has to be struck between benefits and side-effects. For functionally disabling chorea, drugs such as sulpiride, olanzapine, risperidone and tetrabenazine may be useful by non-specifically damping down movements in general, but they can worsen speech, swallowing and gait and balance, so need careful monitoring.

Tics

Tics are typically relatively brief rapid intermittent purposeless involuntary movements (motor tics) or sounds (vocalizations). Classically, they can be suppressed, at least temporarily, by an effort of will, but at the expense of rising inner tension, often followed by a rebound exacerbation. Most tics are abrupt in onset and duration (clonic tics), but may also be slow and sustained, either dystonic (associated with more sustained muscle contractions) or tonic (if muscle contractions are not associated with any movement, e.g. arm or abdominal tensing).

Gilles de la Tourette syndrome

Gilles de la Tourette syndrome (GTS) is the most common cause of tics. The diagnostic criteria for GTS include multiple motor tics and one or more phonic and/or vocal tics, which must last longer than a year. The motor and phonic tics do not necessarily occur together, characteristically wax and wane over time, occur in bouts and are suggestible and suppressible. The maximum age at onset is 18 years. The mean age at onset of motor tics is about 7 years, and vocal tics 11 years, the worst severity is at 10–12 years, and the majority of symptoms disappear in half of the patients by the age of 18 years. Associated behaviours such as obsessive-compulsive behaviour or obsessive-compulsive disorder (OCB/OCD) may be more evident later.

Tics in GTS can be simple (e.g. blinking, eye rolling, head nodding, facial grimacing) or complex (e.g. touching, squatting). Premonitory sensations (also referred to as premonitory urges, mental urges or inner tension) precede both motor and phonic tics in up to 80% of patients; these may be localized (burning feeling in the eye before an eye-blink, or a sensation similar to nasal stuffiness before a sniff – the sensation has been likened to that which occurs before a sneeze). They may be localized (around the area of the tic) or generalized (covering a wide area of the body). New tics may appear in response to a new somato-sensory sensation, such as a cough (phonic tic) persisting after an upper respiratory tract infection. Tics usually begin in the head and face, and blinking is one of the most common first tics. Simple phonic tics include sniffing, throat clearing, gulping, snorting and coughing. Complex vocal tics include barking, the making of animal noises, inappropriate voice intonations and uttering strings of words. Tics characteristically are suggestible, suppressible, there is rebound after suppression and they have a waxing and waning course. Other important and characteristic features of GTS include echolalia (copying what other people say), echopraxia (copying what other people do) and palilalia (repeating the last word or part of sentence said by the individual). Coprolalia (inappropriate involuntary swearing, often disguised by the patient) is uncommon, occurring in only 10–15%, starting at around 15 years. Many clinicians are under the misapprehension that coprolalia must be present in order to make the diagnosis. Instead of the whole swear word, many individuals say only parts of the word and disguise it (by coughing, saying something, covering their mouths). Copropraxia (e.g. the V sign) may also occur but is rare.

Epidemiology, history and prevalence

GTS has been described worldwide but with apparent different prevalence rates. The male : female ratio is 3 : 1. Clinical characteristics are similar irrespective of the country of origin. In some instances it seems that within families, the affected males have tic symptoms, whereas the females often have OCB. GTS was once considered to be uncommon. However, recent studies report a prevalence of 0.4–3.8% for youngsters aged 5–18 years, and most recently a figure of 1% worldwide overall prevalence has been calculated. The prevalence of GTS in special educational

populations (individuals with learning difficulties) or autistic spectrum disorders can be as high as 6–10%. It is important to note that GTS individuals identified in community settings have more behavioural, mental health and educational difficulties than their peers. Many people with GTS never come to medical attention. Among those who do, the correct diagnosis is often missed as many clinicians remain under the misapprehension that coprolalia is necessary for the diagnosis.

Psychopathology and associated co-morbidity

About 90% of GTS individuals have psychiatric co-morbidity. The most common is attention deficit hyperactivity disorder (ADHD), followed by OCB and OCD. Checking rituals, 'evening up', counting rituals and compulsions to touch objects or people may be present, but are not often volunteered and need to be asked about. Anger control problems, sleep difficulties, coprolalia and self-injurious behaviours (SIB) are more common in those with co-morbidity. Patients with GTS have more depression, anxiety, hostility, obsessional symptomatology and personality disorders than controls. Individuals with GTS only appear to be different to those with GTS together with ADHD.

Assessment

GTS is a clinical diagnosis. Standardized schedules are available to describe the phenomenology, and quantify and qualify associated behaviours and psychopathology, and to monitor response to treatment. Investigations are usually not necessary, but may be helpful in diagnosing alternative causes of tics (see below).

Current aetiological theories

Various causes have been postulated including genetic influences, neuro-immunological reactions to infections, and prenatal and peri-natal difficulties. Complex segregation analysis suggested that GTS was genetic, consistent with a single major gene and autosomal dominant transmission, but with incomplete penetrance. However, much of the genome has been excluded, so the genetics of GTS is much more complicated than previously thought. The term PANDAS (paediatric autoimmune neuropsychiatric disorders associated with streptococcal infections) was recently coined for children with post-streptococcal OCD and tics. This pathogenic mechanism is somewhat controversial but most centres that have sought them have also found antibasal ganglia antibodies (ABGAs) in a subgroup of patients with GTS. Streptococcal infection (with group A beta-haemolytic strains) probably does not cause GTS, but individuals may inherit a susceptibility to GTS and to the way they react to some infections.

Multiple phenotypes of GTS

Many non-expert clinicians prefer not to make a diagnosis of GTS when the patient presents with only simple motor and phonic tics, when they simply call it a 'tic disorder'. However, several recent studies have demonstrated by hierarchical cluster analysis or principal component factor analysis that there is more than one type of GTS. Moreover one factor (phenotype), replicated by several centres, consists almost solely of simple motor and phonic tics. Other factors include complex tics and associated psychopathologies, as well as aggressivity and SIB. There have been initial suggestions that the varying phenotypes may have different aetiologies.

Other forms of tic disorder

Tic disorders, usually referring to motor tics, are much more common than GTS, although prevalence figures differ, depending on the population studied. They have been reported to occur with a point prevalence of 1–29% of young people. The most common tic disorders can be divided into the following:

1 Transient tic disorder (TTD), in which there are single or multiple motor and vocal tics occurring for at least a month but for no longer than a year;

2 Chronic motor or vocal tic disorder (CMTD), in which motor or vocal but not both have been present in excess of a year; or

3 Tic disorder not otherwise specified, such as adult onset tic disorder with an age at onset after 18 years.

Once again, tics are more frequent in those individuals with behavioural difficulties, learning difficulties, and those requiring special education placement or those seen as 'problem children'.

Other diseases that can cause tics

Tics may also be seen in WD, neuro-acanthocytosis, Lesch–Nyhan syndrome, neuroferritinopathy, autism spectrum disorders, and in association with acquired lesions of the caudate nucleus and after chronic neuroleptic drug intake. However, they are usually only a part of the clinical picture, so should not be confused with primary tic disorder. Not all vocalizations are tics – they can be seen in dystonia, HD and tardive dyskinesia, for example.

Investigation of tics

In the typical case (the vast majority) no investigations are necessary. If the presentation is unusual, the following could be helpful: serum copper and coeruloplasmin and slit-lamp examination for WD; ASO titre, throat swab, anti-DNA antibodies and ABGAs for post-streptococcal tics; fresh thick blood films (×3), creatine phosphokinase, nerve conduction studies, MRI, chorein and ChAc gene testing for neuro-acanthocytosis.

Management of GTS and tics

In mild cases, explanation, reassurance and psycho-education may be the only interventions required. When the condition is causing problems, supportive psychotherapy, cognitive–behavioural therapy (CBT) and more recently documented habit reversal training (HRT) may be useful: HRT specifically targets tics. Ideally, management should be multidisciplinary and treatment should be targeted at symptoms.

In many patients, medication may be required for the treatment of the tics and psychopathologies. The main agents for the tics are the typical and atypical neuroleptics, given in small doses (relative to treating psychosis), e.g. haloperidol 0.5–3 mg/day or

sulpiride 100–400 mg/day. The older 'typical' neuroleptics such as haloperidol, pimozide, sulpiride and tiapride, and the newer 'atypical' neuroleptic such as risperidone have all been shown to be superior to placebo in double-blind trials. Tetrabenazine can also be effective but can often cause depression. Clonidine or guanfacine can help tics, impulse control or ADHD. If these agents are used, baseline ECG is advisable, as is regular monitoring of pulse and blood pressure. Recently the newer 'atypical' neuroleptics (risperidone, quetiapine, aripiprazole) as well as sulpiride and tiapride are becoming more popular because of the unacceptable side effects of the older agents. The response to medication in GTS patients is idiosyncratic. Importantly, individuals with this often lifelong, generally benign, condition should be warned of the possibility of developing a superimposed tardive movement disorder after chronic treatment with neuroleptic drugs.

Antidepressants, especially SSRIs, are useful for depression (using the standard dose, e.g. fluoxetine 20 mg), whereas the dose for OCB/OCD is higher (e.g. 40–60 mg). Clomipramine (a tricyclic) may be useful in OCB/OCD, but usually has more side effects than the SSRIs and is dangerous in overdose. SSRIs have been reported to cause suicidal ideation and there are now strict guidelines for the use of SSRIs in young people. In some patients, botulinum toxin injections to the affected areas (e.g. vocal cords if loud distressing vocal tics/coprolalia) can improve the tics and the urge to tic. DBS of internal capsule, GPi or thalamus in some carefully selected, severely affected and treatment-resistant patients has apparently helped.

When a patient has GTS + ADHD, one should assess which symptoms are most problematic, and attempt to treat these. Clonidine helps tics, ADHD and sleep. It was once thought that stimulants (e.g. methylphenidate) that improve ADHD increased tics, and were therefore contraindicated, but this is now known not to be the case in most patients. Newer once-daily slow-release preparations may increase compliance. If the ADHD and tics pose equal difficulties, try clonidine; if ADHD is the greatest problem, try stimulants. The next option is to use stimulants with clonidine. Stimulants may also be given with neuroleptics.

Myoclonus

Myoclonus comprises sudden brief shock-like involuntary movements caused by muscular contractions or inhibitions. Muscle contraction produces positive myoclonus and muscle inhibition causes negative myoclonus or asterixis (e.g. liver flap). Myoclonus can be focal, multifocal, generalized, spontaneous or reflex. It may occur at rest, when maintaining a posture or during action. Myoclonus can be classified as cortical, subcortical, spinal or peripheral, based on the presumed physiological mechanism underlying its generation. Alternatively, based on its aetiology, it can be classified as physiological, essential, epileptic or symptomatic (Table 5.12).

Physiological myoclonus

This includes hypnic jerks (initial phases of sleep), hiccup (physiological myoclonus of diaphragm) and startle response (commonly exacerbated by anxiety).

Essential myoclonus

See section on myoclonus-dystonia (DYT11) above in dystonia section.

Epileptic myoclonus

This term is used to denote conditions where myoclonic jerks are part of an epileptic syndrome (see Neurophysiological assessment below and Chapter 6). Generalized myoclonus can occur in the syndromes of idiopathic generalized epilepsy or in the secondarily generalized epilepsies which include the progressive myoclonic epilepsies or the static epileptic encephalopathies. Epileptic myoclonus is accompanied by generalized epileptiform discharges, but the myoclonus itself may be focal, segmental or generalized. Focal myoclonus can occur in secondary symptomatic epilepsy as a result of infection, inflammation, vascular disease, trauma or tumours.

Familial cortical tremor (also called benign autosomal dominant familial myoclonic epilepsy)

Clinically, this superficially resembles essential tremor. It is associated with infrequent or rare generalized seizures. It is an autosomal dominant, benign condition characterized by fine shivering-like 'tremor'. It usually presents in the third or fourth decade of life and there is no significant clinical progression. The myoclonus usually responds to valproate, carbamazepine or primidone, and has been mapped in Japanese families to chromosome 8q and in Italians to chromosome 2p.

Epilepsia partialis continua

This is spontaneous, regular or irregular muscle twitching of cortical origin confined to one part of the body and continuing for a period of hours, days or weeks. This condition is further described in Chapter 6.

Secondary myoclonus

This occurs in the context of an underlying neurological or non-neurological disorder brought about by trauma, brain hypoxia or progressive myoclonic encephalopathies. Often there is clinical or pathological evidence of diffuse or focal nervous system involvement.

Non-progressive myoclonic encephalopathies

It is important to recognize metabolic causes (renal or hepatic failure, vitamin E deficiency, increased level of antithyroid autoantibodies), toxic causes (bismuth, methyl-bromide, tethraethyl, chloralose poisoning) or drugs (levodopa, lithium, tricyclic antidepressants, morphine, antibiotics, SSRIs, MAOIs, antipsychotic and anaesthetic agents) that may cause myoclonus. Usually such myoclonus is multifocal and often stimulus-sensitive, and may include negative myoclonus.

Table 5.12 Classification of myoclonus. (From Caviness & Brown (2004) with permission.)

I. Physiological myoclonus
Sleep jerks (e.g. hypnic jerks)
Hiccough (singultus)

II. Essential myoclonus (+/– dystonia)
Hereditary (autosomal dominant)
Sporadic

III. Epileptic myoclonus
***Progressive myoclonic epilepsy* (*PME*)**
Mitochondrial disease
Lafora body disease
GM2 gangliosidosis (Tay–Sachs disease)
Ceroid lipofuscinosis (Batten/Kufs disease)
Sialidosis

***Progressive myoclonic ataxia** (*PMA*)**
Mitochondrial disease
Unverricht–Lundborg disease
Spinocerebellar degenerations
Coeliac disease

Other myoclonus epilepsy
First year of life:
Infantile spasms
2–6 years:
Lennox–Gastaut syndrome
Older children and adolescents (and adults)
Photosensitive epileptic myoclonus
Myoclonus absences
Juvenile myoclonic epilepsy
Epilepsia partialis continua
Cortical reflex myoclonus

IV. Symptomatic myoclonus
A. Storage diseases
See III (above) PME

B. Spinocerebellar degenerations
Friedreich's ataxia
Ataxia-telangiectasia

C. Other degenerations
Basal ganglia degenerations
Wilson's disease
Dystonia
Hallervorden–Spatz disease
Huntington's disease
Multiple system atrophy
Cortico-basal degeneration
Dentatorubro-pallidoluysian atrophy (DPRLA)

D. Dementias
Creutzfeldt–Jakob disease
Alzheimer's disease,
Dementia with Lewy bodies
Parkinson's disease dementia
Frontotemporal dementia

E. Infectious or post-infectious
Subacute sclerosing panencephalitis
HIV
Post-infectious encephalitis

F. Metabolic
Hyperthyroidism
Hepatic failure
Renal failure
Dialysis syndrome
Hyponatraemia
Hypoglycaemia
Non-ketotic hyperglycaemia
Biotin deficiency
Mitochondrial disease

G. Malabsorption
Coeliac disease
Whipple's disease

H. Toxic and drug-induced syndromes

I. Physical encephalopathies
Post-hypoxic action myoclonus (Lance–Adams)
Post-traumatic

J. Paraneoplastic encephalopathies
K. Opsoclonus-myoclonus syndrome
Idiopathic
Paraneoplastic
Infectious

L. Focal nervous system damage
Post-stroke
Post-thalamotomy
Tumour
Trauma
Inflammation

M. Exaggerated startle syndrome
Hereditary/sporadic/secondary

N. Palatal myoclonus (tremor)
Idiopathic/symptomatic

O. Spinal myoclonus
Segmental
Propriospinal

P. Peripheral nervous system
Hemifacial spasm

Q. Psychogenic myoclonus

* Myoclonus and cerebellar features main problem, perhaps with mild mental impairment and epilepsy.

Postanoxic action myoclonus (Lance–Adams syndrome)

This is a distinct condition secondary to severe cerebral hypoxia (usually after respiratory rather than cardiac arrest) characterized by action myoclonus, usually without other neurological disturbances, after a latent interval of 24–28 hours (Chapter 19). Myoclonus may be positive, triggered by movement, or negative when the limbs are outstretched against gravity. The voice may be fragmented by the myoclonic jerks. It can be multifocal or generalized. It is most commonly cortical reflex myoclonus, but reticular reflex myoclonus and exaggerated startle may also occur. With treatment using clonazepam, sodium valproate or piracetam or levetiracetam, distal myoclonus can be greatly improved, but asterixis in proximal leg muscles ('bouncy legs') may continue to render the patient wheelchair-bound.

Opsoclonus-myoclonus

This is a well-delineated syndrome that most often occurs in children with neuroblastoma (a tumour that can remit without treatment) or medulloblastoma, or in adults in association with small cell carcinoma of the lung, breast carcinoma or melanoma. It also may be post-infectious or metabolic (coeliac disease) or drug-related. This syndrome is characterized by rapid involuntary saccadic eye movements (opsoclonus) and sudden involuntary muscle contractions (myoclonus). Ataxia is quite often also present. This syndrome is thought to be mediated by autoantibodies directed against onconeural antigens that are expressed by the tumours and also by neurones. Treatment of the underlying cause often leads to an improvement in the syndrome. In idiopathic cases, steroids and/or

immuno-modulatory treatment have been used with some success.

Myoclonus in neurodegenerative disorders

Cortical myoclonus is present in about 15% of patients with DLB or PD-D but is uncommon in PD patients without dementia.

Patients with MSA often display irregular small-amplitude myoclonic movements (mini-polymyoclonus) of the hands and/or fingers on posture (jerky postural tremor) that are stimulus-sensitive, or occur during voluntary movements. A cortical origin can often be demonstrated by back-averaging techniques, and somato-sensory evoked potentials (SSEPs) are sometimes 'giant'.

Myoclonus occurs in most patients with CBD, usually appearing focally in the arm and less commonly in the legs, together with other manifestations such as apraxia, rigidity, dystonia and alien limb phenomenon. It may occur in repetitive rhythmic fashion (jerky tremor) at rest and more commonly when attempting to activate the arm or following somato-sensory stimulation (reflex myoclonus). A cortical origin has been postulated. In contrast to CBD, myoclonus is rare in progressive supranuclear palsy (PSP), another tauopathy.

HD can rarely be associated with myoclonus, usually in individuals with a juvenile onset and longer CAG repeats. Myoclonus is more common in DRPLA, when it is usually associated with epilepsy.

In Alzheimer's disease, myoclonus is usually multifocal but can also be generalized. There can be sporadic large myoclonic jerks or repetitive small ones which may occur at rest, during action or be stimulus-sensitive. Commonly, myoclonus appears in middle and late stages of the disease, affecting about 50% of patients. It may occur at the onset of the disease in patients with earlier age of onset, rapid progression and in familial causes of Alzheimer's disease.

Myoclonus has recently been described in some patients with fronto-temporal dementia and parkinsonism linked to chromosome 17 (FTDP-17). Myoclonus is often observed (82–100%) in sporadic, familial and new-variant Creutzfeldt–Jakob disease (CJD) during the course of the disease, in which the jerks are often diffuse, generalized, relatively rhythmic and associated with periodic sharp-wave EEG activity (1–1.5 Hz). They are stimulus-sensitive and can persist during sleep.

Subcortical myoclonus

Rhythmic myoclonus in a brainstem or spinal segmental distribution suggests a focal lesion at or near that segment of the brainstem or spinal cord. Generalized jerks most commonly reflect an origin in the brainstem reticular formation while axial jerks usually suggest a spinal cord lesion.

Startle syndromes

The startle reflex is a bilaterally synchronous shock-like set of movements evoked by sudden stimuli. Its most prominent features are forceful closure of the eyes, raising of flexed arms above the head, and flexion of the neck, trunk, elbows, hips and knees. The auditory startle reflex originates in the caudal brainstem, more specifically in the bulbo-pontine reticular formation. The nucleus reticularis pontis caudalis seems particularly important. Startle syndromes occur in three different groups of disorders with abnormal response to startling events: hyperekplexia, neuropsychiatric startle syndrome and startle-induced epilepsy.

The major form of hyperekplexia is characterized by generalized stiffness noticeable soon after birth, but subsiding during the first years of life, excessive startling to an unexpected stimulus that remains throughout life, and generalized stiffness in response to startle that lasts a few seconds and which commonly produces a fall forwards 'as stiff as a board' while fully conscious. In this form, mutations in the α1 subunit of the glycine receptor gene, *GLRA1*, or related genes have been identified. A minor form of hyperekplexia is characterized by excessive startle only, with latencies of muscle activation longer than in the major form. No definite genetic substrate for this form has been found. Excessive startle also occurs in the context of neuropsychiatric conditions such as anxiety, panic attack, post-traumatic stress disorders or culture-specific disorders such as the jumping Frenchmen of Maine.

Startle epilepsy is an asymmetric tonic epileptic seizure typically induced by a sudden stimulus, mostly observed in young patients with infantile cerebral hemiplegia.

Palatal myoclonus

See under Palatal tremor, above.

Spinal myoclonus

Segmental myoclonus involves one or two contiguous spinal segments, whereas in proprio-spinal myoclonus several segments are involved because electrical activity spreads upwards and downwards from a spinal generator via slower proprio-spinal pathways. Spinal myoclonus has been reported in association with spinal cord trauma, vascular disease, disc herniation, drugs and infection. It is usually rhythmic or periodic, involving muscles belonging to one or two spinal segments.

Proprio-spinal myoclonus may also be rhythmic or arrhythmic but is characterized by axial jerks with flexion of the trunk and limbs. It occurs mainly when the patient is relaxed, predominantly when lying on a bed or falling asleep, and may be a cause of insomnia. Jerk duration is usually longer and more variable (50–1000 ms) than in cortical myoclonus.

Peripheral myoclonus

Peripheral myoclonus is rare and characterized by rhythmic or semi-rhythmic myoclonus secondary to nerve, root or anterior horn cell disease. Hemifacial spasm is the most common example. Peripheral myoclonus can be also multifocal in anterior horn cell disease (as in post-polio syndrome).

Psychogenic myoclonus

Psychogenic myoclonus can occur spontaneously or following an external insult. It may be focal (restricted to a few muscles or

limb) or generalized. Jerks usually have an inconsistent character over time, occasionally associated with other unusual neurological symptoms, with sudden onset and offset. There is often underlying psychopathology, the jerks are commonly distractible and may respond to placebo or psychotherapy (see also under Other movement disorders below).

Drug-induced myoclonus

Many different drugs can cause myoclonus. These include antidepressants (especially SSRIs), opiates, antiparkinsonian medications, some antibiotics (especially quinolones), lithium, bismuth, neuroleptics, anaesthetic agents (especially propofol), cholinesterase inhibitors and, perhaps surprisingly, anxiolytics (especially benzodiazepines) and anticonvulsants.

Treatment of myoclonus

The treatment of myoclonus depends upon the underlying disorder. Depending upon its aetiology, myoclonus can be partially or totally reversed, as in drug-induced or metabolic myoclonus, or surgically treatable lesions. Unfortunately, treatment of the underlying disorder is not always feasible.

Most causative conditions are poorly responsive to pharmacological treatment and often require polytherapy but this may cause side effects such as ataxia and drowsiness.

In cortical myoclonus, sodium valproate is particularly effective, possibly by increasing cortical GABA concentrations and potentiating GABAergic post-synaptic inhibitory activity. Benzodiazepines and barbiturates are also effective and believed to facilitate GABAergic transmission: clonazepam is the most useful antimyoclonic agent. Primidone and phenobarbital are occasionally useful. Piracetam and levetiracetam have been shown to be very useful agents although at the moment limited controlled studies are available. Lamotrigine may be effective alone.

Myoclonus dystonia responds partially to clonazepam, which is also particularly useful in hyperekplexia and in spinal myoclonus. Bilateral pallidal DBS can help severe myoclonus dystonia. Injection of botulinum toxin can help in palatal myoclonus and in hemifacial spasm.

Other movement disorders

Psychogenic movement disorders

Psychogenic movement disorders (PMD) can present as any movement disorder, although dystonia and tremor are the most common manifestations and psychogenic parkinsonism and chorea are rare. PMD represent 4–25% of all new cases seen in specialist movement disorders clinics.

The diagnosis of a PMD is primarily clinical, although investigations to exclude alternative diagnoses, and specific electrophysiological tests for certain forms of PMD, may have an important role. However, PMD is not simply a diagnosis of exclusion, and positive features suggesting the diagnosis should be sought. These include marked fluctuations during examination; distractibility; increase with attention or suggestion; incongruence with patterns of recognized movement disorders; the presence of other non-organic signs or a psychiatric disorder; discrepancy between objective signs and disability; abrupt onset with rapid progression to maximum severity; inconsistency over time; a history of previous somatizations; and a sustained and substantial response to placebo or psychotherapy. While none of these features is pathognomonic, they allow a classification based on degree of diagnostic certainty (Table 5.13).

Specific PMDs may have additional clinical and investigational features that support the diagnosis. In psychogenic tremor these include co-activation of antagonist muscles; entrainability of tremor to the frequency of contralateral hand movements; and an increase of amplitude or change of tremor frequency when the limb is loaded with a weight. In psychogenic myoclonus the presence of a Bereitschaftspotential (premovement potential) preceding myoclonic movements, of prolonged or variable duration EMG-bursts, and of long latency and variable recruitment in stimulus-sensitive myoclonus all support the diagnosis.

However, in some cases investigations may exclude a psychogenic cause. Thus, in myoclonus, consistent duration of myoclonic bursts less than 70 ms or latency to stimulus-sensitive myoclonus of less than 70 ms or the presence of giant SEPs or cortical correlates of myoclonic jerks on back-averaged EEG exclude a psychogenic aetiology. Similarly, an abnormal DaT SPECT scan excludes a diagnosis of psychogenic parkinsonism. However, the specificity of many tests that are reported to be abnormal in certain movement disorders, e.g. reciprocal inhibition in dystonia, is currently unknown and these tests cannot therefore be relied upon to differentiate them from PMD. In addition, many classic features of movement disorders, e.g. geste

Table 5.13 Diagnostic criteria for psychogenic dystonia. As only the first two categories provide a clinically useful degree of diagnostic certainty they have been combined to one category of 'Clinically definite'.

Documented Persistent relief by psychotherapy, suggestion or placebo has been demonstrated, which may be helped by physiotherapy, or the patient was seen without the dystonia when believing him or herself unobserved
Clinically established The dystonia is incongruent with classic dystonia or there are inconsistencies in the examination, plus at least one of the following three: other psychogenic signs, multiple somatizations or an obvious psychiatric disturbance
Probable The dystonia is incongruent or inconsistent with typical dystonia, or there are psychogenic signs or multiple somatizations
Possible Evidence of an emotional disturbance

antagoniste in dystonia or treatment-induced dyskinesias in PD, can be seen in PMD. The perceived difficulty of imitating a movement disorder is not sufficient to exclude this diagnosis, and this is exemplified in rare cases of psychogenic palatal tremor. Nevertheless, a diagnosis of PMD should not be made simply because the movement disorder is bizarre. Sometimes it is necessary to observe the patient over time to reach a diagnosis.

The prognosis of long-standing PMD is generally poor, although patients with PMD presenting soon after onset appear to have a better prognosis. Management of PMD is often difficult but should include thorough initial investigations followed by discussion of the diagnosis in a clear but unconfrontational manner emphasizing the unconscious origin of PMD. Where appropriate, exploration of psychiatric disorders or psychological factors underlying the disorder, appropriate referral for diagnosis and treatment, initiation of pharmacological and physical therapy, and continued follow-up by a multidisciplinary team (including the neurologist) should be considered. Avoiding both unnecessary drug treatment and perpetuating illness beliefs are clearly important management goals, particularly in complex and long-standing cases.

Movement disorders associated with dopamine receptor blockade or dopamine depletion

Dopamine receptor blocking drugs are commonly used for psychiatric indications (neuroleptics) but also in the treatment of nausea, vomiting, vertigo, unsteadiness and migraine. Dopamine depletors originally included reserpine (for hypertension), but now only tetrabenazine (for hyperkinetic movement disorders) is licensed. All of the following types of movement disorder can be produced by any of these drugs, except that tetrabenazine does not cause tardive movement disorders.

Drug-induced parkinsonism (DIP) occurs frequently. Often mild, it can nevertheless sometimes be severe, and can be asymmetrical. It is reversible, the vast majority of cases remitting within weeks to 3 months, and a dwindling residual between 3 and 12 months of stopping the offending drug. The longer the duration of parkinsonism after withdrawal of the causative drug, the greater the chance that the individual was already in the early stages of PD (or other parkinsonian disorder). Management is to withdraw the causative agent if possible, and if not, to substitute an atypical neuroleptic drug with less anti-D2 dopaminergic effect. Anticholinergics can help. So too can levodopa, but this risks psychiatric relapse, and has limited effectiveness until the causative drug is withdrawn. DaT SPECT scan is normal in pure DIP.

Acute dystonic reactions affect about 2% of individuals exposed to these drugs. They arise within hours of starting the medication and predominantly affect head and neck, with oculogyria and jaw and neck dystonia, sometimes painful. They spontaneously subside over hours, but within seconds to minutes after IV administration of a centrally acting anticholinergic.

Akathisia ('not sitting') can occur early or late in treatment (the latter, tardive akathisia, can persist after drug withdrawal). The patient has an inner compulsion to move, a 'motor restlessness' that causes them to pace up and down or shift from one foot to the other, with rather stereotyped movements. Treatment is unsatisfactory.

Tardive dyskinesia arises after weeks, months or years of treatment, but persists for a variable time period, sometimes permanently. It can begin, or worsen temporarily, after discontinuing the offending drug. Most cases display relatively rapid, predominantly choreiform buccolinguomasticatory movements, with lip-smacking and sometimes tongue protrusion. These are more common with increasing age and female sex.

Tardive dystonia, more common in younger male subjects, phenomenologically resembles idiopathic dystonia, so can take the form of torticollis or axial dystonia for example. However, retrocollis, or opisthotonic trunk movements, are more common than in idiopathic torticollis or axial dystonia, as are so-called 'copulatory' pelvic thrusting movements. Tardive dystonia can often be functionally, as well as socially disabling. The remission rate for this condition is very low – only 14% even 8 years after discontinuation of the offending drug, which nevertheless remains the best prognostic feature.

Although the newer 'atypical' neuroleptic drugs appear to be safer with regard to the provocation of tardive movement disorders than older drugs, there are no entirely safe dopamine receptor blocking drugs and, at least for tardive dystonia, no safe period of use. Unfortunately, centrally acting dopamine receptor blocking drugs continue to be used inappropriately for depression and anxiety and also for gastrointestinal disorders such as nausea or vomiting (e.g. metoclopramide).

Anticholinergics can worsen choreiform tardive dyskinesia, but may improve tardive dystonia. Tetrabenazine can sometimes help both. Paradoxically, just as tardive dyskinesia can present when the offending neuroleptic drug has its dose reduced, or is discontinued, an increase in the dose of the offending drug can improve the movements, but only in the short term, before further aggravating the problem.

Tardive tics, myoclonus and tremor have been described, but are very uncommon.

The neuroleptic malignant syndrome (NMS) is a potentially fatal reaction to the introduction, increase or change of dosage of dopamine receptor blocking drugs (Chapter 19). In its fully developed form it involves the subacute appearance of severe muscle rigidity (sometimes with necrosis and myoglobinuria, leading to renal failure), akinesia, diaphoresis, agitation progressing to stupor and coma, and hyperpyrexia. CPK levels are elevated, often markedly, and a polymorphonuclear leucocytosis is common. Management includes stopping the offending drug, intensive care, cooling, antipyretics, and traditionally the administration of dantrolene and bromocriptine. Mortality in severe cases can still be up to 20%, but is much less in milder cases. The underlying mechanism is thought to be a combination of hypothalamic and striatal dopamine receptor blockade. Rarely an NMS-like syndrome can occur in PD after acute reduction or withdrawal of dopaminergic drugs.

Restless legs syndrome

Restless legs syndrome (RLS) is probably the most common movement disorder, affecting to some degree 3–10% of the population, with most of those needing treatment being over the age of 50 years. It causes unpleasant sensations or an urge to move in the legs (and sometimes other body parts), classically on retiring to bed at night, which is only, and almost instantly, relieved by getting up and walking about. It can also occur when trying to relax when sitting or lying down during the day. Some (younger onset) cases are dominantly inherited. There are associations with iron deficiency, uraemia, pregnancy, peripheral neuropathy and possibly with PD. Serum ferritin is often low (Chapter 19).

Essential criteria for diagnosis are as follows:

1 An urge to move the legs, usually accompanied by uncomfortable or unpleasant sensations in the legs.

2 These symptoms begin or worsen during periods of rest or inactivity such as lying or sitting.

3 Symptoms are partially or totally relieved by movement, at least for as long as the activity continues.

4 Symptoms are worse, or only occur, in the evening or at night.

Supportive criteria are as follow:

1 Positive response to dopaminergic treatment;

2 Periodic limb movements during wakefulness or sleep; and

3 Positive family history suggestive of autosomal dominant inheritance.

If drug treatment is needed, dopamine agonists (e.g. pramipexole and ropinirole) are currently favoured over levodopa because chronic levodopa treatment can lead to 'augmentation' – i.e. spillover of symptoms to the daytime, an increase in severity of symptoms, and involvement of other body parts. Second line drugs that sometimes help are opiates, gabapentin, carbamazepine and clonazepam. If there is iron deficiency or low ferritin, iron supplementation is indicated.

RLS is commonly associated with periodic leg movements of sleep (PLMS). Several gene associations for RLS (with or without PLMS) and for PLMS (with or without RLS) have recently been discovered.

Painful legs and moving toes

This rare condition is characterized by slow undulating flexion–extension movements of the toes, accompanied by pain in the legs, usually unilateral. There may be evidence of peripheral nerve or root lesion involving the affected leg. No treatment is effective.

Stiff person syndrome, stiff limb syndrome and encephalomyelitis with rigidity

Stiff person syndrome is characterized by axial rigidity at rest involving mainly trunk (causing hyperlordosis) and sometimes also proximal lower limb muscles. A crucial finding is the presence of continuous motor unit activity in the paraspinal muscles that persists even when trying to relax, so that EMG electrical silence cannot be obtained. The rigidity and continuous motor unit activity lessen, or even disappear, during sleep and after spinal or general anaesthesia, indicating a central source.

Exteroceptive or cutaneo-muscular reflexes are enhanced, habituate poorly and spread as reflex spasms into muscles normally not involved in the reflex. These findings point to enhanced spinal interneurone excitability, caused by defects either within spinal interneuronal networks at a segmental level or their descending control. Polysynaptic reflexes are characteristically exaggerated in both upper and lower limbs as well as the axial (paraspinal) muscles.

Most patients have anti-GAD antibodies in serum and CSF, and some have additional diabetes or other autoimmune disturbances or markers. Typically, patients show a useful response to high-dose baclofen and diazepam, and remain ambulant.

The stiff limb syndrome is rarer, and characterized by rigidity, painful spasms and abnormal postures of (usually one) distal limb (more commonly a leg than an arm). Affected patients show continuous motor unit activity in the affected limb, abnormal exteroceptive reflexes and abnormally segmented EMG activity during spasms. Auto-immune markers are infrequent, and the condition responds poorly to treatment, most patients becoming wheelchair-bound.

A third, even rarer, disorder comprises patients with a rapidly progressive and fatal inflammatory encephalomyelitis with rigidity, usually with abnormal CSF and additional denervation.

Neurophysiological assessment of movement disorders

Neurophysiological investigations in movement disorders are objective methods to investigate and support clinical diagnosis of different abnormal movements, and to monitor their severity and the effects of treatment.

Many methods are available, most of them useful for research purposes, but often of limited clinical utility. All electrophysiological tests should be interpreted in conjunction with clinical features but neurophysiology may disclose information that it is not possible to obtain by clinical observation alone.

Tremor

Tremor is the movement disorder most subjected to neurophysiological study. It can be characterized on the basis of its frequency, pattern of muscle activation, and duration and amplitude of the muscle bursts. Multichannel EMG recording and accelerometer data can be very useful to assess freqency and other characteristics of muscle activation in tremor.

The situation in which tremor occurs (rest, postural, action), and the presence of associated neurological signs, are important to guide the electrophysiological diagnosis of tremor. Tremor frequency can be helpful to some degree. Thus, the upper limit of frequency of physiological or voluntary tremor in healthy subjects is 11 Hz. Tremor above this frequency is always pathological, and most commonly caused by orthostatic tremor with a

frequency of 13–18 Hz. Tremor at 5–7 Hz is often seen in patients with PD and essential tremor (ET) and tremor at >9 Hz in patients with enhanced physiological tremor (EPT). Low frequency tremor <4 Hz may be seen in Holmes tremor, dystonic tremor and cerebellar tremor. However, there is considerable overlap in frequency between different tremor disorders. Tremor amplitude is of little value for diagnostic purposes.

Tremor can arise from different sources. External loading (500–1000 g in the hand) typically reduces the tremor frequency in peripheral tremor (physiological tremor, EPT), but not in central tremor (PD, ET).

Cortical tremor (rhythmic cortical myoclonus) may show burst duration as short as 25–50 ms. Otherwise, burst duration is not particularly useful in identifying the anatomical origin of a tremor. Multichannel EMG recording may show a rostro-caudal pyramidal progression of the pattern of muscle recruitment, or rhythmic arrests of muscle tone as in negative cortical myoclonus or asterixis. The pattern of muscle activation between agonist and antagonist muscles (synchronous versus alternating) is not very helpful in guiding the diagnosis.

Dystonic tremor is an irregular tremor usually below 7 Hz. It is associated with dystonic postures in the affected extremity or elsewhere, is subject to position- and task-specific worsening, and increases with attempts to move the body part in the opposite direction to the dystonic pattern.

In psychogenic tremor, amplitude often diminishes and frequency may change during distraction (counting, or tapping with the opposite limb). Furthermore, tapping different frequencies with the unaffected hand 'entrains' to the same frequency as that on the tremulous side. Tremor amplitude and frequency usually increase when adding a load to the affected limb.

Dystonia

Many neurophysiological abnormalities have been found in patients with dystonia, but these are only partially useful for diagnostic purposes in individual patients. Impaired reciprocal inhibition of forearm flexor muscles at intermediate and long latency, reduced cortical silent period duration, and short- and long-interval intracortical inhibition have been seen in different studies in dystonic patients.

More sophisticated analyses of EMG discharges consider EMG–EMG coherence. This may disclose the character of the descending discharges responsible for the abnormal muscle activity in dystonia. An abnormal 4–7 Hz drive is seen in dystonic muscles in patients with the *DYT1* gene mutation, idiopathic torticollis and myoclonus dystonia. In the arms there is evidence of an abnormal cortico-muscular drive in the 15–30 Hz band leading to co-contraction between antagonistic muscles, with the exception of writer's cramp where a discrete peak in EMG–EMG coherence may be seen at 11–12 Hz.

Myoclonus

Myoclonus is classified according to its physiopathological basis as cortical, reticular or spinal.

Cortical myoclonus

This is usually arrhythmic but can also be rhythmic (cortical tremor). It is characterized by jerks of short duration (typically <50 ms) involving many muscles and usually synchronously in agonists and antagonists. EMG recording from an extremity can demonstrate spread of jerks from the proximal muscle to distal with velocity corresponding to that of alpha motor fibres.

In cortical myoclonus, the EEG often shows multifocal or generalized spike and wave or multiple spike and wave which is usually time-locked to the muscle jerks. However, in some cases the EEG does not show any time-locked abnormality. EEG back-averaging can disclose myoclonus-related EEG activity that may not be recognized on the conventional polygraph. This technique can determine the precise time interval from the EEG activity to the myoclonus. It also identifies the scalp distribution of the myoclonus-related EEG activity based on simultaneous multichannel recordings. Back-averaging analysis shows a positive–negative biphasic spike at the central electrode somatotopically representing the muscle from which the myoclonus is recorded. The initial positive precedes the onset of myoclonic EMG discharge in a hand muscle by approximately 20 ms. The more distal the muscle the myoclonus is recorded from, the longer is the EEG–EMG time interval. Myoclonus-related discharge spreads through the motor cortex within one hemisphere, and also transcallosally to the homologous area of the contralateral motor cortex (10–15 ms). Unfortunately, EEG back-averaging analysis is limited by muscle activity in the scalp and also in cases where the jerks are of high frequency, or are infrequent.

In subjects in whom myoclonic EMG bursts are of small amplitude, or repeat rhythmically at high frequency, frequency analysis has advantages over back-averaging. Frequency analysis of EMG–EMG and also EEG–EMG coherence can detect a pathologically exaggerated common drive in distal limb muscles, showing significant coherence in the physiological range (15–60 Hz) but also, in some cases, at much higher frequencies.

Patients with cortical myoclonus may also show giant sensory evoked potentials; the initial components, a post-central negative peak (N20) and a precentral positive peak (P20), are not enhanced; however, the subsequent components (P25, P30, N35) are 3–10 times as large as normal. Long loop reflexes (C-reflexes) obtained by the motor subthreshold stimulation of the median nerve, recording from both thenar muscles, are also enhanced with a latency in the thenar muscle of around 45 ms, and 10–15 ms longer contralaterally because of the transcallosal transit time. Negative myoclonus is produced by a sudden (50–400 ms) interruption of a tonic muscle contraction, associated with an ictal discharge.

In CJD, myoclonus is not stimulus-sensitive and occurs continuously and quasi-periodically in the resting condition every 600–1500 ms. There may be accompanying dystonic posturing. EMG bursts are similar to, or slightly longer than, those of classic cortical myoclonus. Periodic sharp discharges (PSDs) are usually associated with muscle jerks, but can occur independently. EEG spike-wave and EMG activity correlate loosely. On back-averaging,

the negative spike-wave is much smaller than the PSD recorded with raw EEG. The time interval between EEG and jerks is 50–85 ms (much longer than required for conduction through the pyramidal tract). Typical cortical reflex myoclonus may be seen in late stages of disease.

In subacute sclerosing panencephalitis (SSPE) sudden movements, followed by a tonic phase ('hung-up jerks'), can be related to periodic high-amplitude EEG discharges occurring every 4–13 s.

Essential myoclonus, myoclonus dystonia (except for SSPE), palatal and oculo-palatal myoclonus are characterized by EMG discharges lasting up to 400 ms. In such cases the EEG does not show any specific correlate to the EMG discharge.

Reticular, or brainstem, myoclonus

This is characterized by generalized jerks with prominent involvement of proximal and flexor muscles. Jerks may be spontaneous or stimulus-induced, particularly with respect to sound.

Jerks originate from the brainstem reticular formation; the first muscle to be activated is trapezius or sternomastoid; subsequently there is spread to the cranial and caudal muscles with different velocities of activation.

Myoclonic jerks may be associated with cortical spikes. However, the lack of correlation between the two suggests that spikes are projected to, but do not originate at the cortex. Evoked potentials are not increased, but there may be an enhanced C-reflex.

The normal human startle response consists of a brief flexion response, most marked in the upper half of the body, elicited by unexpected auditory, and sometimes somaesthetic, visual or vestibular stimuli. Conduction of efferent impulses both upwards and downwards from the generator, possibly in the medial reticular formation, is slow. The shortest latencies are 20–50 ms for the orbicularis oculi muscle. In the quadriceps muscle the latencies of the responses are 100–150 ms.

Electromyographic responses in the intrinsic hand and foot muscles are particularly delayed. However, the auditory startle reflex electromyographic latencies are rather variable. The constant reflex EMG activity in orbicularis oculi is the most important event in the normal auditory startle reflex. If one considers the auditory blink reflex in orbicularis oculi as separate from the startle response, then the earliest muscle recorded is the SCM, with a latency of <100 ms. The activity then spreads up the brainstem from the XIth nerve to the Vth cranial nerve and down the spinal cord (reflex brainstem myoclonus). In physiological startle the stimulus-induced response tends to habituate, and disappears after 4–6 stimuli. Exaggerated startle responses are seen in hyperekplexia, in neuropsychiatric startle syndrome and in stimulus-induced epilepsy and stiff person syndrome.

Spinal myoclonus

Two different patterns of spinal myoclonus are recognized: proprio-spinal myoclonus and segmental myoclonus. Myoclonus is most often positive, but negative myoclonus may also occur.

Proprio-spinal myoclonus is characterized by arrhythmic sequences or runs of axial jerks producing flexion or extension of the trunk. Bursts of muscle activity vary from 50 ms to 4 s. EMG jerks arise from abdominal or cervical spinal segments and slowly spread rostrally and caudally at <10 m/s. Cranial muscles are not involved, with the exception of the neck. It can be stimulus-sensitive.

Segmental myoclonus is described as regular or irregular repetitive jerks, involving a group of muscles innervated by one or two spinal segments.

6 Epilepsy and Related Disorders

Simon Shorvon, John Duncan, Matthias Koepp, Josemir Sander, Shelagh Smith, Matthew Walker

Epilepsy is a common condition. It accounts for about 20% of all neurological consultations and is associated with significant medical, social and secondary handicap. The World Health Organization (WHO) has estimated that epilepsy causes 6.4 million disability-adjusted life years (DALYs) and 1.32 million years of life (YLL) lost worldwide, and amongst neurological diseases is less only than stroke and dementia in its impact.

A standard definition of epilepsy is as a disorder of brain characterized by an ongoing liability to recurrent epileptic seizures. An epileptic seizure is defined as the transient clinical manifestations that result from an episode of epileptic neuronal activity. The epileptic neuronal activity is a specific dysfunction, characterized by abnormal synchronization, excessive excitation and/or inadequate inhibition, and can affect small or large neuronal populations. The clinical manifestations are sudden and usually brief. They include motor, psychic, autonomic and sensory phenomenon, with or without alteration in consciousness or awareness, and the symptoms depend on the part of the brain involved in the epileptic neuronal discharge, and the intensity of the discharge.

Epidemiology

The incidence of epilepsy is in the region of 80 cases per 100,000 persons per year, with different studies showing rates varying mostly between 50 and 120 per 100,000 per year. Its point prevalence has been found to be 4–10 cases per 1000 persons in most studies, although higher figures are found from settings in resource-poor countries. The frequency of epilepsy is also slightly higher in lower socio-economic classes. The incidence of seizures is age dependent, with the highest rates in the first year of life and a second peak in late life. About 40% of patients develop epilepsy below the age of 16 years of age and about 20% over the age of 65 years.

Neurology: A Queen Square Textbook Edited by Charles Clarke, Robin Howard, Martin Rossor and Simon Shorvon
ISBN: 978-1-405-13443-9

An isolated (first and only) seizure occurs in about 20 persons per 100,000 each year. The cumulative incidence of epilepsy – the risk of an individual developing epilepsy in his/her lifetime – is 3–5%. The fact that prevalence is much lower than cumulative incidence demonstrates that in many cases epilepsy remits. In fact, the prognosis is generally good, and within 5 years of the onset of seizures 50–60% of patients will have entered long remission. However, in about 20% of cases, epilepsy, once developed, never remits. Fertility rates are reduced by about 30% in women with epilepsy. Standardized mortality rates are also 2–3 times higher in patients with epilepsy than in others in the population. The excess mortality is caused largely by the underlying cause of the epilepsy. However, some deaths are directly related to seizures and there are higher rates of accidents, sudden unexpected death and suicides amongst patients with epilepsy when compared with the general population. The rates of death are highest in the first few years after diagnosis – reflecting the underlying cerebral disease (e.g. tumour, stroke). In chronic epilepsy, the excess mortality is partly a result of sudden unexpected death in epilepsy (SUDEP). The rates of SUDEP range from about 1 death per 2500 persons per year in mild epilepsy to 1 death per 100 patients per year amongst those with severe and intractable epilepsy.

About 30% of children with epilepsy and 20% of adults with epilepsy have additional learning or neurological disabilities. Epilepsy occurs in about 20% of those with learning disability. Of adults with newly diagnosed epilepsy, 18% show additional cognitive impairment and 6% motor disabilities (usually hemiplegia due to stroke) and 6% severe psychiatric disorders. About 1 in 15 persons with epilepsy is dependant on others for daily living because of epilepsy and the associated handicaps.

ILAE classification of seizure type

The International League Against Epilepsy (ILAE) classification of seizure type is the most widely accepted classification scheme for epilepsy. It has undergone a series of revisions since it was first

Table 6.1 The International League Against Epilepsy (ILAE) Classification of Seizure Type (1981).

I. Partial (focal, local) seizures

A. Simple partial seizures

1. With motor signs
2. With somatosensory or special sensory symptoms
3. With autonomic symptoms or signs
4. With psychic symptoms

B. Complex partial seizures

1. Simple partial onset followed by impairment of consciousness
2. With impairment of consciousness at onset

***C. Partial seizures evolving to secondarily generalized seizures* (tonic–clonic, tonic, or clonic)**

1. Simple partial seizures evolving to generalized seizures
2. Complex partial seizures evolving to generalized seizures
3. Simple partial seizures evolving to complex partial seizures evolving to generalized seizures

II. Generalized seizures (convulsive and non-convulsive)

A. Absence seizures

1. Absence seizures
2. Atypical absence seizures

B. Myoclonic seizures

C. Clonic seizures

D. Tonic seizures

E. Tonic–clonic seizures

F. Atonic seizures

III. Unclassified epileptic seizures

proposed and further revisions are under consideration. The current classification divides seizures into generalized and partial categories (Table 6.1). Generalized seizures are those that arise from large areas of cortex in both hemispheres, in which consciousness is always lost, and are subdivided into seven categories. Partial seizures are those that arise in specific often small loci of cortex in one hemisphere. They are divided into simple partial seizures which occur without alteration of consciousness and complex partial seizures in which consciousness is impaired or lost. A secondarily generalized seizure has a partial onset (the aura) which spreads to become a generalized attack. Simple partial seizures may spread to become complex partial seizures, and either can spread to become secondarily generalized. The classification is based entirely on clinical and electroencephalography (EEG) phenomenology, but some generalized seizure types occur only in specific types of epilepsy. Partial seizures invariably imply focal brain pathology, although this may not necessarily be demonstrated by conventional clinical investigation. About two-thirds of newly diagnosed epilepsies are partial and/or secondarily generalized.

Partial seizures

Simple partial seizures

These are defined as partial seizures in which consciousness is not impaired. Complex partial seizures are those in which consciousness is impaired. Both imply focal cerebral disease and seizures can arise from any cortical region, the most common sites being the frontal and temporal lobes.

The symptomatology depends on the anatomical localization of the seizures. Motor manifestations can include jerking, spasm or posturing, speech arrest, dysarthria, choking sensations, version of the head or eyes or, less commonly, rotation of the whole body can occur in epilepsy arising in many cortical areas. Todd's paralysis can occur after a seizure, and is a reliable lateralizing sign of epilepsy arising in contralateral motor cortex. Sensory manifestations can take the form of tingling or numbness or pain. Visual phenomena such as flashing lights and colours occur if the calcarine cortex is affected. A rising epigastric sensation is the most common manifestation of a simple partial seizure arising in the mesial temporal lobe. Autonomic symptoms occur such as changes in skin colour, blood pressure, heart rate, pupil size and piloerection.

Complex perceptual or affective 'auras' can take various forms, and are more common in complex partial than in simple partial seizures. They can occur in epilepsy arising from temporal, frontal or parietal foci. There are six principal categories:

1 *Dysphasic symptoms* can occur if cortical speech areas (frontal or temporoparietal) are affected and should be distinguished where possible from anarthria (speech arrest) which suggests a fronto-central origin.

2 *Dysmnestic symptoms* (disturbance of memory) such as flashbacks, déjà vu, jamais vu, or distortions of memory are most common in mesial temporal lobe seizures although also occur in inferior frontal or lateral temporal lobe seizures.

3 *Cognitive symptoms* include dreamy states and sensations of unreality or depersonalization and occur primarily in temporal lobe seizures.

4 *Affective symptoms* include fear (the most common symptom), depression, anger, elation, erotic thoughts, serenity or exhilaration. These are encountered most common in mesial temporal lobe epilepsy. Laughter (without mirth) is a feature of the automatism of seizures (known as gelastic seizures) which arise in frontal areas, and are a consistent feature of the epilepsy associated with hypothalamic hamartomas.

5 *Illusions* of size (macropsia, micropsia), shape, weight, distance or sound are usually features of temporal or parieto-occipital epileptic foci.

6 *Structured hallucinations* of visual, auditory, gustatory or olfactory forms, which can be crude or elaborate, are usually caused by epileptic discharges in the temporal or parieto-occipital association areas. Hallucinations of taste, usually an unpleasant taste, are a frequent symptom of temporal lobe epilepsy. Visual hallucinations can vary greatly in sophistication from simple colours or flashing lights in epilepsy arising in calcerine cortex to complex visual perceptual hallucinations in posterior temporal association

areas. Auditory hallucinations and changes in auditory perception also vary in complexity, and most commonly occur in seizures arising in Herschl's gyrus.

Complex partial seizures

These arise from the temporal lobe in about 60% of cases, the frontal lobe in about 30% and from other cortical areas in about 10% of cases. The clinical features reflect the site of onset of the seizures. The complex partial seizure may evolve during its course and in some seizures it is possible to identify three distinct components: the aura, the absence (loss of consciousness) and the automatism. The aura is in effect a simple partial seizure. It is usually short-lived, lasting a few seconds or so, although in rare cases can be prolonged. Many patients experience isolated auras as well as full-blown complex partial seizures. The symptoms in the aura can take any of the forms described above and depend on the anatomical location of the epileptic discharge. Absence is characterized by motor and speech arrest, during which the patient appears vacant (the 'motionless stare').

Automatisms are defined as involuntary motor actions that occur during or in the aftermath of epileptic seizures, in a state of impaired awareness. The patient is usually totally amnesic for the events of the automatism. Sometimes the actions have purposeful elements, are affected by environment and can involve quite complex activity. Automatisms should be distinguished from post-ictal confusion. Automatisms are most common in temporal and frontal lobe seizures. The most common automatisms are as follow:

- *Oro-alimentary automatisms* in which orofacial movements occur such as chewing, lip smacking, swallowing or drooling. These are characteristic of partial seizures of mesial temporal origin.
- *Gestural automatisms* include fiddling movements with the hands, tapping, patting or rubbing, ordering and tidying movements. Complex actions such as undressing are quite common also as are genitally directed actions. These too are most common in mesial temporal lobe epilepsy.
- *Ambulatory automatisms* involve walking, circling, running and are most common in frontal lobe epilepsy, but do occur in temporal lobe epilepsy also.
- *Verbal automatisms* include words and sentences, meaningless sounds, humming and whistling. Speech during the seizure suggests a non-dominant focus and dysphasia after the seizure a dominant focus. Verbal automatisms can occur in both frontal and temporal seizures.
- *Violent behaviour* can occur in an automatism, is best considered as a response in an acutely confused person and is especially likely if the patient is restrained. The violent actions of the epileptic automatism are generally never premeditated, never remembered, never highly coordinated or skilful and seldom goal-directed; these are useful diagnostic features in a forensic context.

Partial (focal) epilepsy can also be classified by anatomical location. This is a phenomenological classification, based largely on the clinical and EEG appearances of the seizures, and is obviously important when considering surgical therapy. The most common schemes divide seizures into those arising in frontal, temporal, parietal and occipital lobes and also in the central region (pre- and post-central gyrus). Subdivisions are proposed, but because epileptic seizure discharges spread extensively, anatomical classifications are often not as specific as might be hoped. Sixty per cent of partial epilepsies arise in the temporal lobe (Table 6.2).

Partial seizures may spread to become generalized. The partial seizure is often experienced as an aura in the seconds before the generalized seizure. The generalized seizure is usually tonic–clonic, tonic or atonic.

The EEG during a complex partial seizure of mesial temporal lobe onset typically shows, at the onset, a rhythmic (5–7 Hz) discharge localized to the anterior mid temporal lobe. In lateral temporal seizures, the ictal onset EEG changes are more likely to have a spiked or high-frequency pattern. Complex partial seizures of frontal lobe epilepsy show ictal EEG onset patterns that are typically generalized or widespread, comprising high-frequency activity or slow rhythms or attenuation. Ictal onset EEG patterns in parietal and occipital seizures vary, in part dependent on pathways of seizure propagation, and there is a higher rate of false localization and lateralization.

Generalized seizures

Six forms are defined in the ILAE classification although, in practice, transitional forms or manifestations modified by therapy are common. Consciousness is impaired from the onset of the attack, motor changes are bilateral and more or less symmetric, and the EEG patterns are bilateral and grossly synchronous and symmetrical over both hemispheres.

Typical absence seizure (petit mal seizure)

The seizure takes the form of an abrupt sudden loss of consciousness (the absence) and cessation of all motor activity. Tone is usually preserved, and there is no fall. The patient is not in contact with the environment, inaccessible and often appears glazed or vacant. The attack ends as abruptly as it started, and previous activity is resumed as if nothing had happened and there is no post-ictal confusion. The patient is often unaware that an attack has occurred. Most absence seizures (>80%) last less than 10 seconds. Blinking, subtle clonic movements, alterations in tone and/or brief automatisms can occur, particularly in longer attacks. The attacks can be repeated, sometimes hundreds of times a day, often cluster and are often worse when the patient is awakening or drifting off to sleep. Absences may be precipitated by fatigue, drowsiness, relaxation, photic stimulation or hyperventilation. Typical absence seizures develop in childhood or adolescence and are encountered almost exclusively in the syndrome of idiopathic generalized epilepsy. The EEG during a typical absence is diagnostic, shown high voltage, regular, symmetric and synchronous 3 Hz spike-wave paroxysms. The features useful in differentiating a complex partial seizure and a typical absence are shown in Table 6.3.

Table 6.2 Partial seizures arising in different brain regions.

Brain region of origin	Clinical features
Mesial temporal lobe origin	Tripartite seizure pattern (aura, absence, automatism), although only one feature may be present Auras are common and include: visceral, cephalic, gustatory, dysmnestic, affective, perceptual or autonomic auras Partial awareness commonly preserved, especially in early stages Slow evolution of seizure Prominent motor arrest or absence (the 'motionless stare') Dystonic posturing of the contralateral upper limb common in the early stages of the seizure In seizures arising in the dominant temporal lobe, speech arrest common during the seizures and dysphasia common post-ictally Seizures longer than frontal lobe seizures (typically >2 min), with a slower evolution and more gradual onset/offset Post-ictal confusion and dysphasia common Autonomic changes (e.g. pallor, redness, and tachycardia) Automatisms: less violent than in frontal lobe epilepsy, and usually take the form of oro-alimentary (lip smacking, chewing, swallowing), or gestural (e.g. fumbling, fidgeting, repetitive motor actions, undressing, walking, sexually directed actions, walking, running) and sometimes prolonged In hippocampal epilepsy, history of febrile seizures, onset in childhood or adolescence, initial early response lost after several years
Lateral temporal lobe onset	Features overlap with mesial temporal lobe onset, with the following differences: Motor arrest and absence less prominent Aura more likely to take the form of complex perceptual changes, visual and auditory hallucinations Tonic posturing more common More frequent secondary generalization
Frontal lobe origin	Frequent attacks with clustering Brief stereotyped seizures (<30 s) Nocturnal attacks common Sudden onset and cessation, with rapid evolution and awareness lost at onset Absence of complex aura Version of head or eye common Prominent ictal posturing and tonic spasms Prominent complex bilateral motor automatisms involving lower limbs; often bizarre and misdiagnosed as pseudoseizures Absence of postictal confusion Frequent secondary generalization History of status epilepticus
Parietal and occipital lobe origin	Somatosensory symptoms (e.g. tingling, numbness or more complex sensations – may or may not march) Sensation of inability to move Sexual sensations Illusions of change in body size/shape Vertigo Gustatory seizures Elementary visual hallucinations (e.g. flashes, colours, shapes, patterns) Complex visual hallucinations (e.g. objects, scenes, autoscopia palinopsia, often moving) Head turning (usually adversive, with sensation of following or looking at the visual hallucations) Visuo-spatial distortions (e.g. of size (micropsia, macropsia), shape, position) Loss or dulling of vision (amaurosis) Eyelid fluttering/blinking/nystagmus
Central cortical origin	Often no loss of consciousness Contralateral jerking (which may or may not march) Contralateral tonic spasm or dystonia Posturing, which is often bilateral Speech arrest and paralysis of bulbar musculature (producing anarthria or a choking, gurgling sound) Contralateral sensory symptoms Short duration and frequently recurring attacks Prolonged seizures with slow progression (and episodes of epilepsia partialis continua) Post-ictal Todd's pareisis

Table 6.3 Differentiation between typical absences and complex partial seizures.

	Typical absence	Complex partial seizure
Age of onset	Childhood or early adult	Any age
Aetiology	Idiopathic generalized epilepsy	Any focal pathology or cryptogenic epilepsies
Underlying focal anatomical lesion	None	Limbic structures Neocortex
Duration of attack	Short (usually <30 s)	Longer, usually several minutes
Other clinical features	Slight (tone changes or motor phenomena)	Can be prominent; including aura, automatism
Postictal	None	Confusion, headache, emotional disturbance are common
Frequency	May be numerous	Usually less frequent cluster
Ictal and interictal EEG	3 Hz generalized spike-wave	Variable focal disturbance
Photosensitivity	10–30%	None
Effect of hyperventilation	Often marked increase	None, modest increase

Table 6.4 Clinical features differentiating typical and atypical absence seizures.

	Typical absence	Atypical absence
Context	Otherwise no neurological signs or symptoms	Usually in context of learning difficulty, and other neurological abnormalities
Consciousnes	Totally lost	Often only partially impaired
Focal signs in seizures	Nil	May be present
Onset/offset of seizures	Abrupt	Often gradual
Coexisting seizure types	Sometimes tonic–clonic and myoclonic	Mixed seizure disorder common, all seizure types

Atypical absence seizure

This, like typical absence seizures, takes the form of loss of awareness (absence) and hypo-motor behaviour (Table 6.4). However, the duration is longer, loss of awareness is often incomplete and much less marked and associated tone changes are more severe than in typical absence seizures. The onset and cessation of the attacks are not so abrupt. Amnesia may not be complete and the subject may be partially responsive. The ictal EEG shows usually diffuse but often asymmetric and irregular spike-wave bursts at 2–2.5 Hz, and sometimes fast activity or bursts of spikes and sharp waves. The background interictal EEG is usually abnormal, with continuous slowing, spikes or irregular spike-wave activity, and there is overlap of ictal and interictal EEG features. Atypical absences occur in the symptomatic epilepsies, are usually associated with learning disability, other neurologic abnormalities or multiple seizure types. These seizures most commonly form part of the Lennox–Gastaut syndrome and occur at any age.

Myoclonic seizure

This takes the form of a brief contraction of a muscle, muscle group or several muscle groups brought about by a cortical discharge. It can be single or repetitive, varying in severity from an almost imperceptible twitch to a severe jerking, resulting, for instance, in a sudden fall or the propulsion of handheld objects. Recovery is immediate, and the patient often maintains that consciousness was not lost. Myoclonic seizures occur in idiopathic generalized epilepsy, in the childhood epileptic encephalopathies (e.g. Lennox–Gastaut syndrome) and in epilepsy associated with other forms of learning disability, and in the progressive myoclonic epilepsies. Focal myoclonus can also occur in focal epilepsy of frontal or occipital origin. Epileptic myoclonus needs to be differentiated from non-epileptic myoclonus of spinal and subcortical origin.

Clonic seizure

Clonic seizures are most frequent in neonates, infants or young children, and are always symptomatic.

Tonic seizure

This takes the form of a tonic muscle contraction with altered consciousness without a clonic phase. Often there is extension of the neck; contraction of the facial muscles, with the eyes opening widely, upturning of the eyeballs, contraction of the muscles of respiration, spasm of the proximal upper limb muscles causing the abduction and elevation of the semi-flexed arms and the shoulders. The ictal EEG may show flattening (desynchronization), fast activity (15–25 Hz) with increasing amplitude (to about 100 μV) as the attack progresses, or a rhythmic 10 Hz discharge similar to that seen in the tonic phase of the tonic–clonic seizure. Tonic seizures occur in the setting of diffuse cerebral damage, learning disability, are invariably associated with other seizure types and are the characteristic and defining seizure type in the Lennox–Gastaut syndrome.

Tonic–clonic seizure (grand mal seizure)

This is the 'convulsion' or 'fit'. It is sometimes preceded by a prodromal period during which an attack is anticipated, often by an ill-defined vague feeling or sometimes more specifically, for instance, by the occurrence of increasing myoclonic jerking. If an aura then occurs (in fact a simple or complex partial seizure) in the seconds before the full-blown attack, this indicates that the tonic–clonic seizure is secondarily generalized. The seizure takes the form of loss of consciousness, sometimes with the epileptic cry (a loud guttural sound), tonic stiffening (and the patient will fall if standing) initially sometimes in flexion but then in axial extension, with the eyes rolled up, the jaw clamped shut, the limbs stiff, adducted and extended, and the fists clenched. Respiration ceases and cyanosis is common. The eyes remain open and the pupils dilated and unreactive. There are frequently heart rate changes, which are sometimes marked and can take the form of tachycardia or bradycardia and even asystole. This tonic stage lasts on average 10–30 seconds and is followed by the clonic phase, during which convulsive movements, usually of all four limbs, jaw, and facial muscles occur; breathing can be stertorous and arrest of respiration can occur; and saliva (sometimes blood-stained owing to tongue biting) may froth from the mouth. The convulsive movements decrease in frequency (eventually to about four clonic jerks per second), and increase in amplitude as the attack progresses. The attack is usually followed by a period of flaccidity of the muscles and consciousness is slowly regained. Confusion is invariable in the post-ictal phase. The patient often has a severe headache, feels dazed and extremely unwell, and often lapses into deep sleep. Petechial haemorrhages around the eyes, lethargy and muscle aching is common. Tonic–clonic seizures are encountered in many different types of epilepsy, including idiopathic generalized epilepsy, symptomatic generalized epilepsies, epileptic encephalopathies, in various epilepsy syndromes, in febrile convulsions and in acute symptomatic seizures. They have no pathological or syndromic specificity.

Atonic seizure

The most severe form is the classic drop attack (astatic seizure) in which all postural tone is suddenly lost causing collapse to the ground like a rag doll. The seizures are short and are followed by immediate recovery. Longer (inhibitory) atonic attacks can develop in a stepwise fashion with progressively increasing nodding, sagging or folding. The seizures are always associated with diffuse cerebral damage, learning diability and are common in severe symptomatic epilepsies (especially in the Lennox–Gastaut sndrome and in myoclonic astatic epilepsy).

ILAE classification of the epilepsies and epilepsy syndromes

An epileptic syndrome is defined as 'an epileptic disorder characterized by a cluster of signs and symptoms customarily occurring together', and the ILAE classification scheme attempts to categorize epilepsy according to syndrome (Table 6.5). Some

Table 6.5 The International League Against Epilepsy (ILAE) classification of the epilepsies and epilepsy syndromes (1989).

1. Generalized

Idiopathic generalized epilepsies with age-related onset (in order of age)
- Benign neonatal familial convulsions
- Benign neonatal convulsions
- Benign myoclonic epilepsy in infancy
- Childhood absence epilepsy
- Juvenile absence epilepsy
- Juvenile myoclonic epilepsy
- Epilepsy with generalized tonic–clonic seizures on awakening
- Other generalized idiopathic epilepsys not defined above
- Epilepsies with seizures precipitated by specific modes of activation

Cryptogenic or symptomatic generalized epilepsies (in order of age)
- West's syndrome
- Lennox–Gastaut syndrome
- Epilepsy with myoclonic astatic seizures
- Epilepsy with myoclonic absences

Symptomatic generalized epilepsies
- Non-specific aetiology
  - Early myoclonic encephalopathies
  - Early infantile encephalopathy with burst suppression
  - Other symptomatic epilepsies not defined above
- Specific syndromes
- Epilepsies in other disease states

2. Localization-related epilepsies

Idiopathic with age-related onset
- Benign epilepsy with centrotemporal spikes
- Childhood epilepsy with occipital paroxysms
- Primary reading epilepsy

Symptomatic
- Epilepsia partialis continua
- Syndromes characterized by specific modes of precipitation
- Temporal lobe epilepsies
- Frontal lobe epilepsies
- Parietal lobe epilepsies
- Occipital lobe epilepsies

Idiopathic

3. Epilepsies and syndromes undetermined as to whether focal or generalized

With both generalized and focal seizures
- Neonatal seizures
- Severe myoclonic epilepsy in infancy
- Electrical status epilepticus in slow-wave sleep
- Acquired epileptic aphasia

Other undetermined epilepsies (not defined above) with unequivocal generalized or focal features

4. Special syndromes

Febrile convulsions

Isolated seizures or isolated status epilepticus

Seizures occurring only when there is an acute metabolic or toxic event due to factors such as alcohol, drugs, eclampsia, non-ketotic hyperglycinaemia

syndromes have single aetiologies and specific features, but others have multiple causes and heterogenous clinical features. The syndromes are often age specific, and over time in individual patients one epileptic syndrome can evolve into another (e.g. West's syndrome commonly evolves into Lennox–Gastaut syndrome). The same seizure type can occur in very different syndromes (e.g. myoclonic seizures in the benign syndrome of juvenile myoclonic epilepsy and the refractory syndromes of the progressive myoclonic epilepsies). The classification scheme allows a more comprehensive approach to categorization than simply classifying by seizure type, but is not widely used in routine clinical practice.

The following are the most common syndromes.

Idiopathic generalized epilepsy

This term should be used to denote a common and important category of epilepsy that has a characteristic clinical and electrographic pattern and a presumed genetic basis. Idiopathic generalized epilepsy (IGE) accounts for about 10–20% of all patients with epilepsy. There is probably usually a polygenic basis, but no common susceptibility genes have yet been found.

The condition is sometimes subdivided into separate syndromes, although this is contentious and there is a great deal of overlap. The core clinical features shared to a greater or lesser extent by these syndromes (at least those with onset in later childhood or early adult life) and the common subdivisions are shown in Table 6.6. The most important subdivisions are:

Childhood absence epilepsy

This condition, more common in girls, appears in childhood (peak age 6–7 years), and is not associated with learning disability or other neurological problems. It accounts for 1–3% of newly diagnosed epilepsies and up to 10% of childhood epilepsies. The seizures take the form of generalized absence attacks. These comprise an abrupt sudden loss of consciousness and the cessation of all motor activity. Tone is preserved, and there is no fall. The patient is not in contact with the environment, and appears glazed or vacant. The attack ends as abruptly as it started, and previous activity is resumed as if nothing had happened. There is no confusion and the patient is often unaware that an attack has occurred. Sometimes there is blinking, slight clonic movements, partial loss of tone and/or brief automatisms. The attacks can cluster and can be very frequent (sometimes hundreds of times a day) and are precipitated by fatigue, drowsiness, relaxation, photic stimulation or hyperventilation. The classic EEG pattern is a regular 3-Hz spike-wave. About one-third of patients also develop generalized tonic–clonic seizures. The prognosis is good, and rapid remission on therapy is expected in 80% or more of patients. When followed up after age 18 years, only approximately 20% of previously diagnosed patients are still having seizures.

Table 6.6 Subdivisions of idiopathic generalized epilepsy.

Epilepsy with myoclonic absences
Childhood absence epilepsy
Juvenile absence epilepsy
Juvenile myoclonic epilepsy
Epilepsy with grand mal seizures on awakening
Absence epilepsy with peri-oral myoclonus

Juvenile myoclonic epilepsy

This is the most common subtype of IGE, and accounts for up to 10% of all epilepsies. The characteristic seizures are brief myoclonic jerks, occurring in the first hour or so after awakening, and usually in bursts. These are sudden, shock-like jerks, affecting mainly the shoulders and arms, usually but not always symmetrically. It is often not clear whether consciousness was retained or lost. In 80% of cases, the myoclonus develops between the ages of 12 and 18 years. In about 80% of cases, generalized tonic–clonic seizures also occur, usually months or years after the onset of myoclonus, and it is these that often trigger the diagnosis. About one-third of patients also develop typical absence seizures, again usually on awakening. About 5% of patients exhibit strong photosensitivity. The myoclonic seizures (and other seizures) can be precipitated by photic stimuli, lack of sleep, alcohol, hypoglycaemia and poor compliance with medication. Complete response to treatment can be expected in 80–90% of cases, but lifelong therapy may be needed.

Epilepsy with grand mal seizures on awakening

This condition overlaps considerably with other generalized epilepsies especially with juvenile myoclonic epilepsy in which most affected people also have generalized tonic–clonic seizures (GTCS) on awakening. The EEG usually has a normal background with bursts of generalized spike-waves or polyspike-waves. Whether this syndrome represents a discrete entity or simply part of the spectrum of other forms of IGE has been the subject of discussion for several decades, without clear resolution.

Benign partial epilepsy syndromes

There are a number of benign partial epilepsy syndromes. As with the IGEs, there is overlap between syndromes and the subdivision is a matter of some contention.

Benign partial epilepsy with centrotemporal spikes

This condition (BECTS; *syn*: rolandic epilepsy, benign epilepsy with rolandic spikes) is the most common 'idiopathic' partial epilepsy syndrome, accounting for perhaps 15% of all epilepsies. The peak age of onset is 5–8 years and over 80% of cases have onset at 4–10 years. The condition reflects an age-related genetically determined neuronal hyperexcitability in the rolandic area. The characteristic EEG feature is the high-amplitude rolandic spike, and 10% of children with the EEG disturbance do not actually have seizures. The seizures are infrequent, and 50% of children experience a total of less than five attacks in all. Fifty per cent of seizures occur only at night, and the daytime seizures usually occur when the child is tired or bored. The complex

partial seizures take a characteristic form, usually beginning with spasm and clonic jerking of one side of the face and throat muscles, then speech arrest and guttural vocalizations. The seizures may evolve to secondarily generalized tonic–clonic attacks. There are no associated neurological disturbances and intellect is normal. The epilepsy ceases in almost all cases, usually by the age of 12 years, without long-term sequalae. There is an excellent response to therapy with carbamazepine or other antiepileptic drugs. The condition is usually quite benign although some children have associated learning difficulties and the characteristics of more severe cases merge into other more severe childhood epileptic syndromes.

Early onset benign occipital epilepsy (*syn*: Panayiotopoulos syndrome)

This syndrome occurs between 1 and 14 years (mean 4–5 years). The partial seizures take the form of eye deviation, nausea and vomiting, with subsequent evolution into clonic hemiconvulsions. Typically, the seizures are prolonged, often lasting hours and are infrequent (mean number three). The interictal EEG shows occipital spikes, with a morphology similar to that in BECTS, often continuous and abolished by eye opening (the fixation-off phenomenon). However, it is misleading to consider these as 'occipital lobe' seizures and the spikes may reflect spread. Some seizures consist only of vomiting, of syncopal symptoms or prominent autonomic symptoms. The prognosis is uniformly excellent, and the epilepsy always remits over time without adverse sequaelae. This syndrome is often misdiagnosed as migraine.

West syndrome

West syndrome has an incidence of 0.25–0.42/1000 live births. It is defined by the occurrence of infantile spasms and the EEG changes of hypsarrhythmia. The infantile spasms take the form of sudden, generally bilateral and symmetrical contractions of the muscles of the neck, trunk or limbs, tend to cluster and may occur hundreds of times a day. In the most common type, the flexor muscles are predominantly affected, and the attack takes the form of sudden flexion with arms and legs held in adduction (the so-called salaam attacks). The peak age of onset is 4–6 months and 90% develop in the first year of life. Most cases have an underlying cerebral developmental pathology. The most common cause is tuberous sclerosis (7–25% of all cases); neonatal ischaemia and infections (about 15% of all cases); lissencephaly and pachygyria and hemimegalencephaly (about 10% of cases); Down syndrome and acquired brain insults. The prognosis is poor, with most cases developing severe epilepsy, intellectual and psychomotor deterioration. About 5% of children die in the acute phase of spasms.

Lennox–Gastaut syndrome

This term is used to denote an age-specific epileptic encephalopathy with a characteristic clinical seizure and EEG pattern and learning disability. However, whether it is a specific syndrome or whether the symptoms and EEG changes simply reflect severe childhood epilepsy with learning disability is a source of contention. There are many potential underlying causes and there is no specific histopathological change nor specific treatment. About 1–5% of childhood epilepsies conform to this pattern. The age of onset is between 1 and 7 years and it can develop in patients who earlier had West syndrome, myoclonic astatic epilepsy or neonatal seizures. In one-third of cases no cause is identifiable (cryptogenic Lennox–Gastaut syndrome). About one-third of cases are caused by malformations of brain development. The epilepsy is very severe, with seizures usually occurring many times a day. These take the form of atypical absence, tonic, myoclonic, tonic and tonic–clonic seizures, and later complex partial and other seizure types develop. The most characteristic are tonic attacks, which occur most often in non-REM (but not REM) sleep and in wakefulness. Non-convulsive status (atypical absence status) may last hours or days and be repeated on an almost daily basis. The EEG shows a characteristic pattern with the presence interictally of long bursts of diffuse slow (1–2.5 Hz) spike-wave activity, widespread in both hemispheres, roughly bilaterally synchronous but often asymmetrical. The background activity is abnormal with an excess of slow activity and diminished arousal or sleep potentials. Learning disability is the other major feature of the condition. At least 50% of cases have an intelligence quotient (IQ) below 50. The prognosis for control of seizures and for the development of intellectual impairment is poor, and many patients require institutional care in childhood and in adult life, and are dependent for daily activities. Response to treatment is often poor, and the seizure disorder can be exacerbated by over treatment or therapy with sedating drugs. Carbamazepine and benzodiazepines may exacerbate tonic or atonic seizures.

Febrile seizures

Febrile seizures are seizures that occur in the context of an acute rise in body temperature in children between 3 months and 5 years of age, in whom there is no evidence of intracranial infection or other defined cause. About 3–5% of children will have at least one attack, and 19–41/1000 infants with fever will convulse. The first febrile seizure happens in the second year of life in 50%. In over 85%, the seizures are generalized and are usually brief. The seizure usually occurs early in the febrile illness, and in about one-quarter of cases is the first recognizable sign of the illness. These essentially benign seizures need to be differentiated from the 5–10% of first seizures with fever in which the seizure is in fact caused by viral or bacterial meningitis, and from other cases where the fever lights up an existing latent predisposition to epilepsy. About 35% of susceptible children will have a second febrile seizure and 15% three or more. Recurrence is more common if the initial convulsion was at a young age, in those in whom the convulsion occurred at a relatively low temperature and in those with prolonged initial convulsions. In about 10–20% of children, subsequent neurodevelopment problems are noted, but these usually reflect pre-existing problems and are not brought about by the convulsions. About 2–10% of children with febrile seizures will later develop epilepsy. The risk is higher in

those with pre-existing neurodevelopmental dysfunction. It has been proposed that febrile convulsions can sometimes cause hippocampal sclerosis, and by this mechanism subsequent temporal lobe epilepsy, particularly if the febrile convulsion was prolonged or severe; how frequently this occurs is unknown.

Causes of epilepsy

Epilepsy is often a multifactorial condition, and even if there is a predominant cause, genetic and environmental factors often play a part in its clinical manifestations. The range of causes differs in different age groups, patient groups and geographical locations. Broadly speaking, genetic, congenital and perinatal conditions are the most common causes of early childhood onset epilepsy, whereas in adult life, epilepsy is more likely to be result from external non-genetic causes, but this distinction is by no means absolute. In late adult life vascular disease is increasingly common. In certain parts of the world, endemic infections such as malaria or cysticercosis are common causes. The approximate frequencies of different aetiologies in a typical Western population are shown in Table 6.7.

Idiopathic epilepsy (epilepsy resulting from genetic or developmental causes)

The 'idiopathic' epilepsies are likely to have a strong genetic basis, usually polygenic or oligogenic in nature, and their expression is often age dependent. Single gene disorders probably underlie only 1–2% of all epilepsies, and usually in these conditions there are additional neurological or systemic features.

Pure epilepsies resulting from single gene disorder

There is a small number of rare conditions in which epilepsy is the main or only manifestation that is Mendelian in its inheritance pattern. These include benign familial neonatal convulsions which start in the first 10 days of life and which usually remit spontaneously, although 10% of patients develop subsequent epilepsy. This is an autosomal dominant condition resulting from mutations of voltage-gated potassium channel genes *KCNQ2* and *KCNQ3*.

Autosomal dominant nocturnal frontal lobe epilepsy (ADNFLE) is another condition brought about by mutations in the α_4 and β_2 subunits of the nicotinic acetylcholine receptor. In this condition, purely nocturnal frontal lobe complex partial seizures occur, sometimes each night. The seizures are brief, lasting less than 1 minute, and are clustered around the onset and end of sleep. The seizures can be misdiagnosed as parasomnias or even pseudoseizures (in spite of the fact that pseudoseizures never arise from sleep), and are not uncommonly resistant to therapy.

Generalized epilepsy with febrile seizures (GEFS+) is a more heterogeneous form of epilepsy, inherited in an autosomal dominant fashion, with age-specific manifestations and variable penetrance. Febrile seizures are the most constant feature, in which seizures are precipitated by fever and tend to occur throughout childhood, but other afebrile seizures also occur. The phenotype is wide and it is arguable whether this condition really deserves to be called a syndrome. Various mutations underlying the epilepsy in these families have been identified in the α or β subunits of the voltage-gated sodium channel genes *SCN1A* and *SCN1B*, and γ_2 subunit of the $GABA_a$ receptor.

Dravet syndrome (severe myoclonic epilepsy of infancy [SMEI]) is a severe epilepsy, developing in early life and with a poor prognosis. Most cases have mutations in the *SCNIA* gene, the same gene that causes the more benign GEFS+, and indeed there are families in which both phenotypes coexist. Seizures occur between the ages of 2 and 9 months, and are often prolonged clonic or tonic–clonic seizures, and are precipitated by fever or even hot baths. Myoclonic seizures develop later and episodes of non-convulsive status epilepticus are common. The prognosis is poor with intractable epilepsy, early death, severe retardation or institutionalization in all cases.

Pure epilepsies with complex (presumed polygenic) inheritance

These are much more common than the single gene epilepsies. These are divided into idiopathic generalized epilepsies and benign partial epilepsies of childhood. Although presumed to be genetic, no common susceptibility genes have yet been identified. To what extent other cryptogenic epilepsies have a genetic basis is less clear (e.g. febrile convulsions, cryptogenic West's syndrome, cryptogenic Lennox–Gastaut syndrome). These conditions are probably best conceptualized as polygenic disorders in which the phenotype is the result of interactions between susceptibility genes and environmental effects. There is often no strong family history and genetic studies have to be conducted using case control methodology in large populations.

Epilepsies in other single gene disorders

At least 240 single gene and chromosomal disorders result in neurological disorders in which epilepsy is part of the phenotype. Most are rare or very rare, and manifest initially in childhood (Table 6.8).

Table 6.7 Causes of epilepsy and approximate frequency.

Cause	Frequency (%)*
Idiopathic (?oligogenic)	10–30
Vascular	10–20
Congenital	5–10
Neurodegenerative/other neurological conditions	5–10
Hippocampal sclerosis	5–10
Neoplasm	5–10
Trauma	5
Childhood epilepsy syndrome	5
Infection/metabolic/toxic	3–5
Genetic (single gene disorder)	1–2
Unknown/cryptogenic	25–30

*Approximate prevalent frequency in Western population.

Table 6.8 Some single-gene disorders causing epilepsy.

Agenesis of the corpus callosum
Acute intermittent porphyria
Angelman's disease
Arginino-succinicaciduria
Carnitine palmitoyltransferase 11 deficiency
Chorea-acanthocytosis (neuro-acanthocytosis)
DRPLA
Familial cavernoma
Glucocerebrosidase deficiency (Gaucher disease)
Hexosaminindase A deficiency
Huntington's disease
Isovaleric acidaemia
Lafora body disease
Maple syrup urine disease
Menkes disease
Methylmalonic aciduria
Mitochondrial diseases (MERFF, MELAS, Leigh syndrome)
Mucopolysaccharidoses
Neuronal ceroid lipofuscinoses
Niemann–Pick disease
Ornithine trans-carbamylase deficiency
Peri-ventricular heterotopia
Peroxisomal enzyme deficiencies
Phenylalanine hydroxylase deficiency (phenylketonuria)
Pyridoxine deficiency
Pyruvate dehydrogenase deficiency
Rett's syndrome
Sialidoses
Tuberous sclerosis
Unverricht–Lundborg disease
Urea cycle disorders
Wolf–Hirshhorn syndrome
Zellweger's syndrome

List excludes the single gene disorders causing 'pure epilepsy' – see text.
DRPLA, dentato-rubro-pallido-luysian atrophy; MERFF, myoclonic epilepsy with ragged red fibres; MELAS, Mitochondrial myopathy, encephalopathy, lactic acidosis, and stroke.

Table 6.9 Causes of progressive myoclonic epilepsy (PME).

Most common causes
Baltic myoclonus (Unverricht–Lundborg disease)
Ceroid lipofuscinoses
DRPLA
Lafora body disease
Mitochondrial disease (MERRF)
Sialidoses
Rarer causes
Alper's disease
Alzheimer's disease
Biotin-responsive progressive myoclonus
Coeliac disease
Gaucher's disease
GM2 gangliosidosis (juvenile type)
Hexosaminidase deficiency
Huntington's disease
Juvenile neuroaxonal dystrophy
Menkes disease
Non-ketotic hyperglycinaemia
Phenylketonuria
Tetrahydrobiopterin deficiencies

In a significant proportion of patients, no cause can be identified.
DRPLA, dentato-rubro-pallido-luysian atrophy; MERFF, myoclonic epilepsy with ragged red fibres.

Progressive myoclonic epilepsy

This form of epilepsy can be caused by various genetically determined neurological disorders (Table 6.9). In most parts of the world, the four most common are: mitochondrial diseases, Unverricht–Lundborg disease, dentato-rubro-pallido-luysian atrophy (DRPLA) and Lafora body disease.

Unverricht–Lundborg disease (Baltic myoclonus) is the most benign form. It is an autosomal recessive disorder resulting from dodecamer repeats in the *EPM1* gene coding for the cystatin B protein, a protease inhibitor. The condition is particularly common in Finland (where the incidence is in excess of 1/20,000 persons) and other Scandinavian countries as a result of founder effects. Myoclonus develops, usually between the ages of 6–15 years, and the condition slowly progresses. Ataxia and tremor later become major clinical features. There is a very slow intellectual decline.

DRPLA is inherited in an autosomal dominant fashion. It is particularly common in Japan (a frequency of 0.2–0.7/100,000 persons) and northern Europe. It is a triplet repeat disorder involving the *DRPLA* gene which is of uncertain function. The condition presents in childhood or adult life and is slowly progressive. Ataxia, choreoathetosis, dementia and behavioural changes, myoclonus and epilepsy occur.

Lafora body disease is an autosomal recessive condition, most common in southern Europe, and characterized by Lafora bodies, periodic acid–Schiff (PAS) positive intracellular polyglucosan inclusions found in neurones, sweat glands and elsewhere. The age of onset is 6–19 years and patients develop progressive myoclonic, tonic–clonic and partial seizures. There is also a progressive and severe dementia, and ataxia and dysarthria also occur. Death occurs within 2–10 years. Up to 80% of patients have a mutation in the *EPM2A* gene, which codes for Laforin, a tyrosine phosphatase protein. A second gene, *EPM2B* has been identified, which codes for Malin, a ubiquitin ligase protein.

Mitochondrial cytopathy (myoclonic epilepsy with ragged red fibres [MERRF]) is one of the phenotypes of mitochondrial cytopathy. In 90% of cases, the genetic defect is an A–G transition at nucleotide-8344 in the $tRNA^{lys}$ gene of mtDNA, and some other cases are caused by *T8356C* or *G8363A* mutations. This is a multi-system disorder with a very variable phenotype in which myoclonic seizures are often the first symptom, followed by generalized epilepsy, myopathy, ataxia and dementia.

Heteroplasmy is responsible for some of the phenotypic variation (Table 6.9).

Epilepsies in neurocutaneous syndromes

The neurocutaneous conditions often result in epilepsy. Tuberous sclerosis complex, Sturge–Weber syndrome and neurofibromatosis (type 1) are the most important. Other rare conditions causing epilepsy include hypomelanosis of Ito, epidermal naevus syndrome (Jadassohn's syndrome), hereditary haemorrhagic telangiectasia, midline linear naevus syndrome, incontinentia pigmenti and Klippel–Trenaunay–Weber syndrome.

Tuberous sclerosis

This is a not uncommon condition (1/5800 live births in some studies) and there is a high spontaneous mutation rate (1/25,000). It is inherited in an autosomal dominant fashion. To date, about 300 unique *TSC1* or *TSC2* mutations have been identified. The clinical features of the condition are variable. Epilepsy is the presenting symptom in 80% or more of patients. It can take the form of neonatal seizures, West's syndrome, Lennox–Gastaut syndrome or as adult onset partial or generalized seizures. About two-thirds of patients present with seizures before the age of 2 years, with motor seizures, drop attacks or infantile spasms. About 25% of all cases of West's syndrome are caused by tuberous sclerosis. The skin is abnormal in almost all patients, and skin lesions include: hypomelanotic macules (87–100% of patients), facial angiofibromas (47–90%), shagreen patches (20–80%), fibrous facial plaques and subungual fibromas (17–87%). CNS tumours are the leading cause of morbidity and mortality. The brain lesions can be distinguished on the basis of magnetic resonance imaging (MRI) studies and comprise: subependymal glial nodules (90% of cases), cortical tubers (70% of cases) and subependymal giant cell astrocytomas (6–14% of cases). Fifty per cent of patients have developmental delay or mental retardation. An estimated 80% of children with tuberous sclerosis have identifiable renal tumours by the age of 10 years. Cardiac and retinal lesions also occur.

Sturge–Weber syndrome

This is an uncommon sporadic developmental disorder, of uncertain causation. The cardinal features are a unilateral or bilateral port wine naevus, epilepsy, hemiparesis, mental impairment and ocular signs. The port wine naevus is usually but not exclusively in the distribution of the trigeminal nerve. It can cross the midline and spread into the dermatomal distribution of the upper cervical nerve. In one-third of cases the naevus is bilateral. The epilepsy can be focal or generalized. It is often the earliest symptom, and most patients with Sturge–Weber develop seizures within the first year of life (at least 70%) and almost all have developed epilepsy before the age of 4 years. Adult onset epilepsy can occur occasionally. The early seizures are often triggered by fever. The seizures take the form of partial or multi-focal attacks often with frequent and severe secondary generalization. Convulsive status occurs in over half of cases. Seizures developing in the neonatal period can be very difficult to control and carry a poor prognosis. The hemiplegia and mental impairment deteriorate in a stepwise fashion following a severe bout of seizures, and this is one of the few situations where clear-cut cerebral damage results directly from epileptic attacks, presumably by ischaemic or excitotoxic mechanisms. Severe learning disability is now less common because of better control of the epilepsy. Status epilepticus particularly often results in a permanent and significant worsening of the neurological deficit. The epilepsy should be aggressively treated to prevent neurological deterioration. Resective surgery (either lesionectomy, hemispherectomy or lobectomy) should be given early consideration.

Cortical dysplasia

Cortical dysplasia (*syn*: cortical dysgenesis, malformations of cortical development) is a term that is applied to developmental disorders of the cortex producing structural change. In most cases the cause is unknown, but a minority are caused by identifiable genetic abnormalities and others by environmental influences such as infection, trauma, hypoxia, exposure to drugs or toxins. The clinical features vary, but epilepsy and learning disability are the most common manifestations. Cortical dysplasia is the underlying cause of the epilepsy in up to 30% of children and 10% of adults referred to epilepsy centres for intractable epilepsy.

Hemimegalencephaly

In this condition, one cerebral hemisphere is enlarged and is structurally abnormal with thickened cortex, reduced sulcation and poor or absent laminar organization. Giant neurones are found throughout the brain and in 50% of cases balloon cells too. The condition can occur in isolation, associated with other cortical dysplasias or as part of other syndromes (notably tuberous sclerosis or other rarer neurocutaneous syndromes). Hemimegalencephaly results in severe epilepsy with learning disability, hemiplegia and hemianopia. Surgical therapy (hemispherectomy or hemispherotomy) can be curative.

Focal cortical dysplasia

There are a variety of subtypes, with different histological appearances caused possibly by formation at different stages of embryogenesis. In some the cortical lamination is normal, but in others there may be associated widespread macrogyria and polymicrogyria. Epilepsy is the leading symptom, and other features depend on the extent of the lesion and include learning disability and focal deficits.

Schizencephaly

This term denotes the presence of clefts in the cortex, stretching from the surface to the ventricle. Schizencephaly can be unilateral or bilateral and is often peri-sylvian in location. The causes are heterogeneous, and include germline mutations of the homeobox gene *EMX2* and environmental insults during development including radiation, infection and ischaemia. Epilepsy is the most common symptom (over 90% of cases), associated usually but by no means always with learning disability or cognitive changes.

Focal neurological deficit is common in extensive or bilateral cases.

Agyria pachygyria band spectrum (lissencephaly, pachygyria, agyria and subcortical band heterotopia)

These abnormalities of cortical gyration are grouped together as they show an interconnected genetic basis. In all the gyration is simplified and the cortex is thickened. Lissencephaly (literally, smooth brain) is the most severe form, in which gyration is grossly diminished or even absent. Subcortical band heterotopia (*syn*: double cortex syndrome) denotes the presence of a band of grey matter sandwiched by white matter below the cortical grey matter. The band may be thin or thick, and can merge with overlying cortex in which case the cortex takes a macrogryic form. It is caused in about 80% of cases by germline deletions in the DCX (*XLIS*) gene and occurs almost always (but not exclusively) in females. The pachygyria and bands are anteriorly predominant. The genetic anomaly in the other 20% of cases has not been identified.

Macrogyria refers to thickened cortex, and can occur as an isolated phenomenon, is variable in extent and when focal is indistinguishable on clinical or imaging grounds from some forms of focal cortical dysplasia. Isolated lissencephaly is present in 12 per million live births and results in profound retardation, epilepsy and spastic quadrapareisis. In less severe cases, where the lissencephaly is restricted to one region of the brain (albeit usually bilaterally, with an anterior or posterior gradient), the epilepsy and learning disability may be mild. Of cases of isolated lissencephaly, 60–80% are caused by identifiable mutations in the *LIS1* or *XLIS* (also known as the DCX) genes, on 17p13.3 and Xq22.3-q24, respectively, and in 40% the entire gene is deleted. Other forms of lissencephaly have more widespread associations. The best known is the Miller–Dieker syndrome, caused by large deletions of *LIS1* and of several other contiguous genes on 17p13.3, in which the lissencephaly is associated with epilepsy, facial dysmorphism, microcephaly, small mandible, failure to thrive, retarded motor development, dysphagia, decorticate and decerebrate postures. All these conditions usually present in children with epilepsy and learning disability. The clinical severity of the syndrome seems to correlate with the extent of the cerebral anomaly.

Agenesis of the corpus callosum

This anomaly occurs in various genetic and congenital disorders. Epilepsy is invariable and is the leading symptom. In Aicardi's syndrome, the corpus callosum agenesis is associated with periventricular heterotopia, thin unlayered cortex and diffuse polymicrogyria.

Polymicrogyria

The appearance of small and prominent gyri, separated by shallow sulci, is known as polymicrogyria. It can have a genetic or environmental cause. Epilepsy is the leading clinical feature, associated with learning disability and focal neurological signs and the manifestations vary greatly in severity. Bilateral peri-sylvian polymicrogyria (Kuzniecky syndrome) is a condition in which there is severe upper motor neurone bulbar dysfunction and diplegia as well as severe epilepsy and mental retardation.

Peri-ventricular nodular heterotopia (syn: bilateral peri-ventricular nodular heterotopia, subependymal nodular heterotopia)

In this condition, subependymal nodules of grey matter are present, usually bilateral and located along the supralateral walls of the lateral ventricles. It is much more common in females, inherited in an X-linked dominant fashion and almost all cases have shown mutations in the *FLN1* (filamin-1) gene. The clinical presentation can vary from mild epilepsy presenting in older children or young adults to severe infantile or childhood partial epilepsy.

Symptomatic epilepsy (epilepsy resulting from acquired causes)

Almost any condition affecting the cerebral grey matter can result in epilepsy. The epilepsy usually takes a partial or secondarily generalized form and, in most causative conditions, the epilepsy does not have any particularly distinctive features. After an acute cerebral event, the epilepsy is often divided into 'early' (i.e. seizures occurring within a week of the insult) and 'late' (i.e. chronic epilepsy developing later). There is often a 'silent period' between the injury and the onset of late epilepsy, and the nature of the epileptogenic process occurring during this period is largely unknown. The occurrence of a silent period raises the possibility that neuroprotective interventions to inhibit these processes could prevent later epilepsy, but to date no effective neuroprotectant agent is available. Antiepileptic drug therapy will prevent early epilepsy but does not reduce the frequency of late seizures. Early seizures are often not followed by late epilepsy – a fact important to emphasize to patients.

Hippocampal sclerosis

Hippocampal sclerosis is the most common cause of mesial temporal lobe epilepsy which is itself the most common form of partial epilepsy. It is found in over one-third of patients with refractory focal epilepsy attending hospital clinics in whom there is no other structural lesion, but is less frequent in those with mild epilepsy. Hippocampal sclerosis typically causes complex partial seizures of mesial temporal origin. There is a clear association with a history of childhood febrile convulsions, and it has been proposed that the febrile convulsions, especially if prolonged or complex, results in hippocampal sclerosis which itself results in subsequent temporal lobe epilepsy. Serial MRI studies have demonstrated that status epilepticus also can result in hippocampal sclerosis and there is clear evidence from animal experimentation that prolonged partial seizures can cause hippocampal damage and in some cases progression of the hippocampal atrophy and worsening seizures. In other cases, hippocampal sclerosis may be a congenital lesion, and hippocampal sclerosis can also occur after severe brain trauma or vascular damage.

Cerebral palsy, perinatal and prenatal injury

Cerebral palsy is a non-specific term that covers many prenatal and perinatal pathologies. It is strongly associated with epilepsy. In the US National Collaborative Perinatal Project, a prospective cohort study of infants followed to the age of 7 years, epilepsy was found to occur in 34% of children with cerebral palsy, and cerebral palsy was present in 19% of children developing epilepsy. In the same cohort, the risk of learning disability (associated with cerebral palsy) was 5.5 times higher among children developing epilepsy following a febrile seizure than in children with a febrile seizure alone. Learning disability (IQ <70) is present in 27% of children with epilepsy, and seizures are present in about 50% of children with mental retardation and cerebral palsy. In controlled studies, only severe perinatal insults have been found to increase the risk of subsequent epilepsy, e.g. perinatal haemorrhage, ischaemic hypoxic encephalopathy. Factors such as pre-eclampsia, eclampsia, forceps delivery, being born with the 'cord round the neck', low birth weight or prematurity have only a very modest association, if any, with subsequent epilepsy.

Post-vaccination encephalopathy

The possible role of vaccination (particularly pertussis vaccination) in causing a childhood encephalopathy and subsequent epilepsy and learning diability has been the subject of intense study, with contradictory claims. The UK National Childhood Encephalopathy Study found that children hospitalized with seizures and encephalopathy were more likely to have received DTP (diptheria, tetanus, pertussis) vaccination in the previous 7 days than control children. However, the potential methodological bias of this study has been severely criticized. A more recent large series of 368,000 children after immunization, found no difference in rates of epilepsy when compared with controls. Similarly, suggestions that MMR (mumps, measles, rubella) vaccine increases the risks of autism and epilepsy are now thought to be unfounded. A recent study has shown that many cases of so-called post-vaccination encephalopathy have in fact the causal mutation of SMEI and so the vaccination was in all likelihood a non-causal factor in the development of the encephalopathy. Conventional medical advice is now that vaccination is safe, and although a small number of children do develop encephalopathic reactions that result in later epilepsy, this number is considerably less than the risk of encephalopathy after the naturally occurring viral illnesses that vaccination prevents. The vaccines that have been thought to be associated with post-vaccination encephalomyelitis are smallpox, measles, DTP, Japanese B encephalitis and rabies.

Cerebral tumour

About 6% of all newly diagnosed cases of epilepsy are caused by cerebral tumours. The incidence of tumour is higher in adults than in children. Seizures occur in about 50% of all brain tumours. Tumours of the frontal and temporal regions are more likely to cause epilepsy than other cortical tumours and epilepsy is rare in subcortical or cerebellar tumours.

Gliomas are most common brain tumour causing epilepsy, and low grade gliomas are more epileptogenic than high-grade tumours. Overall, slow-growing or benign tumours account for about 10% of all adult epilepsies. There can be a history of epilepsy for many years. In chronic refractory tumoural epilepsy, oligodendrogliomas account for 10–30%, dysembryoplastic neuroepithelial tumours (DNETs) for 10–30%, astrocytomas for 10–30%, gangliogliomas for about 10–20% and hamartomas for 10–20%. The epilepsy derives from the surrounding tissue (and this can have implications for surgical therapy). Epileptogenesis can be caused by impaired vascularization of the surrounding cortex, changes in the excitatory and inhibitory synapisis or other morphological changes.

Ganglioglioma are mixed developmental tumours that are composed of neoplastic glial and neuronal cell types and comprise 10% of more of the neoplasms removed at temporal lobectomy. Seizures are the primary presenting symptom in 80–90%. The dysembryoplastic neuroepithelial tumour (DNET or DNT) is a pathological entity only recently differentiated from other forms of 'benign gliomas' and account for 10–30% of resected tumours in the temporal lobe. They are benign tumours with only a slight propensity for growth, and epilepsy is usually the only clinical symptom. As these are developmental in origin, they have instrinsic epileptogenesis (in contrast to other cerebral tumours) and are important to identify as partial resection will often control the seizures. Hamartomas are benign tumours which account for 15–20% of tumours removed at temporal lobectomy. These are more common in children.

The hypothalamic hamartoma is a particular form of hamartoma. These are benign tumours, usually confined to the tuber cinereum. They characteristically present with gelastic seizures, learning disability, behavioural disturbance and later with precocious puberty. The lesions are subtle and can be very easily missed on even high-quality MRI scanning. Gelastic seizures are characteristic of hypothalamic hamartoma but do occur in other midline lesions and also occasionally in temporal lobe epilepsy. The attacks take the form of sudden laughter associated with other variable motor features (clonic movements, head and eye deviation). The laughter is 'mirthless', is not associated with any emotional feelings of joy or happiness and occurs in situations that do not provoke humour.

Meningiomas are also common causes of adult epilepsy, and epilepsy is the presenting symptom of the tumour in 20–50% of cases. Meningiomas were more likely to cause epilepsy when located over the convexity, parasagittal/falx and sphenoid ridge meningiomas, and with evidence of peri-tumoural oedema. There is no relationship between the presence of epilepsy and histological type.

Cerebrovascular disease

Stroke is the most commonly identified cause of epilepsy presenting over the age of 50 years, and occult stroke also explains the occurrence of other apparently cryptogenic late onset epilepsy. A history of stroke has been found to be associated with

an increased lifetime occurrence of epilepsy (OR 3.3; 95% CI 1.3–8.5).

About 5–10% of patients with cerebral haemorrhage develop epilepsy. The incidence of early epilepsy (seizures in the first week) is higher, up to 30% in some series and about one-third of those with early seizures continue to have a liability to epilepsy. Epilepsy is more common after large haemorrhages and haemorrhages that involve the cerebral cortex and almost always develops within 2 years of the haemorrhage. After cerebral infarction, epilepsy occurs in about 6% of patients within 12 months and 11% within 5 years of the stroke. Epilepsy is more common in cerebral infarcts located in the anterior hemisphere, and involving cortex. Epilepsy can also complicate occult cerebrovascular disease. Late onset epilepsy can be the first manifestation of cerebrovascular disease, and in the absence of other causes, newly developing seizures after the age of 40 years should prompt a screen for vascular risk factors.

Arteriovenous malformation

An arteriovenous malformation (AVM) is a congenital malformation comprising a network of arterial and venous channels communicating directly with each other. Between 17% and 36% of supratentorial AVMs present with seizures, with or without associated neurological deficits, and 40–50% with haemorrhage. Smaller AVMs (<3 cm diameter) are more likely to present with haemorrhage than large ones. Conversely, large and/or superficial malformations are more epileptogenic, as are AVMs in the temporal lobe. About 40% of patients with large AVMs have epilepsy, and epilepsy is the presenting symptom in about 20%. The annual risk of bleeding of an AVM is in the region of 2–4% per year, irrespective of whether the malformation presented with haemorrhage, and the average mortality about 1% per year. Venous malformations are congenital anomalies of normal venous drainage and these have a very low risk of haemorrhage or epilepsy.

Cavernous haemangioma (cavernoma)

Cavernous haemangiomas account for 5–13% of vascular malformations of the CNS. At least 15–20% of patients remain symptom-free throughout their lives. Patients present with seizures (40–70%), focal neurological deficits (35–50%), nonspecific headaches (10–30%) and cerebral hemorrhage. The seizures are typically partial in nature and often brief, infrequent and minor in form. Family histories can be found in about 10–30% of cavernous haemangiomas, and three different genes (or loci) have been identified.

Other vascular lesions

Cortical venous infarcts are particularly epileptogenic, at least in the acute phase, and may underlie a significant proportion of apparently spontaneous epileptic seizures complicating other medical conditions and pregnancy for instance. Seizures occur in several connective tissue disorders and in patients with cerebral vasculitis. The most commonly encountered is systemic lupus erythematosus. Seizures also occur with cerebrovascular lesions secondary to rheumatic heart disease, endocarditis, mitral valve prolapse, cardiac tumours and cardiac arrhythmia, or after carotid endarcterectomy. Epilepsy is also common in eclampsia, hypertensive encephalopathy and malignant hypertension and in the annoxic encephalopathy that follows cardiac arrest or cardiopulmonary surgery. Unruptured aneurysms can cause epilepsy especially if large and if embedded in the temporal lobe.

Dementia and degenerative disorders

Epilepsy is a common feature of degenerative neurological disease that involves the grey matter, but is seldom a leading symptom in pure leucodystrophy.

The most common neurodegenerative disorders are the dementias in late life. Six per cent of persons over the age of 65 years have dementia, and the rate increases exponentially as a function of age. Alzheimer's disease is the most common cause of dementia, and patients with Alzheimer's disease are six times more likely to develop epilepsy than age-matched controls. Partial and secondarily generalized seizures occur, and are usually relatively easily treated with conventional antiepileptic therapy. Myoclonus is another common finding in patients with Alzheimer's disease, occurring in about 10% of autopsy-verified cases and is a late manifestation. Five percent of patients with Huntington's disease have epilepsy, usually in the later stages. Epilepsy is more common in the juvenile type, and occasionally takes the form of a progressive myoclonic epilepsy. Epilepsy, and indeed status epilepticus, can be the presenting feature of Creutzfeldt–Jakob disease. Generalized tonic–clonic or partial seizures occur in 10% of established cases, and myoclonus in 80% and can be induced by startle or other stimuli.

Post-traumatic epilepsy

Head trauma is an important cause of epilepsy. It is customary to draw a distinction between open head injury, where the dura is breached, and closed head injury, where there is no dural breach. Post-traumatic seizures are traditionally subdivided into immediate, early and late categories. Immediate seizures are defined as those that occur within the first 24 hours after injury, early seizures are those that occur within the first week and late seizures occur after 1 week.

Closed head injuries are most common in civilian practice, usually from road traffic accidents, falls or recreational injuries, and in different series have accounted for 2–12% of all cases of epilepsy. Traumatic brain injury in the USA has been estimated to have an incidence of 825 cases per 100,000 per year, with about 100–200 per 100,000 per year admitted to hospital. Early seizures after closed head injury occur in about 2–6% of those admitted to hospital, with a higher frequency in children than in adults. If mild injury is included, early seizures indicate a more severe injury, but have not been found generally to be an independent predictive risk factor of late seizures. Approximately 5% of patients requiring hospitalization for closed head trauma will subsequently develop epilepsy (late post-traumatic seizures; although estimates have varied between 2% and 25%). Mild head

injury – defined as head injury without skull fracture and with less than 30 minutes of post-traumatic amnesia – is, in most studies, not associated with any markedly increased risk of epilepsy. Moderate head injury – defined as a head injury complicated by skull fracture or post-traumatic amnesia for more than 30 minutes – is followed by epilepsy in about 1–4% of cases. Severe head injury – defined as a head injury with post-traumatic amnesia of more than 24 hours, intracranial haematoma or cerebral contusion – is followed by epilepsy, in most studies, in about 10–15% of patients. The excess risk of epilepsy is highest during the first year, with onset of epilepsy peaking 4–8 months post-injury, and diminishes during the ensuing years. Post-traumatic epilepsy is much more frequent after open head injury. This is particularly so in penetrating wartime injuries, with 30–50% of patients developing subsequent epilepsy. Overall, the risk of late epilepsy, if early epilepsy is present, is about 25% compared to 3% in patients who did not have early seizures. The risk of epilepsy after open head injury is greatest if the extent of cerebral damage was large and involved the frontal or temporal regions.

Calculations of the risk of epilepsy in various circumstances following injury have been made. The presence of a dural breach (e.g. with a depressed fracture), an intracranial haematoma and long post-traumatic amnesia (≥24 hours) have been found consistently to increase significantly the risk of subsequent epilepsy. In one series, the risk of seizures by 2 years was 27% in the presence of depressed skull fracture, 24% with subdural haematoma (and 44% if this was severe enough to need surgical evacuation), 23% with intracranial haematoma and 12% with long post-traumatic amnesia.

Antiepileptic drug therapy reduces the risk of early seizures. However, there has been controversy about the role of longer term prophylactic antiepileptic drug treatment after head trauma. Early retrospective reports suggested that such prophylactic treatment reduced the incidence of subsequent epilepsy, although none of the subsequent large-scale prospective trials showed any protective effect on late seizures. Nevertheless, it is now usual to prescribe antiepileptic drugs after severe head injury for a period of 6 months or so.

Epilepsy after neurosurgery

The risk of late postoperative seizures is greater in patients with younger age, early postoperative seizures and severe neurological deficit. The incidence of seizures varies according to the nature of the underlying disease process, its site and extent. A large retrospective study found an overall incidence of 17% for postoperative seizures in 877 consecutive patients undergoing supratentorial neurosurgery for non-traumatic conditions. The patients had no prior history of epilepsy and the minimum follow-up was 5 years. The incidence of seizures ranged from 4% in patients undergoing stereotactic procedures and ventricular drainage to 92% for patients being surgically treated for cerebral abscess. The risk of craniotomy for glioma was 19%, for intracranial haemorrhage 21% and for meningioma removal 22%. All these risks were greatly enhanced if seizures occurred pre-operatively. Among patients developing postoperative seizures, 37% did so within the first postoperative week, 77% within the first year and 92% within the first 2 years. If early seizures occurred (i.e. those occurring in the first week), 41% of patients developed late recurrent seizures.

Studies after unruptured aneurysm show an overall risk of about 14%. The risk of a middle cerebral aneurysm resulting in epilepsy is 19%, and anterior communicating aneurysms and posterior communicating aneurysms carry a risk of about 10%. If the aneurysm has bled, causing an intracranial haematoma, the incidence of epilepsy is much higher.

An overall risk of epilepsy following shunt procedures is about 10%, although this depends on the site of the shunt insertion.

It is not clear whether the prophylactic use of anticonvulsants after neurosurgical procedures is worthwhile. Currently, it is usual to prescribe prophylactic anticonvulsant drugs for several months after major supratentorial neurosurgery and then gradually to withdraw the medication unless seizures have occurred.

Bacterial or viral meningitis and encephalitis

CNS infections are a major risk factor for epilepsy. Seizures can be the presenting or the only symptom, or one component of a more diffuse cerebral disorder.

Encephalitis and meningitis result in a sevenfold increase in the rate of chronic epilepsy compared to that in the general population. The increased risk is highest during the first 5 years after infection, but remains elevated for up to 15 years. The risk is much higher after encephalitis (RR 16.2), especially herpes simplex virus 1 (HSV-1) infection, than bacterial meningitis (RR 4.2) or aseptic meningitis (RR 2.3). The incidence of severe HSV-1 encephalitis is about 1 per million persons per year, and seizures are a frequent symptom in the acute phase of severe HSV encephalitis. Most survivors are left with neurological sequelae including severe epilepsy. Epilepsy is also a leading symptom of tuberculoma. In patients presenting simply with epilepsy, it is now usual to treat with antitubercular and antiepileptic drugs (with a short course of adjunctive steroids), and to defer surgery. When medical therapy is initiated without diagnostic confirmation from a biopsy, the patient should be carefully monitored, and if the mass does not decrease in size after 8 weeks of therapy, biopsy should be reconsidered.

Pyogenic brain abscess is an uncommon but serious cause of infective epilepsy. The estimated annual incidence of brain abscess in the USA is 1/10,000 hospital admissions, and abscess surgery accounts for 0.7% of all neurosurgery operations. Brain abscess can develop in association with a contiguous suppurating process (usually otitis media, sinus disease or mastoiditis, 50%), from haematogenous spread from a distant focus (25%), as a complication of intracranial surgery (15%) and trauma (10%). Commonly isolated organisms are streptococci, including aerobic, anaerobic and microaerophilic types. *Streptococcus pneumoniae* is a rarer cause of brain abscesses, which are often the sequel to occult cerebrospinal fluid (CSF) rhinorrhoea and also to pneumococcal pneumonia in elderly patients. Enteric bacteria and *Bacteroides*

are isolated in 20–40% of cases and often in mixed culture. Anaerobic organisms have become increasingly important organisms and in many instances more than a single bacterial species is recovered. Gram-negative bacilli rarely occur alone. Staphylococcal abscesses account for 10–15% of cases and are usually caused by penetrating head injury or bacteraemia secondary to endocarditis. Clostridial infections are most often post-traumatic. Rarely, *Actinomyces* or *Nocardia* are the causative agents in a brain abscess.

Parasitic diseases

Neuro-cysticercosis is the most common parasitic disease of the CNS. Epilepsy is the most common clinical manifestation and usual presenting symptom and neuro-cysticercosis a major cause of epilepsy in endemic areas in parts of Latin America, Asia and West Africa. A solitary cerebral parenchymal lesion is a common form of presentation, but lesions are often multiple. Over time, the cysts shrink progressively and then calcify or disappear completely. Seizures develop when a cyst is degenerating or around a chronic calcified lesion. Where there is a single cyst it is usual to control seizures with antiepileptic drugs and not to use anticysticercal drugs. If anticysticercal drugs are to be used, steroids need to be given in co-medication to prevent sudden rise in intracranial pressure and exacerbation of symptoms.

In endemic regions, a common clinical scenario is the occurrence of a seizure with a single enhancing lesion on CT. The differential diagnosis includes neuro-cysticercosis, tuberculosis, gliomas and other tumours, toxoplasmosis and other infective lesions. Over 90% of the lesions in India are caused by neurocysticercosis, and currently the usual management strategy is to screen the patient for other signs of tuberculosis and if none are present, not to give antitubercular therapy. CT is repeated in 12 weeks and if the lesion has not regressed, or has increased, a review of diagnosis including surgical biopsy is the preferred approach. Antiepileptic drugs are given.

Malaria causes a 9–11-fold (95% CI 2–18) increase in the risk of chronic epilepsy – a risk that is at least double the risk of epilepsy after complex febrile seizures.

Rasmussen's encephalitis

This is an unusual condition in which chronic inflammation develops slowly and progressively in the cortex of one cerebral hemisphere. It usually begins in childhood although rare adult onset cases are described. The inflammatory process may evolve for up to 10 years or more and the symptoms and signs are usually initially slowly progressive and then eventually stabilize. The cause of the inflammation is quite unclear, but it is presumed to be an auto-immune response, and its remarkable unihemispheric distribution is also completely unexplained. The condition presents with focal and secondarily generalized seizures which can be severe and periods of epilepsia partialis continua (EPC) are common. Associated with the seizures is commonly progressive loss of motor and cognitive skills and speech (if in the dominant hemisphere). Hemipareisis and hemianopia are common. Diagnosis is suspected on MRI scanning which shows marked unilateral and progressive unihemispheric focal atrophy. Aphasia may develop in the dominant hemisphere. Treatment is difficult. Antiepileptic drugs are usually ineffective in controlling seizures. Various attempts to suppress or modulate the immune system, in particular with corticosteroids and/or intravenous immunoglobulin (IVIg) have proved effective in some cases. Surgery to control seizures can be carried out. Large resections are needed and hemispherectomy and hemispherotomy can be strikingly effective at controlling seizures and improving behaviour and cognition.

Differential diagnosis of epilepsy

Epileptic seizures feature in many differential diagnoses of transient neurological dysfunction. There are a wide variety of epileptic seizures and syndromes, with some age-specific aspects. Patients may present with more than one dominant form of episode, so the approach taken is to consider the principal differential diagnoses of the common presenting themes. There are some differences to the common presentations and differential diagnoses in adults, infants and children and we largely confine this discussion to adult patients.

The key to making a correct diagnosis is a detailed history from the individual patient and from a reliable witness who has seen the episodes in question. In individuals attending clinics with 'first seizures', not more than 25% of patients are usually considered to have had an epileptic seizure. The most common diagnostic error is to diagnose a syncopal episode as an epileptic seizure. Undue reliance is often placed on investigations, particularly the EEG and MRI. Inappropriate weight is often given to EEG findings that are 'compatible with epilepsy'.

It is a sound aphorism that the diagnosis of epilepsy is made primarily on the history, and the role of the EEG is to assist in the subsequent classification of the type of epileptic seizures and the epilepsy syndrome. The role of MRI is not to diagnose epilepsy, but to identify any underlying structural cerebral abnormality in those with diagnosed epilepsy.

There is considerable scope for the misdiagnosis or inaccurate diagnosis of epilepsy and epilepsy syndrome, which can have very serious consequences. In tertiary referral practice it is estimated that in 26% of those with a diagnosis of refractory epilepsy the diagnosis is incorrect or inaccurate.

When taking the history it is a good tactic to first allow the individual and witnesses to give their own freehand account of the points that they consider most important and to then go through the salient points in a systematic manner. It is not uncommon that a dramatic event causes the individual to seek advice and for minor events that may have occurred for some time to have been overlooked. Such minor events may produce important diagnostic clues and so need to be specifically enquired for. For example, episodes of an epigastric rising sensation, déjà vu and premonition suggest temporal lobe focal seizures; brief

blank staring spells and flurries of upper limb jerks in the first hour after waking suggest a generalized epilepsy. In contrast, a greying of vision and unsteadiness on prolonged standing, which is likened to the head rush that occurs when rising up quickly from a crouch, suggest presyncope.

In those who have had repeated episodes, a videotape recording of an episode is frequently invaluable, conveying more information that can be relayed by even the most careful witness, and has the benefit of being objective. It is not uncommon for witnesses (including carers) to relate important details incorrectly, such as which arm was stiff and extended and which was jerking. As video cameras, particularly on mobile telephones, and Internet communications become increasingly prevalent, this is becoming more of a practical proposition and it is commonplace for individuals to send video recordings into the clinic, which are often extremely helpful.

The clinical examination is usually less rewarding than the history, but is still important. In addition to determining if there are any focal neurological deficits or evidence of raised intracranial pressure, the individual's mood and mental state need to be assessed. The skin should be examined for evidence of a neurocutaneous syndrome and blood pressure checked. If an individual presents with episodes of loss of awareness or falling, a cardiac examination and checking of lying and standing blood pressure is indicated.

Epileptic seizures need to be considered in the differential diagnosis of a range of presentations (Table 6.10).

Loss of awareness

Whatever the cause, the patient may have amnesia for both the event and its exact circumstances. The three main causes are syncope, seizures and cardiac arrhythmias. Transient cerebral ischaemia caused by vascular abnormalities is less common. Microsleeps (very short daytime naps) may occur with any cause of severe sleep deprivation or disruption. Other causes of diagnostic confusion are much less common and include hypoglycaemia or other intermittent metabolic disorders, structural anomalies of the skull base affecting the brainstem, or lesions affecting the circulation of the CSF.

Table 6.10 Clinical presentations of epilepsy.

Loss of awareness
Generalized convulsive movements
Drop attacks
Transient focal motor attacks
Transient focal sensory attacks
Facial muscle and eye movements
Psychic experiences
Aggressive or vocal outbursts
Episodic phenomena in sleep
Prolonged confusional or fugue states

Syncope

Syncope is the most common cause of episodes of loss of awareness. Simple faints or vasovagal syncopal attacks can usually be related to identifiable precipitants. Most often they occur on getting up quickly or standing for prolonged periods, particularly if associated with peripheral vasodilatation (e.g. during hot stuffy weather, crowded trains or rooms, or are related to drug or alcohol use). Frightening, emotional or unpleasant scenes and painful stimuli may also be triggers, because of increased vagal activity.

There are other causes of syncope, and classification depends on terminology. Cough and micturition syncope are well recognized. Changes in intrathoracic pressure (cough syncope), impaired baroreceptors resulting from atheroma of the carotid (carotid sinus syncope), cardiac arrhythmias or autonomic disturbances may also lead to cerebral hypoperfusion and fainting. As these may not be caused by vasovagal reflex changes, the typical aura of vasovagal syncope may not be present.

Epilepsy

Several types of epileptic seizure may present with loss of awareness as the only reported feature. These include absences, complex partial, tonic or atonic seizures. Typical absences involve cessation of activity, reduced or lost awareness, eyelid blinking or twitching, and sometimes small myoclonic facial or limb jerks, or brief facial automatisms such as lip smacking or chewing. Typical absences are usually brief but often occur many times per day. There may also be isolated myoclonic jerks. Atonic seizures usually give rise to drop attacks but may appear to cause blank spells if the patient is sitting or lying down and so cannot fall. Complex partial seizures may cause loss of awareness with few if any other features. Detailed enquiry must always be made for any associated psychic or motor phenomena that may raise the possibility of a seizure disorder.

Cardiac disorders

There are often prodromal features similar to simple syncope, as well as palpitations, chest pain, shortness of breath or other features of cardiovascular insufficiency. Attacks resulting from transient complete heart block or asystole are abrupt and short with rapid loss of consciousness. Lack of cardiac output may also be caused by short episodes of ventricular tachycardia or fibrillation. Prolongation of the QT interval may lead to such events. Attacks may be preceded by palpitations, extreme fatigue or presyncopal features.

Patients with mitral valve prolapse and aortic stenosis may present with episodic loss of awareness caused by fluctuating cardiac output or associated arrhythmias. Those with aortic stenosis and hypertrophic cardiomyopathy are especially prone to present with episodes of sudden collapse with loss of awareness during exercise. A cardiological opinion should be sought if there is the possibility of cardiac dysfunction causing episodes of loss of awareness, falls or convulsions (see below). A 12-lead electrocardiogram (ECG) should be carefully inspected, particularly for

evidence of prolongation of the QT interval and consideration given to prolonged ECG monitoring with an implanted ECG loop recorder.

Microsleeps

Any cause of sleep deprivation can lead to brief daytime naps, sometimes lasting for only a few seconds. Impaired quality of sleep may also be a factor. The most important is obstructive sleep apnoea, although microsleeps also occur in other sleep disorders. Microsleeps are a common problem when driving, particularly on featureless straight roads and are the cause of many road traffic accidents. There are usually clear warning signs such as the driver feeling a need to close their eyes, yawn, turn the radio volume up or open the windows. These events are of legal significance as a driver who continues to drive despite such warning signs and who causes an accident is likely to be prosecuted for dangerous driving. Narcolepsy can present with short periods of suddenly falling asleep during the day. Systematic enquiry should be made for other symptoms of the narcolepsy cataplexy syndrome, such as loss of body tone precipitated by emotion or laughter, sleep paralysis and hypnogogic hallucinations.

Panic attacks

Panic attacks usually start with feelings of fear and anxiety, associated with autonomic changes and hyperventilation. This leads to dizziness or light-headedness, orofacial and/or peripheral paraesthesia (which may be asymmetric), carpopedal spasm, twitching of the peripheries, blurred vision or nausea. Occasionally these preludes may be forgotten, and attacks present with loss of awareness. Often, but not always, there is a clear precipitant, such as a particular situation. Panic attacks are almost always longer than seizures. However, none of these features are consistent, and differentiation from epilepsy can be difficult.

Hypoglycaemia

Hypoglycaemic attacks causing loss of consciousness are extremely rare except in patients with treated diabetes mellitus. Very occasional cases may be seen caused by insulin secreting tumours. There is usually a history of events occurring if meals are delayed or missed and prodromal symptoms of anxiety, sweating and unease which improve with taking glucose.

Other neurological disorders

If a head injury causes loss of consciousness, there is amnesia. In accidental head injury, particularly road traffic accidents, it may be difficult to distinguish amnesia caused by the injury from cases in which there was a loss of consciousness that caused the accident. Isolated episodes of loss of awareness may also be caused by abuse of psychotropic drugs or other substances.

Dissociative seizures

Dissociative seizures, sometimes known as non-epileptic attack disorder (NEAD) or pseudoseizures typically gives rise to episodes of two broad types:

1 Attacks involving motor phenomena; and

2 Attacks of lying motionless.

The latter are often prolonged, continuing for several minutes or sometimes hours. Such behaviour is very rare in epileptic seizures: there will nearly always be other positive phenomena in epileptic attacks that last for more than a few minutes. In addition, attacks are often precipitated by external events or stress. Patients with dissociative seizures often have a history of abnormal illness behaviour. Dissociative seizures are much more common in females than males, and usually commence in adolescence or early adulthood (Table 6.11).

Table 6.11 Differentiation of epileptic seizures and dissociative seizures.

	Epileptic seizure	Dissociative seizures
Precipitating cause	Rare	Common, emotional and stress-related
When alone or asleep	Common	May be reported
Onset	Usually short	May be short or over several minutes
Aura	Various, usually stereotyped	Fear, panic, altered mental state
Speech	Cry, grunt at onset; muttering, words in automatisms	Semi-voluntary, often unintelligible
Movement	Atonic, tonic; if clonic, synchronous small amplitude jerks	Asynchronous flailing of limbs; pelvic thrusting; opisthotonos
Injury	Tongue biting, fall; directed violence rare	May bite tongue, cheeks, lip, hands, throw self to ground. Directed violence not uncommon
Consciousness	Complete loss in generalized tonic–clonic; may be incomplete in complex partial	Variable, often inconsistent with seizure type
Response to stimulation	None in generalized tonic–clonic; may respond in complex partial and post-ictally	Often reacts and this may terminate episode
Incontinence	Common	Sometimes
Duration	Few minutes	Few minutes, may be prolonged.

Generalized convulsive movements

Epilepsy

A generalized convulsion is generally the most readily diagnosed epileptic seizure. Classically, there is a cry, generalized stiffening of body and limbs, followed by rhythmic jerking of all four limbs, with loss of awareness, eyes staring blankly, tongue biting and urinary incontinence. The generalized convulsive movements usually last for a minute or so, and as the attack proceeds the jerking slows in frequency and increases in amplitude. There is often tachycardia, apnoea and cyanosis, and afterwards irregular breathing followed by confusion, headache and sleepiness.

Syncope with secondary jerking movements

People who faint often have myoclonic twitches of the extremities for less than 1 minute. This may be associated with limb posturing and stiffening. With prolonged cerebral hypoperfusion, as may occur if the person is held upright by well-meaning bystanders, or an aircraft seat, these may be more prominent and prolonged, and be reported as 'a convulsion'. Incontinence of urine may occur, particularly if the bladder is full and tongue biting may occur if the tongue is caught between the teeth as the individual falls to the ground.

Primary cardiac or respiratory abnormalities presenting with secondary anoxic seizures

Episodes of complete heart block or transient asystole may have syncopal features followed by collapse to the ground and secondary anoxic seizures. More commonly, there is an abrupt collapse with no warning and the person is observed to be pale and witnesses commonly remark that 'they thought the person was dead'. The attacks last for less than 1 minute, but may be followed by a prolonged period of confusion, particularly in elderly patients. There should be a low threshold for obtaining a cardiological opinion in such cases and consideration given to insertion of an implanted ECG loop recorder to identify occasional cardiac arrhythmias.

Involuntary movement disorders and other neurological conditions

There is no alteration in consciousness. The best known is paroxysmal kinesiogenic choreoathetosis. Attacks are usually precipitated by sudden specific movements and last a few seconds to minutes. Paroxysmal dystonia can present with attacks that last for minutes to hours. Patients with involuntary movement disorders such as idiopathic torsion dystonia may show severe acute exacerbations that may mimic convulsive movements.

Patients with mental retardation often have stereotyped or repetitive movements, which may include head banging or body rocking, and more subtle movements which may be difficult to differentiate from complex partial seizures.

Hyperekplexia

Hyperekplectic attacks are characterized by excessive startle, may cause stiffening and collapse with a sudden jerk of all four limbs. Attacks are provoked by sudden unexpected stimuli, most commonly auditory. Hyperekplexia needs to be distinguished from seizures induced by startle, which commonly arise from the frontal lobe.

Dissociative seizure

Dissociative seizures involving prominent motor phenomena are more common than those with arrest of activity. Movements are varied but often involve semi-purposeful thrashing of all four limbs, waxing and waning over many minutes, distractibility or interaction with the environment, prominent pelvic movements and back arching. Dissociative seizures may be difficult to differentiate from complex partial seizures of frontal lobe origin, which can present with very bizarre motor attacks. The key feature of the latter is that the episodes are usually stereotyped and occur during both wake and sleep.

Drop attack

Any cause of loss of awareness may proceed to a sudden collapse or drop attack. Epilepsy, syncope and other cardiovascular disorders are the more common causes of drop attacks.

Epilepsy

Sudden drop attacks are common in patients with learning disability and secondary generalized epilepsies. The falls may be tonic or atonic in nature and frequently cause severe facial injuries if the individual falls forwards.

Cardiovascular

If cerebral hypoperfusion is sufficient to cause sudden collapse there is usually loss of awareness (see above), but a drop attack may be the dominant presenting symptom.

Movement disorder

Most movement disorders that cause drop attacks have other more prominent features that make the diagnosis clear (e.g. Parkinson's disease). Paroxysmal kinesiogenic choreoathetosis may cause drop attacks if there is lower limb involvement.

Brainstem, spinal or lower limb abnormality

There are usually fixed neurological signs that give a clue towards the diagnosis. Tumours of the third ventricle, such as colloid cysts, may present with sudden episodes of collapse. Spinal cord vascular abnormalities may present with abrupt episodes of lower limb weakness leading to falls, without impairment of awareness.

Cataplexy

Cataplexy usually occurs in association with narcolepsy, although it may be the presenting clinical feature. There is no loss of consciousness with attacks. Attacks may be precipitated by emotion, especially laughter. Often there is only loss of tone in the neck muscles, with slumping of the head, rather than complete falls.

Metabolic disorder

Periodic paralysis caused by sudden changes in plasma potassium is rare. The condition may be familial or associated with other endocrine disorders or drugs. Usually there is a gradual onset, and the attacks last for hours.

Idiopathic drop attack

These attacks are most common in middle-aged females. They take the form of a sudden fall without loss of consciousness. Characteristically, the patients remember falling and hitting the ground. Recovery is instantaneous, but injury may occur.

Vertebrobasilar ischaemia

This condition is over-diagnosed and probably accounts for very few drop attacks. Typically, the attacks occur in the elderly, with evidence of vascular disease and cervical spondylosis. The attacks may be precipitated by head turning or neck extension resulting in distortion of the vertebral arteries and are of sudden onset, with features of brainstem ischaemia such as diplopia, vertigo and bilateral facial and limb sensory and motor deficits.

Transient focal motor attack

The most common cause of transient focal motor attacks is epilepsy. Tics may develop in adolescence. Paroxysmal movement disorders are rare, although unilateral paroxysmal kinesiogenic choreoathetosis may mimic motor seizures. Transient cerebral ischaemia usually presents with negative phenomena, although positive phenomena can occur with critical carotid stenosis. Tonic spasms of multiple sclerosis are usually seen in the context of other features of the illness, but may be a presenting feature.

Focal motor seizure

Focal motor seizures may involve jerking and posturing of one extremity, or reflect the spread of epileptic activity along the primary motor cortex. There is often associated paraesthesia. Following the attack, there may be localized transient weakness for seconds or minutes, sometimes longer. Seizures arising in many different brain regions may cause dystonic posturing.

Epilepsia partialis continua is a rare form of epilepsy that often causes diagnostic confusion. There is very frequent focal motor activity such as jerking of the hand or part of the face. This can persist for hours or days, continue into sleep, and may go on for years. The movements often become slow and pendulous, with some associated dystonic posturing.

Tics

Tics usually present with stereotyped movements in childhood or adolescence, sometimes restricted to one particular action (e.g. eye blinking) but may be multiple in nature. Tics may be confused with myoclonic jerks. They can be suppressed voluntarily, although to do so leads to a rise in psychological tension and anxiety which is then relieved by the patient allowing the tics to occur. Repetitive tics and stereotypies are particularly common in those with intellectual disability.

Transient cerebral ischaemia

Transient ischaemic attacks (TIAs) usually present with negative phenomena, i.e. loss of use of a limb, hemiplegia or other deficits, although positive phenomena such as paraesthesiae may occur. TIAs may last for a few minutes, but may persist for up to 24 hours. TIAs are not usually stereotyped or repeated with the frequency of epileptic seizures, and there are usually associated features to suggest vascular disease.

Tonic spasms of multiple sclerosis

These spasms usually occur in the setting of known multiple sclerosis, but may be the presenting feature, although other evidence of multiple sclerosis will usually be found on examination and investigation. The spasms may last for several seconds and sometimes longer than 1 minute.

Paroxysmal movement disorder

Paroxysmal kinesiogenic choreoathetosis may present with focal motor attacks that are very similar to epileptic seizures. Tremor can occur in a variety of movement disorders and is usually sufficiently persistent to make the non-epileptic nature clear, but may be difficult to distinguish from certain forms of epilepsia partialis continua. Myoclonus of subcortical origin may be suspected from the distribution of involved muscles (e.g. spinal myoclonus may be restricted to specific segments, either unilateral or bilateral). Peripheral nerve entrapment usually presents with weakness but occasionally can present with episodic jerks or twitches.

Transient focal sensory attack

Somato-sensory attack

Epileptic seizures involving the primary sensory cortex are less common than motor seizures, and may cause spreading paraesthesia. Seizures involving the second sensory areas or medial frontal cortex can cause sensory symptoms. There are usually other epileptic features because of involvement of adjacent or related brain structures. Transient sensory phenomena may also be seen in peripheral nerve compression or other abnormalities of the ascending sensory pathways, hyperventilation or panic attacks and in TIAs. TIAs are not usually stereotyped or repeated with the frequency of epileptic seizures, and there are usually associated features to suggest vascular disease.

Lesions of sensory pathways cause persistent symptoms, but diagnostic confusion may arise early on in the natural history, when complaints are intermittent, or if they are posture related. Hyperventilation may be associated with unilateral and localized areas of paraesthesia (e.g. one arm). Intermittent sensory illusions may be experienced in relation to amputated or anaesthetic limbs. Migrainous episodes may also cause localized areas of paraesthesia, but usually have the distinction of a gradual evolution of sensory phenomena, both positive and negative, and associated features of migraine.

Transient vestibular symptoms

Acute attacks of vertigo may occasionally be caused by a seizure in the parietal or temporal lobes. In these cases there are generally associated features that point to cerebral involvement, such as a focal somato-sensory symptoms, déjà vu or disordered perception. Peripheral vestibular disease is a much more common cause and may give rise to paroxysmal rotational vertigo and perception of linear motion and there are often also other symptoms of auditory and vestibular disease such as deafness, tinnitus, pressure in the ear and relation to head position.

Visual symptoms

Migraine is a common cause of episodic visual phenomena. The evolution is usually gradual, over several minutes, with fortification spectra and associated photophobia, nausea and headache. Epileptic phenomena are usually much shorter, evolving over seconds, and the visual hallucinations are more commonly of coloured blobs rather than jagged lines. On occasion, a migraine attack may be followed by an epileptic seizure.

Facial muscle and eye movements

Facial movements occur in many neurological conditions including partial seizures, tics, dystonias or other paroxysmal movement disorders, drug-induced dyskinesias and hemifacial spasm, and psychological disorders.

Partial seizures

Benign childhood epilepsy with centro-temporal spikes usually presents with seizures in childhood affecting the face, often with unilateral grimacing, hemibody sensory and motor phenomena, or secondarily generalized seizures occurring in sleep. Focal motor seizures may cause twitching of one side of the face which may be restricted to specific areas.

Complex partial seizures may cause automatisms with lip smacking, chewing, swallowing, sniffing or grimacing, with amnesia and impaired awareness. If these features are caused by seizure activity the attacks are usually relatively infrequent. Dystonia or other movement disorder episodes are likely to be more persistent or occur many times per day.

Movement disorders

Hemifacial spasm typically presents in the elderly or middle aged with clusters of attacks that initially involve the eye but subsequently spread to the rest of that side of the face. Facial weakness may develop and continue between attacks.

Bruxism may occur either during the day or in sleep, especially in children with learning disability. Episodes are usually more prolonged than with the automatisms of complex partial seizures, and there are no associated features to suggest an epileptic basis.

As with dystonia and other movement disorders affecting the face, there may be evidence of involvement elsewhere, and attacks are usually more frequent than is seen with isolated seizures.

Other neurological disorders

Defects of eye movement control are common in patients with a wide range of neurological disorders. There are usually associated features that indicate a non-epileptic basis. Bizarre eye movements also occur in blindness and may be mistaken for epileptic activity. Careful examination is required to ascertain the precise features of the eye movement disorder, and in particular any precipitating factors or features of cerebellar or brainstem disease.

Psychic experiences

Intermittent psychic phenomena can be seen in partial seizures (especially of temporal lobe origin), migraine, panic attacks, transient cerebral ischaemia, drug-induced flashbacks, or with illusions associated with loss of a sensory modality as well as psychotic illnesses.

Epilepsy

Partial seizures of temporal lobe origin are commonly associated with fear, déjà vu, memory flashbacks, visual, olfactory or auditory hallucinations. Other features include altered perception of the environment with a distancing from reality or change in size or shape of objects; altered language function; emotions such as sadness, elation and sexual arousal.

Psychic experiences may have some relation to past experiences. They are usually recalled as brief scenes, sometimes in a sequence. They are usually unclear, e.g. a patient may describe an illusion of someone standing in front of them who they know, but they cannot name them or describe them in detail. A rising epigastric sensation may occur alone or in association with such experiences. Elemental visual phenomena, such as flashing lights or coloured circles, are more often seen in occipital lobe epilepsy.

Migraine

Migrainous psychic phenomena may involve an initial heightening of awareness. The principal features are usually visual illusions which may be elemental or complex. They rarely have the same intense emotional components of temporal lobe illusions or hallucinations. The time course is usually more prolonged than with partial seizures, with an evolution over several minutes and there are associated features of a pounding headache, photophobia and nausea or vomiting. There may be identifiable precipitants, and there is often a relevant family history.

Panic attack

These are usually associated with feelings of fear and anxiety. Hyperventilation may lead to dizziness and light-headedness. There are often unpleasant abdominal sensations similar to the epigastric aura of partial seizures. The evolution, associated increases in heart rate and respiration, longer time course and history of precipitating factors usually make the diagnosis clear, but distinction from temporal lobe seizures may be difficult.

Drug-induced flashback

These share many of the qualities of psychic temporal lobe seizures. They are individualized hallucinations usually related to the circumstances of the drug abuse, often with emotional content of fear or anxiety. A careful history should be taken for substance abuse, especially LSD, psilocybin, peyote and mescaline.

Hallucination or illusion caused by loss of a primary sense

Hallucinations and illusions of an absent limb are well-recognized in amputees. Similarly, people who lose sight either in the whole or part field may experience visual hallucinations or illusions in the blind field. Such phenomena can be elemental or complex and include evolving scenes. Similar experiences can occur with deafness.

Such experiences resulting from the loss of a primary sense present particular diagnostic difficulty when they occur in the setting of a structural lesion, which could result in both phenomena. An occipital infarction, for example, could cause visual loss and could also give rise to epileptic seizures. Often the hallucinations caused by sensory loss are more prolonged, lasting for minutes or hours, but may be brief.

Psychotic hallucination and delusion

Hallucinations and delusions are the hallmark of psychotic illnesses. The following features would suggest a psychiatric rather than epileptic basis: complex nature with an evolving or argued theme, auditory nature involving instructions or third person language, paranoid content or associated thought disorder. Psychotic episodes are usually more longer lasting than isolated epileptic seizures, although intermittent psychosis may have a similar time course to non-convulsive status. Persistent mood changes may be a helpful guide, but even short temporal lobe seizures may be followed by mood changes lasting for hours or days. Furthermore, flurries of epileptic attacks may themselves cause an organic psychosis lasting for several days. Ruminations and pseudohallucinations, in which the patient retains some insight, can occur in affective disorders.

Dissociative seizure

Dissociative seizures may be associated with reports of hallucinations and illusions. Initially, the symptoms may seem plausible, but should be suspected if they are florid and multiple in type (e.g. auditory, olfactory and visual at different times) with evolving stories or patterns of expression.

Aggressive or vocal outburst

These are rarely epileptic in nature if they occur in isolation. They are especially common in adults and children with mental retardation. In this setting there is organic brain disease that could lower the overall seizure threshold. A not infrequent forensic issue is the occurrence of violent, or other, crimes in patients with epilepsy, in which it is a defence claim that the crime was committed in a state of automatism. Certain features are strong evidence against an epileptic basis to the attack:

- Absence of a prior history of epilepsy with automatisms;
- Premeditation and evidence of planning or preparation;
- Directed violence;
- Evidence of complicated and organized activity during the episode;
- Recall of events during the episode;
- Witness accounts not indicative of a disturbance of consciousness; and
- Subsequent attempts at escape or concealment of evidence.

Episodic phenomena in sleep

Attacks occurring during sleep present particular diagnostic difficulties because they are often poorly witnessed, and the patient may have little, if any, recall of the event or the preceding circumstances.

Normal physiological movement

Whole body jerks commonly occur in normal subjects on falling asleep. Fragmentary physiological myoclonus usually involves the peripheries or the face, and occurs during stages 1 and 2 and REM sleep. Periodic movements of sleep may be an age-related phenomenon, being seen in less than 1% of young adults, but occurring with increasing frequency during middle and old age such that they are present in perhaps half of the elderly population. Typically, these movements occur at regular intervals of 10–60 seconds and may occur in clusters over many minutes.

Frontal lobe epilepsy

Frontal lobe seizures can display specific sleep-related characteristics causing diagnostic confusion. Such attacks are often frequent, brief, bizarre and may only occur during sleep. Attacks may include apnoea, dystonic, myoclonic or choreiform movements which may be unilateral or bilateral, and some retention of awareness. The attacks are scattered throughout the night, and usually arise from non-REM sleep. Frequency is highly variable, but some patients have more than 20 attacks in a night. An important clue to the diagnosis is the occurrence of additional secondarily generalized seizures and seizures occurring in wakefulness.

Other epilepsies

Seizures arising in other brain regions may present with nocturnal attacks. Patients may be aroused by an aura, although often this is not recalled when attacks arise from sleep. Complex automatisms, in which patients get out of bed and wander around, may cause confusion with parasomnias. With nocturnal seizures of any type the partner is frequently awoken by particular components, such as vocalization, and does not witness the onset. Generalized tonic–clonic seizures not uncommonly occur on or shortly after awakening.

Pathological fragmentary myoclonus

Excessive fragmentary myoclonus persisting into sleep stages 3 and 4 may be seen with any cause of disrupted nocturnal sleep.

Restless leg syndrome

The restless leg syndrome is characterized by an urge to move the legs, especially in the evening when lying or sitting. It may be associated with various unpleasant paraesthesiae. All patients with restless legs have periodic movements of sleep. These may be severe and can also occur during wakefulness. In addition, there may be a variety of brief daytime dyskinesias.

Non-REM parasomnia

This involves night terrors or sleep walking. Non-REM parasomnias usually present in childhood or adolescence, and are often familial. The attacks arise from slow wave sleep, typically at least 30 minutes, but not more than 4 hours, after going to sleep and the timing is often consistent. Attacks may be spaced out by months or years and rarely occur more than once per week, and usually no more than one attack occurs in a single night. They are more likely after stressful events, or when sleeping in a strange bed.

Night terrors involve intense autonomic features (sweating, flushing, palpitations) and a look of fear. Patients may recall a frightening scene or experience, but do not usually recount a vivid dream prior to the attacks. Certainly children do not recall events. They may be difficult to arouse, and confused for several minutes. Vocalizations are common. Sleep walking may involve getting out of bed and performing complex tasks. Sometimes it is possible to lead the patient back to bed without awakening. They may respond if spoken to, but their speech is usually slow or monosyllabic. Brief abortive episodes are more common, involving sitting up in bed with fidgeting and shuffling (mimicking a complex partial seizure). Non-REM parasomnias may cause self-injury but rarely directed aggression. They are associated with enuresis.

REM parasomnia

REM parasomnia usually occurs in middle age or the elderly, and shows a marked male predominance. It more often occurs in the later portion of sleep. During REM sleep, patients may have an increase in the frequency or severity of fragmentary myoclonus, thrash about, call out, display directed violence or appear to enact vivid dreams. Attacks may last from seconds to minutes. If awoken, patients may recall part of these dreams. Although REM sleep behaviour disorders may occur in healthy elderly subjects, they are also seen in association with drugs (e.g. tricyclics) or alcohol, or CNS diseases such as multi-system atrophy. The possibility of REM sleep disorders needs to be considered both at initial presentation, and also in patients known to have CNS disorders.

Sleep apnoea

Patients with sleep apnoea usually present with daytime hypersomnolence. However, the apnoeic episodes can cause episodic grunting, flailing about or other restless activity that can appear to mimic nocturnal epilepsy. Occasionally, the resultant hypoxia precipitates secondary seizures.

Other movements in sleep

Nocturnal body rocking may occur in patients with learning disability, or following head injury. In patients with many different forms of daytime dyskinesias, similar movements may occasionally occur during overnight sleep, usually in the setting of brief arousals.

Prolonged confusional or fugue state

Epileptic seizures usually last for seconds or minutes. After generalized tonic–clonic seizures (or, less often, complex partial seizures) there may be confusion lasting for many minutes, but rarely more than an hour. Such episodes only present diagnostic difficulty if the initial seizure is unwitnessed. Nevertheless, epileptic states can last for longer periods of time, as can other types of cerebral disorder and the differential diagnosis of prolonged epileptic confusional states (non-convulsive status) should include acute encephalopathy, non-convulsive status epilepticus, transient global amnesia, intermittent psychosis and dissociative seizures.

Acute encephalopathy

Virtually any severe metabolic disturbance can cause an acute encephalopathy (e.g. diabetic ketoacidosis; hypoglycaemia; respiratory, renal or hepatic failure; drug ingestion; hyperpyrexia; sepsis). Transient metabolic disturbances are most often seen in treated diabetes mellitus resulting from insulin-induced hypoglycaemia. Occasionally, metabolic disorders, such as porphyria and urea cycle enzyme defects, may present with exacerbations with symptoms lasting for hours or days and may give the appearance of an episodic condition. Acute neurological conditions also need to be considered, particularly encephalitis, meningitis, other intracranial infection, head injury, cerebral infarction or haemorrhage. Drug abuse can cause isolated episodes or recurrent bouts, related to intoxications.

Non-convulsive status epilepticus

Patients with complex partial seizures, typical or atypical absences may present with prolonged confusional states caused by complex partial epilepticus or absence status. Such attacks may be the first manifestation of the seizure disorder, or occur in the setting of known epilepsy.

Intermittent psychosis

Although usually more sustained, psychiatric disorders may present with episodes of delusions, hallucinations or apparent confusion, lasting for hours or days.

Transient global amnesia

These episodes typically commence acutely, and last for minutes or hours and involve both retrograde and anterograde amnesia. Patients may perform complex activities, but afterwards have no recall of them. There is a lack of other neurological features to the attacks, and consciousness appears to be preserved. During an attack, the patients do not appear overtly confused. The attacks

may involve bilateral medial temporal dysfunction, which in some patients may be on the basis of ischaemia, while others may have an epileptic basis.

Hysterical fugue

A fugue state may arise without an organic physical cause, as a conversion symptom. These episodes may be brief or very prolonged, lasting for days or even weeks. If seen during the episode, inconsistencies are often found on examination of the mental state. There is usually a history of serious psychiatric disturbance or alcohol or dug abuse. In some cases, the question of malingering arises, most commonly in a situation in which the person's state prevents questioning by law officers and when the subject professes no memory of events. The diagnosis is more difficult to identify if the patient is only seen subsequently. The matching of witness accounts and the apparent sequence of events is essential, but it may remain difficult to come to a firm conclusion.

Investigation of epilepsy

Electroencephalography

Electroencephalography (EEG) was introduced into clinical practice in the early 1940s, and has since developed into an array of digitally based techniques, integrated with video and other investigative modalities. However, like all investigations, it has limitations which must be recognized, and its applications should be targeted to specific clinical questions (Table 6.12).

Clinical questions that can be addressed by EEG

EEG in the diagnosis of epilepsy

EEG is the primary investigation in epilepsy. However, it should not be forgotten that the diagnosis of epilepsy is essentially clinical, and EEG has a high false negative rate and a low but important false positive rate. EEGs are liable to misinterpretation when there is insufficient knowledge of the range of normal and non-specific EEG phenomena – this has repeatedly been identified as a common reason for false diagnosis of epilepsy.

Up to about half of patients with epileptic disorders may have one normal interictal EEG, and around 10% of patients with epilepsy never show interictal spikes. A normal or negative EEG cannot therefore be used to rule out the clinical diagnosis of an epileptic seizure. Specificity of EEG in epilepsy is higher than its sensitivity, but a small percentage of otherwise normal subjects may show epileptiform abnormalities in their EEG. The incidence of epileptiform discharge is around 0.5% in adults with no known history of epilepsy, and about 2–4% in children. Epileptiform phenomena may also be seen in 10–30% of patients who have neurological disorders or cerebral pathologies (e.g. tumour, head injury, cranial surgery), without a history of seizures. Thus, an abnormal EEG showing epileptiform activity does not in itself indicate that the subject must have a seizure disorder.

Table 6.12 Use of electroencephalography (EEG) in clinical practice.

Diagnosis of epilepsy	Management of seizure disorders
Is the paroxysmal event an epileptic seizure?	Probability of recurrence after single unprovoked seizure
Is seizure onset focal or generalized?	Why has cognitive function deteriorated?
Syndromic classification	Is behavioural change brought about by non-convulsive status?
Identification of seizure triggers,	Likelihood of seizure recurrence after AED withdrawal

AED, antiepileptic drug.

Epileptiform phenomena

EEG features classified as epileptiform are spike discharges, spike or polyspike wave complexes, and sharp waves. The appearance of epileptiform discharge depends on the degree of neuronal synchronization and how the discharge spreads through cortex. Some epileptiform phenomena – 3 per second spike-wave discharge, hypsarrhythmia and generalized photoparoxysmal responses – are strongly correlated with clinical epilepsy. Others, such as focal sharp waves in centro-temporal regions, are moderately correlated with clinically evident seizures. The EEG of normal subjects can show a range of spikey features that resemble epileptiform activity, particularly in sleep. Physiological or pathological but non-epileptogenic variants include wicket spikes, 14 and 6 Hz spikes, rhythmic mid-temporal theta, and subclinical rhythmic epileptiform discharge in adults (SREDA). These variants mostly have no link with epilepsy, but are a potential source of confusion and EEG misinterpretation.

Location of electrodes and site of epileptic focus, age of patient, the presence of medication, diurnal timing of the EEG and the frequency, severity and type of epilepsy all influence the chance of detecting epileptiform discharges. The timing of EEG in relation to last seizure event may be relevant and one study has found that an interictal EEG within 24 hours of a seizure revealed an abnormality in 51% compared to 34% who had later EEG.

Routine EEG testing

A routine interictal EEG recording typically takes 20–30 minutes, and should include standard activation procedures of hyperventilation and photic stimulation, following published protocols. Most EEG departments use the international 10–20 system of scalp electrode placement, but additional electrodes are often useful, especially to record from the anterior temporal lobe region (superficial sphenoidal electrodes). The combination of wake and sleep records gives a yield of 80% in patients with clinically confirmed epilepsy. Sleep EEG can be achieved by recording natural sleep, or with hypnotics to induce sleep. Whether sleep deprivation has additional value for induction of epileptiform activity is unclear, but there is some evidence that it specifically activates spikes in IGEs. Evaluation of different EEG protocols in young people (<35 years) with possible epilepsy found that sleep-deprived EEG provided significantly better yield than routine

EEG or drug-induced sleep EEG, and it may be the most cost-effective protocol for investigation of new epilepsy.

Prolonged interictal sampling using long-term monitoring increases diagnostic yield by about 20%, and many EEG departments now offer 24-hour ambulatory multi-channel digital EEG. Other methods include repeating EEG at different times of day and 60–120 minute out-patient EEG. After a first seizure, the pick-up rate depends on the syndrome and seizure type.

The National Institute for Clinical Excellence (NICE) guidelines for diagnosis and management of the epilepsies in adults and children recommend that routine EEG should be performed in adults in whom the clinical history suggests an epileptic seizure. In children, EEG is recommended after a second seizure, as the diagnostic yield from routine EEG after a single seizure is considered too low to influence management.

EEG in the classification of epileptic seizures and syndromes

Clinical criteria alone may not be sufficient for characterization of epilepsy type, or infallible. Both epileptiform activity and interictal background cortical rhythms provide information that can complement the history and aid diagnosis. EEG findings contribute to diagnostic refinement at different levels: by establishing whether the seizure disorder is focal or generalized, idiopathic or symptomatic, or part of an epilepsy syndrome.

Although division of seizure types into partial and generalized is a cornerstone of clinical practice, it is important to appreciate there can be EEG (and clinical) overlap between the two. Rapid generalization of epileptiform activity secondary to a symptomatic focus can mimic idiopathic generalized epilepsy; focal spikes and regional accentuation of generalized spike-wave discharge are well-recognized in IGE syndromes.

Idiopathic generalized epilepsy

The typical EEG findings in IGE are generalized spike or polyspike and slow wave discharges at 3–5 Hz (Figure 6.1), normal background cortical rhythms and a relatively high occurrence of photosensitivity. In childhood absence epilepsy, with typical absence seizures, there is characteristic bilateral synchronous 3-Hz spike wave, usually lasting 5–10 seconds. Background cortical rhythms are normal, but some children show runs of occipital rhythmic delta (up to 40% of cases), which may persist after remission of absences. Photosensitivity is uncommon (less than 10%), and possibly indicative of poorer prognosis. Patients with juvenile absence epilepsy usually show polyspike discharge or spike-wave frequency above 3 Hz. In juvenile myoclonic epilepsy, the interictal and ictal EEG characteristic is brief bursts of polyspike (sometimes single spike) and wave discharge. Variable asymmetry of the discharge is common, and interictal focal abnormalities occur in up to 40%, and photosensitivity in 40–50%. Not all patients with IGE show typical electrographic findings in the first EEG. Generalized absence epilepsy is most likely to show diagnostic EEG abnormalities at initial investigation, whereas other syndromes may need serial recording to elucidate diagnosis. This should not delay appropriate treatment.

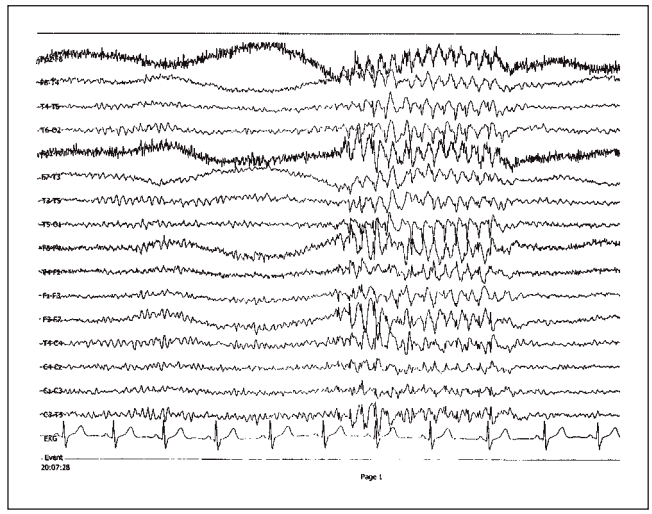

Figure 6.1 Typical spike wave discharge in a patient with absence epilepsy.

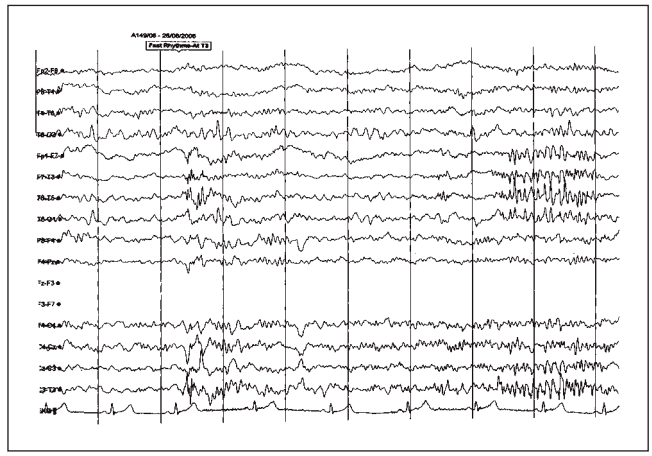

Figure 6.2 High-frequency interictal discharge in a patient with neocortical or lateral temporal lobe epilepsy.

IGE can present in adult life. Most cases have either generalized tonic–clonic seizures with or without myoclonus, and electroclinical manifestations are similar to those in IGE presenting in the more classic age groups.

Typical absence seizures in IGE should be distinguished from atypical absences that occur in the epileptic encephalopathies. The EEG signature of this seizure type is a relatively slow (<2.5 Hz) and less regular spike-wave discharge, and the EEG shows abnormalities of background cerebral activity, in keeping with the mainly severe symptomatic generalized epilepsies, in which these types of absences occur.

Benign childhood epilepsy syndromes

The EEG is diagnostic of benign childhood epilepsy with centrotemporal spikes, the characteristic being high-amplitude focal

sharp wave discharges in central and temporal regions, either bilateral or unilateral, and potentiated by sleep. A few children show focal discharges in other brain regions or generalized spike-wave activity. Background cerebral rhythms are normal. The EEG is often very abnormal even in the presence of infrequent (or indeed any) seizures. Benign childhood occipital epilepsy (BCOE) has more variable EEG features; paroxysms of occipital spike-wave on eye closure (fixation off sensitivity) are typical of the early onset form or Panayiotopoulos syndrome. Otherwise, multifocal discharges, rolandic spikes and generalized spike wave are common. The clinician should be alerted to a diagnosis of BCOE in a child with infrequent seizures or paroxysmal autonomic symptoms whose routine EEG shows frequent multi-focal discharges.

Electrical status epilepticus in sleep

This condition is defined by the presence of continuous spike-wave discharge occupying 85% or more of the sleep record. It occurs in a number of childhood epilepsies, including the Landau–Kleffner syndrome of acquired aphasia and epilepsy.

Progressive myoclonic epilepsies

These epilepsies show generalized spike-wave discharge, photosensitivity, 'giant' sensory-evoked potentials (SEPs), facilitation of motor-evoked potentials (MEPs) by afferent stimulation, and abnormalities of background cerebral activity, typically an excess of slow activity. The background abnormalities are usually progressive, particularly in syndromes with dementia or significant cognitive decline such as Lafora body disease. Some specific features occur in some cases: vertex sharp waves in sialidosis, occipital spikes in Lafora body, and giant visual-evoked potentials (VEPs) in lipofuscinosis.

Partial epilepsy

Broadly speaking, localized EEG changes are more common in temporal lobe partial epilepsy than in extratemporal epilepsies (Figures 6.2 and 6.3), and spiked and/or high-frequency discharge is more likely to occur in foci that are located superficially in neocortex. Interictal EEG can be normal or non-localizing in partial epilepsies if the epileptogenic region is:

1 Extensive;
2 Remote from scalp electrodes, e.g. mesial frontal lobar areas;
3 Involves too small a neuronal aggregate for synchronized activity to be registered on the scalp.

In partial epilepsies, the most important ictal EEG changes for seizure localization are those that occur within the first 30 seconds after the seizure onset. Later changes are of limited value for localization or lateralization of the epileptogenic region, because the discharge will by then have propagated to other brain areas.

Temporal lobe epilepsy

Mesial temporal lobe epilepsy (TLE) associated with unilateral temporal lobe pathology, usually hippocampal sclerosis,

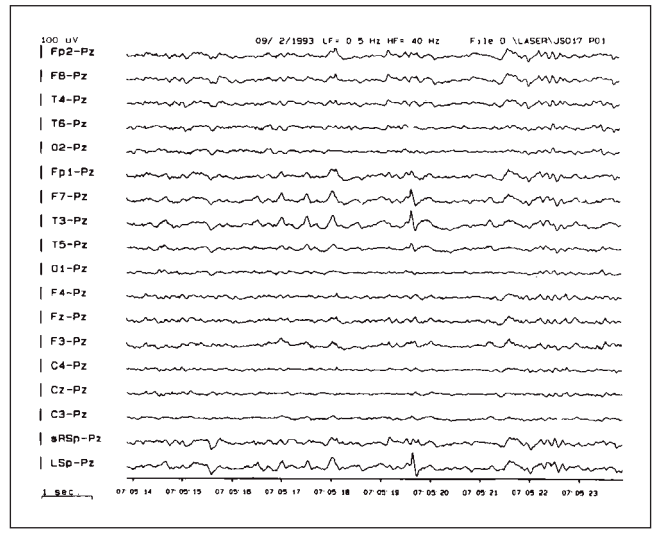

Figure 6.3 Interictal EEG: left mesial temporal lobe epilepsy, referential recording. Focal spikes at electrodes sited near the left anterior temporal lobe (F7 and Sp1) and mid temporal lobe (T3).

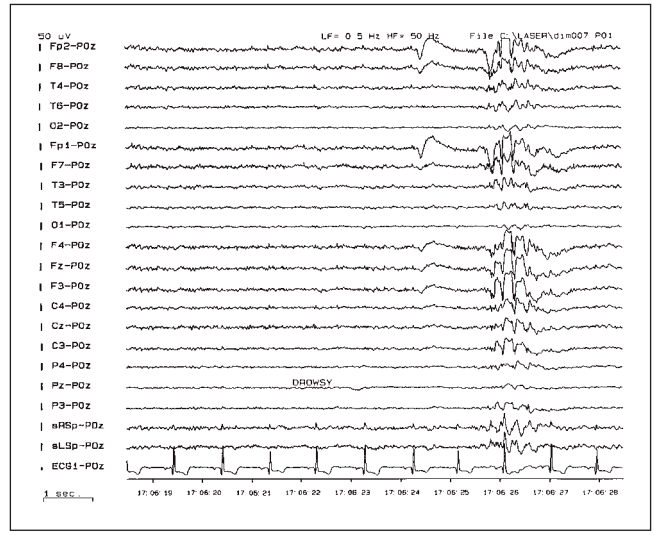

Figure 6.4 Widespread bilateral spike-wave discharge in a man with frontal lobe complex partial seizures (hypermotor semiology).

shows anterior and mid temporal interictal spikes, and a characteristic rhythmic 5–7 Hz ictal discharge accompanying seizures in 80%. Post-ictal ipsilateral slow activity and potentiation of spikes can also help to lateralize the epileptogenic region. Independent bitemporal interictal spikes are common, but predominate over the pathological temporal lobe in 60% of cases. Frequent or dominant spikes over the contralateral temporal lobe are associated with poorer seizure outcome after temporal lobectomy.

In lateral temporal lobe epilepsies, interictal spikes tend to be located over the mid and posterior temporal lobar regions; the

ictal EEG discharge is typically high frequency, and lateralized in about 50% of cases.

Frontal lobe and other extratemporal epilepsies

Focal interictal EEG abnormalities are the exception, and there are no specific patterns associated with the subtypes of frontal lobe epilepsy. Many patients show widespread or even generalized abnormalities (Figure 6.4), because of rapid spread to other lobar regions and secondary generalization. The same is true for ictal changes, the most common pattern in frontal lobe epilepsy being either high-amplitude slow or a diffuse fast discharge followed by generalized attenuation and/or bilateral slow activity.

EEG localization in extratemporal symptomatic partial epilepsy of parietal and occipital lobe is limited for the same reasons as frontal lobe epilepsy, and the majority of patients with simple partial seizures manifesting with sensory symptoms will have negative scalp EEGs.

EEG and prediction of seizure recurrence

If the initial EEG shows definite epileptiform discharge, there is a greater risk of seizure recurrence in individuals presenting with the first unprovoked seizure, particularly if idiopathic in type. EEG has distinguished between high and low risk groups in a number of studies: one systematic review showed risk of recurrence at 2 years was 27% if the EEG was normal, but 58% if the epileptiform activity was present.

EEG and withdrawal of antiepileptic medication

The type of epilepsy syndrome is the most important variable in predicting likelihood of seizure recurrence for patients in remission who are considering withdrawal of medication. EEG can provide supplementary information: presence of spike-wave discharge in patients with IGE and evidence of a generalized photosensitive response/photoparoxysmal response are associated with high risk of recurrence. The prognostic significance of other patterns and abnormalities in other types of epilepsy is less clear.

EEG and antiepileptic drugs

Acute administration of barbiturates and benzodiazepines suppresses interictal discharge, but the effect declines when these drugs are given as chronic therapy. Sodium valproate suppresses generalized spike-wave and photoparoxysmal responses, and EEG can be used to monitor therapeutic efficacy. Lamotrigine may have a similar effect, and ethosuximide also suppresses generalized discharges. Other antiepileptic drugs have variable or inconsistent effects on either focal or generalized epileptiform activity, and EEG is therefore of little or no use in monitoring response to drug treatment. 'Treating the EEG' is generally undesirable.

Antiepileptic drugs can affect background cortical rhythms, but significant slowing does not occur unless there is drug toxicity.

Long-term EEG monitoring

Long-term monitoring (LTM) allows extended EEG recording, which can be undertaken as an ambulatory procedure using a portable recorder, or via hard wired recorders with time-linked video in a hospital setting. Usually, the aim is to document 'attacks' rather than the interictal state. LTM has been shown in several studies to change diagnosis and affect management in >50% of difficult to treat cases. Its principal applications are shown in Table 6.13.

Ambulatory EEG monitoring is most suited to clinical problems that do not require concurrent synchronized video to document clinical features, or for monitoring in a specific environment. In-patient video EEG telemetry units have specialized staff who are experienced in the identification of subtle clinical events and care of patients during seizures. These units are the safest environment for reduction in medication dose to provoke seizures. The optimal length of study for LTM depends on the clinical problem, and frequency of attacks – if it is less than once per week, LTM is not likely to be beneficial.

Neurophysiology for assessing patients for epilepsy surgery

Interictal and ictal EEG are pivotal investigations in presurgical evaluation, but are generally more important in resective surgical procedures than in functional procedures such as callosotomy and vagal nerve stimulation (Table 6.14).

The number of seizures that need to be recorded varies from case to case, and depends to some extent on the localizing strength of other data. Most epilepsy surgery candidates can be adequately investigated by scalp interictal and ictal EEG, but complex cases

Table 6.13 The principal clinical applications of long-term electroencephalogram (EEG) monitoring.

Differential diagnosis of paroxysmal neurological attacks
Distinction between nocturnal epilepsy and parasomnias
Diagnosis of psychogenic non-epileptic seizures
Characterization of seizure type and the electro-clinical correlates of epileptic seizures
Quantification of epileptiform discharge and seizure frequency
Evaluation in epilepsy surgery candidates
Identification of sleep-related epileptiform discharge/electrical status in children
Electro-clinical characterization of neonatal seizures
Monitoring of status epilepticus (convulsive, non-convulsive, electrographic)

Table 6.14 Aims of neurophysiological assessement in pre-operative evaluation.

Ensuring seizures are epileptic (a small percentage of patients in surgical programmes have co-morbid psychogenic non-epileptic seizures)
Documentation of electro-clinical seizure features, to show concordance with other data
Demonstration of epileptogenicity in the presumed pathological substrate
Identification of possible other epileptogenic foci
Functional assessment using cortical stimulation when pathology is located in or close to eloquent cortex

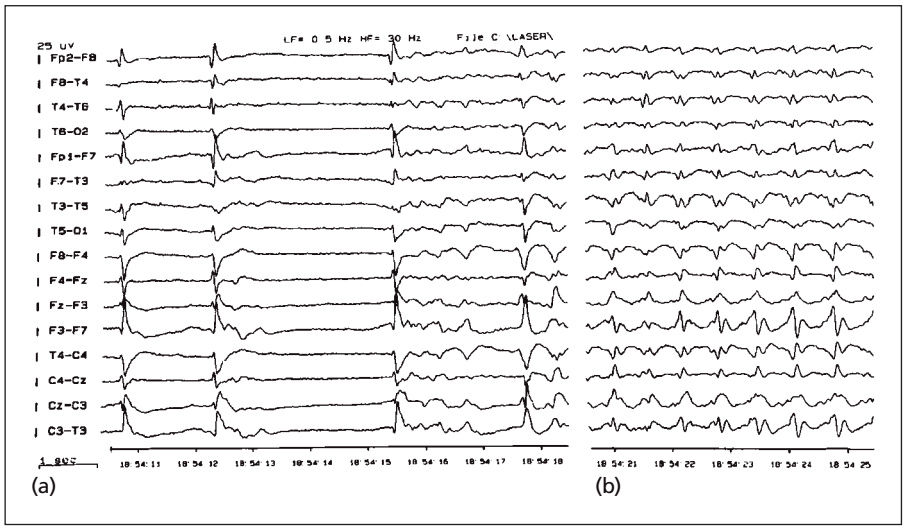

Figure 6.5 Segments from EEG monitoring in convulsive status: (a) burst suppression and some breakthrough discharge; (b) electrographic status.

may need invasive neurophysiological studies. The usual indications for invasive EEG are dual or possible multiple potential epileptogenic pathologies, bilateral hippocampal sclerosis, focal lesions in eloquent cortex, and individuals with negative neuroimaging in whom other investigations have suggested likely location of the epileptogenic region. Invasive EEG uses a range of electrode types (depth, strip, grid) inserted neurosurgically. Electrode choice and placement is determined by where the epileptogenic region is sited: subdural grids are best for coverage of a large area of cortex, depth electrodes are more suited to deeper lying foci. Cortical stimulation can be performed with any of these intracranial electrodes. The main risks of invasive EEG are haemorrhage and infection.

EEG and status epilepticus

EEG is essential for diagnosis and management of status epilepticus in convulsive (Figure 6.5) and non-convulsive forms. As a minimum standard, EEG should be performed within 12–24 hours for admissions with uncontrolled seizures or confusional states, and before transfer to intensive care unit (ICU). EEG monitoring should be available during treatment of refractory status. There are generally no specific EEG markers of the different electro-clinical types of status: all show variations of waxing and waning rhythmic patterns, with or without frank epileptiform discharges.

EEG is used in convulsive status epilepticus to:

1 Confirm status and exclude pseudostatus;

2 Differentiate causes of altered mental status – continuing seizures, drug-induced coma or encephalopathy; and

3 In the refractory stage to monitor and guide treatment, as clinical manifestations of ongoing seizure activity may then be subtle or absent.

The usual end-point of anaesthetic treatment is burst suppression (Figure 6.5), but seizure suppression may be sufficient in patients unable to tolerate higher dose anaesthesia. EEG may also contribute information of prognostic value: continuing electrographic status after the convulsive phase is associated with worse outcome in convulsive status.

Non-convulsive status epilepticus

This incorporates a range of conditions, with variable clinical features and causes. EEG is necessary for diagnosis of non-convulsive status epilepticus (NCSE), especially when the clinical manifestations are subtle. The EEG expression of non-convulsive status depends on cause, and includes any of continuous spike-wave discharge (generalized in absence status epilepticus), discrete localized electrographic seizures, diffuse slow activity with or without spikes, and periodic and/or repetitive epileptiform discharge (ED). Electrographic confirmation of NCSE is often difficult in simple partial status, when the EEG is unchanged or non-specific; in epileptic syndromes, such as Lennox–Gastaut syndrome, where there is overlap of ictal and interictal EEG patterns; and in patients with acute cerebral damage, e.g. caused by infection or trauma, because EEG abnormalities may be directly related to the primary pathology. Preferably, EEG should be recorded during acute administration of intravenous benzodiazepine or other antiepileptic therapy to confirm effective treatment of NCSE.

When should EEG be performed in the intensive care patient?

EEG has three main roles in the ICU patient. First, it can be used to distinguish coma from diminished responsiveness resulting from other causes (psychiatric, sedation, neuromuscular, locked in syndrome); secondly, to detect non-convulsive or clinically subtle seizures (most cases of status on the ITU are non-convulsive or difficult to identify on clinical grounds alone); thirdly, to identify an encephalopathy.

Cognitive deterioration

Acute confusional states or acute and/or subacute cognitive decline in epilepsy may be due to frequent subtle or clinically unrecognized seizures; a marked increase in epileptiform discharge; a metabolic or toxic encephalopathy; or non-convulsive status. EEG can be very helpful in determining the cause in acute confusional states, but is less likely to be useful in chronic cognitive decline other than to confirm an organic brain syndrome.

Imaging in epilepsy

X-ray computed tomography

MRI is generally the imaging modality of first choice for epilepsy. X-ray computed tomography (CT) is useful in acute situations when MRI is not appropriate. CT is also helpful to identify focal cortical calcification and in diagnosing tuberous sclerosis and Sturge–Weber syndrome. CT is not as sensitive and specific as MRI for identifying common epileptogenic abnormalities, such as indolent gliomas, cavernomas, malformations of cortical development (MCD) and lesions in the medial temporal lobe. CT is also helpful where there are contraindications to MRI, such as a cardiac pacemaker or cochlear implants.

Magnetic resonance imaging

Most patients who develop epilepsy or whose chronic epilepsy has not been fully assessed should be investigated with MRI. The ILAE commission suggested the following indications for MRI in the investigation of patients with epilepsy, although these will depend on availability and clinical circumstances:

- Focal onset of seizures;
- Onset of generalized or unclassified seizures in the first year of life, or in adulthood;
- Focal deficit on neurological or neuropsychological examination;
- Difficulty in obtaining seizure control with first-line antiepileptic drugs; or
- Loss of seizure control or change in the seizure pattern.

In patients with newly diagnosed epilepsy, MRI identifies a causal epileptogenic lesion in 12–14%. MRI is not required in patients with a definite electroclinical diagnosis of idiopathic generalized epilepsy, or benign childhood epilepsy with centrotemporal spikes, who go into early remission. In chronic epilepsy, MRI detects lesions in up to 50–70%.

All patients with intractable epilepsy considered for surgery should undergo high-resolution structural MRI as the success of surgery is directly related to the ability to pinpoint the site of seizure onset and underlying structural abnormalities. A structural abnormality does not necessarily indicate the site of seizure origin, and clinical EEG and other data need to be correlated with imaging. Postoperative MRI is useful to identify the extent of a cortical resection or the presence of residual pathology, particularly if seizures continue after surgery.

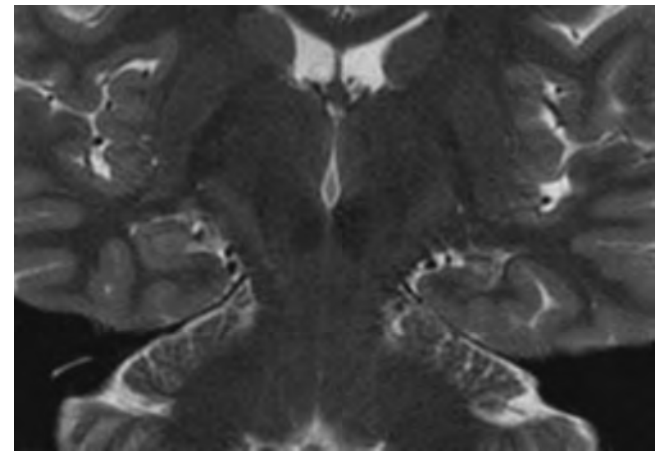

Figure 6.6 Left hippocampal sclerosis. Coronal T2-weighted image showing atrophy and increased T2 signal in the left hippocampus. The right hippocampus is normal.

Hippocampal sclerosis

The hippocampus is best visualized by acquiring thin slices (1–3 mm) orthogonal to its long axis. The primary MRI features of hippocampal sclerosis are hippocampal atrophy, demonstrated with coronal T1-weighted images, and increased signal intensity within the hippocampus on T2-weighted images (Figure 6.6). Additionally, decreased T1-weighted signal intensity and disruption of the internal structure of the hippocampus may be present. Other MRI abnormalities associated with hippocampal damage include atrophy of temporal lobe white matter and cortex, dilatation of the temporal horn and a blurring of the grey–white border in the temporal neocortex. Atrophy of the amygdala and entorhinal cortex variably accompany hippocampal damage but may also occur in patients with TLE and normal hippocampi. FLAIR images provide an increased contrast between grey and white matter, and facilitate differentiation of the amygdala from the hippocampus.

Visual assessment can reliably detect hippocampal volume asymmetry of more than 20%; however, lesser degrees of asymmetry require quantitative volumetric analysis. The use of contiguous thin slices increases the reliability of measurements and permits localization of atrophy along the length of the hippocampus. Hippocampal volumes need to be corrected for intracranial volume to identify symmetrical bilateral atrophy. Patients with unilateral hippocampal volume loss, no other imaging abnormality and concordant clinical and EEG data have more than 70% chance of being seizure free after surgery. Measurement of T2 relaxation time is another objective way to assess hippocampal damage. The advantage of this technique is that hippocampal T2 (HT2) times are absolute values, which can be compared against control data. Increased HT2 reflects gliosis and neuronal loss. HT2 prolongation also correlates with the hippocampal volume loss. Both volumetry and T2 relaxometry techniques can be used to identify subtle amygdala pathology.

Malformations of cortical development

There are many forms of malformations. The MRI features of focal cortical dysplasia (FCD) are focal cortical thickening, simplified gyration, blurring of the cortical–white matter junction, and T2 prolongation in the underlying white matter, which forms a cone tapering towards the lateral ventricle. This is particularly well seen with a thin slice FLAIR acquisition. Complete surgical removal of FCD is accompanied by a 30–50% remission rate, but the epileptogenic zone may be more extensive than the abnormality visible on MRI. The abnormalities may be subtle and only be evident if optimal MRI techniques are used. Polymicrogyria with an excessive number of small and prominent convolutions is a frequently identified MCD that develops secondary to abnormal late migration. Several syndromes of region-specific symmetric polymicrogyria have been reported, and some have been linked to specific genetic loci. Schizencephalia (cleft brain) is often found in MRI in conjuction with polymicrogyria. Periventricular heterotopia has a characteristic MRI appearance (Figure 6.7).

Primary brain tumour

Patients with low-grade primary brain tumours frequently have intractable focal seizures as a presenting symptom. Underlying histopathologies include dysembryoplastic neuro-epithelial tumours, ganglioglioma, gangliocytoma, and pilocytic and fibrillary astrocytoma. Most lesions have low signal on T1- and high signal on T2-weighted images, and are not usually associated with vasogenic oedema. Complete resection of the neoplasm and overlying cortex results in successful control of seizures in most cases.

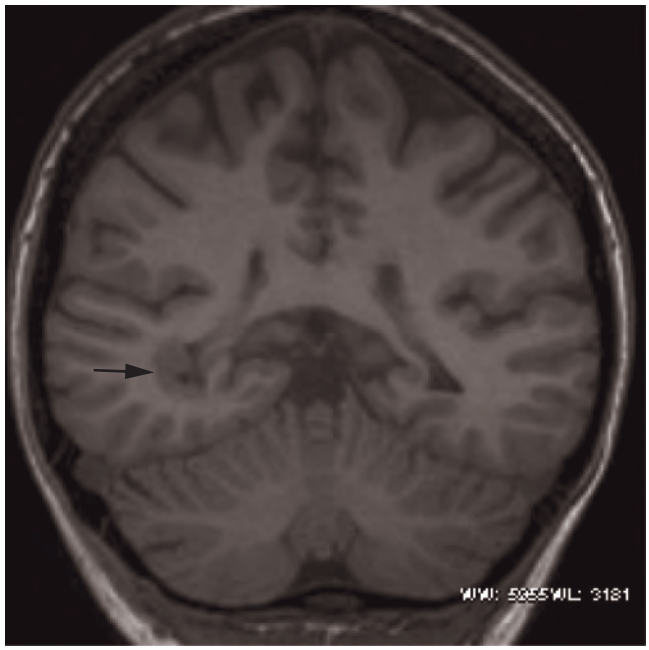

Figure 6.7 Subependymal heterotopia on the right (arrow) in coronal IR_{prep} T1-weighted image. Nodules of grey matter density are shown in the wall of the lateral ventricle.

Dysembryoplastic neuro-epithelial tumours are benign developmental tumours with features of a focal circumscribed cortical mass which may indent the overlying skull. Cyst formation and contrast enhancement may occur. Some cases calcify and may be more readily demonstrated with X-ray CT. Confident differentiation from low-grade astrocytomas and gangliogliomas is not possible by MRI.

Vascular malformation

Cavernous haemangiomas (cavernomas) are relatively common lesions which are important to identify as they are often surgically resectable. Most cavernous haemangiomas are not visible on CT but are identified on MRI scanning. The lesions are circumscribed and have the characteristic appearance of a range of blood products on MRI (Figure 6.8). The central part contains areas of high signal on T1- and T2-weighted images, reflecting oxidized haemoglobin, with darker areas on T1-weighted images as a result of deoxyhaemoglobin. The ring of surrounding haemosiderin appears dark on a T2-weighted image. Up to 50% of cavernous malformations are multiple, and may occur on a familial basis. AVMs with high blood flow have a different and distinctive appearance with a nidus, feeding arteries and draining veins.

Acquired damage

Focal or diffuse cortical damage can develop as a consequence of trauma, infarction or infection of the CNS. Cerebrovascular disease associated with epilepsy is particularly common in older age groups. Worldwide, neurocysticercosis and tuberculomas are the most common causes of intractable focal epilepsy. These lesions have typical appearances on MRI which evolve with time and which, unless calcified, may resolve.

Functional magnetic resonance imaging

Functional MRI (fMRI) can visualize regional brain activity. The areas detected with changes in blood oxygenation level-dependent (BOLD) contrast that occur during cognitive, sensory and other tasks, and allow the mapping of networks involved in the performance of these tasks. The most important clinical application of fMRI is in the localization and lateralization of cognitive functions of epilepsy patients evaluated for surgery in order to minimize the risk of causing a fixed deficit. However, the studies require patient cooperation, both in performing tasks and limiting motion. For pre-operative fMRI, it is important to choose activation procedures that are appropriate tests of function in the area of brain to be resected.

Magnetic resonance spectroscopy

Magnetic resonance spectroscopy (MRS) provides measurements of specific brain metabolites. Metabolites that are detectable with ^{1}H MRS include *N*-acetylaspartate (NAA), choline (Cho), creatine (Cr), lactate, γ-aminobutyric acid (GABA) and glutamate. There is evidence that NAA is located primarily within neurones and precursor cells. Creatine and choline are found in both neurones and glia. Accurate definition of brain anatomy and the

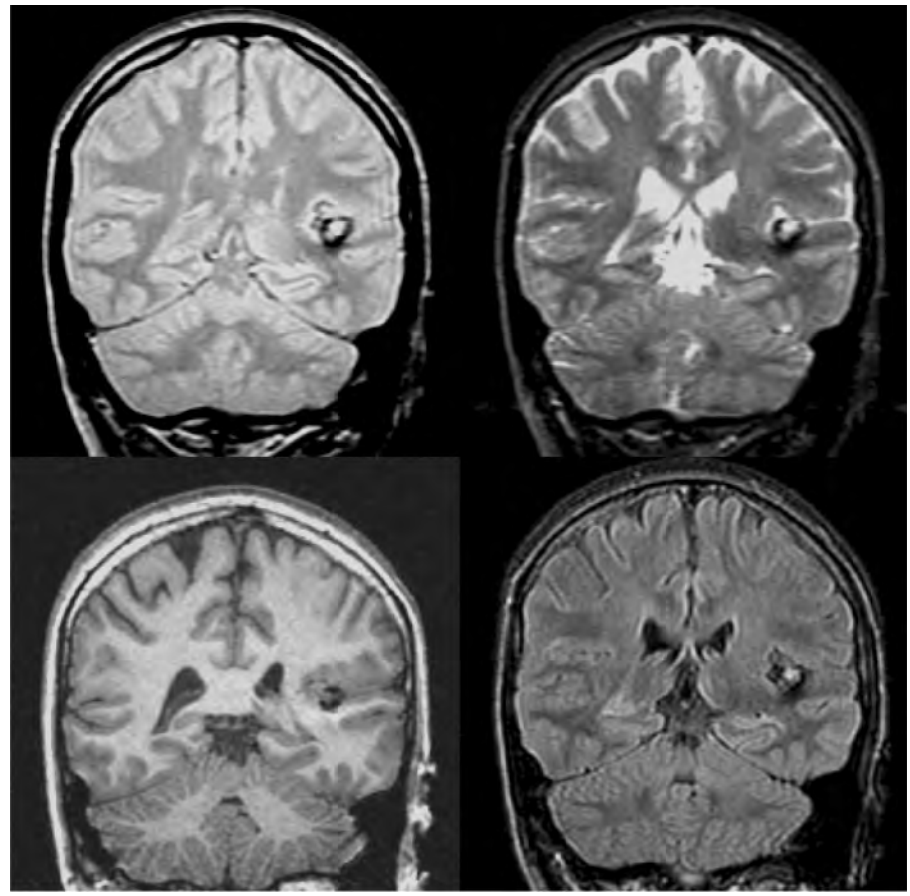

Figure 6.8 Cavernoma on the left (coronal 3.0 T MRI). Proton density (top L), T2-weighted (top R), IR_{prep} T1-weighted (low L), FLAIR (low R). The acquisitions demonstrate heterogeneous hyperintense signal caused by blood products in different stages of evolution, surrounded by a rim of low signal intensity from haemosiderin.

identification of structural abnormalities with MRI are necessary for the interpretation of MRS.

Single-photon emission computed tomography

Single-photon emission computed tomography (SPECT) allows measurements of regional cerebral blood flow changes in the areas affected by epileptic activity. Radioligands principally used in SPECT studies are ^{99m}Tc-hexamethyl-propylenamine oxime (^{99m}Tc-HMPAO) and technetium-^{99m}Tc-cysteinate dimer (ECD, bicisate). Currently available stabilized forms of ^{99m}Tc-HMPAO and ECD are stable i*n vitro* for several hours, whereas unstabilized ^{99m}Tc-HMPAO needs to reconstructed immediately before intravenous injection. Seventy-five per cent of ^{99m}Tc-HMPAO is extracted across the blood–brain barrier, reaching peak concentrations within 1 minute after injection. The images can then be acquired up to 6 hours after tracer injection. Both ictal and postictal SPECT studies should be performed during simultaneous video-EEG monitoring to determine the relationship between seizure onset and tracer injection. Interictal SPECT images serve as a reference baseline study for the interpretation of ictal images.

Ictal ^{99m}Tc-HMPAO SPECT is highly sensitive and specific in localizing seizure onset in intractable TLE. Correct localization of complex partial seizures may be achieved in over 90% of TLE patients. The use of subtraction ictal SPECT co-registered to MRI (SISCOM) improves the rate of localization. A characteristic pattern in temporal lobe seizures is an initial hyperperfusion of the temporal lobe, followed by medial temporal hyperperfusion and lateral temporal hypoperfusion. Postictal and interictal SPECT injections are easier to perform than ictal injections, but the images are more difficult to interpret and have lower sensitivity and specificity and are not clinically as useful as a stand-alone test.

Extratemporal seizures are often brief and it is therefore difficult to obtain an ictal recording. Accurate localization of an extratemporal seizure focus may be possible in 90% of the cases using the SISCOM technique. Ictal SPECT demonstrates ipsilateral frontal hyperperfusion in frontal lobe epilepsy. Activations may also be detected in the ipsilateral basal ganglia and contralateral cerebellum. The method provides additional information in patients with unrevealing EEG and MRI results, and can also be used to study the blood flow changes underlying specific clinical features observed in extratemporal seizures. Postictal and interictal SPECT is of very limited localizing value in extratemporal epilepsy.

Ictal SPECT provides a complementary method for localizing seizure foci in patients with intractable focal epilepsy evaluated

for surgical treatment. The investigation may be particularly valuable in patients with normal MRI and presumed extratemporal seizures in order to generate a hypothesis that may then be tested with intracranial EEG recordings.

Positron emission tomography

^{18}*F-deoxyglucose*

Positron emission tomography (PET) maps cerebral glucose metabolism using ^{18}F-deoxyglucose (^{18}FDG). Interictally, PET shows areas of reduced glucose metabolism that usually include the seizure focus but are more extensive. Regional hypometabolism is best analysed with co-registration of PET scans to MRI. Voxel-based statisitical parametric mapping (SPM) has been shown to be useful in clinical evaluation of the data, and quantitative analysis with correction for partial volume effects further improves the accuracy of the method. The spatial resolution of quantitative ^{18}FDG-PET is superior to SPECT. Ictal ^{18}FDG-PET scans are difficult to obtain because cerebral uptake of ^{18}FDG occurs over 40 minutes after injection.

^{18}FDG-PET detects interictal glucose hypometabolism ipsilateral to the seizure focus in 60–90% of TLE patients. Unilateral, or asymmetric bilateral diffuse regional hypometabolism usually extends medially and laterally in the temporal lobe. ^{18}FDG-PET has some additional sensitivity over optimal volumetric MRI but does not provide clinically useful information if hippocampal atrophy is present. ^{18}FDG-PET is more useful lateralizing than localizing the epileptic focus. Unilateral focal temporal hypometabolism in ^{18}FDG-PET predicts a good outcome of surgery for TLE. Absence of unilateral hypometabolism, however, does not preclude a favourable outcome. Symmetric bilateral temporal hypometabolism is associated with higher incidence of postoperative seizures as are areas of severe extratemporal cortical, or thalamic hypometabolism.

^{18}FDG-PET has lower sensitivity for lateralization of epileptic foci in extratemporal epilepsies than in TLE. The areas of decreased glucose metabolism are also less frequently well-localized. Sixty per cent of the patients with frontal lobe epilepsy show regional hypometabolism in ^{18}FDG-PET, and a relevant underlying structural pathology is found on MRI in 90% of them. The area of hypometabolism may be either diffuse or widespread, or restricted to the co-localizing MRI lesion. In the majority of patients with frontal lobe epilepsy, however, ^{18}FDG-PET does not appear to provide additional clinically useful information.

In summary, the place of interictal ^{18}FDG-PET is in determining the lateralization of epileptic focus, especially in the presurgical assessment of patients where there is not good concordance between MRI, EEG, and other data, in order to generate a hypothesis to be tested with intracranial EEG recordings.

Medical treatment

Principles of treatment of newly diagnosed patients

The decision to initiate drug therapy has important implications for every person with epilepsy. In addition to its biological effects, therapy confers illness status, confirms the state of 'being epileptic', can affect self-esteem, social relationships, education and employment. The decision to treat depends essentially on a balance between the benefits and the drawbacks of therapy, and should be tailored to requirements of the individual patient. The benefits of therapy include the lower risk of recurrence of seizures, and thus of potential injury and even death, the psychological and social benefits of more security from seizures. The drawbacks of therapy include the potential drug side effects, the psychological and social effects, the cost and inconvenience. Chronic, long-term or subtle side effects are not easily detected, and weigh heavily on the decision to treat. One example is the potential adverse effect on learning in children, and partly because of this paediatricians initiate therapy less early than adult neurologists. The following factors influence the decision.

Diagnosis

It is essential to establish a firm diagnosis of epilepsy before therapy is started. This is not always easy, particularly in the early stages of epilepsy. There is almost no place at all for a 'trial of treatment' to clarify the diagnosis; it seldom does. A good first-hand witnessed account is essential, as diagnostic tests are often non-confirmatory. In practice, the misdiagnosis rate is quite high. For example, about 20% of all patients referred to a tertiary level epilepsy service have psychogenic attacks.

Risk of recurrence of seizure

The estimation of risk of seizure recurrence is obviously a key factor in deciding whether or not to initiate therapy. It is now generally accepted that about 50–80% of all patients who have a first unprovoked non-febrile seizure will have further attacks. The risk of recurrence is high initially and then falls over time. In a national UK study, the risk of a recurrence after the first seizure was 44% in the initial 6 months, 32% in the next 6 months and 17% in the second year. It follows also that the greater the elapsed time since the first attack, the less likely is subsequent recurrence (Figure 6.9). In many cases, by the time of presentation, seizures will have already recurred. In a hospital-based study from the UK, the median number of tonic–clonic seizures occurring before the diagnosis was made was 4 (range 1–36) and the median number of partial seizures was 6 (range 1–180).

If more than one spontaneous seizure has occurred, the risk of further attacks in the future without treatment is, in most clinical circumstances, over 80%, and generally speaking the more seizures that have occurred prior to therapy, the greater the risk of further attacks. The risk of recurrence is influenced by a number of factors:

• *Aetiology* The risk is greater in those with structural cerebral disease, and least in acute symptomatic seizures provoked by metabolic or drug and/or toxin exposure. The risk of recurrence of 'idiopathic' or 'cryptogenic' seizures is approximately 50%, and lower after actue symptomatic (provoked) seizures providing the provoking factor is removed.

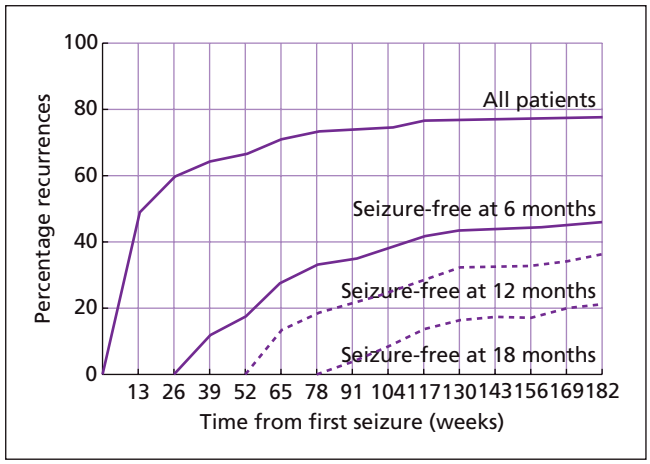

Figure 6.9 Actuarial percentage risk of recurrence after a first seizure (from the National General Practice Study of Epilepsy [NGPSE]). The lines show the risk of recurrence in all patients ($n = 564$) at the time of the first seizure, and then the subsequent risks for patients still seizure-free at 6, 12 and 18 months after the first seizure.

Table 6.15 Principles of antiepileptic drug treatment in patients with newly diagnosed epilepsy.

Aim for complete control without adverse-effects
Diagnosis of epileptic seizures should be unequivocal
Seizure type, syndrome and aetiology should be established
Baseline haematological and biochemical investigations should be performed prior to drug initiation
Use one drug at a time (monotherapy), at least initially
Initial titration should be to low maintenance doses
Further upward titration will depend on response and side-effects
If first drug fails, alternative monotherapies should be tried
Upward and downward titration should be in slow, stepped doses
Polytherapy should be used only if monotherapy will at least three first choice drugs has failed to control seizures
Patients should be fully counselled about goals, role, risk, outcome and logistics of drug treatment

• *EEG* Evidence in this area is contradictory. While there is consensus that the risk of recurrence is high if the first EEG shows spike and wave discharges, the predictive value of a normal EEG or an EEG with other types of abnormality after a single seizure – and if there is any predictive value – is slight.
• *Age* The risk of recurrence is somewhat greater in those under the age of 16 or over the age of 60 years, probably because of the confounding effect of aetiology.
• *Seizure type and syndrome* Partial seizures are more likely to recur than generalized seizures, again because of the confounding effect of aetiology. Children with most of the benign epilepsy syndromes (e.g. BECTS) have a few seizures only. In the other more severe childhood epilepsy syndromes, recurrent seizures are almost inevitable.

Type, timing and frequency of seizure

Some types of epileptic seizure often have a minimal impact on the quality of life; e.g. simple partial seizures, absence or sleep attacks. The benefits of treating such seizures, even if happening frequently, can be outweighed by the disadvantages. If the baseline seizure frequency is very low, the disadvantages of treatment can be unacceptably high. It would be unusual to treat a person having less than one seizure a year, especially if this was confined to sleep, or a minor or partial seizure.

A protocol for initial treatment

A protocol for the initial treatment in newly diagnosed patients is as follows (summarized in Table 6.15). Details of the available antiepileptic drugs are summarized in Tables 6.16–6.20:

1 Establish diagnosis. There is little place for a 'trial of treatment'. Investigation will usually involve EEG and neuroimaging, and other investigations as necessary. Neuro-imaging should be with MRI scanning in all patients with partial-onset epilepsy or epilepsy developing after the age of 15 without good explanation. The MRI must be of high quality, with T1-, T2-weighted and FLAIR sequences. Volumetric scanning is useful as this allows reformatting and quantitation.

2 Identify and counsel about precipitating factors – if these can be avoided, this occasionally obviates the need for drug therapy.

3 Decide upon the need for antiepileptic drug therapy. If therapy is needed, baseline biochemical and haematological parameters should be measured.

4 Advise about the goals, likely outcome, risks and logistics of therapy. Patients should be given clear instructions to seek immediate medical attention if signs of hypersensitivity or idiosyncratic drug reactions develop.

5 Start monotherapy with the chosen first-choice drug, initially at low doses, and titrating up slowly to a low maintenance dose. Emergency drug loading is seldom necessary except where status epilepticus threatens.

6 If seizures continue, titrate the dose upwards to higher maintenance dose levels (guided, where appropriate, by serum level monitoring). In about 60–70% of patients, these simple steps for initial therapy will result in complete seizure control.

7 In remaining patients, alternative monotherapy should be tried with another appropriate first-choice antiepileptic drug. The second drug should be introduced incrementally at suitable dose intervals, and the first drug then withdrawn in slow decremental steps. The second drug should be titrated first to low maintenance doses. Then, if seizures continue, the dose should be increased incrementally to maximal doses.

8 If the steps in (7) fail, a third alternative monotherapy should be tried in the same manner. If seizures continue, or recur after initial therapy with 1–3 drugs tried in monotherapy as above:

9 The diagnosis should be reassessed in patients with continuing attacks. It is not uncommon in this situation to find that the attacks do not have an epileptic basis. Investigation should be

Table 6.16 The range of antiepileptic drugs in current use.

Drug (year of introduction)	Putative mode(s) of action	Route(s) of elimination and metabolites	Main indication	Usual daily maintenance dose in adolescent and adults (mg)	Major safety issues or concerns
Acetazolamide (1952)	Carbonic, anhydrase inhibition	Renally excreted	Last resort broad spectrum drug	500–1000	Idiosyncratic rash; rarely Stevens–Johnson syndrome and toxic epidermal necrolysis; aplastic anaemia
Carbamazepine (1963)	Sodium channel inhibition	Hepatic metabolism; active metabolite	First line drug for partial and tonic-clonic seizures	400–1800	Idiosyncratic skin reactions; rarely, Stevens–Johnson syndrome; aplastic anaemia, hepatotoxicity
Clobazam (1986)	GABA augmentation	Hepatic metabolism; active metabolite	Broad spectrum adjuvant drug	10–30	Rarely, idiosyncratic rash
Clonazepam (1975)	GABA augmentation	Hepatic metabolism	Broad spectrum adjuvant drug	1–6	Rarely, idiosyncratic rash, thrombocytopenia
Diazepam (1965)	GABA augmentation	Hepatic metabolism; active metabolite	Emergency or rescue use only	N/A	Respiratory depression
Ethosuximide (1953)	Calcium channel modification	Hepatic metabolism; 25% excreted unchanged	Generalized absences only	500–1500	Rarely, idiosyncratic skin rash, Stevens–Johnson syndrome, aplastic anaemia
Felbamate (1993)	Glutamate reduction	Hepatic metabolism; active metabolites	Last resort broad spectrum drug	1800–3600	Hepatic failure, aplastic anaemia
Gabapentin (1993)	Calcium channel modulation	Not metabolized, urinary excretion unchanged	Second line drug in partial seizures	1800–3600	Paradoxical increase in seizures
Lamotrigine (1991)	Sodium channel inhibition; glutamate reduction	Hepatic metabolism by glucuronidation	Broad spectrum first line drug	100–400	Idiosyncratic skin rashes; rarely, Stevens–Johnson syndrome, toxic epidermal necrolysis, liver failure, aplastic anaemia, multi-organ failure
Levetiracetam (1999)	Synaptic vesicle protein modulation	Non-hepatic metabolism; renal excretion	Broad spectrum first line drug	750–4000	Behavioural problems
Lorazepam (1972)	GABA augmentation	Hepatic metabolism	Emergency or rescue use only	N/A	Respiratory depression
Phenobarbital (1912)	GABA augmentation	Hepatic metabolism; 25% excreted unchanged	Broad spectrum drug currently used as second line drug	30–180	Idiosyncratic rash; rarely, toxic epidermal necrolysis; hepatotoxicity; osteomalacia; Dupuytren contracture
Phenytoin (1938)	Sodium channel inhibition	Saturable hepatic metabolism	Of use in partial epilepsy	200–400	Idiosyncratic rash; rarely: peripheral neuropathy; Stevens–Johnson syndrome; Dupuytren contracture; hepatotoxicity; osteomalacia
Pregabalin (2004)	Calcium channel modulation	Not metabolized, excreted unchanged	Second line drug for partial seizures	100–600	Weight gain; rarely, increased seizures
Primidone (1952)	GABA augmentation	Hepatic metabolism	As for phenobarbital	500–1500	Idiosyncratic rash; rarely, agranulocytosis; thrombocytopenia; lupus-like syndrome
Oxcarbazepine (1990)	Sodium channel inhibition	Hepatic metabolism	First line drug for partial seizures	900–2400	Idiosyncratic rash; hyponatraemia
Tiagabine (1996)	GABA augmentation	Hepatic metabolism	Second line drug for partial seizures	30–45	Increased seizures; non-convulsive status
Topiramate (1995)	Glutamate reduction; sodium channel modulation; calcium channel modification	Mostly hepatic metabolism, with renal excretion	First line broad spectrum drug	75–400	Weight loss; kidney stones; impaired cognition
Valproate (1968)	GABA augmentation	Hepatic metabolism; active metabolites	First line drug for all generalized seizures and useful in partial seizures	400–2000	Teratogenicity; rarely, acute pancreatitis; hepatotoxicity; thrombocytopenia; encephalopathy; polycystic ovarian syndrome
Vigabatrin (1989)	GABA augmentation	Not metabolized 85% excreted unchanged	Very restricted use	1000–2000	Visual field defects, increased seizures
Zonisamide (1990)	Calcium channel inhibition	Hepatic metabolism; renal excretion	Second line drug for partial and generalized seizures	200–600	Skin rash; rarely, blood dyscrasias

Table 6.17 Drug options by epilepsy syndrome seen in adult practice (modified from NICE).

Epilepsy syndrome	First line drugs	Second line drugs	Other drugs	Drugs to be avoided (may worsen seizures)
Juvenile absence epilepsy	Lamotrigine Sodium valproate Ethosuximide	Levetiracetam Topiramate	Clonazepam Clobazam	Carbamazepine Phenytoin Oxcarbazepine Tiagabine Vigabatrin
Juvenile myoclonic epilepsy	Lamotrigine Sodium valproate Levetiracetam Topiramate	Clobazam Clonazepam	Acetazolamide	Carbamazepine Gabapentin Oxcarbazepine Phenytoin Pregabalin Tiagabine Vigabatrin
Generalized tonic–clonic seizures only	Carbamazepine Lamotrigine Sodium valproate Levetiracetam Topiramate	Clobazam Clonazepam Oxcarbazepine Zonisamide	Acetazolamide Phenobarbital Phenytoin Primidone	Tiagabine Vigabatrin
Focal epilepsies: cryptogenic, symptomatic	Carbamazepine Lamotrigine Oxcarbazepine Levetiracetam Sodium valproate Topiramate	Clobazam Gabapentin Levetiracetam Phenytoin Pregabalin Tiagabine Topiramate Zonisamide	Acetazolamide Clonazepam Gabapentin Phenobarbital Primidone	
Benign epilepsy with centrotemporal spikes	Carbamazepine Lamotrigine Oxcarbazepine Sodium valproate			
Benign epilepsy with occipital paroxysms	Carbamazepine Lamotrigine Oxcarbazepine Sodium valproate	Levetiracetam Topiramate		

Table 6.18 Drug options by seizure type (modified from NICE).

Seizure type	First line drugs	Second line drugs	Other drugs that may be considered	Drugs to be avoided (may worsen seizures)
Generalized tonic–clonic	Carbamazepine Lamotrigine Levetiracetam Oxcarbazepine Sodium valproate Topiramate	Clobazam Clonazepam	Acetazolamide Phenobarbital Phenytoin	Tiagabine Vigabatrin
Absence	Ethosuximide Lamotrigine Sodium valproate	Clobazam Clonazepam Topiramate	Phenobarbital	Carbamazepine Gabapentin Oxcarbazepine Pregabalin Tiagabine Vigabatrin

1 Value for active metabolite.
2 Phenytoin has non-linear kinetics, and so half-life can increase at higher doses.
3 Absorption of tiagabine is markedly slowed by food, and it is recommended that the drug is taken at the end of meals.
4 The time to peak concentration varies according to formulation (0.5–2 hours for normal formulation, 3–8 hours for enteric coated).
5 Half-life varies with co-medication.
6 Absorption of gabapentin is by a saturable active transport system, and rate will depend on capacity of the system.
* Minor interactions common, but not usually of much clinical relevance.
** Many interactions, frequently of clinical relevance and many require dose modification.
† Half-life in healthy adult.

considered to exclude the possibility of a progressive lesion. The possibility of poor compliance should be explored.

10 Alternative monotherapies or polytherapy should be considered.

11 The patient should be referred for specialist advice.

Treatment protocol for patients with chronic epilepsy

When first seeing a patient with chronic uncontrolled epilepsy, a two-stage procedure should be adopted. First, an assessment of diagnosis and previous treatment history should be made. As a second step, a treatment plan should be devised (Table 6.21).

Assessment

The steps in the assessment are summarized in Table 6.21. The review of previous treatment history is an absolutely essential step, often omitted. The response to a drug is generally speaking relatively consistent over time. Find out which drugs have been previously tried, what was the response (effectiveness, side effects), what was the maximum dose and why the drug was withdrawn.

Treatment plan

A treatment plan (schedule) should be formed on the basis of this assessment. The plan should take the form of a stepwise series of treatment trials, each to be tried in turn (if the previous trial fails to meet the targeted level of seizure control). The treatment plan is ideally devised to trial each available antiepileptic in turn, in a reasonable dosage, singly or as two-drug therapy (or, more rarely, three-drug combinations). This will involve deciding which drugs to introduce, which drugs to withdraw and which drugs to retain. Decisions will also be needed about the duration of each treatment trial. There is often nihilistic inertia in much of the treatment of chronic epilepsy which should be resisted, and an active and logical approach to therapy can prove very successful.

Choice of drug to introduce or retain

Generally, these should be drugs that are appropriate for the seizure type and that have either not been previously used in optimal doses or that have been used and did prove helpful (Tables 6.16–6.20). Rational choices depend on a well-documented history of previous drug therapy. Other factors are also important – and therapy where possible should be tailored to individual requirements; such factors include co-morbidities, co-medication, obesity, gender, lifestyle, age and renal or hepatic disease.

Choice of drug to withdraw

These should be drugs that have been given an adequate trial at optimal doses and that were either ineffective or caused unacceptable side effects. There is obviously little point in continuing a drug that has had little effect, yet it is remarkable how often this is done.

Duration of treatment trial

This will depend on the baseline seizure rate. The trial should be long enough to have differentiated the effect of therapy from that of chance fluctuations in seizures.

Trial of therapy

It is usual to maintain aim for therapy with either one or two suitable antiepileptic drugs. If drugs are being withdrawn, it is wise to maintain one drug as an 'anchor' to cover the withdrawal period.

Drug withdrawal

Drug withdrawal needs care. The withdrawal, or sudden reduction in dose, of antiepileptics can result in a severe worsening of seizures or in status epilepticus – even if the withdrawn drug was apparently not contributing much to seizure control. Only one drug should be withdrawn at a time. If the withdrawal period is likely to be difficult, the dangers can be reduced by covering the withdrawal with a benzodiazepine drug (usually clobazam 10 mg/day), given during the phase of active withdrawal.

Drug addition

New drugs added to a regimen should also be introduced slowly, at least in the routine clinical situation. This results in better tolerability, and too fast an introduction of these drugs will almost invariably result in side effects. It is usual to aim initially for a low maintenance dose, but in severe epilepsy higher doses are often required.

Limits of therapy

Drug therapy will fail in about 10–20% of patients developing epilepsy. In this situation, the epilepsy can be categorized as 'intractable' and the goal of therapy changes to defining the best compromise between inadequate seizure control and drug-induced side effects. Individual patients will take very different views about where to strike this balance. Intractability is inevitably

Table 6.21 Principles of antiepileptic drug treatment in patients with chronic epilepsy.

Assessment
Review diagnosis and aetiology (history, EEG, imaging)
Classify seizures and syndrome
Review adherence to prescription
Review drug history:
Which drugs were useful in the past
Which drugs were not useful in the past
Which drugs have not been used in the past
(also dosage, length of therapy, reasons for discontinuation)
Review precipitants and non-pharmacological factors
Treatment plan
Document proposed sequence of drug 'trials'
Decide what background medication to continue
Decide upon the sequence of drug additions and withdrawals
Decide the duration of drug 'trials'
Decide when to do serum level monitoring
Consider surgical therapy
Consider non-pharmacological measures (e.g. lifestyle, alternative therapy)
Recognize the limitations of therapy
Provide information on above to patients

an arbitrary decision. There are over 10 first line antiepileptic drugs, and far more combinations (with 10 first line antiepileptic drugs there are 45 different two-drug and 36 different three-drug combinations). All combinations cannot therefore be tried.

Monotherapy versus combination therapy

Single-drug therapy will provide optimal seizure control in about 70% of all patients with epilepsy, and should be chosen whenever possible. The advantages of monotherapy are:

- Better tolerability and fewer side effects;
- Simpler and less intrusive regimens;
- Better compliance; and
- No potential for pharmacokinetic or pharmacodynamic interactions with other antiepileptic drugs.

Combination therapy is needed in about 20% of all those developing epilepsy, and in a higher proportion of those with epilepsy that has remained uncontrolled in spite of initial monotherapy (chronic active epilepsy). The prognosis for seizure control in these patients, even on combination therapy, is far less good. Nevertheless, skilful combination therapy can make a substantial difference by optimizing control of the epilepsy and minimizing the side effects of treatment. The choice of drugs in combination has not been satisfactorily studied. It has been proposed, but without any substantial supporting evidence, that mixing drugs with differing modes of action has a synergistic effect. Patients need to be advised carefully about the implications of polytherapy in terms of drug interactions, teratogenesis and potential pharmacodynamic effects.

Role of antiepileptic drug level measurements

The measurement of drug levels of some antiepileptic drugs is helpful for a number of reasons – and in chronic refractory patients these include assessing optimal doses, assessing toxicity and side effects, assessing interactions with other drugs and compliance. The levels of phenytoin should be regularly measured due to the non-linear kinetics of this drug.

Patient information

All treatment is a balance between benefits (seizure control) and risk (e.g. side effects) and it is important to tell patients of the risks of therapy so that an informed decision can be made. Written information is generally better than simple verbal instruction. Consent to therapy must be informed and patients should be given enough time to discuss and explore the various treatment options.

Treatment of patients with epilepsy in remission

Epilepsy can be said to be in remission when seizures have not occurred over long time periods (conventionally 2 or 5 years). Some 70–80% of patients will be in remission at some point after the initiation of therapy. Many cases of untreated epilepsy also remit and in the long-term at least 50% of patients are in remission and off medication. The clinical management of ongoing therapy in patients in remission is usefully straightforward. Drug doses should be minimized, and it is usually possible to avoid major adverse effects. In most cases, little medical input is required with appropriate care provided at primary care level and annual visits to the specialist. The seizure type, epilepsy syndrome, aetiology, investigations and previous treatment should be recorded. Routine haematological or biochemical checks are recommended on an annual basis in an asymptomatic individual. Enquiry should be made of long-term side-effects (e.g. bone disease in post-menopausal women) and counselling about issues such as pregnancy made where appropriate. At some point, the calm of this ideal situation is likely to be disturbed by the question of discontinuation of therapy.

Table 6.22 Some factors that increase the risk of seizure recurrence after withdrawal of therapy in patients with epilepsy in remission.

Short duration of seizure freedom prior to drug withdrawal
Age above 16 years
History of myoclonic seizures or secondarily generalized seizures
History of multiple seizure types
Certain epilepsy syndromes (e.g. juvenile myoclonic epilepsy, childhood encephalopathies)
Symptomatic epilepsy
Prolonged period of active epilepsy before achieving seizure control
History of seizures after treatment was initiated
Seizure control requiring multiple drug therapy
EEG showing generalized spike-wave discharges
Presence of learning disability or associated neurological handicaps

Discontinuation of drug therapy

It is often difficult to decide when (if ever) to discontinue drug treatment. The decision should be made by a specialist who is able to provide an estimate of the risk of reactivation of the epilepsy. This risk is influenced by the factors listed in Table 6.22; but it must be stressed that withdrawal is never entirely risk free. The decision whether or not to withdraw therapy will depend on the level of risk the patient is prepared to accept.

Probability of remaining seizure free after drug withdrawal

The best information comes from the Medical Research Council (MRC) antiepileptic drug withdrawal study, which included 1013 patients who had been seizure free for 2 years or more (Figure 6.10). Within 2 years of starting drug withdrawal 59% remained seizure free (compared to 79% of those who opted to stay on therapy). Other studies have had essentially similar findings.

Seizure-free period

The longer the patient is seizure free, the less is the chance of relapse. The overall risk of relapse after drug withdrawal, for instance, after a 5-year seizure-free period of is under 10%.

Duration of active epilepsy

This is probably an under-studied factor. One has a strong impression that the shorter the history of active seizures (i.e. the duration of time from the onset of epilepsy to the onset of remission), the less is the risk of relapse.

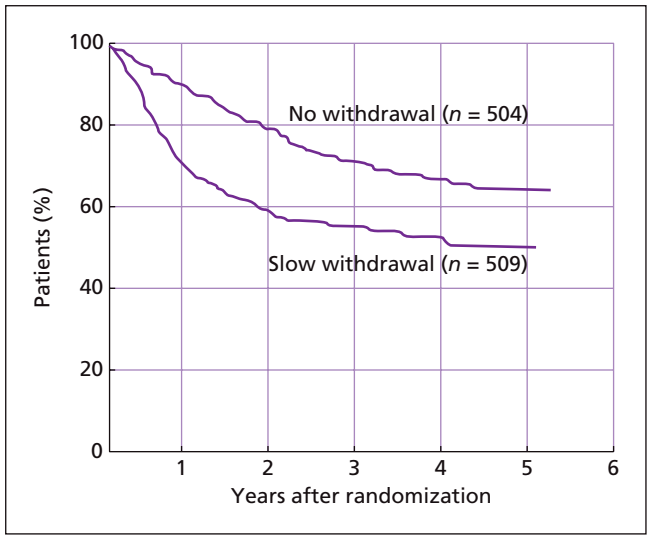

Figure 6.10 Medical Research Council (MRC) drug withdrawal study. Actuarial percentage of patients seizure-free amongst those randomized to continuing or to slow withdrawal of antiepileptic drugs. A study of 1013 patients who were seizure-free for 2 years or more. Two years after randomization, 78% of those who continued treatment and 59% of those who withdrew antiepileptic drugs were seizure-free.

Type and severity of epilepsy

The type of epilepsy and its aetiology are important influences on prognosis. The presence of symptomatic epilepsy, secondarily generalized or myoclonic seizures, neurological deficit or learning disability greatly lessen the chance of remission, and also increase the chances of recurrence should remission occur. The higher the number of seizures prior to remission, the greater the number of drugs being taken to control the seizures and the presence of two or more seizure types (a surrogate for severity of epilepsy) all increase the risk of relapse.

EEG

The persistence of spike-wave in those with IGE is the most useful prognostic EEG feature, indicating a higher chance of relapse. Other EEG abnormalities have no great prognostic utility, and the presence of focal spikes or changes to EEG background in adults are of little help in estimating the chances of remission or relapse after drug withdrawal.

Age

There is no clear overall relationship between age and the risk of relapse, although there are age-specific syndromes that have specific prognostic patterns. There is a low chance of relapse in the benign epilepsies of childhood or in generalized absence epilepsy. These data simply emphasize the obvious point that the over-riding determinant of prognosis is the type and aetiology of epilepsy.

How to withdraw therapy – the importance of slow reduction

When a decision to withdraw therapy is made, the drugs should be discontinued slowly one at a time. Fifty per cent of patients who are going to experience seizure recurrence on withdrawal do so during the reduction phase, and 25% in the first 6 months after withdrawal; this should be explained carefully to the patient, and driving restrictions should be applied during the withdrawal period and the subsequent 6 months.

The fastest recommended rates of withdrawal are given in Table 6.19, although in many instances there is no need to proceed so rapidly. In general terms, the slower the withdrawal, the less likely are seizures to recur. If seizures do recur, the drug should be immediately restarted at the dosage that controlled the attacks. About 10% of patients will not regain full remission even if the drug is replaced at the dosage that previously resulted in long remission. Why this should be the case is unclear, but in some patients at least, it seems that recurrence alters subsequent seizure risk.

Management of epilepsy in learning disability

Definition

Learning disability is a descriptive diagnosis or concept, not a disease or illness. Learning disability is defined as a composite of:

1 Deficiency in learning with an IQ of less than 70 (i.e. 2 standard deviation below the mean);

2 Difficulties with daily living skills; and

3 An onset within the developmental period (less than 18 years of age).

It does not infer a particular aetiology. Social functioning is an integral part of the diagnosis. It is different from mental illness; a person with learning disability can also develop mental illness. As a concept, it is also different from learning difficulties, which generally refers to specific learning problems (e.g. dyslexia), rather than a global impairment or intellect and function, although some ambiguity does exist in the use of the terms.

Prevalence of epilepsy in people with learning disability

People with learning disabilities are 30 times more likely to experience seizures than the general population. In most cases, both the cognitive difficulties and the seizures represent overt symptoms of the underlying pathology. The risk of epilepsy increases with more significant intellectual disabilities and additional motor and sensory impairments. Prevalence of epilepsy in people with severe learning disabilities and additional impairments ranges from 50 to 75%. The mortality ratio of people with learning disabilities and epilepsy is also higher than that of people with learning disabilities alone.

Assessment

The evaluation of epilepsy in people with learning disabilities is compounded by recollection and communication difficulties, coexistence of mental illness and by related problems that may mimic epileptic seizures.

Communication difficulties –'management by proxy'

People with learning disabilities and epilepsy tend to have consistently poorer adaptive and social skills and additional speech difficulties than people with intellectual disabilities alone. In this population, it is common to make a diagnosis and decisions

about treatment based on carers' reports, a witness report from a carer or family member is common, a report from the individual is less so. Thus, history and management will commonly progress through another – 'management by proxy'. The degree of this will increase as the individual's communicative skills decrease. This is problematic, as people with learning disability often rely on paid care staff. Even though the content of concerns was found to be similar between families, care staff and clinicians, care staff showed the lowest degree of concern with poorest interrater reliability of all three groups, reflecting the level of emotional involvement with the client.

Psychiatric co-morbidity – 'diagnostic overshadowing'

People with learning disability and epilepsy are twice as likely to experience mental health problems, particularly affective disorders, than their peers without epilepsy. 'Diagnostic overshadowing' is common with a person's presenting symptoms put down to their learning disability, rather than seeking another, potentially treatable cause. Is the observed strange behaviour caused by epilepsy, mental illness (i.e. depression, psychosis related or unrelated to epilepsy), physical ailment (i.e. pain, deterioration in vision), an attempt at communication, a response to a stressful situation (i.e. change in carers, bereavement) or a side effect of a drug? People with learning disabilities can experience difficulties recognizing or communicating their internal experiences and therefore it is particularly important for this group that those around them survey all factors potentially implicated in behavioural change, e.g. antiepileptic drug intoxication.

With an increase in prevalence of nearly all forms of psychiatric disorders, people with learning disability and additional epilepsy are further socially disadvantaged with having a potentially life-threatening illness causing accidents, head injuries resulting in further brain damage and dependency on others. They often have less effective and cruder coping mechanisms, which can lead to difficulties in the diagnostic and treatment process:

- Non-epileptic attack disorders are more common in people with learning disability who have limited communication skills to express emotional conflicts;
- Self-induced seizures can be stress-avoidance mechanisms with pleasurable auras experienced in photosensitive patients, or providing a sense of control over the unpredictable epilepsies;
- Increased aggression is often reported, when seizures are reduced, either because of complex electrophysiological interactions ('forced normalization'), or less seizure-related sedation and, thus, greater awareness mixed with limited communication skills and ways to express frustration.

Behaviour or seizure

Seizures are paroxysmal episodes of abnormal behaviour. A generalized tonic–clonic convulsion is well defined and does not mimic many other conditions. Other seizure types, however, are less well defined and are dependent on the verbal description of the individual and witnesses for a diagnosis. Patterns of behaviour seen in complex partial seizures, particularly when there are associated ictal or post-ictal automatisms, can be difficult to differentiate from psychiatric disturbances or from non-epileptic attack disorders. Differentiating these in people with learning disability is further complicated by communication issues and the high prevalence of repetitive episodes of manneristic or stereotyped behaviours and motor disorders in this population.

It is not entirely clear how epilepsy is related to challenging behaviour. The results of studies have been at times contradictory, with some finding a relationship and others not. This is perhaps not surprising considering the wide variety of aetiologies and syndromes encompassed under the general umbrella of epilepsy and the fact that it is usually associated with additional impairments. There is a complex relationship between poor impulse control and people with learning disability and epilepsy, in particular arising from the frontal lobe. These people have been found to be more at risk of displaying challenging behaviour or episodic rage and aggression, which appears to be involuntary, has features of frontal lobe seizures and most likely is brought about by frontal lobe dysfunction.

Diagnostic difficulties

People with learning disabilities often have difficulties complying with medical procedures. Good planning and communication between the person and staff, carers and/or relatives is important to increase the chance of tolerating an EEG and/or MRI or any other tests. Even though people with learning disability often have diffuse brain abnormalities, and thus are poor candidates for resective curative surgery, both MRI and EEG can provide important diagnostic clarification and prognostic information. People with learning disabilities are often under-investigated and epilepsy often undiagnosed because of therapeutic nihilism on behalf of some doctors as well as management-by-proxy disproportionately carried out by poorly paid people with little understanding of the complexities of people with learning disabilities or carers from a very strong social background and little appreciation of health issues.

Treatment

As for all those with epilepsy, antiepileptic medication constitutes the first line of treatment. However, seizures remain poorly controlled for approximately 68% of clients with learning disabilities, despite the fact that around 40% regularly take more than one antiepileptic drug.

There is little evidence-based prescribing in people with learning disability and epilepsy who are usually excluded from most regulatory antiepileptic drug trials.

The majority of data on pharmacological studies comes from add-on open non-randomized design, usually with the novel antiepileptic drugs. Trials using open non-controlled methodology in populations with learning disability and refractory epilepsy have shown a 50% reduction in seizures in 33% of patients at 3 months follow-up on vigabatrin, with a reduction in this response by one-third at 5-year follow-up. A similar methodology using lamotrigine in a childhood population showed a

50% improvement in seizure control in 74% of children, with an associated improvement in quality of life using clinical judgement.

There are few randomized controlled trials, mainly focusing on the difficult to define epileptic syndrome of Lennox–Gastaut, which is strongly associated with learning disability. Both lamotrigine and topiramate led to significant reduction in atonic (drop) attacks and improvement in global health or reduction in seizure severity as assessed by parents. In West's syndrome, an impressive efficacy for vigabatrin was shown in both open and a limited placebo-controlled trials.

For the majority of people, we therefore apply knowledge on interventions gained in the general population to this special population, but the validity of this approach in this population remains unproven.

Seizure reduction, although still the prime aim of epilepsy treatment, should not be the only parameter by which the success of interventions can be assessed. Broader quality of life issues should be considered to evaluate the impact of epilepsy on an individual. This would seem particularly important in this already disadvantaged group, for whom freedom from seizure can also be very elusive. The UK government's 2001 White Paper emphasizes the need to involve the person with learning disabilities and to devise individually planned care. It seems vital therefore that we consider the individual's own concerns about their epilepsy if we are to develop more effective, broader treatments enabling people with learning disability who also have epilepsy to achieve their aspirations in life unimpeded by their epilepsy.

Antiepileptic drug treatment

Currently available antiepileptic drugs are presented in alphabetical order. Tables 6.16–6.20 comprise a summary of clinical, pharmacological and pharmacokinetic properties for each drug.

Acetazolamide

Acetazolamide, a carbonic anhydrase inhibitor, is primarily used in ophthalmology but can also be used in epilepsy. It is a broad-spectrum antiepileptic drug but it is used mainly in seizure disorders in the paediatric age group. In the adult population, it can be useful for intermittent use in catamenial epilepsy. One caveat is that many responders develop tolerance to its antiepileptic action if used continuously. Common side effects include paresthesia of extremities, alterations of taste, nausea and vomiting, diarrhoea, athralgia, loss of appetite, dizziness, fatigue, irritability, thirst and polyuria. Very rarely, rashes including Stevens–Johnson syndrome and toxic epidermal necrolysis may occur. As a carbonic anhydrase inhibitor, acetazolamide is associated with an increased risk of kidney stones. Patients should be advised to increase fluid intake to decrease this risk. Its main clinical relevant interaction is with carbamazepine as acetazolamide may increase its levels.

Benzodiazepines

Benzodiazepines are useful in epilepsy as both a rescue medication for serial seizures or prolonged seizures as well as for long-term treatment. Benzodiazepines such as diazepam, midazolam or lorazepam are not well suited for chronic oral treatment except as a last resort; however, they are useful in the emergency treatment of status epilepticus, serial or prolonged seizures. Clobazam and clonazepam are better suited for long-term treatment. Clobazam, a 1,5 benzodiazepine, may be very useful as an add-on for patients with refractory seizures, either partial or generalized, and may produce long-lasting seizure freedom in up to 30% of patients. Clonazepam can also be used, particularly in myoclonic seizures, but tends to be less well-tolerated. The main disadvantages of benzodiazepines are sedation, tolerance and the tendency to cause problems on withdrawal. Hypersensitivity reactions do not usually occur with benzodiazepines. Nevertheless, depression, fatigue or irritability may develop. Benzodiazepines are relatively devoid of clinically significant interactions.

Carbamazepine

Carbamazepine, an iminodibenzyl, is a first line drug for initial treatment of partial seizures and tonic–clonic seizures. Carbamazepine is a potent auto-inducer and must be started at a low dose to keep development of transient neurotoxicity at a minimum. The dose can be increased every 1–2 weeks to a maintenance level that controls the seizures. Even when taking this cautious approach, some patients may experience diplopia, nausea, dizziness or headache on initiation of therapy, although these effects are usually transient. Common side effects, apart from these, include drowsiness, ataxia, confusion and agitation (particularly in the elderly), hyponatraemia, neutropenia, idiosyncratic skin rashes. Very rare side effects include hepatitis, Stevens–Johnson syndrome, toxic epidermal necrolysis and cardiac conduction disturbances. Fluid retention may limit the use of carbamazepine in the elderly or those with cardiac failure. In addition, carbamazepine may aggravate bradycardia in patients with heart disease. Hyponatremia seen with carbamazepine is rarely symptomatic but occasionally leads to confusion, peripheral oedema and an increase in the number of seizures. The associated neutropenia does not usually cause any clinical manifestations. Controlled release preparations are preferable as they reduce toxicity associated with peak plasma concentrations of the drug. Carbamazepine, as an enzyme inducer, reduces the effectiveness of several drugs, such as oral contraceptives, steroids, haloperidol, antineoplastic drugs, antihypertensive drugs, tricyclic antidepressants, antipsychotic drugs, theophylline and warfarin. Conversely, other drugs inhibit its metabolism which may result in neurotoxicity; these include cimetidine, clarithromycin, dextropropoxyphene, diltiazem, erythromycin, imidazole antifungal drugs, isoniazid, tricyclic antidepressants, antipsychotic drugs, verapamil and viloxazine. Interactions of carbamazepine with other antiepileptic drugs are also common. Carbamazepine increases the clearance particularly of ethosuximide, sodium valproate, topiramate and lamotrigine. Inhibition or enzyme

induction is seen with phenobarbital, phenytoin or primidone with usually small but unpredictable changes in the plasma concentrations of these drugs.

Ethosuximide

Ethosuximide, a succinimide, is a first line drug for the treatment of generalized absence seizures in children and young adults. It is not generally effective for other seizures types. The most important side effects are sedation, headaches, malaise, nausea, vomiting, abdominal pain and anorexia. Very rarely, it can cause psychotic episodes with paranoid ideation, aplastic anaemia, systemic lupus erythematosus and Stevens–Johnson syndrome. Ethosuximide-induced headache and abdominal pain can be severe in individual patients. Ethosuximide does not inhibit or induce the metabolism of other drugs but its clearance is reduced by valproate.

Felbamate

Felbamate, a dicarbamate, is an effective broad-spectrum drug particularly useful in refractory partial epilepsy and it was the first antiepileptic drug to have shown efficacy as add-on treatment in refractory Lennox–Gastaut syndrome. Its use is currently restricted to very refractory cases for safety reasons as it has been associated with an idiosyncratic reaction leading to aplastic anaemia or hepatotoxicity. These rare but often fatal reactions affect about 1/4000 people exposed. Felbamate is not currently licensed in the UK but can be obtained for selected cases on a named-patient basis. It interacts with many drugs and this needs to be taken into consideration when using felbamate.

Gabapentin

Gabapentin, an amino acid, is a mild antiepileptic drug occasionally useful as add-on treatment of partial seizures. It is not effective for any other seizure type. Its major indication currently is an analgesic for chronic neuropathic pain. Side effects of gabapentin include nausea, vomiting, peripheral oedema, dizziness, drowsiness, ataxia, tremor, asthenia, emotional lability, weight gain, dysarthria and diplopia. Rare side effects include pancreatitis, depression, psychosis, headache, myalgia and urinary incontinence; hepatitis, jaundice, movement disorders, thrombocytopenia and acute renal failure. Gabapentin is devoid of interaction and this is one of the few advantages of this drug.

Lamotrigine

Lamotrigine, a triazine, is a first line drug for partial and generalized seizures. It is a broad-spectrum drug but may occasionally exacerbate myoclonic seizures particularly as part of severe myoclonic epilepsy of infancy. The initiation of lamotrigine therapy should be at a very low dosage with a slow upward titration to decrease the risk of the development of skin rash, which is one of the most common and important side effects. The rash may be severe and lead to Stevens–Johnson syndrome in some rare cases, particularly if the medication is not stopped promptly. Other side effects include nausea, fatigue, dizziness, insomnia, tremor, agitation, confusion, hallucinations and blood disorders (including leucopenia, thrombocytopenia, pancytopenia). Lamotrigine has the potential for interaction. The elimination of lamotrigine is accelerated by enzyme-inducing antiepileptic drugs, such as carbamazepine, phenytoin and phenobarbital, and inhibited by valproate. Therefore, if lamotrigine is used as an add-on then dose and titration schedule needs to be adjusted according to the concomitant medication. In women, lamotrigine levels may be reduced, occasionally dramatically, with the use of the combined contraceptive pill or during pregnancy and dose adjustments may be necessary to avoid breakthrough seizures.

Levetiracetam

Levetiracetam, a pyridoline, is a broad-spectrum first line medication for partial and generalized seizures which is well tolerated overall. The most frequent side effects encountered in clinical practice are lethargy, irritability, ataxia, nausea and vomiting, drowsiness, ataxia, dizziness, headache, tremor, hyperkinesia, emotional lability, irritability, insomnia, anxiety, anorexia and diplopia. Irritability and behavioural change can be severe. Rare side effects include confusion, psychosis, leucopenia, thrombocytopenia and alopecia. Levetiracetam should be started at a low dose and titrated up weekly to initial target dosage. However, if there are clinical needs and under supervision, levetiracetam can be started at the maintenance dose either orally or as an intravenous infusion. No clinically relevant interaction with other drugs has yet been described; however, it is likely that it has pharmacodynamic interactions with other antiepileptic drugs.

Phenobarbital

Phenobarbital, the oldest barbiturate, is an effective broad-spectrum antiepileptic against most seizure types, intravenously or chronic oral use. Currently, it is hardly used in developed countries as a chronic oral use drug, although it is used in emergency situations intravenously. In patients controlled at low daily doses, phenobarbital is a relatively cost-effective and relatively well-tolerated medication and is used especially in resource-poor countries. The main disadvantages of phenobarbital are its potential to affect cognition or pharmacokinetics interactions. Common side effects are drowsiness, depression, lethargy, cognitive slowing, Dupuytren contracture, ataxia and allergic skin reactions. In the elderly, hyperactivity, restlessness and confusion may be seen, while hyperkinesia is a problem in children. Megaloblastic anaemia is a chronic side effect and the use of concomitant folic acid supplementation is recommended. Phenobarbital interacts with a number of drugs, antiepileptic or otherwise, and this must be taken into account when using it. It interacts with steroids, antibiotics, oral contraceptives, tricyclic antidepressants, antipsychotic drugs, antineoplastic and other drugs. It decreases the levels of carbamazepine, lamotrigine, phenytoin, valproate, zonisamide and ethosuximide.

Phenytoin

Phenytoin, a hydantoin, is an effective oral treatment of partial seizures and tonic–clonic seizures and is also useful intravenously

in status epilepticus. However, because of its great potential to cause chronic side effects and pharmacokinetic interactions, it is now not used as first line therapy in many countries. The most common side effects include cosmetic changes as gingival hyperplasia, acne, hirsutism, facial coarsening and neuropsychiatric disturbance, particularly depression, fatigue and cognitive slowing. Other side effects include nausea, tremor, paraesthesias, dizziness, headache, anorexia and skin rash. Rarely, it may cause hepatotoxicity, peripheral neuropathy, Dupuytren contracture, lymphadenopathy, osteomalacia, megaloblastic anaemia, leucopenia, thrombocytopenia, lupus erythematosus and Stevens–Johnson syndrome. The use of concomitant folic acid supplementation with phenytoin is recommended. It has non-linear pharmacokinetics and this can result in large increases in plasma concentrations even with small dose increments; conversely, levels may fall abruptly even with modest dose reduction. Routine monitoring of plasma levels of phenytoin is recommended. Phenytoin is a potent enzyme inducer, and as such can be expected to lower levels of other drugs such as carbamazepine, phenobarbital, and other antiepileptic drugs, anticoagulants, amiodorone, antihypertensive drugs (including losartan), chloramphenicol, digoxin, statins, steroids, ciclosporin, sulphonamides, imidazole antifungal drugs, tricyclic antidepressants, antipsychotic drugs, antineoplastic drugs, and the oral contraceptives. Conversely, the metabolism of phenytoin can be inhibited by enzyme inducers such as allopurinol, chloramphenicol, cimetidine, isoniazid, metronidazol, phenothiazine and sulphonamides.

Pregabalin

Pregabalin, a gabapentin analogue, is a second line antiepileptic for partial seizures. It has no indication in any other seizure type. In addition to epilepsy, pregabalin also has use in generalized anxiety disorder and neuropathic pain. Its side effects include dizziness, drowsiness, irritability, speech disorder, paraesthesia, confusion, fatigue, weight gain and visual disturbances. Less common side effects include increased salivation, taste disturbance, oedema, nasal dryness, stupor, depression, insomnia, mood swings, asthenia, muscle cramp and rash. Rare effects include pancreatitis, arrhythmia, rhinitis, menstrual disturbances, breast discharge, breast hypertrophy, neutropenia, rhabdomyolysis and renal failure. Like gabapentin, it seems devoid of any clinically significant interactions.

Primidone

Primidone is a barbiturate that is largely metabolized to phenobarbital, and its effects are very similar to those of phenobarbital. It is currently rarely used for the treatment of epilepsy.

Oxcarbazepine

Oxcarbazepine is a structural variant of carbamazepine with a similar efficacy as an add-on drug for refractory partial seizures and as a first line agent in previously untreated patients with tonic–clonic and partial seizures. It also shares many side effects with carbamazepine but overall oxcarbazepine is perceived as being better tolerated. Common side effects include nausea, dizziness, headache, drowsiness, agitation, lethargy, ataxia, impaired concentration, depression, tremor, hyponatraemia; acne, alopecia, skin rash and diplopia. Rare side effects include hepatitis, pancreatitis, arrhythmias, hypersensitivity reactions, thrombocytopenia, systemic lupus erythematosus and Stevens–Johnson syndrome. Hyponatremia is more marked than with carbamazepine and occasionally leads to confusion and increase of seizures. Cross-sensitivity with carbamazepine in skin rashes is seen about one-third of patients. Oxcarbazepine should be started at a low dose and titrated up weekly to initial target dosage. However, if there are clinical needs and under supervision, oxcarbazepine can be started at the maintenance dosage. It has less potential for pharmacokinetic interactions than carbamazepine but nevertheless interactions occur, e.g. with oral contraceptives, and comedication with oxcarbazepine can significantly lower lamotrigine levels. Oxcarbazepine can lower the levels of ciclosporin.

Tiagabine

Tiagabine, a GABAergic drug, has a mild to moderate efficacy in the control of partial seizures. It has no indication in other seizure types and indeed is known to exacerbate generalized seizures. The most common adverse events are CNS-related and consist of sedation, tremor, headache, mental slowing, emotional lability, speech impairment, tiredness, depression and dizziness. Rarely, confusion, psychosis and leucopenia may occur. Increases in seizure frequency and episodes of non-convulsive status may also occur, particularly when used in idiopathic generalized epilepsy. Enzyme inducers tend to accelerate the clearance of tiagabine and higher doses may be required if they are used concomitantly.

Topiramate

Topiramate, a sulfamate-substituted monosaccharide, is a broad-spectrum drug for partial and secondarily generalized seizures. Topiramate can cause predominantly neurological side effects, particularly at high dosage and if titrated too fast. These adverse effects include headache, sedation, impaired memory and concentration, speech disturbance, asthenia, anxiety, depression, sleep disorders, visual disturbances and confusion. Nausea, abdominal pain, dry mouth, taste disturbance, anorexia, weight loss and paraesthesia can also occur. Very rarely, it may cause acute myopia with secondary angle-closure glaucoma which is reversible. To lessen the incidence of treatment limiting side effects, topiramate needs to be started at a low dosage and it should be titrated up slowly. Topiramate is a weak inhibitor of carbonic anhydrase and as such is associated with an increased risk of renal stones; patients should be advised to increase fluid intake during treatment to decrease this risk. Enzyme inducers tend to accelerate the clearance of topiramate and higher doses may be required if they are used concomitantly.

Valproate

Valproate, a pentanoic acid, is a first line drug for initial treatment of idiopathic generalized epilepsy with absences and

juvenile myoclonic epilepsy and for generalized tonic clonic seizures on awakening. It is a broad-spectrum antiepileptic drug and is also efficacious against partial seizures. Common side effects include tremor, behavioural disturbances, weight gain, thrombocytopenia, menstrual disturbances, ankle swelling and usually minor loss of hair. Cognitive impairment is sometimes seen. Encephalopathy has been occasionally reported, possibly because of hyperammonemia, which is a common result of valproate therapy. Rare cases of fatal hepatotoxicity have occurred, especially in infants during polytherapy. The use of valproate during pregnancy is associated with an increased risk of teratogenicity and there are concerns that it could also lead to increased educational needs in children exposed to it *in utero* even when there is no malformation. Valproate should therefore be used cautiously in women with childbearing potential. Valproate mildly inhibits the metabolism of other antiepileptic drugs which is rarely of clinical relevance except when prescribed with lamotrigine. Valproate inhibits the metabolism of lamotrigine, leading to greatly elevated plasma levels. Interactions with phenytoin and carbamazepine can be significant also. Carbapenem antibiotics cause a profound lowering of valproate levels and this combination should be avoided. Valproate concentrations are also lowered by some antineoplastic drugs. Valproate concentrations can be greatly elevated with co-medication with antidepressant drugs. The full pharmacological action of valproate may take several weeks to develop after steady-state concentrations have been reached. Valproate monitoring is not recommended as there is no relationship between clinical effects and the plasma concentration.

Vigabatrin

Vigabatrin, a GABAergic drug, is a last resort drug in refractory partial seizures (it is still a first line drug for infantile spasms). Its use is currently limited by the occurrence of visual field defects in at least one-third of patients on long-term therapy. Irreversible visual field defects, which may be asymptomatic in the early stages, can lead to blindness.

Zonisamide

Zonisamide, a sulphonamide, is a broad-spectrum drug effective for partial seizures and for refractory generalized seizures particularly myoclonic. The common side effects of zonisamide include nausea, drowsiness, dizziness, irritability, depression, ataxia, speech disorder, impaired memory and attention, anorexia and weight loss, pyrexia, diplopia and skin rash. Less common effects include psychosis and hypokalaemia. Rare side effects include hallucinations, suicidal ideation, amnesia, coma, neuroleptic malignant syndrome, heat stroke, hydronephrosis, renal impairment, blood disorders, rhabdomyolysis, impaired sweating, Stevens–Johnson syndrome, hepatitis and pancreatitis. Zonisamide is associated with an increased risk of kidney stones; patients should be advised to increase fluid intake during treatment to decrease this risk. Enzyme inducers tend to accelerate the clearance of zonisamide and higher doses may be required if they are used concomitantly.

Emergency drug treatment

Prolonged convulsions or serial seizures

If a tonic–clonic seizure continues for 5–10 minutes, benzodiazepine therapy, either intravenously or rectally, is usually given. Undiluted IV diazepam is given at a rate not exceeding 2–5 mg/min, using the Diazemuls© formulation. The adult bolus intravenous or rectal dose is 10–20 mg, and in children the equivalent bolus dose is 0.2–0.3 mg/kg. Intravenous lorazepam is an alternative with some advantages over IV diazepam (longer time of action, less risk of cardiovascular collapse) The dose is 4 mg in adults or 0.1 mg/kg in children. Out of hospital, buccal midazolam 10 mg is increasingly used as an alternative to rectal diazepam and is preferred by patients and carers for ease of use and preservation of dignity.

If clusters of seizures occur, acute therapy after the first seizure can be given to prevent subsequent attacks. Oral clobazam (10–20 mg) is a common choice, and will take effect within 1–2 hours and last for 12–24 hours.

Tonic–clonic status epilepticus

If tonic–clonic status epilepticus is allowed to persist for more than about 2 hours, there is a substantial risk of seizure-induced cerebral damage. The risk rises the longer the seizures continue. For this reason, the drug treatment of tonic–clonic status epilepticus is best divided into stages:

1 First stage (early status) is defined as the first 30 minutes of seizure activity;

2 Second stage (established status) is reached if early stage treatment fails;

3 Third stage (refractory status) is reached if seizures continue for more than 1–2 hours after initiating therapy, despite early or established stage therapy.

A systematic protocol-driven approach is important in this emergency situation. The choice of drug regimen is somewhat arbitrary. A protocol favoured is shown in Table 6.23 and details of the drugs used are given in Tables 6.24 and 6.25.

Epilepsy surgery

Epilepsy surgery can be carried out with three objectives: to stop seizures, to ameliorate the seizures or to remove a progressive lesion or one that carries other risks such as haemorrhage. Here we concentrate on the assessment, surgery and outcome of those who have surgery primarily for their epilepsy. These are patients whose epilepsy proves resistant to antiepileptic drugs. Given the conservative estimates that approximately 20% of patients are resistant to treatment with antiepileptic drugs, and 50/100,000 people per year develop epilepsy, then every year approximately 1/10,000 people develop refractory epilepsy (i.e. 6000 every year in the UK). In the UK, approximately 1000 of these patients (3% of the incident cohort) are suitable for

Table 6.23 Protocol for the treatment of status epilepticus in adults.

Stage of early status (0–30 min)
Lorazepam 4 mg IV bolus (can be repeated once)

↓ (if seizures continue after 30 min)

Stage of established status (30–60/90 min)
Phenobarbital IV infusion 10 mg/kg at 100 mg/min
or
Phenytoin IV infusion 15 mg/kg at 50 mg/min
or
Fosphenytoin IV infusion 15 mg PE/kg at 100 mg PE/min
or
Valproate IV infusion 25 mg/kg at 3–6 mg/kg/min

↓ (if seizures continue after 30–90 min)

Stage of refractory status (>60/90 min – general anaesthesia)
Propofol: IV bolus 2 mg/kg, repeated if necessary, and then followed by a continuous infusion of 5–10 mg/kg/hour initially, reducing to a dose sufficient to maintain a burst suppression pattern on the EEG (usually 1–3 mg/kg/hour)
or
Thiopental: IV bolus 100–250 mg given over 20 seconds with further 50 mg boluses every 2–3 min until seizures are controlled, followed by a continuous iv infusion at a dose sufficient to maintain a burst suppression pattern on the EEG (usually 3–5 mg/kg/hour)
or
Midazolam: IV bolus 0.1–0.3 mg/kg at a rate not exceeding 4 mg/min initially, followed by a continuous IV infusion at a dose sufficient to maintain a burst suppression pattern on the EEG (usually 0.05–0.4 mg/kg/hour)

When seizures have been controlled for 12 hours, the drug dosage should be slowly reduced over a further 12 hours. If seizures recur, the general anaesthesic agent should be given again for another 12 hours, and then withdrawal attempted again. This cycle may need to be repeated until seizure control is achieved

Table 6.24 Drugs used in the pre-anaesthetic management of convulsive status epilepticus.

	Route of administration	Adult dose	Paediatric dose
Diazepam	IV bolus (not exceeding 2–5 mg/min)	10–20 mg	0.25–0.5 mg/kg
	Rectal administration	10–30 mg	0.5–0.75 mg/kg*
Midazolam	IM or bucal	5–10 mg*	0.15–0.3 mg/kg*
	IV bolus	0.1–0.3 mg/kg at 4 mg/min*	
	IV infusion	0.05–0.4 mg/kg/h	
Clonazepam	IV bolus (not exceeding 2 mg/min)	1–2 mg at 2 mg/min*	250–500 mg
Fosphenytoin	IV bolus (not exceeding 100 mgPE/min)	15–20 mg PE/kg	
Lorazepam	IV bolus	0.07 mg/kg (usually 4 mg)*	0.1 mg/kg
Phenytoin	IV bolus/infusion (not exceeding 50 mg/min)	15–20 mg/kg	20 mg/kg at 25 mg/min
Phenobarbital	IV bolus (not exceeding 100 mg/min)	10–20 mg/kg	15–20 mg/kg
Valproate	IV bolus	15–30 mg/kg	20–40 mg/kg

* May be repeated. PE, phenytoin equivalents.

Table 6.25 Anaesthetic drugs used in status epilepticus.

Midazolam	0.1–0.3 mg/kg at 4 mg/min bolus followed by infusion of 0.05–0.4 mg/kg/hour
Thiopentone	100–250 mg bolus over 20 seconds then further 50-mg boluses every 2–3 min until seizures are controlled. Then an infusion of 3–5 mg/kg/hour to maintain burst suppression
Pentobarbital	10–20 mg/kg bolus at 25 mg/min followed by an infusion of 0.5–1 mg/kg/hour increasing to 1–3 mg/kg/hour to maintain burst suppression
Propofol	2 mg/kg bolus followed by an infusion of 5–10 mg/kg/hour to maintain burst suppression

presurgical assessment of whom approximately half (500) patients per year are suitable for surgery. As surgical techniques and presurgical evaluation improve, it is hoped we will be able to identify a greater number of patients who may benefit from epilepsy surgery. In addition to those undergoing presurgical evaluation, there are also a growing number of palliative operations, in particular vagal nerve stimulation.

All patients who are being considered for surgery need a detailed presurgical evaluation, this is necessary not only to assess the likelihood of surgical success, but also to establish the suitability of the patient, to determine the type of operation (including further invasive investigations) and to assess the potential risks.

Who is suitable for presurgical assessment?

The main criterion for selecting patients for presurgical assessment is drug resistance. There therefore has to have been an adequate trial of medical therapy, but what is adequate? This question has generated a certain amount of debate. Although some studies have suggested that failure to respond (rather than withdrawal because of side effects) to an initial treatment results in 11% chance of becoming seizure free with subsequent treatments, this is probably overly pessimistic. Patients who are turned down for surgery or refuse surgery have a 15–25% chance of becoming seizure free over subsequent years. This is partly because patients seen at time of presurgical assessment are at the nadir of their disease, but also new antiepileptic drugs have had an impact; adding new antiepileptic drugs in a sequential fashion to the drug regimen of refractory patients can render one-quarter of these patients seizure free. A generally accepted minimum is that a person should have tried at least two first line antiepileptic drug treatments at appropriate dosage over a period of 2 years. Whether to continue with trials of antiepileptic drugs or to refer directly for surgery depends upon the chance of surgical success and the severity of the epilepsy.

Epilepsy severity is difficult to characterize and to evaluate; it has to be considered on an individual basis and assessed in the light of the likely success and adverse effects of surgery. It is also important to consider the morbidity and mortality attached to even infrequent seizures. SUDEP has a particularly high incidence in patients evaluated for but refused surgery – over 1% per year. Nevertheless, it has to be established that reducing the frequency or stopping the seizures will result in a significant improvement of quality of life. In people with multiple problems (e.g. epilepsy and severe psychiatric disease or severe learning difficulties), the epilepsy may only contribute a small amount to the person's disability. Indeed, during the presurgical period it is paramount to ascertain the expectations that both carers, family and the patient have of surgery. Only too often, people feel that epilepsy surgery will resolve all problems, and so are disappointed if seizure freedom has had little impact on their lives. Counselling is therefore necessary so that all involved can have realistic expectations.

A further consideration is the risk of operation. Thus, even in cases where there may be a high chance of seizure freedom, the risks of surgery may be unacceptable. This is dependent not only upon the specific operation (e.g. removal of eloquent cortex or memory problem following dominant temporal lobe resection), but also upon the health of the individual (e.g. surgery in patients with other medical conditions may represent an unacceptable risk). However, the immediate risks of operation may be offset by longer term benefits (e.g. the mortality of the operation may be offset by the reduction in the chance of SUDEP, or the loss of memory following an operation may be offset by the risks to memory of continued seizures).

Pre-operative evaluation

Pre-operative evaluation is a multidisciplinary process, and involves not only determining the nature of the operation, but also the risks and possible benefits. This requires assessment and discussion involving the neurologist, neurosurgeon, psychologist, psychiatrist, neurophysiologist and radiologist.

There are two main strategies for the surgical treatment of seizures. The first involves curative resective surgery, in which the aim of the surgery is the removal of the epileptogenic zone (defined as the area that has to be removed in order to render someone seizure free). This can be restricted to a focal lesion or may involve lobar or multi-lobar resection (e.g. hemispherectomy). The second approach is palliative in order to decrease the frequency or severity of seizures.

The assessment of curative resective surgery is mainly aimed at identifying the epileptogenic zone. This relies upon the convergence of presurgical investigations including clinical history, seizure semiology, scalp EEG, neuroimaging and neuropsychometry. Discordance between these may lead to a lesser chance of surgical success and the need for further investigation (imaging, invasive EEG recordings). The relative weight that is lent to each of these investigations varies depending on the type of operation and the pathogenesis of the epilepsy and in many instances is either controversial or undetermined.

Clinical history

The clinical history contains a number of details that are critical in pre-operative assessment. The age of the patient is relevant as surgery has a greater neuropsychological impact on older patients. Further, there is some evidence to suggest that the longer someone has had mesial temporal lobe epilepsy, the less chance that there will be of long-term seizure freedom following resection. Handedness gives an indication of hemisphere dominance. Antecedent history is of relevance, for example a history of febrile seizures is a good prognostic factor for surgery in those with hippocampal sclerosis, but a poor prognostic factor in those undergoing frontal lobe resection. The semiology of the seizures is critical (see below). The presence of secondary generalized seizures is predictive of poorer outcome. It is also important to have details of social support and psychiatric concerns (see below).

Psychiatric history

A psychiatric assessment is necessary prior to surgery. First, there are relative contraindications to surgery including active depression or psychosis that will need treating. It is also important to ascertain whether the person would be able to sign an informed consent. The additional presence of dissociative seizures (non-epileptic attacks with a psychological basis) is a relative contraindication, as they can often worsen after resective surgery. The risks of post-resective depression and/or psychosis also need to be estimated. Certain patients may require additional psychiatric support both peri- and post-operatively. About one-quarter of patients have transient mood disturbances in the first year following surgery and approximately 10% may require treatment for depression.

Neuroimaging

High-quality MRI has become a cornerstone of pre-operative assessment. The presence of an identifiable well-defined lesion has a considerable impact on the surgical approach and the prognosis for surgery. If it can be shown that a lesion is the substrate for the epilepsy, then complete resection of that lesion stands a high chance of rendering the patient seizure free, while failure to resect or incomplete resection carry a poorer prognosis. The presence of an identifiable lesion on MRI also increases the chance of surgical success compared to 'MRI-negative' patients. At a minimum the MRI investigation should involve T2-weighted sequences, proton density sequences, FLAIR sequences and T1-weighted volume acquisition (partition size less than 1.5 mm). Finer cuts and also other sequences may also be helpful.

The role of FDG-PET, other PET ligands and ictal SPECT remains less certain, but they are useful in MRI-negative patients, on occasions when there is discordance between other investigations and in patients in whom there are extensive or multiple pathologies (e.g. tuberous sclerosis).

Functional MRI can be used to identify eloquent cortex and to lateralize language. It is likely that as a non-invasive investigation, fMRI will be increasingly used as a method for correlating structure with function such as in the assessment of memory.

Neurophysiological investigation

Scalp EEG with video has become a necessary investigation in pre-operative assessment, although there are cases with clear-cut pathology, typical history and typical interictal EEG in whom video-EEG telemetry may be unnecessary.

The interictal EEG is useful and can be of prognostic relevance (e.g. atypical epileptiform abnormalities in patients with hippocampal sclerosis predicts poorer outcome). However, ictal video-EEG telemetry in order to define the electroclinical origin of the seizure is usually required. The hope is that this is concordant with neuroimaging, as discordance reduces the chance of a good outcome and can necessitate invasive EEG recordings. How many seizures need to be recorded varies depending on aetiology and results of neuroimaging. If there are doubts about laterality or localization then more seizures will need to be recorded. Protocols for electrode placement and drug reduction vary from unit to unit. In all patients being investigated for temporal lobe epilepsy additional EEG electrodes covering the sphenoidal area are used (the authors use surface zygomatic electrodes and have found no significant advantage in using needle sphenoidal electrodes).

Intracranial EEG monitoring over 1–2 weeks with subdural electrodes and/or depth electrodes may be required in cases of discordance to test a hypothesis, e.g. if video-EEG telemetry is discordant with an MRI demonstrating only hippocampal sclerosis. Invasive recordings are also necessary with certain pathologies such as cortical dysplasia or encephalomalacia in order to define accurately the epileptogenic zone. Acute electrocorticography at the time of resection is used in some units to define the extent of resection, but we usually use more chronic recordings. Depth electrodes can only cover a small area (usually there are 6–8 contacts) and have approximately a 1% risk of haemorrhage or infection. Subdural grids do not broach the pial boundary, have a lesser chance of causing haemorrhage and can cover a much larger area. The disadvantage of subdural grid electrodes is that they require a craniotomy and carry a higher risk of infection (approximately 3–5%); over one-quarter of patients develop an aseptic meningitis – usually restricting recordings to 10 days or less. The placement of the electrodes is dependent on the hypothesis that is to be tested. Intracranial stimulation either during awake craniotomy or with chronic subdural electrodes may also be necessary to delineate eloquent cortex and so determine the safe margins of resection.

The role of magneto-encephalography (MEG) has yet to be defined. Measuring changes in the electric field has the advantage of detecting currents that run perpendicular to the brain surface (such currents are often undetectable by scalp EEG). MEG may also detect spikes that originate deeper in the cortex. The limitation is that MEG cannot be used continuously to detect ictal changes.

Neuropsychology

Neuropsychological assessment has a role in localization; neuropsychological deficits implicating cortex distinct from the putative epileptogenic cortex may indicate more widespread cortical pathology. Psychometric testing may also be used to estimate the psychological sequelae of epilepsy surgery. Most commonly, this is in the context of memory deterioration following temporal lobe resection.

Injection of sodium amytal into each hemisphere (the 'amytal test') to anesthetize each hemisphere in turn was originally devised to lateralize language in uncertain cases, but this is now increasingly determined by fMRI. However, the amytal test was extensively used to determine the possible neuropsychological sequalae of temporal lobe resection. The problems are that, because of variations of blood flow, access of the drug to relevant structures (e.g. the mesial temporal structures) and cross flow, the amytal test can be misleading. More selective amytal tests can be performed by super-selective injections of amytal into specific

cerebral vessels; however, these are more technically challenging and provide a greater risk for the patient. In some units, an intracarotid sodium amytal test is used in every patient undergoing temporal lobe resection. Other units restrict the use of this test to patients in whom there is discordance between neuropsychometric testing and neuroimaging. The authors now rarely use the amytal test and depend upon the information gleaned from standard neuropsychometric testing and neuroimaging. The amytal test has a 0.5% morbidity.

Counselling

All patients should be counselled prior to surgery. They should be given details of risks and benefits; the authors find it advantageous not only to record these discussions in the notes, but also to send a letter to the patient with all these details. An estimate of the odds of success along with associated risks including catastrophic risks (stroke/death), neuropsychological risks, neuropsychiatric risks and more specific risks (e.g. visual defect) is given to the patient. The counsellor will also describe in more detail the practicalities (e.g. the length of time off work). They will also ascertain the degree of postoperative social support.

Surgery

Surgery for epilepsy can be divided into resective, curative surgery and palliative surgery, although there is sometimes a blur between these, as some forms of palliative surgery can render patients seizure free, and on some occasions resective surgery is performed to palliate rather than necessarily cure the epilepsy.

Curative resective surgery

Although resective surgery has been the mainstay of curative surgical techniques, other approaches such as stereotactic radiosugery using a gamma knife have grown in popularity. The gamma knife is ideal for lesions that are difficult to resect (e.g. hypothalamic hamartomas) or for patients who are unlikely to be able to tolerate resective surgery. Whether the technique has a place in other situations remains to be determined. The main disadvantages are a lack of long-term follow-up and a significant delay from the radiosurgery to obtaining maximum benefit (as long as 1 year).

Lesionectomy

Patients with discrete lesions have a good outcome from resective surgery, provided that the lesion can be completely removed and that there is no concomitant pathology. Thus, patients with dysembryoplastic neuro-epithelial tumours or discrete vascular lesions have a 50–80% chance of seizure freedom following removal of the lesion. In situations where the lesion is less well defined or is associated with more widespread abnormalities, the chance of seizure freedom drops markedly. Thus, focal cortical dysplasia visualized on MRI may only be the 'tip of the iceberg' and resection margins invariably have to be delineated using intracranial recordings. Nevertheless, resections of focal cortical dysplasia have a 40–50% chance of rendering someone seizure free. Temporal lobe lesion are frequently associated with hippocampal sclerosis, and experience dictate that removal of both the lesion and the hippocampus is usually necessary for a successful outcome. The complications of surgery depend upon the location of the lesion, and in particular its proximity to eloquent cortex.

Temporal lobe epilepsy

Temporal lobe resection is the most common operation for seizure control. The most common pathology is hippocampal sclerosis. There have been a variety of surgical approaches to temporal lobe resection. These approaches minimize the temporal neocortex resection, while maintaining the hippocampal resection, and fall broadly into two camps: anterior temporal lobectomy or selective amygdalo-hippocampectomy. The advantages and disadvantages of each of these approaches are probably a minor consideration compared to the effects of surgical experience. These operations result in approximately 50–70% of patients becoming seizure free (this figure may be higher in those with hippocampal sclerosis and concordant investigations) and 20% are improved. However, the chances of remaining seizure free diminish over time (probably by 3% per year for the first 5 years). The overall mortality of temporal lobectomy is less than 0.5%. A transient hemiparesis can occur in up to 5%, but the risk of permanent hemiparesis is less than 1%. The chance of significant memory decline depends upon baseline memory test, age and side of operation (dominant versus non-dominant). Significant visual field defects occur in 10%, and 5% of patients in the UK may be unable to drive because of these. Postoperative depression is not uncommon. Postoperative psychosis is less common and usually occurs in patients whose seizures are continuing.

Extratemporal surgery

Extratemporal surgery is performed less frequently and mainly consists of frontal lobe surgery. The presence of a lesion is the most important predictor of surgical success. Overall, approximately 40–50% become seizure free, but a normal MRI reduces these odds. The risks of operation are related to the site of resection.

Hemispherectomy

This is particularly effective in controlling seizures, with approximately 80% becoming seizure free. This operation is only suitable for people with a profound hemiparesis, and care needs to be taken if it is the dominant hemisphere. Early theories concerning language development suggested that resection of the dominant hemisphere should not occur after the age of 6 years, but recent experience suggests a cut-off of 9 years and indeed language recovery has been noted at even later ages. The operation is usually carried out in people with extensive abnormalities of one hemisphere or with a pathology affecting one hemisphere (e.g. Rasmussen's encephalitis). Mortality is approximately 1–2%. In the past, long-term outcome was poor because of problems resulting from hydrocephalus and superficial haemosiderosis.

These risks have diminished with modern refinements of the operation – most centres now carry out a functional hemispherectomy. In this operation, the temporal lobe is removed, a corpus callosotomy is performed and the frontal and occipital lobes are disconnected.

Palliative procedures

These operations aim to reduce the frequency or severity of seizures but rarely render people seizure free.

Corpus callosotomy

Callosotomy is considered when resective surgery is not possible and when atonic, tonic or, more controversially, tonic–clonic seizures are a prominent and disabling part of the patient's epilepsy. The chances of seizure freedom with this operation are slim, 5%, and the morbidity from this operation can be considerable. When language representation occurs in both hemispheres, then language problems can occur (some centres advocate an amytal test in all patients). Furthermore, disconnection syndromes with apraxia and 'alien' hand are the cause of considerable disability. These tend to be more prevalent in older patients (after the age of 12 years). Because of this risk, the operation is often performed as a two-stage procedure with first section of the anterior two-thirds and then, if seizure control is inadequate, a further procedure to section the posterior one-third can be considered. Because of the morbidity and disappointing long-term results, many centres would use vagal nerve stimulation in preference (see below).

Multiple subpial transection

This procedure is considered when eloquent areas of cortex form part of the epileptogenic zone. It is nowadays usually performed as an adjunct to, and in combination with, a cortical resection. The concept around which this procedure is based is that the functional cortical activity occurs in a radial plane, while seizures spread in a tangential plane. Thus, by making radial sections it should be possible to prevent seizure spread without interfering with physiological function. The cortex is exposed and acute corticography is used to determine the extent of the irritative zone. Radial cuts are made at intervals of less than 5 mm and the procedure is deemed successful once interictal discharges are abolished or minimized. The success rate for this procedure is contentious, with some groups reporting 60–70% having a 95% reduction in seizure frequency. However, 20–30% of patients will have a resultant deficit, and there is a significant long-term relapse rate. The operation is now largely confined to treating patients with Landau–Kleffner syndrome or occasionally carried out in conjunction with a cortical lesion resection.

Stimulation

The use of stimulation of various structures has a long and chequered history, but has recently been placed on a more scientific basis with better trials and a better understanding of mechanisms of action.

Vagal nerve stimulation for epilepsy has now been licensed throughout the world. This involves the placement of a stimulator under the skin with a wire to the left vagus nerve which is then intermittently stimulated. The stimulation parameters vary but are usually in the range: amplitude 0.25–3.5 mA; pulse width 250–500 μs; frequency 20–30 Hz; duty cycle 30 seconds on, 5 minutes off. In addition, patients can activate a cycle with a magnet in order to try to abort a seizure during an aura. The success rate is poor. Approximately 50% of patients can expect a 50% or greater reduction in seizures. Good results have been reported in patients with tonic or atonic seizures, and vagal nerve stimulation is increasingly being used by some centres in preference to corpus callosotomy. Dyspnoea, throat pain and hoarse voice are the main adverse events.

Stimulation of other targets such as the thalamus, subthalamic nuclei and the hippocampus are still in the early stages of development, but these methods are beginning to show promise not only as palliation, but also as potential cures.

Follow-up

All patients undergoing epilepsy surgery need close follow-up in order to detect postoperative problems (e.g. depression, seizure recurrence), to inform surgical practice and to counsel patients regarding such issues as drug withdrawal. The authors routinely repeat neuropsychological tests and MRI at 3–6 months following surgery, and then may repeat the neuropsychology again at a year.

If a patient becomes seizure free, then drug withdrawal will need to be considered. In the authors' series less than 30% of those who are seizure free following surgery choose to withdraw AEDs completely. In those who do wish to reduce or withdraw medication, some authorities start withdrawal at 1 year postoperatively and slowly taper over the subsequent year (drug withdrawal thereby usually occurs by 2 years post-operation). Others withdraw drugs more slowly, and the authors' practice is not to withdraw drugs in the first five years. The occurrence of early seizures, the inability to remove all the pathology, normal preoperative MRI, longer duration of epilepsy and older age all predict a less successful withdrawal from drugs.

Other aspects of treatment

Role of epilepsy specialist centres

In the UK, it is an accepted recommendation that all patients with suspected epilepsy should be referred to the specialist neurology services for diagnosis, and that patients with chronic epilepsy should be referred to an epilepsy specialist.

Epilepsy clinic

An epilepsy clinic is defined as a clinic run by a specialist with an interest in epilepsy (usually a neurologist but could be a GP or psychiatrist) in which all the clientele have epilepsy. About 30% of patients who develop epilepsy will continue to have seizures

despite treatment with antiepileptic drugs, and most of these will require further specialist follow-up. The NICE guidelines propose that the diagnosis of epilepsy should be established by specialist practitioners with training and expertise in epilepsy. Treatment (where appropriate) should be initiated by the epilepsy specialist, who should also plan the continuation of treatment, and manage, or provide guidance for, withdrawal of antiepileptic drugs. A management plan should be formulated jointly by the hospital and general practice to alleviate the mismatch that could occur when the patient's epilepsy is being looked after by secondary or tertiary care, but when the patient has access only to the GP when acute problems occur.

Epilepsy centre

An epilepsy centre is directed by a neurologist (or occasionally another physician) with a special interest in epilepsy, but emphasis is on shared care between general practice and hospital. Epilepsy centres have a multidisciplinary team to deal with patients who have previously proved refractory to treatment. The function of this service is to:

- Confirm the diagnosis;
- Initiate treatment, if indicated;
- Provide initial counselling and information to patients and their families;
- Monitor the response to the initial treatment; and
- Refer the patient back to the GP if the condition is stable.

There are several epilepsy centres in the UK specializing in the assessment and care of children (i.e. National Centre for Young People with Epilepsy [NCYPE], David Lewis Centre), or adults (i.e. National Society for Epilepsy [NSE], David Lewis Centre) with complex epilepsy and other neurological conditions, including learning disability and challenging behaviour. These epilepsy centres provide a range of medical, educational, residential and assessment services tailored to the needs of each individual. Patients benefit from the expert care of multidisciplinary teams consisting of neurologists, epilepsy specialist nurses, neurological or learning disability psychiatrists, neuropsychologists, physiotherapists, occupational therapists, social worker, teachers and others. An epilepsy centre offers specialized and appropriate investigations, including:

- Routine and ambulatory EEG recordings as well as video-EEG telemetry;
- Therapeutic drug monitoring; and
- Access to specialized and dedicated neuro-imaging (MRI) facilities.

However, these tests should not be used routinely, but only when clinically indicated. Epilepsy clinics and centres are considered to be better than general neurology clinics in the management of people with epilepsy: they are more likely to follow-up patients and to provide a greater continuity of care, perform fewer CT scans, but more antiepileptic drug concentration testing and EEGs. Patients attending these clinics are either given or retain more information, and are generally more satisfied with the service provided compared with those attending general neurology clinics. Although the epilepsy clinics and centres are more expensive, the additional costs can be offset by a reduction in other services, such as the number of GP visits, the amount of antiepileptic drugs prescribed, unnecessary CT scans and hospital admissions for either drug toxicity or poor seizure control.

Driving

In the UK, it is the role of the Driving and Vehicle Licensing Agency (DVLA) to issue driving licenses. Epilepsy is a condition in which special rules for licensing apply, and the patient must notify the DVLA of the occurrence of epilepsy. In other countries different rules apply.

Licensing rules in the UK

Group 1 licensing

Driving rules for a group 1 licence (a normal driving licence for car and motorcycles) are:

1 A person who has had an epileptic attack while awake must refrain from driving for 1 year from the date of the attack before a driving licence may be issued.

2 A person who has had an attack while asleep must also refrain from driving for 1 year from the date of the attack. However, if a pattern of sleep-only attacks has been established for 3 years or more, without any awake attacks occurring during this period, licensing is allowed even if sleep attacks have occurred in the preceding year; and (in both cases)

3 The person must comply with advised treatment and check-ups for epilepsy, and the driving of a vehicle by such a person should not be likely to cause danger to the public.

Group 2 licensing

Group 2 licences cover the driving of lorries, buses and taxis, and the rules are much stricter. During the period of 10 years immediately preceding the date when the licence is granted the applicant/licence holder should be:

1 Free from *any* epileptic attack; and

2 Have not required medication to treat epilepsy; and

3 Should not otherwise be a source of danger while driving.

For both types of licence

A person having a solitary seizure must normally satisfy the above regulations, except where a solitary seizure occurs in relation to alcohol and/or drug or substance misuse.

A person with a structural intracranial lesion who has an increased risk of seizures will not be able to drive vehicles of this group until the risk of a seizure has fallen to no greater than 2% per annum, the level recommended by the panel, which permits compliance with the regulations.

A provoked or acute symptomatic seizure may be dealt with on an individual basis by the DVLA if there is no previous seizure history. The decision to prohibit driving in this situation will be influenced by such aspects as:

1 Whether the provoking stimulus carries any risk of recurrence;
2 Whether the stimulus had been successfully or appropriately treated or was unlikely to occur at the wheel.
Thus, for example, the following seizures are usually considered provoked: eclamptic seizures; reflex anoxic seizures; an immediate seizure at the time of a head injury; a seizure in first week following a head injury, which is not associated with any damage on CT scanning, nor with post-traumatic amnesia of longer than 30 minutes; a seizure at the time of a stroke/TIA or within the ensuing 24 hours; or a seizure occurring during intracranial surgery or in the ensuing 24 hours. Seizures associated with alcohol or drug misuse, sleep deprivation or a structural abnormality are not considered as 'provoked' for licensing purposes.

Role of the doctor vis-à-vis the driving regulations
The following policy should be followed. The doctor must make it clear to a driving licence holder that they have a condition that may affect their safety as a driver, and therefore that the driver has a legal duty to inform the DVLA about the condition.

If the patient refuses to accept the diagnosis or the effect of the condition on their ability to drive, the doctor should advise the patient that a second opinion can be sought and appropriate arrangements should be made for this. It is important that the patient is advised not to drive until the second opinion has been obtained. If the patient continues to drive when not fit to do so, the doctor should make every reasonable effort to dissuade driving. If the patient continues to drive despite the above measures, the doctor should disclose relevant medical information immediately, in confidence, to the DVLA. Before giving information to the DVLA, the doctor should inform the patient of the decision to do so. Once the DVLA has been informed, the doctor should also write to the patient to say that a disclosure has been made.

7 Cognitive Impairment and Dementia

Martin Rossor, John Collinge, Nick Fox, Robin Howard, Giovanna Mallucci, Catherine Mummery, Jason Warren

Introduction

Cognitive impairment is very common and accompanies many neurological as well as systemic diseases. The array of syndromes arising from damage to the neural circuitry underlying cognition can be as bewildering as the terminology. Cognitive impairment is a useful umbrella term which encompasses the severe dementia of late stage degenerative diseases such as Alzheimer's disease (AD), the mild cognitive slowing of a patient on a sedative drug and the florid confusional state or delirium in the severely systemically ill. A useful distinction, easier in theory than in practice, is the distinction between delirium and dementia. Delirium, also referred to as an acute confusional state, is characterized by fluctuation, prominent impairment of attention and/or arousal, and accompanied often by agitation and autonomic features. Delirium is commonly seen in systemic diseases and as a side effect of a variety of drugs and toxins (see delirium tremens, Chapter 18). Dementia, by contrast refers to widespread cognitive impairment in the setting of normal arousal. This distinction can be difficult especially because confusional states can supervene in patients with many forms of dementia, especially dementia with Lewy bodies (DLB), that can present with fluctuating arousal and attentional deficits.

Definitions of dementia vary. The key features of ICD and DSM definitions are that the disruption of cortical function should involve more than one cognitive domain which should include memory, more specifically episodic memory. The requirement for a memory impairment has largely been determined by the prototypic dementia Alzheimer's disease which normally has a major amnestic component. However, other dementias such as frontal lobe dementia may only develop memory impairment, late in the disease. The cognitive deficits should be sufficiently severe to cause significant social and occupational impairment. It is often assumed that dementia is progressive but a dementia can be progressive, static or reversible, depending on the aetiology. There is an increasing need to identify patients early before they fulfil the criteria of dementia, which has led to the introduction of terms such as mild cognitive impairment (MCI) to describe those patients with early disease who have not progressed to fulfil the criteria for dementia. If memory is impaired (amnestic MCI) most patients are in the early stages of AD.

A useful distinction has been drawn between patients with prominent cognitive deficits arising from pathology in the cerebral cortex (cortical dementia) and those with prominent basal ganglia, thalamic or brainstem pathology (subcortical dementia). The latter patients are often very slow but accurate and exemplified by progressive supranuclear palsy (PSP). Cortical and subcortical pathologies often overlap, but the clinical distinction is useful.

It is important to realize that:

- Dementia is a syndrome caused by many different diseases; and
- Dementia may be reversible if the correct diagnosis of the cause is made and treated.

Epidemiology: delirium and dementia

Delirium is a problem of universal importance; it is encountered in all branches of medicine, and in both community and hospital practice. It has been estimated to occur in 5–15% of patients in general hospital wards, and a higher proportion in intensive care units. A plethora of systemic and intracranial disease processes may give rise to delirium (Table 7.1); the elderly and patients with any pre-existing cognitive impairment, and those with chronic systemic illness are especially vulnerable.

Dementia is an issue of enormous medical and socio-economic significance in societies with ageing populations. Prevalence rates

Table 7.1 Causes of delirium and dementia.

Category of disease	Delirium	Dementia
Acquired/sporadic		
Metabolic disturbance	Electrolyte disorders (especially hyponatraemia, hypercalcaemia), hypoglycaemia, respiratory failure/hypoxia (any cause), uraemia, liver failure, pancreatic encephalopathy, cardiac failure, dehydration, severe anaemia	Uraemia, dialysis dementia (now rare), liver failure, respiratory failure, cardiac failure, pancreatic encephalopathy, chronic/recurrent hypoglycaemia (e.g. insulinoma)
Intoxication/withdrawal syndromes	Alcohol, anticholinergics, antihistamines, anxiolytic-hypnotics, corticosteroids, anticonvulsants, cardiovascular drugs, opiates, L-dopa, dopaminergic agonists, neuroleptic malignant syndrome, prescription of multiple drugs, illicit drugs, carbon monoxide, heavy metals, herbicides (organophosphates), industrial poisons	Alcohol, carbon monoxide, heroin (inhaled), heavy metals, organic solvents, organophosphates, lithium, methotrexate, alpha-interferon
Nutritional deficiency	Thiamine (Wernicke–Korsakoff syndrome), nicotinic acid	Thiamine, vitamin B_{12}, nicotinic acid, multiple vitamin deficiencies
Endocrinopathies	Thyroid, adrenal, parathyroid, pituitary	Thyroid, adrenal, parathyroid, pituitary
Infections	Systemic Urinary tract infection, viral exanthemas, pneumonia, endocarditis, septicaemia (all causes)	
	CNS Encephalitis (especially herpes simplex), meningitis, brain abscess, HIV, cerebral malaria, neurocysticercosis, *Mycoplasma*, post-infectious syndromes	*CNS* HIV, neurosyphilis, tuberculosis, Whipple's disease, Lyme disease, cryptococcal/fungal meningitis, neurocysticercosis, JC virus (PML), measles (SSPE), encephalitis lethargica (may be post-infectious-autoimmune)
Inflammation and autoimmune	ADEM, cerebral vasculitis (primary CNS or systemic), voltage-gated potassium channel antibody/other channelopathies	Multiple sclerosis (primary progressive), cerebral vasculitis (primary CNS or systemic), neurosarcoidosis, Behçet's disease, voltage-gated potassium channel antibody/other channelopathies, anti-basal ganglia antibody syndrome, Hashimoto's encephalopathy, coeliac disease
Epilepsy	Epileptic status (non-convulsive), post-ictal states	Non-convulsive status, transient epileptic amnesia, Rasmussen's encephalitis
Neoplastic	Raised intracranial pressure (including acute hydrocephalus), carcinomatous or lymphomatous meningitis, paraneoplastic limbic encephalitis, post-radiotherapy (acute radionecrosis, thrombo-angiopathy)	Brain tumours (especially frontal/callosal/midbrain), CNS lymphoma, carcinomatous/lymphomatous meningitis, limbic encephalitis and other paraneoplastic syndromes, post-radiotherapy (accelerated cerebral atherosclerosis, radiation leucodystrophy)
Vascular	Subarachnoid haemorrhage, venous sinus thrombosis, arterial stroke (esp posterior circulation, non-dominant parietal), hyperviscosity syndromes, polycythaemia	Multiple cortical or subcortical strokes, lacunar state, strategic infarct (esp thalamus, medial frontal), hyperviscosity syndromes, polycythaemia, sickle cell disease, steal syndromes (e.g. AVM), Susac's syndrome
Head injury	Post-concussional syndrome, diffuse axonal injury, subdural haematoma, focal cerebral trauma	Subdural haematoma, repeated head injury/dementia pugilistica, late deterioration post-head injury
Other treatable causes	Pain, sleep deprivation, sensory deprivation and distortion (as in ITU), hypothermia, heat stress, postoperative recovery (multifactorial), migraine	Obstructive sleep apnoea, normal pressure hydrocephalus, obstructive hydrocephalus/aqueduct stenosis
Degenerative	Rapid cognitive fluctuation in Lewy body/Parkinson's disease dementia	Alzheimer's disease, Parkinson's disease/dementia with Lewy bodies, fronto-temporal lobar degenerations, corticobasal degeneration, progressive supranuclear palsy, motor neurone disease dementia, neurofilament inclusion body disease, Creutzfeldt–Jakob/other prion diseases
Genetic		
Metabolic	Metabolic crises in porphyria, urea cycle disorders, others	Wilson's disease, acute intermittent porphyria, lysosomal and peroxisomal storage disorders, urea cycle disorders, leucodystrophies, others
Arteriopathies	Strokes and stroke-like episodes	CADASIL, cerebral amyloid angiopathies, British dementia, Fabry's disease, others
Degenerative	Rapid cognitive fluctuation in familial parkinsonism syndromes	Familial Alzheimer's disease, fronto-temporal lobar degeneration (chromosome 17/chromosome 3/other), Huntington's disease, DRPLA, familial Parkinson's disease/Lewy body disease, mitochondrial encephalopathies, spinocerebellar ataxias, neuro-acanthocytosis, pantothenate kinase-associated neurodegeneration, neuro-ferritinopathy, neuro-serpinopathy, familial prion diseases, others (Table 7.8)

Ab, antibody; ADEM, acute demyelinating encephalomyelopathy; AVM, arteriovenous malformation; CADASIL, cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy; DRPLA, dentato-rubro-pallido-luysian atrophy; HIV, human immunodeficiency virus; PML, progressive multifocal leucoencephalopathy; SSPE, subacute sclerosing panencephalitis.

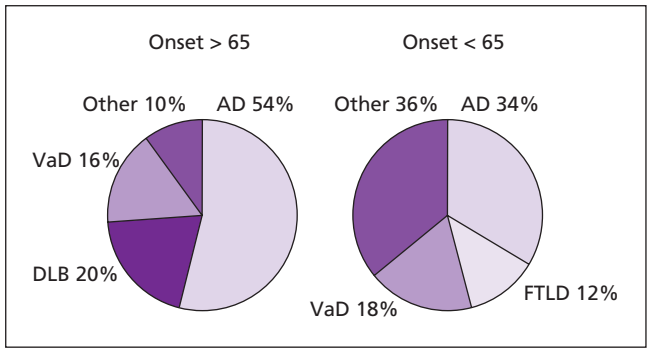

Figure 7.1 Epidemiology of dementia in older adults (onset age >65 years) and younger adults (onset age <65 years). Composite prevalence data derived from European series are displayed. The prevalence of dementia with Lewy bodies (DLB) shows wide variation between series. AD, Alzheimer's disease; DLB, dementia with Lewy bodies; FTLD, frontotemporal lobar degeneration; VaD, vascular dementia.

in Europe, for people over the age of 65 years, are approximately 6% for all causes of dementia and approximately 4% for AD. Dementia in people under the age of 65 years (young onset dementia) is increasingly recognized as an important clinical and social problem, with UK prevalence rates estimated as 67–81/100,000 in people aged 45–65 years. Although data for individual diseases are limited by diagnostic accuracy, as a group degenerative diseases are numerically the most important causes of dementia in both older and younger adults in Western countries and probably worldwide. The young onset forms of these diseases are frequently familial. Some rarer degenerative dementias such as variant Creutzfeldt–Jakob disease (vCJD) occur typically in the young patient, while other disease processes, such as fronto-temporal lobar degeneration (FTLD) and alcohol-related dementia, are also common in younger age groups. In contrast, DLB, a common cause in patients over 65 years of age, accounts for only a small proportion of young onset cases. Vascular disease is a common cause of dementia across all age groups. The epidemiology of dementia diseases in younger and older adults is presented graphically in Figure 7.1.

Cognitive functions and their clinical syndromes

Cognition, like other aspects of human brain function, has a modular organization, and different cognitive functions have distinct anatomical substrates. While a global impairment of cognitive function is often observed in delirium, specific cognitive profiles in acute brain disease are potentially of great localizing and diagnostic value. This is exemplified by the different subtypes of dysphasia in left hemisphere strokes, or the profound amnesia of Wernicke–Korsakoff syndrome. Our present understanding of the dementias has been transformed by the concept that different brain regions are affected in a characteristic and non-uniform manner as disease evolves (Table 7.2); the identification of an evolving rather than static pattern of cognitive deficits is often critical in establishing a clinical diagnosis of dementia.

Attention

Considered very broadly, attention is the ability to gate and focus sensory information and to direct awareness. The control mechanisms for attention are mediated by a hierarchy of brain structures: awareness and alertness are maintained by the ascending reticular activating system in the brainstem which projects to the thalamus and cortex; a bilateral frontal and parietal cortical network enables selective attention to particular events and types of stimuli, and divided attention to multiple events and stimuli. This cortical control system modulates activity in sensory cortices as well as the motor areas involved in response preparation. The distributed brain networks that regulate attention are vulnerable to many different disease processes. Deficits of attention are a cardinal feature of delirium, and impaired or inefficient attention is a feature of many dementias. However, the most striking deficits of attention, and those with greatest localizing value, occur with focal lesions such as stroke involving the non-dominant parietal lobe. The syndrome of hemi-neglect manifests as unawareness of contralateral (most frequently left) space. The patient may not perceive contralateral stimuli, or contralateral stimuli may be perceived when presented alone, but extinguished on presentation of simultaneous bilateral stimuli (sensory extinction). The neglect syndrome is not simply attributable to sensory deficits such as hemianopia or hemianaesthesia. Failure to direct attention to the affected field is illustrated by constructional or cancellation tasks in which stimulus features on the affected side are systematically omitted or overlooked, and there may be associated neglect of contralateral auditory stimuli that have a bilateral cortical sensory representation. Breakdown in body schema is suggested by lack of awareness of deficits involving the contralateral side of the body (anosognosia) or failure of the patient to own their contralateral limbs. The deficit may also extend to mental imagery.

Memory

Impaired memory is a defining feature of acute disorders of cognition such as the amnestic syndrome and the discrete clinical syndrome of transient global amnesia, and a very common complaint in a variety of different dementias. In order to make an accurate diagnosis, it is important to determine the nature of the memory complaint. Memory is a multi-component process supported by anatomically and functionally distinct brain networks. There is a fundamental distinction between explicit memory, the contents of which can be consciously accessed, and implicit memory, the contents of which are accessed automatically and do not depend on conscious mediation. Explicit memory has 'short-term' and 'long-term' components. In the neuropsychological sense, 'short-term' memory refers to the span for which information is retained for immediate repetition or reproduction, without rehearsal or other reinforcement (typically, less than a minute). Information that is retained for longer periods

Table 7.2 Clinical and other features in selected dementias.

Disease	Episodic memory	Visuospatial perception	Halluc	Literacy skills	Praxis	Speech prod	Speech comp	Exec	Cogn slowing	Behav	Mood	Brain MRI	EEG	CSF	Other*
Alzheimer's disease	+	+	±	+	+		±	±			±	Disprop hippo atrophy	Abn alpha		Myoclonus
Posterior cortical atrophy	±	+		+	+										
Corticobasal degeneration		+		+	+	±		±	±						Asymmetry, alien limb, EPS
FTLD:															
Fronto-temporal dementia	±					±		+		+	±				
Semantic dementia				+			+	±		±		L > R TL atrophy			
Progressive non-fluent aphasia						+		±		±		L > R peri-sylvian atrophy			
Vascular dementia	+	±		±	±		±	+	+	+	±	Vasc changes	Bitemp slowing		Strokes, brisk reflexes
Lewy body/Parkinson	+	+	+	±	±			+	+	+	±		Abn alpha		EPS Fluctuation
Huntington's disease§		±						+	+	+	+	Caudate atrophy			Chorea/other EPS, genetics
Prion disease	+	+	±	±	±			+	±	+	+	Abn BG signal	Periodic compl		Myoclonus, ataxia, rapid
Transient epileptic amnesia	+							±		±	±	Abn MTL signal/atrophy	Epilep changes		Fluctuation, seizures
Limbic encephalitis	+	±	+					±		+	+		Epilep changes	Cells, OCBs	Ca, ANAb VGKC, rapid
Cerebral vasculitis	±	±	±	±	±	±	±	±	±	±	±	Abn signal	Slowing	Cells, OCBs	Rapid
Multiple sclerosis	±							+	+	±	+	Abn wm signal		OCBs	VEPs, BAERs, abn MRI cord
Metabolic dieseases	±							+	+	+	±				Metabolic, other invest
Psychiatric disease	+		±			±		±		+	+				Fluctuation, inconsistency

+, Characteristic feature; ±, less prominent or inconsistent feature.

* Helpful but not invariable.

§ Similar 'subcortical' profile of cognitive impairment in many diseases with basal ganglia involvement.

Abn, abnormal; ANAb, antineuronal antibodies; BAERs, brainstem auditory evoked responses; behav, behaviour; bitemp, bitemporal; ca, cancer; cogn, cognitive; comp, comprehension; compl, complexes; disprop, disproportionate; epilep, epileptiform; EPS, extrapyramidal syndrome; exec, executive function; FTLD, frontoemporal lobar degeneration; halluc, hallucinations; hippo, hippocampal; invest, investigations; L, left; MTL, mesial temporal lobe; OCB, oligoclonal band (especially unmatched); prod, production; R, right; vasc, vascular; VEPs, visual evoked responses; VGKC, voltage-gated potassium channel antibodies; wm, white matter.

constitutes 'long-term' memory. Long-term memory can be further subclassified into memory for episodes or events from the individual's past experience, i.e. remembering what has happened (episodic, event or autobiographical memory), and conceptual knowledge about the world, i.e. remembering what something is (semantic memory).

The selective breakdown of semantic memory is a cardinal feature of the semantic dementia phenotype of FTLD. Episodic memory can itself be further divided into operationally distinct processes: the encoding and subsequent retrieval of new events (anterograde memory); retrieval of events prior to the onset of the illness (retrograde memory); and memory for different types of material (e.g. verbal material, faces and topography).

A characteristic amnestic syndrome with severe deficits of anterograde and retrograde memory in the setting of a clear sensorium and with preserved immediate (short-term) recall was originally described in the setting of thiamine deficiency in chronic alcoholism (Wernicke–Korsakoff syndrome, Chapter 18), and subsequently in patients undergoing bilateral temporal lobe resection for intractable epilepsy (notably the much-studied patient known as H.M.) and in other conditions such as Herpes simplex encephalitis (Chapter 8). Such patients are profoundly disabled, as they are effectively marooned in the immediate present with no capacity to lay down new memories, although it may be possible to demonstrate preserved implicit memory and procedural learning. Amnestic syndromes of varying severity are common after traumatic brain injury.

Less profound and incomplete deficits of verbal, visual and topographical memory are common early in the course of AD, DLB, vascular dementia (VaD) and other diseases. Patients frequently describe an inability to recall the details of conversations and messages, and the names of acquaintances. Impaired verbal episodic memory is the most sensitive cognitive marker of early AD, although it is not specific. Impaired topographical memory commonly presents as a difficulty with route finding, and a tendency to become lost in unfamiliar locations.

The medial temporal lobes (hippocampal formation, parahippocampal gyrus and entorhinal cortex, Chapter 2) are critical for episodic memory. The diencephalic system, comprising the thalamus and its limbic connections including the fornix and mamillary bodies, and the basal forebrain also have important roles. Postmortem findings in Wernicke–Korsakoff syndrome typically include petechial haemorrhages with astrocytic degeneration in the mammillary bodies and medial dorsal thalamic nuclei. Functional imaging studies during transient global amnesia have demonstrated localized transient hypo- or hyperperfusion consistent with dysfunction of these structures and their connections. The ascending cholinergic projection pathways, which exert important modulatory and attentional influences on the medial temporal lobe and neocortex, are disrupted in cholinergic deficient disease states such as AD and DLB. Posterior cortical areas including the posterior cingulate, retrosplenial and temporoparietal association cortex are densely connected via the diencephalic system with the medial temporal lobes and have also been implicated in AD. Memory impairment in the setting of frontal lobe disease is likely to be heterogeneous and multifactorial: memory processes that may be affected include the editing of encoded material, organized search of memory stores, attribution of the source of particular memories, and possibly emotional valence.

Short-term memory comprises separate systems for the temporary storage of auditory verbal, visual and spatial information. Rather than being passively stored, information in short-term memory generally undergoes some form of cognitive manipulation, e.g. when dialling a new telephone number, making sense of an ambiguous spoken message or visualizing an unfamiliar route. These are active processes that are directed by executive systems (see below). The interaction of executive systems with short-term memory stores constitutes 'working memory'. This interaction is illustrated in the distinction between forward digit span (passive storage of information) and backward digit span (active manipulation of online material). Working memory deficits are common in acute conditions with impaired attention and have been documented in many degenerative disorders, including AD, DLB, VaD and FTLD. It is likely that verbal short-term memory is supported by a fronto-parietal network in the left cerebral hemisphere, and visuo-spatial short-term memory by a corresponding network in the right cerebral hemisphere. These short-term storage mechanisms can be regarded as 'slave' systems under the executive control of fronto-subcortical networks.

Paramnesias

The paramnesias are characterized by false or distorted recall and may occur in acute or chronic settings. The patient when prompted to fill a gap in the record of everyday experience may describe events that never occurred, or may spontaneously supply detailed accounts of events that could not possibly have occurred (confabulation). Reduplicative paramnesias are characterized by the belief that particular places or persons have been transposed or duplicated: the patient may report that their house is an exact replica of the 'real' one (topographical paramnesia), or that their spouse has been replaced by an impostor with identical appearance (the Capgras delusion, Chapter 21). Confabulatory disturbances are most often observed in the setting of frontal lobe or fronto-limbic damage.

Transient global amnesia

Transient global amnesia is a distinct syndrome characterized by the sudden onset of severe anterograde amnesia generally lasting less than 24 hours. The patient often appears bewildered, repetitively asking the same questions. There is no disturbance of alertness and, in contrast to psychogenic fugue, personal identity is retained. Procedural and semantic memory are spared (e.g. the person may carry on driving or perform occupational tasks competently during the episode), other cognitive functions are intact and the neurological examination is normal. Complete recovery with amnesia for the period of the episode and a variable retrograde time-span is usual, although there may be persistent subtle

memory deficits, and recurrence is rare. The condition generally occurs in later life. There are a number of associations, including physical exertion, exposure to cold, strong emotion, sexual activity and migraine; however, in the substantial majority, the aetiology remains unclear. Investigations are indicated to exclude mimics such as temporal lobe lesions, but are generally unrevealing. Recurrent attacks, especially on waking from sleep, suggest the syndrome of transient epileptic amnesia (Chapter 6), often accompanied by interictal memory impairment; this is an important differential diagnosis of dementia.

Perception

Perceptual analysis of the environment is a complex multi-stage process. Visual processing is the most widely studied modality and in general the most clinically relevant. The processing of visual objects involves dissociable stages of early sensory analysis, formation of structural representations and the association of those representations with meaning. Objects have locations in space, and the perception of space requires specific neural mechanisms. The mechanisms that process visual objects and visual space can be damaged selectively, supporting a broad anatomical and physiological distinction between ventral 'what is an object' and dorsal 'where is an object' cortical processing streams (Chapter 2). Selective impairments of visual functions such as motion detection (akinetopsia) and colour perception (achromatopsia) have been described with posterior circulation strokes and other focal lesions involving the cortical visual pathways in the posterior cerebral hemispheres (Chapter 13). These syndromes may be transient or appear during the recovery phase of a more extensive visual deficit. Syndromes of progressive visual dysfunction are associated with relatively focal tissue loss and metabolic derangements involving the posterior cerebral hemispheres, and are often classified together on anatomical grounds as the posterior cortical atrophies (PCA). The most frequent tissue pathology is AD; however, a variety of others are represented, including cortico-basal degeneration (CBD), DLB and prion disease.

Cortical blindness may result from bilateral occipital lobe damage and involvement of lateral occipito-parietal areas may be associated with denial of blindness or visual anosognosia (Anton syndrome). Partial forms of cortical blindness affecting visual acuity, stereopsis or the discrimination of elementary visual patterns (form, colour or motion) also occur in PCA. Clinically, such deficits may mimic peripheral visual loss: patients may complain of blurred vision, decreased acuity or desaturation of colours. Letters of similar shape may be confused. Difficulties may be particularly apparent under conditions of reduced contrast or changing illumination. Misperceptions of visual information may occur; patterns on fabric or wallpaper may seem to shift and change, objects in the environment or body parts (especially faces) may appear distorted (metamorphopsia), abnormally persistent or transposed (palinopsia), or multiply reduplicated (polyopia).

Identification of visual objects may be impaired despite intact early visual processing. The patient may fail to recognize common household items or familiar people. There may be difficulty in distinguishing coins, banknotes or playing cards, and on examination the patient may be unable to identify fragmented, distorted or overlapping pictures or letters, silhouettes or unusual views. Such patients have apperceptive visual agnosia: this means an inability to form structural representations of visual objects, the distinctive geometric and volumetric features that enable object identity to be abstracted despite changing contexts and viewpoints. The anatomical substrates of early visual processing and object representation are likely to involve a cortical pathway extending from early visual cortices into parieto-occipital association areas. This pathway is vulnerable to various disease processes, such as infarcts, hypoxic damage and focal degeneration in PCA. Processing of complex objects such as faces involves the ventral 'what' visual stream in the inferior temporal lobe, including the 'fusiform face area'. Damage involving this region may lead to impaired face perception (prosopagnosia).

Deficits in the perception of visual space are more common than selective disorders of visual object processing. These deficits interact with mechanisms for spatial attention, which are generally more severely affected in focal brain lesions such as stroke involving the parietal lobes. However, visuo-spatial deficits are often prominent in dementias affecting the posterior cerebral hemispheres such as AD and DLB. Visuo-spatial disorders can be broadly classified as visual disorientation, the impaired perception of space relative to self (egocentric space), and visuo-spatial agnosia, the impaired perception of spatial configurations that are not referenced to one's own position (exocentric space). Patients with visual disorientation may be unable to locate objects such as cutlery immediately after they are put down or when the item is in front of them, and typically misreach for items. Threading a needle, reading lines of text, writing, using an index or even keeping within traffic lanes when driving may become impossible. Accidents when walking or driving are common, because of loss of the ability to judge distances or motion. Ultimately, such individuals become functionally blind. On examination, these patients have components of Balint's syndrome: fragmented perception of the visual field (simultanagnosia), inability to perform visually guided movements (optic ataxia) and/or inability to direct the eyes to a point in space (ocular apraxia). Because of the retinotopic encoding of egocentric space, these deficits frequently resemble hemi- or quadrantanopic field defects.

Patients with visuo-spatial agnosia may be unable to orient clothing when dressing, a camera when taking a photograph or an envelope when posting a letter. Loss of the ability to tell the time from a clock is characteristic. Patients are commonly unable to navigate familiar routes, and become lost in the neighbourhood or even within their own house (topographical disorientation). Skills such as reading text or maps, writing and calculation, which depend on accurate perception of spatial patterns, are often degraded. On examination, copying and constructional tasks are poorly performed and there may be specific deficits of spatial discrimination or spatial search (such as counting dots in an array). Anatomically, visuo-spatial deficits are associated with

damage to the superior and posterior parietal lobes, within the dorsal cortical 'where' visual processing stream.

Perceptual defects in cognitive disorders are not confined to the visual domain. Cortical deafness is a rare accompaniment of bilateral damage involving auditory cortex and ascending auditory pathways, and auditory agnosia for complex sounds such as music and environmental noises may occur with diseases involving either temporal lobe. Loss or distortions of taste (dysgeusia) occurs with damage involving the gustatory pathways and cortex in the region of the insula. Olfactory identification deficits may occur early in the course of AD, Parkinson's disease and other degenerative dementias, and are likely to be at least partly central in origin. Disorders of cortical somatosensory function such as impaired perception of shape (astereognosis) and spatial configurations on the body surface (such as drawn numbers: agraphaesthesia) and impaired recognition of objects by touch (tactile agnosia) may occur with both acute damage involving the parietal lobes and in degenerative conditions such as CBD.

Hallucinations

Hallucinations are perceptual experiences in the absence of an external sensory stimulus. They may occur in normal individuals under conditions of fatigue or sensory deprivation, or at the onset of sleep (hypnagogic hallucinations). In organic brain disease, hallucinations occur most commonly in the visual modality, and are a frequent feature of delirium. However, hallucinations in other disease states and in non-visual modalities are well recognized (e.g. olfactory hallucinations in temporal lobe epilepsy). Complex verbal (auditory) hallucinations are typical of psychiatric disorders such as schizophrenia but distinctly unusual in organic disease. Visual hallucinations can arise from a variety of insults at different stages of the retino-calcarine and cortical ventral visual pathways. Hallucinations may arise from two general mechanisms: abnormal release of sensory cortex because of loss of sensory inputs from the periphery or other regulatory controls, or abnormal excitation or disinhibition of sensory cortex by irritative processes such as seizures or migraine. Deafferentation of early visual cortex in the setting of peripheral visual loss may be associated with isolated well-formed visual hallucinations in the absence of cognitive decline (Charles Bonnet syndrome). An analogous auditory mechanism may produce musical hallucinations in acquired deafness. Damage involving the ventral midbrain may produce vivid 'dream-like' peduncular hallucinations of cartoon-like images or complex scenes, resulting from dysfunction of the reticular activating system. Structural or functional lesions involving early visual cortices may produce elementary visual hallucinations (exemplified by 'fortification spectra' or teichopsia in migraine) while more complex or multimodal hallucinations, sometimes involving distortions of self-perception, may occur in the setting of temporal lobe disease.

Visual hallucinations are modulated by dysfunction of neurotransmitter pathways. Hallucinations are particularly striking and complex in diseases such as DLB in which there is a cortical deficiency of acetylcholine. Descriptions of hallucinations are often remarkably stereotyped: the patient typically sees unfamiliar people or animals (especially cats or other small creatures), mobile or stationary, often multiple, but generally silent. Hallucinations frequently appear in the evening or in darkness. They may be glimpsed transiently at the edge of view, or emerge from an environmental feature such as a piece of furniture or a garden scene. Extracampine hallucinations are associated with the sense of a presence beyond the field of view. The 'phantom boarder' delusion (the sense that there is another person in the house when there is not) may be a related phenomenon.

Knowledge

The brain mechanisms that mediate the storage and retrieval of knowledge constitute those of semantic memory. The most striking and selective deficits of knowledge are produced by focal lesions involving the ventral visual pathways in the inferior temporal lobes and by focal degeneration of the left temporal lobe in semantic dementia (SD). In SD, disintegration of word knowledge produces a progressive impairment of word-finding and word comprehension which is generally the presenting and most prominent feature of the syndrome. Naming deficits are characteristically early and prominent; a generic or superordinate term is often used in place of the more specific one (e.g. 'animal' in place of 'camel'). These patients do not grasp the meaning of words and typically have particular difficulty with definitions.

The selective inability to associate visual representations of objects with meaning constitutes an associative visual agnosia, which may occur as a relatively isolated deficit with temporo-occipital lesions or may develop in the course of SD. As is the case for verbal knowledge, semantic deficits can be relatively specific for the visual domain. Patients may be unable to identify everyday objects or describe their function despite accurate and detailed analysis of perceptual features. Patients with prosopagnosia lose the ability to recognize familiar faces, including acquaintances, famous people or even close family members. The recognition deficit may be selective for faces, dissociating from other types of person knowledge and from other categories of knowledge.

Neocortical regions in the anterolateral and inferior temporal lobes are likely to be critical for conceptual knowledge. Impaired word knowledge in SD is associated with atrophy involving the dominant (left) anterolateral temporal lobe. Person knowledge is likely to be asymmetrically distributed between the right and left anterior temporal lobes, the left anterior and inferolateral temporal lobe representing verbal information (such as personal names) and corresponding regions of the right temporal lobe representing familiar face information. Progressive prosopagnosia has been described much less frequently than SD. This is likely to be at least partly attributable to the clinical silence of the right temporal lobe relative to the eloquent left temporal lobe.

Voluntary action

Diseases that disturb the cognitive control processes involved in programming and guiding voluntary action produce apraxia: a

disturbance of voluntary movement that cannot be explained by elementary motor or sensory deficits. The classification of apraxia poses conceptual and practical difficulties; however, a basic distinction can be drawn between disorders that affect unfamiliar, novel or meaningless actions (ideomotor apraxia), and disorders that affect previously learned actions (ideational apraxia). Apraxia generally occurs in association with more widespread deficits involving the dominant parietal or frontal lobes; however, cases of primary progressive apraxia have been described.

Apraxia for novel and meaningless actions is a prominent feature of dementias such as AD that involve the posterior hemispheres, and in this setting there is often additional evidence of impaired visuo-spatial perception. Novel tasks requiring mechanical problem-solving (such as assembling prefabricated furniture or models) and learning new motor skills pose particular difficulties. The patient has difficulties in imitating the examiner's meaningless hand positions. There may be particular difficulty when movements must be combined into a short sequence.

Less commonly, apraxia leads to impaired production of actions previously learned. Manual occupations and hobbies may be abandoned, and the patient may be unable to use common household tools and utensils, or attempt to use them inappropriately (e.g. attempting to write with scissors). When instructed to perform a symbolic gesture (such as waving goodbye or saluting) or to pantomime the use of a tool (such as a screwdriver or hammer) an awkward or fragmentary approximation may be produced. Both the configuration of the fingers and the movements themselves are typically abnormal. Action production may be facilitated by holding the corresponding tool or other contextual cues. In addition, the patient may fail to recognize familiar gestures mimed by the examiner.

Apraxias affecting specific parts of the body are well recognized. Asymmetric limb apraxia is a cardinal presenting feature of CBD, where it is characteristically accompanied by asymmetric rigidity and other extrapyramidal or cortical sensory signs. Actions involving the affected limb comprise coarse, uncoordinated or mutilated constituent movements, sometimes termed limb-kinetic apraxia. Impairments affecting the voluntary control of orofacial movements often dissociate from disorders of limb praxis. Orofacial apraxia is often observed in association with impaired speech production. The patient may lose the ability to whistle and may complain of difficulty initiating chewing or swallowing. When instructed to cough, yawn or sigh the patient may produce an inadequate facsimile or simply repeat the instruction emphatically; however, these actions are typically normal when performed spontaneously and the examiner's orofacial gestures may be imitated competently.

So-called constructional apraxia, impaired ability to copy drawings of objects or designs, is observed both with focal lesions and degenerative diseases variously affecting visuo-spatial perception, spatial attention and executive processes. In the majority of cases it is likely to be multi-factorial in origin rather than representing a specific disorder of voluntary action. Similar reservations apply to several other disorders, including dressing apraxia which is probably largely attributable to deficient visuo-spatial analysis, and apraxia of eyelid opening which in many cases has the features of a focal dystonia. The true status of gait apraxia, the selective impairment of walking (and often other axial motor programmes), remains somewhat controversial, as gait abnormalities may arise at various levels of the motor hierarchy. However, it is observed in association with focal lesions and degenerative processes affecting the frontal lobes and subcortical projections (as in hydrocephalus).

Patients with asymmetric limb apraxia may have difficulty in making cooperative movements using both hands because the more affected hand tends to mirror the other or otherwise interferes with the action: the alien limb phenomenon. The patient may complain that the affected arm is useless or seems not to belong to them, and the arm may tend to levitate or assume other odd postures (especially when attention is diverted or during walking). Forced grasping or reaching for objects in the immediate environment may occur, or there may be more organized purposeless actions such as repeatedly removing and replacing spectacles. Among the dementias, the most characteristic association is with CBD, although other pathologies have been described.

The neural control mechanisms for the control of voluntary action are distributed within a network of cortical and subcortical areas, and mixed forms of limb apraxia are common. Conceptual knowledge of gestures is likely to be mediated at least in part by the dominant temporal lobe, while the left parietal lobe is likely to have a key role in the integration of sensory information in the organization of actions. An anterior system for the production of gestures may represent motor programmes for action in each hemisphere, and predominantly unilateral damage involving this system may lead to asymmetric limb-kinetic apraxia involving either side. Orofacial apraxia is associated with focal lesions or degenerative syndromes (such as progressive non-fluent aphasia) with asymmetric atrophy predominantly involving left inferior frontal and opercular regions.

Speech

The complex operations of human speech can be broadly classified as sensory decoding, comprehension, repetition, retrieval and production. Each of these operations can be considered at the level both of single words and sentences. These different operations are affected in a variety of acute and chronic cognitive disorders. Speech and language impairments (the dysphasias) are most commonly the result of focal lesions affecting the cortex of the dominant (left) cerebral hemisphere, but the recent recognition of focal 'language-based' dementias has revolutionized contemporary thinking about the degenerative brain diseases. Classic concepts of the human language system such as that of Lichtheim posited a cortical centre for word concepts connected by transcortical pathways with a posterior centre for processing word sounds and an anterior centre for programming speech output (Chapter 3). This model has undergone considerable refinement

in recent decades, influenced by functional imaging studies in healthy individuals as well as clinical observations in both stroke and focal cortical degenerations. The basic bedside distinction between fluent ('Wernicke's', 'sensory', 'posterior') and non-fluent ('Broca's', 'motor', 'anterior') dysphasia remains useful; however, it is not absolute clinically, anatomically or pathologically. Because of its quite different anatomical and clinical significance, it is important to distinguish fluent dysphasia from confusion (e.g. in the context of delirium); this can usually be accomplished by a careful analysis of the patient's spontaneous speech, in particular the presence of speech errors (paraphasias).

Comprehension of speech depends fundamentally on the accurate decoding of the acoustic signal at the level of its constituent sounds. In the setting of acute disease such as stroke, impaired speech comprehension or Wernicke aphasia is generally associated with damage involving Wernicke's area in the dominant posterior superior temporal lobe. However, the true functional and anatomical status of this area remains contentious. Selective impairments of speech perception manifesting as word deafness have been described rarely with acute bilateral or left-sided damage and degenerative disease affecting the posterior temporal lobe. Such patients have difficulty both in understanding and repeating spoken words despite normal comprehension of written material. Impaired comprehension of single words in the setting of intact acoustic analysis and repetition constitutes a transcortical sensory aphasia (Chapter 3), originally described with posterior watershed infarcts. However, a similar syndrome is associated with breakdown in verbal knowledge systems in SD (see below), suggesting an important role of the left anterior temporal lobe in normal language processing which is more difficult to reconcile with classic models of language organization derived from the study of stroke and other acute lesions. Impaired sentence comprehension occurs in dementias such as progressive non-fluent aphasia (PNFA) in which there is disturbed processing of grammatical structure. Functional disconnection of posterior (input) from anterior (production) language areas produces a selective impairment of speech repetition or conduction aphasia, observed chiefly with focal damage involving the left parieto-temporal junction and the arcuate fasciculus.

Impaired word retrieval leads to word-finding pauses or circumlocutions in everyday conversation and a reduced ability to name (anomia). It is most often studied using confrontational naming tasks, in which nouns must be produced in response to pictures or other stimuli. Failure of retrieval in this situation is characteristic of anomic aphasia, which may be associated with a variety of focal lesions affecting the language system, e.g. during the recovery phase of stroke. Progressive anomia is a hallmark of SD; however, naming (and, more generally, word retrieval) deficits are also observed in AD and many other dementias. It is important to appreciate that confrontational naming depends on many distinct subprocesses, including intact perception and executive function, and intact connections between the cortical areas mediating these functions. This is illustrated by naming impairment resulting from visuo-perceptual deficits in PCA, and modality-specific impairments (e.g. optic and tactile anomia) with focal lesions interrupting transcortical and interhemispheric sensory pathways. Normal propositional speech involves not simply the retrieval of individual words, but the construction of a sentence that conveys an idea or message. Disruption of the process of message generation produces dynamic aphasia, with characteristics similar to transcortical motor aphasia: reduced spontaneous propositional speech despite the ability to produce speech relatively normally in specific contexts such as naming, repetition or reading. Dynamic aphasia has been documented with focal lesions and dementias that damage frontal or fronto-subcortical circuitry.

The spoken output of words and sentences in turn requires a number of distinct operations. The components of the verbal message must be combined according to morphological and syntactic rules. The breakdown of grammatical output (syntax) is a hallmark of Broca's aphasia, observed classically with focal lesions involving the inferior frontal gyrus of the dominant hemisphere. As is the case with Wernicke's area, however, the true functional role of Broca's area has not been fully clarified and should not be equated simply with language output. Broca's aphasia is characterized by effortful, dysfluent and agrammatic speech with a disjointed and telegraphic quality because of omission of verbs, prepositions and other function words. The production of single words involves both the selection and grouping of appropriate syllable codes (phonology) and the articulation of the corresponding motor programme. Progressive breakdown in either or both of these operations commonly occurs in PNFA, and in other disorders such as CBD and motor neurone disease dementia. This syndrome includes relatively pure cases of cortical anarthria. Phonemic paraphasias (such as 'stirel' for 'squirrel') are often accompanied by articulatory errors. Prosody, the pattern of stress and timing that constitutes the melody of speech, is frequently abnormal. It is also important to distinguish dysfluency resulting from a primary disorder of speech production from interrupted output resulting from prolonged word-finding pauses (so-called 'logopenic' aphasia), which may occur in other conditions including AD. The spontaneous production of novel non-words (neologisms) and jargon may accompany fluent aphasia in acute disorders but rarely in degenerative disease.

Disorders that produce selective impairments of speech processing are associated with focal lesions or asymmetric atrophy predominantly involving the left perisylvian region. Deficits of speech perception are associated with damage involving the left posterior superior temporal gyrus, a region that includes early auditory areas. Impaired syntactic comprehension has been correlated with involvement of the left posterior temporo-parietal region. Impaired word retrieval occurs with interruption of a distributed asymmetric (predominantly left-sided) brain network including left lateral temporal cortex, left inferior and lateral frontal areas. Partially overlapping regions including the left inferior frontal gyrus, frontal operculum and anterior insula have been identified in group and single-case studies of speech

production breakdown in stroke, PNFA and other disorders, implicating these dominant anterior regions in the motor programming of speech. The basal ganglia, thalamus and subcortical pathways in the dominant hemisphere participate in distributed cortico-subcortical networks mediating language and speech, and focal lesions involving these structures may closely resemble the corresponding cortical functional deficit.

Literacy and numeracy

An individual's premorbid level of literacy and numeracy is heavily influenced by educational attainment and potentially by specific long-standing limitations such as developmental dyslexia or dyscalculia. Such factors must be taken into account when interpreting the effects of disease.

A basic distinction is often made between reading disorders that occur without writing impairment (alexia without agraphia) and those that are accompanied by writing impairment (alexia with agraphia), originally described with acute lesions such as stroke affecting the posterior cerebral hemispheres. Alexia without agraphia is classically produced by the conjunction of a right homonymous hemianopia and damage involving the posterior corpus callosum, precluding the transfer of information from the left hemi-field (right occipital lobe) to the verbal left hemisphere; alexia with agraphia results from more extensive lesions involving the posterior left hemisphere. An alternative classification of the dyslexias is based on the cognitive operations involved, whereby disturbed visual analysis of written words produces a peripheral dyslexia (often with preserved writing ability) and disturbed analysis of written words for sound or meaning produces a central dyslexia (often with associated deficits of written output). Impaired visual analysis of written words or peripheral dyslexia is often a prominent feature of PCA, in which associated visuo-perceptual and visuo-spatial impairments are common. These individuals typically read letter by letter. Central deficits of written word processing beyond the stage of visual analysis fall into two general categories, which may dissociate: these correspond to two parallel routes to reading, based on analysis for sound (the phonological encoding of print-to-sound correspondences) and analysis of meaning (sight vocabulary). If reading by sound is damaged, there is a failure to use the general rules of phonological encoding (phonological dyslexia). These patients have particular difficulty reading meaningless words, grammatical function words (e.g. 'and', 'if', 'for') and morphological features such as tense or plurals. If reading by sight vocabulary is damaged (surface dyslexia), there is reliance on reading by sound. Irregular words are incorrectly regularized according to surface orthographic features (e.g. 'yacht' may be pronounced 'yached'), while regular words are read correctly. Impaired reading by sight vocabulary is a frequent and characteristic feature of SD.

Visually based (peripheral) dyslexia is associated with bilateral or predominantly left-sided occipito-temporo-parietal damage or hypometabolism and histopathological involvement of the ventral visual pathway. In central dyslexia, impaired reading by sight vocabulary is associated chiefly with degeneration of the left anterior and inferior temporal lobe, in common with other components of the SD syndrome, while impaired reading by sound is associated with pathology in left peri-sylvian language regions.

Impairments of writing and spelling (the dysgraphias) can be broadly classified according to whether the core defect lies with spelling processes (central dysgraphias) or the motor programming and execution of writing (peripheral dysgraphias). As is the case for the dyslexias, mixed forms are common. Spelling can proceed via sound-based (phonological) and vocabulary-based routes, and central dysgraphias affecting each route have been described in patients with dementia. Impaired spelling by sound (phonological dysgraphia) is associated with particular difficulty writing grammatical function words and word endings. The breakdown of vocabulary-based spelling (surface dysgraphia) manifests as regularization errors in rendering exception words (e.g. 'juice' may be spelled 'juse') while phonologically regular words are spelled correctly. Impaired spelling vocabulary is a characteristic feature of the SD syndrome, but also occurs commonly in AD and in other dementias. The various stages of letter shape selection, formation, placement and sequencing that underpin the motor output process of writing may be deranged in disease processes that disrupt visuo-spatial analysis or voluntary action. Dysgraphia is generally a feature of diseases involving the left parietal lobe; however, surface dysgraphia is associated with surface dyslexia and other features of SD in the setting of left temporal lobe atrophy.

Disorders of calculation can be classified according to whether the core defect lies with computation proper or with the procedures required to process written and spoken numbers. Patients typically complain of a loss of facility in handling change or household accounts, and may have relinquished these responsibilities to others. There may be specific difficulties in adding scores and calculating totals in games, in using measuring instruments, or in reading and writing numerals and number words (e.g. when issuing a cheque). Like dysgraphia, dyscalculia is often a prominent feature of diseases affecting the dominant parietal lobe. The association of dysgraphia and dyscalculia with finger agnosia and right–left disorientation is known as Gerstmann's syndrome (Chapter 3) although it is unlikely this particular constellation has special significance other than implicating the dominant angular gyrus.

Executive function

The generation of complex behaviour demands that many cognitive operations are combined, coordinated, adapted to different contexts and directed to relevant goals. The regulatory and supervisory brain mechanisms that achieve this together constitute the cognitive executive. These mechanisms are instantiated chiefly in frontal lobe cortex and its subcortical connections, and indeed the recognition that frontal lobe damage may produce profound alterations in conduct and personality (as in the celebrated case of Phineas Gage) was one of the cornerstones of modern behavioural neurology. However, it is important to recognize that executive dysfunction and frontal lobe impairment are not

equivalent concepts. The cognitive and anatomical organization of the executive remains poorly understood: while it is possible to identify broad syndromes of executive dysfunction, in clinical practice these almost invariably overlap. Executive impairments are produced by a very wide range of acute and chronic diseases.

Perhaps the most striking frontal lobe syndrome is characterized by loss of capacity to gate or modulate the effects of cognitive inputs according to the overall context. Patients with impaired response modulation have particular difficulty in taking account of feedback or assessing the consequences of their own behaviour. Affected individuals almost invariably lack insight into their difficulties, but a change in the patient's personality is all too evident to others, and is accompanied by poor social judgement and inappropriate behaviour or insensitive remarks. Disinhibition and impulsivity may disrupt personal and occupational relationships. There is a reduced capacity for abstract thought, and patients typically display an inflexible and concrete approach to occupational and daily life tasks. Defective processing of social signals may contribute to impaired understanding of the mental states of self and others ('theory of mind'). Checking or counting routines, ritualized daily routes and schedules, clock-watching and hoarding are common. Analogies and similarities may not be recognized, and proverbs interpreted literally ('People in glass houses shouldn't throw stones or the glass will break'). The ability to formulate a strategy for searching cognitive or sensory inputs is often compromised: this commonly manifests as reduced verbal fluency (the number of words generated in 1 minute according to a specified criterion, usually semantic category or initial letter).

An impaired ability to generate behavioural outputs leads to a loss of autonomy and increasing dependency on environmental cues and events to initiate behavioural subroutines. Apathy (abulia), inertia, passivity, perseveration, and motor and verbal stereotypies are common features of this syndrome. Left undisturbed, patients may contentedly spend all day watching television or absorbed in jigsaw puzzles or word games, and they may be disengaged from these activities only with difficulty. Loss of initiative commonly extends to household tasks and personal hygiene. There may be utilization behaviour (e.g. the patient may don spectacles or peel a piece of fruit automatically when the item is placed before them), hyperorality (sometimes including mouthing of inedible items) or mimicry of others' speech (echolalia) or actions (echopraxia).

Slowness of thought (bradyphrenia) and difficulty in switching between behavioural subroutines or 'sets' spontaneously or according to context are hallmarks of fronto-subcortical damage. There may be perseverative errors on attempting to draw a sequence of alternating shapes or produce a sequence of alternating hand movements. Palilalia (repetition of the patient's own words or terminal phrases) also occurs.

Executive difficulties are exposed by tasks that demand planning, abstract thought, flexibility and consideration of alternative solutions. There is often little consistency between tests or even between testing sessions in the individual patient. Characteristic features include implausible but over-precise estimates (distance from London to New York is '266 miles'), impaired performance on dual tasks (such as tracking a visual target while reciting a list of numbers), and difficulty grasping simple rules (sorting multidimensional items by size, shape or colour) or in devising a problem-solving strategy (such as the 'Tower of London' puzzle).

The anatomy and pathophysiology of executive dysfunction remains poorly understood, and there is little consensus regarding the neural correlates of core executive functions. A similar pattern of cognitive and behavioural impairments may be associated with variable findings on structural and metabolic brain imaging. Disinhibition, sociopathic behaviour and altered physiological drives broadly correlate with predominantly right-sided anterior temporal and inferior frontal lobe damage and hypometabolism, and abulia with dorsolateral frontal and anterior cingulate involvement. Disinhibition, impaired theory of mind and disturbed modulation of sensory inputs are associated particularly with orbitofrontal and ventromedial frontal damage.

Emotion

Alhough they have traditionally been regarded as the domain of the psychiatrist, disturbances of emotion comprehension and expression are integral to many neurological disorders and are often closely allied with other behavioural and executive impairments. Defective processing of emotions often has major social consequences. Poor understanding of the emotional states of people and animals, lack of empathy and reduced expressivity are often interpreted as coldness and lack of affection. Other patients display fatuous and puerile emotional responses. Paradoxically, there may be increased engagement with religious, philosophical or artistic pursuits. A dramatic illustration of the breakdown of normal emotion processing is the Klüver–Bucy syndrome, originally described in monkeys following bilateral temporal lobe ablation. The syndrome has been reported rarely in humans, but does occur in the context of acute destructive processes such as herpes simplex encephalitis, and is characterized by loss of normal emotional reactivity, abulia, altered sexual responses and hyperorality.

Disturbances of mood (in particular, depression and dysphoria) are commonly associated with stroke, temporal lobe epilepsy and head injury, and with AD and other degenerative disorders (Chapter 21). These affective changes are likely to be caused, at least in part, by damage involving limbic circuits and their neocortical projections. Specific deficits of emotion comprehension have been documented in both acute and chronic disorders with mesolimbic damage, and are a hallmark of certain degenerative diseases, notably FTLD and Huntington's disease. A distributed predominantly right-sided fronto-temporal network including the amygdala and orbitofrontal cortex is likely to be critical for normal emotion processing: this network is a plausible interface between primitive emotional states linked to biological drives and the neocortical cognitive machinery of complex goal-directed behaviours.

Investigation of the patient with cognitive impairment

Basic principles

The differential diagnosis of delirium and dementia is very extensive (Table 7.1), and a structured approach to the investigation of cognitive impairment is therefore essential. This approach should be tailored to the clinical problem at hand, guided by an accurate and complete history and examination (Tables 7.1 and 7.2). However, the first priority of investigation in every patient is to exclude a reversible condition. Most causes of delirium and a number of causes of dementia fall into this category, and delirium frequently supervenes on a background of more insidious cognitive decline in elderly patients and those with limited cognitive reserve. Accurate diagnosis, particularly in dementia, may have important implications for prognosis and possibly genetic counselling of other family members.

Initial investigation

Initial investigations should be minimally invasive and directed toward the identification of reversible metabolic, infective, inflammatory and other systemic processes. A number of investigations are relevant in the initial approach to both acute and chronic impairment, especially where the precise time course is difficult to establish or more than one process is likely (Tables 7.3 and 7.4). A basic initial battery includes full blood count and differential, biochemistry including serum calcium, renal, liver and thyroid function tests, coagulation profile, serum B_{12} and folate, inflammatory markers (ESR and CRP), an autoimmune screen (antinuclear factor), a chest radiograph, ECG and urinalysis. Clinical judgement is required in interpreting the significance of such screening results, e.g. a low serum B_{12} is common in the elderly, but it is rarely the sole cause of cognitive decline.

Neuropsychometry

Neuropsychometry is an extension of the bedside cognitive examination and can be very valuable in characterizing the cognitive profile in more detail (in particular, the identification of subclinical deficits that might not be volunteered in the history). It is most useful and relevant for the detection of change in cognitive function, either in assessing the effect of static insults, where ongoing deterioration is a diagnostic issue (typically, in the identification of dementia) or in assessing response to therapy. Many neuropsychometric tests provide quantitative and normative data that allow the individual's premorbid cognitive attainment to be estimated and their current cognitive performance to be measured in relation to a healthy age-matched population. Documentation of performance in particular cognitive domains allows the likely origin of the cognitive problem to be specified, because particular patterns of deficit have localizing value (Table 7.2). A plethora of neuropsychological tests is available. These require a trained neuropsychologist to administer and interpret, ideally informed by a clinical summary that identifies the purpose of the referral and areas of chief concern. The timing of test administration should be considered carefully: it is rarely informative to perform neuropsychometry during a delirium or the acute phase of a stroke or head injury (because further alteration

Table 7.3 An approach to investigation of the patient with rapid onset cognitive impairment.

Associated features	Investigations
	Screening investigations
May have systemic symptoms and signs	Blood: full blood count, renal function, electrolytes, liver function, coagulation, glucose, thyroid function, ammonia, amylase, ESR/CRP, ANF urinalysis
	ECG, chest X-ray
	Additional investigations
Head injury, signs of raised ICP, focal cognitive deficit, neurological symptoms and signs, no systemic explanation, neurological assessment unreliable, headache, meningism, fever	Brain imaging: CT, MRI, MRI venography, angiography
	CSF examination, including cultures and viral PCR, septic screens, serology vasculitis screens, neoplasia screens
Recurrent attacks suspicion inherited disease	EEG, echocardiogram autoimmune, thrombotic screens, urinary catecholamines, serotonin metabolites, porphyrins, consider specialized metabolic screens
Drug use/possible toxic exposure	Rationalize medications
	Drug/toxicological screens
Poor nutrition	Nutritional screens
Pain sensory/sleep deprivation environmental factors	Identify source
Major affective disorder, psychosis not attributable to above; fugue state, factitious disorder	Psychiatric evaluation

ANF, antinuclear factor; CRP, C-reactive protein; CSF, cerebrospinal fluid; CT, computed tomography; EEG, electroencephalography; ESR, erythrocyte sedimentaion rate; ICP, intracranial pressure; MRI, magnetic resonance imaging; PCR, polymerase chain reaction.

Table 7.4 An approach to investigation of the patient with dementia.

Associated features	Investigations
	Screening investigations – all patients
May have systemic symptoms and signs	Blood: full blood count, renal function, electrolytes, liver function, coagulation, glucose, thyroid function, ESR/CRP, ANF, syphilis serology, B_{12}, folate, urinalysis
	ECG, chest X-ray, brain imaging: CT, MRI if available
	EEG
	Additional investigations – selected patients
Young onset, non-cognitive neurological features, family history	HIV serology, copper studies, slit lamp examination, consider specialized metabolic and genetic screens, muscle/axillary skin, marrow, liver biopsy
Rapid course, headache, meningism, fever other features atypical of common degenerations (including age <65, systemic features, neurological signs)	Vasculitis, auto-antibody screens (incl ANCA, APL, VGKC Ab, coeliac screens) antineuronal antibodies, other neoplasia screens (incl whole-body PET, CT)
	CSF examination (including cells, protein, glucose, oligoclonal bands, cytology, cultures; may include 14-3-3, S100, Whipple PCR, JC/other viral PCR, cryptococcal Ag, measles Ab, syphilis serology, TB and other special cultures)
	MRI FLAIR sequences, prion genotyping if suspect prion disease, tonsillar biopsy if suspect vCJD
Clinical seizures prominent fluctuation (not in context of DLB)	Prolonged EEG (if routine EEG not diagnostic) autoimmune, thrombotic screens echocardiogram, other vascular screens urinary porphyrins
Sleep disorder	Sleep study
Drug use/possible toxic exposure	Rationalize medications drug/toxicological screens
Poor nutrition, suspicion of deficiency	nutritional screens
Major affective disorder, psychosis not attributable to above; fugue state, factitious disorder	Psychiatric evaluation
Suspicion of treatable (inflammatory) process when diagnosis not established by non-invasive means	Brain biopsy

Ab, antibody; Ag, antigen; ANCA, antineutrophil cytoplasmic antibody; ANF, antinuclear factor; APL, antiphospholipid antibody; DLB, dementia with Lewy bodies; FLAIR, fluid-attenuated inversion recovery; PCR, polymerase chain reaction; PET, positron emission tomography; vCJD, variant Creutzfeldt–Jakob disease; VGKC, voltage-gated potassium channel antibody.

in cognitive state can be anticipated), or repeatedly within a short timeframe (because practice effects are likely to make interpretation difficult). The patient's age and level of education must always be taken into account and, as with any investigation, results should be interpreted in the context of the specific clinical scenario.

Brief mental state schedules such as the 30-point Mini Mental State Examination (MMSE; the Folstein test) are simple to administer at the bedside and give an overall snapshot of cognitive performance, but lack sensitivity for the detection of subtle or isolated cognitive deficits while depending heavily on particular domains, notably verbal processing. Such schedules may be of most value in charting change in cognitive function over time, although they remain crude indices. Frequently used standardized tests include the National Adult Reading Test (NART), which provides an index of premorbid intellectual attainment, and the Wechsler Adult Intelligence Scale (WAIS; revised, WAIS-R), which provides a profile of a range of verbal and non-verbal abilities. A variety of quantitative memory tests are in use, including the Recognition Memory Test for words and faces, which provides measures of verbal and non-verbal material-specific memory. Many tests have been used to assess executive function, including the Wisconsin Card Sorting Test (which requires the classification of stimuli according to various implicit rules) and Raven's Progressive Matrices (a test of abstract pattern continuation that does not depend on verbal mediation); however, this is a notoriously difficult domain to quantify and results are heavily affected by deficits in other domains (e.g. visual perception). Batteries to assess other functions such as visual object and space perception, praxis, naming and semantic knowledge are widely available.

Brain imaging

Structural brain imaging is indicated in all patients with dementia, and in patients with delirium where no systemic cause is identified, or where focal cognitive or neurological signs, headache, evidence of raised intracranial pressure or head trauma are present. This may be particularly critical in situations where neurological status cannot be reliably assessed, e.g. in acute alcohol or drug intoxication, or where an acute process may have supervened on pre-existing cognitive impairment. CT is widely available, and is adequate for detection of hydrocephalus and focal intracranial lesions such as subdural haematoma, brain abscess and tumours. CT is specifically indicated for detection of subarachnoid haemorrhage or intracranial calcification. However, magnetic resonance imaging (MRI) is distinctly superior for examination of the brainstem and posterior fossa structures, the

basal ganglia and detail of cerebral white matter and the cortical mantle. In patients with dementia, T1 MRI sequences can be particularly valuable in detecting pathological atrophy: volumetric MRI employing thin slices can be used to delineate patterns of regional atrophy that may have diagnostic significance, while serial MRI has an increasing role in the assessment of progressive atrophy (both generalized and regional) for diagnosis and prognosis. T2-weighted sequences are used to assess white matter signal change and tissue oedema. Additional sequences may be useful for certain indications, e.g. fluid attenuated inversion recovery (FLAIR) sequences to assess basal ganglia and thalamic signal in suspected prion disease, and diffusion-weighted imaging (DWI) to detect acute ischaemic damage which is probably the most sensitive imaging marker of prion disease with cortical diffusion signal change, reflecting spongiform histology.

Functional brain imaging techniques have a limited role in clinical practice. Metabolic imaging using single photon emission tomography (SPECT) or positron emission tomography (PET) may occasionally be useful in identifying regional functional changes in patients with frontal lobe syndromes and normal structural imaging; however, these techniques are not widely available and interpretation is difficult.

Electroencephalography

The EEG is generally of limited diagnostic usefulness in delirium, which is frequently accompanied by generalized slowing of cerebral rhythms indicating diffuse cortical dysfunction. As a tool for the detection of local pathology it has been largely supplanted by brain imaging techniques; however, it remains essential for the detection and localization of seizure discharges (particularly in non-convulsive status epilepticus). In dementia, the EEG is often helpful in the differential diagnosis. Conditions such as AD with diffuse cortical dysfunction are frequently accompanied by degeneration or loss of the normal alpha rhythm, while in focal dementias such as FTLD alpha rhythm is generally preserved at presentation. The EEG may also detect covert epileptiform changes in amnestic syndromes resulting from partial seizures, or periodic complexes in classic CJD, subacute sclerosing panencephalitis (SSPE) and other conditions with severe cortical derangement. Prolonged ambulatory or video-EEG may be indicated where there is strong suspicion of covert or unrecognized partial seizures.

Cerebrospinal fluid examination

Examination of the CSF is indicated where CNS infection is suspected, provided no contraindications exist (Chapter 8). Lumbar puncture is also recommended for younger patients with dementia and in cases where there is an unusual presentation or rapid course, to exclude an inflammatory process. Suspicious features include a raised CSF cell count (pleocytosis), and/or unmatched oligoclonal bands (indicating local synthesis of immunoglobulin in the CNS). Polymerase chain reaction (PCR) can be used to amplify and detect viral and other infectious agent DNA. Cytological examination may reveal atypical or malignant cells. Elevated total CSF protein is a non-specific finding in isolation. Elevated protein 14-3-3 is associated with rapid neuronal destruction in classic CJD, while elevated S-100 is associated with gliosis. However, despite much recent interest and good evidence that AD is associated with a reduction in CSF Aβ 1–42 and an increase in tau, diagnostically specific CSF protein biomarkers have yet to enter routine clinical practice.

Additional investigations

Additional investigations are dictated by clinical features in conjunction with the results of the initial battery (Tables 7.3 and 7.4). These may include vasculitic, infectious, autoimmune, neoplastic and toxicological investigations, and in younger patients, copper studies, white cell enzymes and genetic testing. HIV serology, although not routine, should always be considered, especially in younger patients or where risk factors exist. The more common familial dementias have autosomal dominant inheritance, and the diagnostic yield of genetic analysis is therefore likely to be higher in the younger patient with a positive family history (see Table 7.8); however, late onset cases of genetically mediated dementia do occur (e.g. in Huntington's disease) and the family history may be censored, incomplete or inaccurate.

Tissue biopsy may be required to establish the diagnosis in a minority of patients with dementia, especially in younger individuals, as directed by clinical features (Tables 7.2 and 7.8). Tonsillar biopsy has gained a place in the diagnosis of a small number of patients with suspected vCJD. Skin biopsy (including apocrine sweat glands) may detect abnormal accumulations in Lafora, Kufs or other storage diseases and in CADASIL (cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy). Nerve biopsy may be diagnostic in rare dementias with peripheral nerve involvement such as metachromatic leucodystrophy. Muscle biopsy including histochemistry and respiratory enzyme analysis may confirm a mitochondrial disorder. Marrow biopsy may identify the 'sea-blue histiocyte syndrome' of Niemann–Pick disease Type C and other storage diseases, and may also be indicated in the diagnosis of haematological and other malignancies in suspected paraneoplastic syndromes. Small bowel biopsy may be indicated to exclude Whipple's disease, and liver biopsy is occasionally indicated to exclude Wilson's disease. In exceptional cases, brain biopsy may be necessary where there is unresolved suspicion of a treatable (inflammatory or infectious) process where the diagnosis cannot be made by other means and potentially toxic treatment is contemplated. In some cases this is directed to a focal lesion; however, in most patients it is necessarily a 'blind' biopsy from the non-dominant frontal lobe. A full-thickness open biopsy including cortex, white matter and meninges should be performed by a neurosurgical team experienced in the technique. Disposable instruments should be used in cases where the risk of prion disease is considered clinically significant. Brain biopsy in patients with dementia carries an approximately 10% combined risk of significant morbidity or mortality, and should always be a carefully weighed decision.

The dementias

Alzheimer's disease

Alzheimer's disease (AD) is the most common cause of cognitive decline with AD pathology, in part or in whole, underlying at least 50% of all cases of dementia. AD is the prototypical cortical dementia against which other dementias are compared in a differential diagnosis. An understanding of the clinical features and diagnostic approach to AD is central to being able to distinguish the different dementias.

The prevalence of AD is strongly age-dependent – doubling every 5 years after the age of 60 years with around 1% of those aged 65–69 years affected rising to almost 20% in those aged 85 years or over. It is therefore important to have a low threshold of suspicion for cognitive decline in elderly patients who may not necessarily have cognitive problems as the presenting complaint; however, these impairments can complicate management of other neurological or medical conditions.

AD is also the most common cause of early onset dementia, arbitrarily defined as symptom onset before the age of 65 years. However, sporadic AD starting before the age of 50 years is very rare, and in these cases a genetic cause should, even in the absence of a family history, be suspected.

A definitive diagnosis of AD requires histopathological examination of brain tissue demonstrating excess accumulation of extracellular amyloid plaques and intracellular neurofibrillary tangles (Figure 7.2). The key building block (Chapter 2) of the amyloid plaque is beta-amyloid (Aβ), a 40–42 amino acid long peptide, formed following the cleavage of a much larger precursor polypeptide called amyloid precursor protein (APP) encoded by the APP gene on chromosome 21. Rare causes of autosomal dominantly inherited AD resulting from mutations in APP are caused by single peptide substitutions largely clustered around either end of the Aβ peptide – at sites of enzymatic cleavage from APP.

In established AD, amyloid plaques are found widely distributed throughout the cortex with heaviest deposition in the cortical association areas. Amyloid may also be laid down in cerebral blood vessels leading to amyloid angiopathy. The relative proportions of parenchymal amyloid (plaques) and vascular amyloid (angiopathy) varies considerably between patients. In familial AD and transgenic mouse models of AD, the relative proportions of these two forms of amyloid deposition seem to be related to the length of peptide generated by the pathogenic mutation, with a higher proportion of Aβ-42 promoting parenchymal deposition whereas relatively greater amounts of Aβ-40 leads to more vascular amyloid.

Neurofibrillary tangles result from the breakdown of the microtubule component of the neuronal cytoskeleton. Tau, a protein whose normal function is thought to be to promote and stabilize microtubule assembly, becomes hyperphosphorylated in

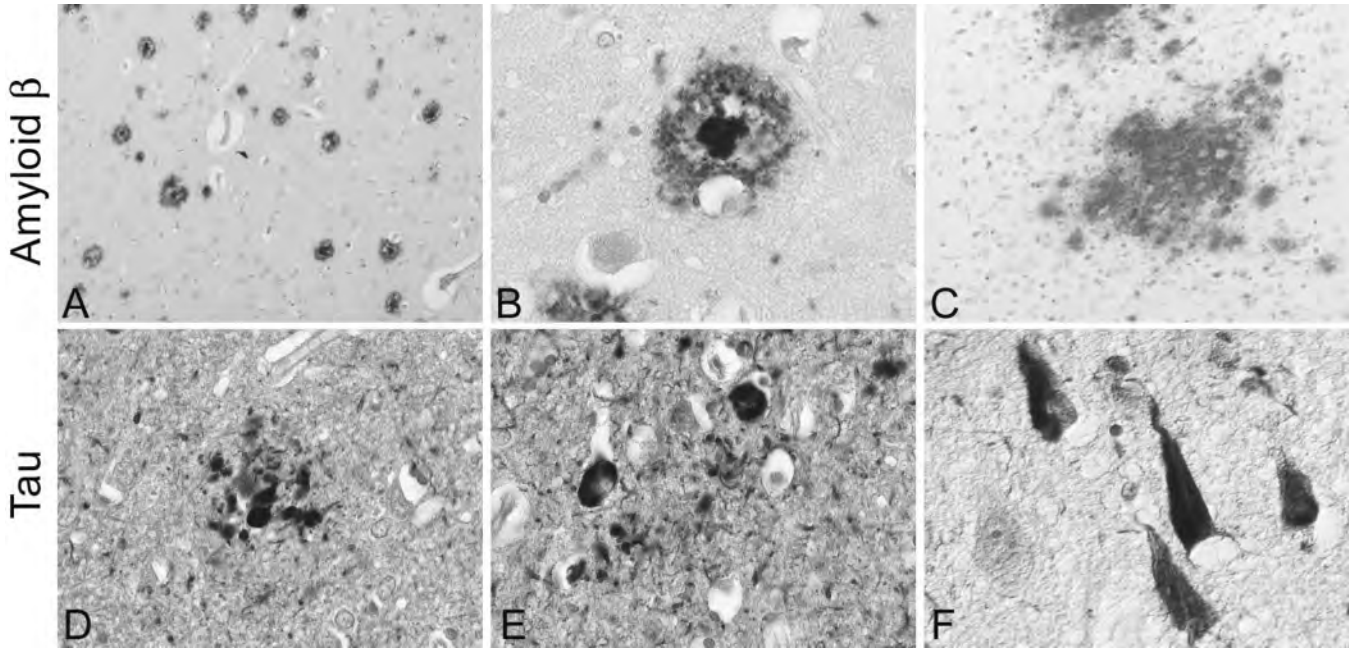

Figure 7.2 Alzheimer's disease: amyloid b (A, B, C) and tau deposits (D, RE, F): A, B: Autopsy specimen with abundant amyloid plaques in the neocortex seen at low power magnification (A), which are predominantly mature (neuritic) plaques which are characterised by a dense core and a peripheral halo seen at high power magnification (B). Diffuse plaques or large protein deposits (C) are probably a precursor of core plaques and can also be found in the ageing brain without being necessarily associated with dementia ('pathological ageing'). Neurites crossing the plaque become dystrophic and contain hyperphosphorylated tau protein, as shown in (D). Tau immunohistochemistry also shows multiple intraneuronal inclusions, so-called neurofibrillary tangles, which may assume various shapes (small globose perikaryal (E) band-shape, or flame shape (F), all at high power magnification.

AD and aggregates into an insoluble tangle within the neurone. Autopsy studies suggest that neurofibrillary tangles first appear in the entorhinal cortex before progressively involving the hippocampus and other limbic structures and then becoming widely distributed in neocortical association areas. Primary motor and sensory cortices are relatively spared.

Mutations in three genes are known to cause autosomal dominant AD with a high level of penetrance and usually with an early age at onset. Together these mutations account for only 1% of all cases of AD. Mutations in the *APP* gene, the first to be discovered, produce symptom onset typically between 45 and 60 years of age. Mutations in the Presenilin-1 gene (*PS-1*) on chromosome 14 account for approximately 50% of all autosomal dominant familial AD and often have the youngest age at onset: typically between 35 and 50 years of age but may be as early as 30 years and may occasionally present after the age of 65 years. Mutations in Presenilin-2 (*PS-2*) on chromosome 1 are relatively rare as causes of AD; cases have a young, although variable age at onset.

The clinical features of familial AD (whether resulting from *APP*, *PS-1* or *PS-2* mutations) are similar to each other and to sporadic AD (there are rare atypical presentations such as a spastic paraparesis in *PS-1*). Therefore, in a patient presenting with cognitive decline suggestive of AD with a family history of early onset dementia, testing for mutations in all three genes is appropriate. Presymptomatic testing of 'at-risk' individuals from known pedigrees is also possible, with appropriate counselling.

Overall, a family history of AD in a first degree relative occurring at any age confers an approximately twofold increase in an individual's lifetime risk. This is largely because of the risk-modifying effect of the apolipoprotein E gene (ApoE). ApoE exists in three isoforms: E2, E3 and E4. The most common isoform is E3, with E4 being less common and E2 relatively rare. Inheriting a single E4 allele increases the risk of AD approximately two- to threefold and is associated with an earlier age at onset. This risk is dose dependent, with homozygosity being associated with a four- to eightfold relative risk, and a mean age at onset 5–10 years earlier than average. However, the E4 allele is neither sufficient (in contrast to APP and presenilin) nor necessary to produce AD: approximately 20–30% of the general population carries one or more E4 alleles, and only 60–70% of all cases of AD have one or more E4 alleles. As a result, consensus guidelines do not recommend testing for ApoE as part of the diagnostic work-up of a patient with possible AD.

Clinical features and assessment

The regional distribution and progression of the pathology of AD largely accords with the march of clinical symptoms, which start insidiously, and gradually and inexorably progress. Obtaining a reliable history is key to the diagnosis. Patients often lack insight and it is essential to obtain a collateral history from a close informant. Partners or family members may not want to embarrass or contradict the patient and therefore, with the patient's consent, it is helpful to speak in part without the patient present in order to understand the extent of an individual's problems.

The most common complaint, often made by a carer, spouse or other family member rather than by the patient, is of problems with memory. Patients become repetitive in questioning, forgetting that they asked the same question recently, be it minutes, hours or days ago. Messages or errands are forgotten and there is progressive difficulty often with misplacing items (e.g. keys, glasses). A particular early feature of the memory deficit is the inability to place memories correctly; thus, patients may remember that someone visited but be unsure of the context (when the visit happened or who else was there). While many of these symptoms may be reported during normal ageing or by patients later determined to be 'worried well', what distinguishes AD is the severity of the deficit and its inevitably progressive nature.

In neuropsychological terms, these early symptoms reflect impairment of episodic memory. Recall is usually worse than recognition memory and although patients commonly lack insight into the severity of their problems they are often aware that memory is a problem. This memory deficit is a harbinger of the progressive impairment of all other higher cortical function. However, an isolated memory deficit is not sufficient for a clinical diagnosis of AD. Diagnostic criteria for AD require deficits in multiple cognitive domains of sufficient severity to impair activities of daily living. In the earliest stages, patients may have objective deficits of episodic memory without any other cognitive impairments and may have little problem continuing their activities of daily living. 'Amnestic Mild Cognitive Impairment' (MCI) describes such individuals with objective impairment of memory (scoring 1.5 standard deviations below the age-related mean for healthy controls) but without dementia. Longitudinal studies have shown that patients fulfilling criteria for MCI develop AD at a rate of about 10–15% per year. However, MCI represents a heterogeneous group and includes individuals who score badly on tests of memory because of anxiety or depression and also individuals who have static deficits, e.g. resulting from vascular damage.

How best to identify those patients who will go on to develop AD is a major topic of research. Some factors in the history may provide clues: if the carer is more aware of the problems than the patient, the probability of the symptoms being caused by AD is more likely. Conversely, if it is the patient who is complaining more of their problems than the informant, an alternative non-neurodegenerative cause is more likely. Asking the patient and informant to provide detailed examples of memory problems is often helpful. It is clearly less significant if someone occasionally forgets a message or cannot remember where they have placed an item when they have been distracted, multi-tasking or simply not been giving it their full attention. However, it is of more concern if the carer reports being asked frequently about the timing of hospital appointments or reports being cooked two evening meals.

There are a number of associated features that may accompany these early deficits. In particular, carers often report that the patient has become less confident, less spontaneous and more apathetic, and may seem depressed. Depression and AD commonly coexist and depressive symptomatology may mimic AD.

It is sensible to have a low threshold for suspecting and treating depression, ideally avoiding anticholinergic antidepressants. However, the presence and proportion of cognitive deficits are the key to determining that depression is related to the onset of AD rather than an alternative explanation. A common complaint of relatives of patients with AD is that initial problems were down to depression, and the cognitive decline overlooked because the informant's history was not properly considered.

As the pathological process progresses beyond the medial temporal lobes, so too do the cognitive deficits. Patients with AD typically develop cortical deficits that are symmetrical (left and right hemisphere involved simultaneously) and generalized (posterior cognitive functions affected as well as anterior). The clinical assessment therefore should aim to assess the pattern of cognitive decline from the history, from bedside testing and, ideally, with formal neuropsychometry. In addition to memory and orientation problems there are often subtle impairments of planning, decision-making and working out complex sequences, and learning new tasks (e.g. failures to master new equipment either at home or at work). Defining the presence of posterior (i.e. parietal and/or occipital) dysfunction should be sought, as this makes an alternative diagnosis of fronto-temporal dementia (FTD, see below) less likely.

Unlike fronto-temporal lobar degneneration (FTLD) syndromes and the frontal subcortical deficits of VaD, AD is not usually associated with marked behavioural and personality change in the early stages apart from a loss of confidence and some apathy. Thus, a useful contrast to FTLD is that spouses of those with AD usually feel that the patient has essentially the same personality. While problems with memory may be profound and individuals with AD are less confident in a number of cognitive areas, maintenance of a good social façade even in the presence of impaired insight, is a common feature of AD.

As the disease progresses, all these initially subtle cognitive deficits become marked and behavioural problems become more common. More severe language problems develop, including naming difficulties. Carers often report that patients no longer read as much as they have before, often because of a combination of impaired memory for what they have read and difficulties following the plot. With time, problems with speech and naming become increasingly marked, eventually leading to significant impairment of communication.

There may also be a history of increasing difficulty in using tools or implements which had previously not been a problem. Problems with praxis, which may sometimes be picked up in the early stages as subtle difficulty in copying complex hand movements, become more obvious with time.

Visuo-spatial difficulties may manifest as a deterioration in an individual's ability to drive, often reported by their passengers. Minor accidents may occur, as a consequence of misjudging distances or making incorrect decisions. This is compounded by a greater tendency to get lost in unfamiliar circumstances, and errors of judgement. Therefore, patients with a diagnosis of AD and their carers must be reminded of their legal obligation to inform licensing authorities (DVLA in the UK) and depending on severity may need to be advised to stop driving. In the later stages, agitation is relatively common and occasionally aggression often associated with frustration may be a major problem. Delusions are common and can be particularly distressing for patient and carer. The kernel of the delusions can often be understood in the context of failing memory and reasoning abilities, e.g. delusions of theft are common as an in-patient.

In the early stages, there are generally no focal neurological signs and apart from the praxis problems mentioned above, the examination may be normal. Myoclonus (often most noticeable in the fingers) may occur later in the disease, although patients with autosomal dominant AD tend to have early and prominent myoclonus, often a harbinger of seizures later on. In the late stages, there may be a generalised increase in tone in a *gegenhalten* fashion.

Brainstem and motor function are typically preserved when many higher cognitive abilities have been significantly degraded. Patients ultimately become unable to self-care but may still be capable of wandering, often with marked sleep–wake cycle reversal. In the later stages, problems with continence develop. Seizures, when present, are usually a late feature. Swallowing difficulties can also develop and contribute to pneumonia, one of the most common causes of death. Survival is age-related but is typically 5–15 years from first symptoms.

Investigations

Apart from familial cases where demonstration of a pathogenic mutation in *APP*, *PS-1* or *PS-2* is diagnostic, there are no definitive laboratory tests for AD. It is therefore important to exclude, as detailed elsewhere in this chapter, alternative causes for cognitive decline.

A number of investigations have positive predictive value for AD. Neuropsychometry is important in establishing the extent and pattern of cognitive deficits, and in established cases typically demonstrating deficits in a broad range of cognitive domains, prominent problems with episodic memory and posterior dysfunction at least as significant as anterior without a marked left–right asymmetry.

Current guidelines suggest that all patients with dementia should undergo structural imaging (CT or MRI) as part of their diagnostic work-up. As with neuropsychometry, structural imaging, in addition to excluding a space-occupying lesion, can help in making a diagnosis of AD by identifying the pattern of loss. AD is associated with marked and disproportionate medial temporal lobe atrophy, which is most easily assessed by looking for evidence of bilateral hippocampal atrophy (Figure 7.3). AD is also associated with ventricular enlargement and generalized cortical atrophy symmetrically involving both parietal and frontal lobes. These findings are best seen with MRI using a coronal T1-weighted volumetric sequence.

Imaging, and in particular MRI (T2-weighted or FLAIR), can be used to assess the extent of cerebrovascular disease. Functional imaging, PET and SPECT, show symmetrical temporo-parietal

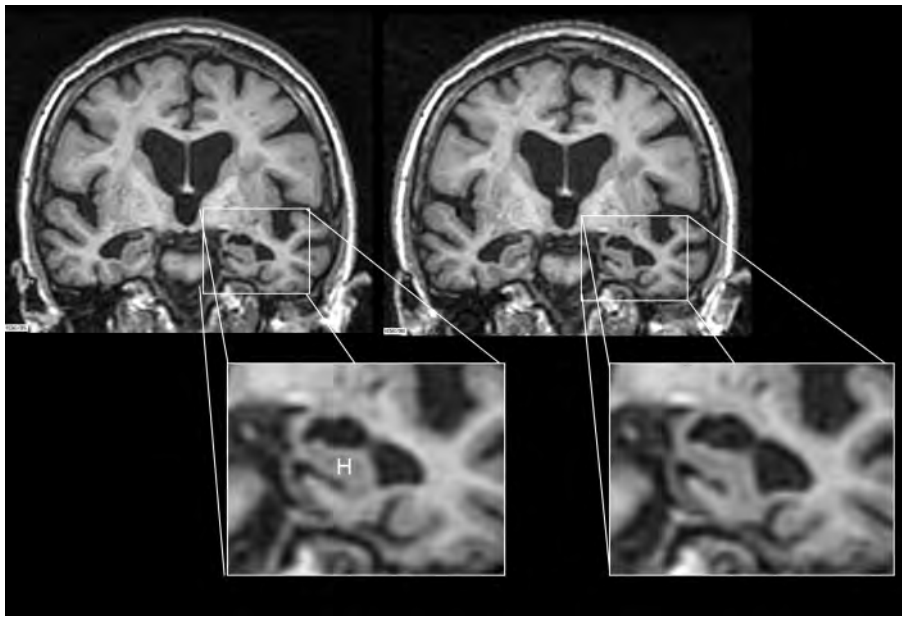

Figure 7.3 Hippocampal atrophy. Two coronal T1-weighted MRI scans of a patient with probable AD – baseline on the left; follow-up one year later registered to baseline. The inset shows a magnified view of the left hippocampus (H) with progressive atrophy over the year.

hypometabolism and hypoperfusion. None the less, the wide range of normality means either structural of functional scans may be reported as normal in the early stages of AD. Molecular imaging for AD (e.g. PET ligands for amyloid) appears very promising but are currently research tools.

EEG may be important to exclude seizure activity as a relatively uncommon cause of memory impairment and, if this is suspected, prolonged recordings may be required. In AD the EEG typically shows generalized slowing and loss of alpha rhythm, although in mild cases may appear normal.

There is increasing interest in using CSF markers to differentiate AD from other neurodegenerative dementias. In AD the CSF is usually acellular with normal protein. CSF tau (total levels and specific phosphorylated forms) are increased in AD while CSF Aβ-42 is reduced. The combination of these markers appears to differentiate AD from controls with sensitivity and specificity of approximately 90% but rather lower discriminatory ability to separate AD from other dementias.

Management

It is important that both patient and carer are considered in management. A holistic approach which covers social support, prognostic information and advice on legal, benefit and support issues is essential. Treatment of depression must be considered. Specific symptomatic pharmacological treatments for AD are discussed below; these include the cholinesterase inhibitors and memantine, an NMDA antagonist.

AD continues to be the subject of intensive research. Drugs aimed at modifying the disease process are under development. One promising strategy is Aβ immunotherapy which is currently undergoing stage III clinical trials. In mice such therapy has been shown to clear amyloid plaques from the brain and be neuroprotective if given before the onset of significant pathology. Other strategies include beta or gamma *APP* secretase inhibitors which aim to reduce Aβ production.

Cholinesterase inhibitors

The cholinesterase inhibitors (AChEIs) have been specifically developed as symptomatic treatment for AD. The rationale for their use is based on neurochemical findings in the cerebral cortex of patients with AD, in whom there is reduced activity of the enzyme choline acetyltransferase, with subsequent reduction in cortical levels of the neurotransmitter acetylcholine (ACh). By inhibiting the breakdown of ACh, AChEIs enhance the levels of ACh in cerebral cortex. There are currently three AChEIs licensed for the treatment of mild to moderate AD: donepezil (Aricept), galantamine (Reminyl) and rivastigmine (Exelon) (Table 7.5) Donepezil is a specific and reversible inhibitor of acetylcholinesterase (AChE), galantamine is a selective, competitive and reversible inhibitor of AChE, which additionally enhances the intrinsic action of ACh on nicotinic receptors, and rivastigmine inhibits both AChE and butyrylcholinesterase. They have similar efficacy; donepezil is available as a once-daily prescription and galantamine is available as a once daily slow-release preparation.

The clinical efficacy of AChEIs has been measured using the Alzheimer's Disease Assessment Scale (ADAS-Cog), which assesses cognitive function, and the Clinician Based Impression of Change

Table 7.5 Summary of NICE Guidelines for treatment of Alzheimer's disease (November 2006). See http://www.nice.org.uk/page.aspx?o=288826

NICE recommend donepezil, galantamine and rivastigmine as options in the management of moderate Alzheimer disease where MMSE is between 10 and 20 under the following conditions:

- Treatment should be initiated by specialists but may be continued by general practitioners using a shared care protocol
- The carer's views should be sought before and during treatment
- The patient should be assessed 2–4 months after a maintenance dose is established. Treatment should only continue if the MMSE has improved or not changed and if behavioural or functional assessment shows improvement
- The patient should be reviewed every 6 months. Treatment should usually only continue if MMSE score remains above 10 and it is considered that treatment is having a worthwhile effect on functioning and behaviour and the person's carer supports continued treatment
- It is recommended that therapy should be initiated with a drug with the lowest acquisition cost
- People with mild AD already on a cholinesterase inhibitor may continue on therapy until they or their carer consider it appropriate to stop

plus carer input (CIBIC-plus), which takes a more holistic view of the patient. A number of large randomized controlled trials have shown statistically significant, if clinically modest, symptomatic benefits of AChEIs on both ADAS-Cog effects and CIBIC over their 6-month duration, equivalent to a delay in symptomatic cognitive decline and temporary stabilization of the patient's clinical and functional state. Further, in open label extensions of these trials effects have been reported to last up to 5 years, and Cochrane reviews of donepezil and rivastigmine also report significant improvements on rating scales for activities of daily living and neuropsychiatric symptoms.

The use of AChEIs in dementia remains a hotly debated subject. There is disagreement over the quality and consistency of the clinical evidence, the size of benefits and the cost-effectiveness of treatment, where the cost of prescription is evaluated against the gain to the patient in terms of quality-adjusted life years (the CQG, or cost per quality year gained). The major criticism is the modest improvement afforded to most patients projected over several years, giving low CQG scores. Clinical experience and carer and patient analysis suggest that, while the response to treatment may be limited in the majority, up to 20% of patients have more dramatic improvements, which are concealed in averaged responses across the patient group. However, even small effects can significantly benefit quality of life for patients and carers. These are not easily costed and the financial calculations do not account for patients in whom treatment had been discontinued because of lack of response, nor for savings in carer input generated by treatment with AChEIs. In the UK, the NICE guidelines for the treatment of AD with AChEIs (November 2006) recommend their use only in patients with moderate AD (MMSE 10–20) (http://www.nice.org.uk). This recent recommendation to exclude patients with mild AD from treatment is based on an apparent lack of cost-effectiveness of treatment in this group. However, as mentioned above, this differs from anecdotal clinic experience. The value to affected individuals and their carers of some means of treating the progressive loss of intellect and personality to which they are condemned is also impossible to cost. The current NICE guidelines for treatment with AChEIs are summarized in Table 7.5.

The major problem in assessment of any individual is predicting who will respond to treatment, and to what extent. In general, when improvement occurs it appears to be maintained over several months, and while the extent of improvement may attenuate, the advantage over placebo can persist for several years. It is likely that use of AChEIs in combination with drugs acting on other neurotransmitter systems may work synergistically.

Treatment should be stopped when benefit is no longer evident. This is often a subjective decision made by the clinician after discussion with the patient and carer, based on either:

- A global impression; or
- Deterioration on a rating scale such as the MMSE.

As AChEIs can provide other benefits, particularly on behavioural and neuropsychiatric symptoms, their effectiveness in all areas should be considered. If in doubt, the drug should be withdrawn for a few weeks and if there is rapid decline in behaviour and/or cognition, the drug should be restarted. A trial of withdrawal should be considered on an annual basis.

Memantine

Memantine has an entirely different mode of action to the AChEIs, potentially preventing glutamate-mediated neurotoxicity. It is a voltage-dependent, moderate affinity, non-competitive *N*-methyl-D-aspartate (NMDA)-receptor antagonist and blocks the effects of pathologically elevated tonic levels of glutamate by preventing calcium influx into the neurone. It has beneficial effects in slowing cognitive decline in mild to moderate AD, but also in vascular dementia and is generally well tolerated. It was previously licensed for use in moderately severe AD. It is currently used when AChEIs are thought to have lost efficacy, in AD patients intolerant of AChEIs or in whom these are contraindicated (e.g. heart block). A recent randomized controlled trial showed that a combination of donepezil and memantine showed greater improvement in cognition, activities of daily living and neuropsychiatric symptoms than donepezil combined with placebo. Side effects are uncommon; they include hallucinations, confusion, dizziness, headaches and tiredness.

Fronto-temporal lobar degeneration

FTLD is an umbrella term that is used to describe the clinical features of a group of non-Alzheimer's neurodegenerative

disorders. These fall broadly into three types, each of which is associated with a distinct set of presenting symptoms and distribution of regional cerebral atrophy involving frontal and temporal regions.

Frontal variant or fronto-temporal dementia

Frontal variant FTLD (fvFTLD) or fronto-temporal dementia (FTD) is the most common presentation of FTLD, accounting for over half of all cases seen. Patients typically present with personality change and breakdown in behaviour, including features such as apathy, sociopathy, disinhibition and euphoria. Invariably there is loss of insight and self-care early on, and later changes in food preference, hyper-religiosity, and stereotypic or repetitive behaviours.

Within fvFTLD, a distinction is recognized between patients who are disinhibited and socially inappropriate, and those who are apathetic. These two presentations are believed to reflect damage to dorsolateral and orbital regions of frontal cortex, respectively, although the prominence of individual symptoms may also depend on hemispheric involvement.

As the disease progresses, disruptive behavioural symptoms usually worsen. Disinhibited patients often develop inappropriate antisocial behaviours, and may even be arrested for stealing or disorderly behaviour. Angry outbursts are common, and conversation can be punctuated by tactless remarks. One-third of cases demonstrate emotional lability, changing quickly from inappropriate jocularity to passivity or anger. When apathy is dominant, patients become progressively inert, robotic and emotionally detached. Utilization behaviour, or environmental dependency, may be observed. For example, if the patient is offered a pair of spectacles then they will put them on; if offered another pair they will put them on over the first. Repetitive behaviours (checking, collecting, repetition of phrases or gestures) commonly develop. Such issues are often the most distressing for the family, and greatly increase the caregiver burden. Drug treatments or other mechanisms for dealing with these problems are unfortunately limited.

Neuropsychological testing may reveal executive impairment as the sole or most prominent finding, particularly within 2–3 years of disease onset. Other specific deficits (and the neuropsychological instruments with which they can be detected) include: a tendency to perseverate (verbal fluency), impaired planning (Wisconsin card sorting test), loss of inhibition, failure of recall with improvement on cueing (Wechsler Memory Scale), limited problem-solving (Raven's progressive matrices) and concreteness of thought (Cognitive Estimates test).

Imaging (MRI) may also be entirely normal in the early stages, revealing an asymmetrical pattern of atrophy of frontal and anterior temporal lobes as symptoms progress.

Temporal variant FTLD

The onset of temporal variant FTLD (tvFTLD), also known as semantic dementia (SD) is insidious, with a prodrome of 5 years or more often recognized retrospectively. Patients may complain of memory problems, but the presenting feature is typically word-finding difficulty, especially problems with producing people's names or common nouns. The earliest recognizable language deficit consists of fluent, and grammatically correct but empty spontaneous speech, with word-finding difficulties, circumlocution, impaired confrontation naming and reduced verbal fluency, especially for conceptual categories (e.g. types of animal or vehicle). Disintegration of general knowledge becomes apparent in failure of single word comprehension, and later of associative knowledge about concepts.

In contrast to the severe semantic deficit, phonology, prosody and grammar are relatively intact. Other aspects of language become affected to a degree, e.g. patients typically show a surface dyslexia such that irregularly spelt words (such as 'sew' or 'pint') are read according to typical spelling-sound mappings (in the example, to rhyme with 'few' and 'mint'). Later changes include loss of comprehension, echolalia (automatic repetition of words/phrases said to them) and bruxism. Other cognitive domains such as episodic memory, perceptual and visuo-spatial abilities are relatively preserved.

Imaging reveals severe asymmetrical anterior temporal lobe atrophy, in particular affecting the fusiform gyrus (Figure 7.4). Left temporal atrophy is dominant when the earliest symptom is one of verbal semantic loss, but when there is initial behavioural change, right temporal atrophy predominates. Left tvFTLD is three times as common as right tvFTLD, but both reflect similar pathophysiological processes (see below). It is unclear why the left temporal lobe should be more vulnerable to neurodegenerative pathology.

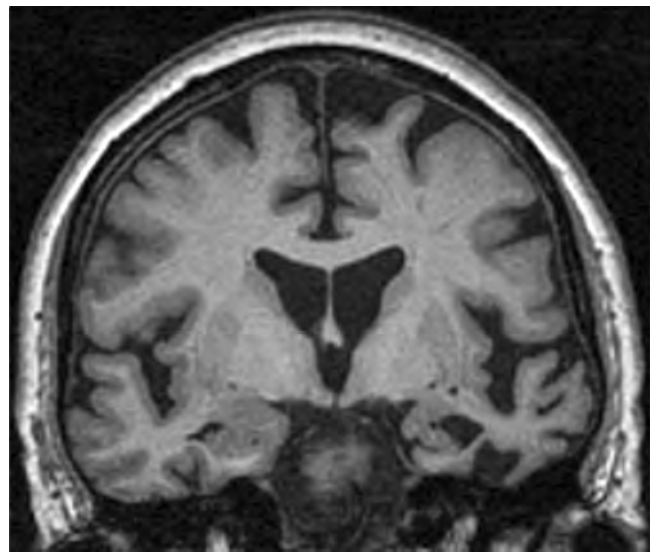

Figure 7.4 Coronal section of T1-weighted brain MRI showing focal atrophy predominantly involving the antero-inferior left temporal lobe, a pattern typical of semantic dementia.

Progressive non-fluent aphasia

The third common presentation is of a non-fluent language disorder, a deficit that usually remains circumscribed for many years, which may cause significant delay in presentation. Patients produce decreasing quantities of effortful, phonologically disrupted language, together with a strikingly preserved ability to understand individual words. Phrases become telegraphic, sentences short and disjointed, and comprehension is often impaired at the sentence level. Writing is similarly affected. Insight is usually retained, often with extreme distress.

In addition to the language-specific features there may be an associated orofacial apraxia, exacerbating the speech disturbance and sometime leading to difficulty swallowing. It is not until late in the course of the disease that behavioural features such as rigidity and loss of concern for others arise. This syndrome is associated with atrophic changes in the left inferior frontal and anterior insular cortex.

Neurological examination in FTLD is usually normal, although a subgroup of cases have or later develop additional signs of weakness and wasting in bulbar and/or limb muscles, in a pattern indistinguishable from amyotrophic lateral sclerosis (ALS). Primitive reflexes such as snout, suck and grasp may also become prominent in mid to late stages. Urinary and faecal incontinence occur in the final stages. Basal ganglia involvement can cause parkinsonism in some, and dysfunction of the frontal eye fields can cause abnormal saccadic eye movements.

Natural history

The three clinical subgroups progressively merge with time, such that in the later stages patients develop features of Klüver–Bucy syndrome: hyperorality may be demonstrated, with excessive gum chewing, smoking, drinking or eating. Most gain weight, although severely affected patients may place non-food items in their mouths. In addition, utilization behaviour (indiscriminate interaction with all items within reach) is often present.

In general, onset occurs between 50 and 65 years, with most patients surviving 6–12 years. Several studies have now suggested a faster rate of progression in FTLD (onset to death 6–8 years) than in AD (9–11 years).

Familial FTLD

Our understanding of the molecular genetics, biochemistry and neuropathology of FTLD is accelerating, thanks to recent advances in the genetics of familial FTLD. A large proportion of FTLD patients (35–50%) have a family history of dementia.

In tau-positive FTLD, microtubule associated protein tau (MAPT) mutations have been found to cause FTD and parkinsonism linked to chromosome 17 (FTDP-17), and have been linked to clinical syndromes resembling PSP, CBD and Pick's disease. Notably, considerable clinical heterogeneity is observed both between mutations and within families with the same mutation. Mutations in the progranulin gene also on chromosome 17 have been found to cause a large proportion of familial cases with tau negative ubiquitin positive inclusions (FTLD-U). Further, recent work has shed light on the nature of the protein components in FTLD-U. For example, TAR DNA-binding protein 43 (TDP-43) has been identified as a key protein in the ubiquitin inclusions of FTLD-U and in ALS, constituting a common pathologic substrate linking the two disorders.

Investigation

In the majority of cases the distinctive anatomical distribution of atrophy can be appreciated on structural or functional imaging. Although overlap at the clinical level inevitably occurs, advances in imaging have undoubtedly improved the accuracy with which the degenerative pathologies underpinning FTLD can be distinguished from that of AD during life.

EEG activity has traditionally been thought of as remaining normal in contrast to AD, in which absent alpha rhythm and generalized slowing are typical. A normal EEG in the context of progressive cognitive decline has therefore come to be regarded as supporting a diagnosis of FTLD. However, EEG abnormalities occur in over half of FTLD cases, and the severity correlates with disease progression in both FTLD and AD groups. The CSF is usually normal although cases associated with tau deposition may have raised CSF tau.

Neuropathology

Postmortem examination of the brains of patients with any of the FTLD syndromes can reveal shrunken cortical gyri, usually restricted to the frontal and/or anterior temporal lobes, reflecting underlying neuronal loss and gliosis. In some frontal cases, atrophy may be mild; the most common focus of frontal atrophy is the orbito-medial region, with additional involvement of the frontal pole, inferior frontal gyrus and insula. Disproportionate involvement of dorsolateral aspects may occur, but is less common. Temporal lobe involvement is typically concentrated in anteromedial regions, particularly the inferior and lateral surfaces, while the posterior two-thirds of the superior temporal gyrus are usually strikingly spared.

Three broad groups of histopathology can be distinguished:

1 Abnormal deposition of tau protein;

2 Inclusions negative for tau but positive for ubiquitin – a protein inclusion first described in association with the pathology of motor neurone disease (MND);

3 Neuronal loss and gliosis unaccompanied by any specific histological features.

Although there is still no universally agreed diagnostic terminology, most authorities refer to tau positive cases as Pick disease, and ubiquitin positive inclusion as fronto-temporal dementia with MND-type inclusions (FTD-MND) or ubiquitin positive FTLD-U and the non-specific cases as 'dementia lacking distinctive histology' (DLDH) (Plate 7.1).

Tau positive inclusions, which occur in around 20% of cases with the typical macroscopical pathology, are found in particularly high density in the hippocampal complex, and in layers II and VI of the frontal and temporal neocortex. A rather larger

proportion have distended achromatic neurones, also immunologically positive for tau protein.

Ubiquitin positive inclusions typically appear in cortical motor neurones and the granule cells of the dentate gyrus. Although originally recognized as a histological characteristic of dementia in the context of MND, it is now known to be a common feature in cases without any neuromuscular involvement. Ubiquitin is a small (76 amino acid) protein forming part of a cytoplasmic system for the degradation and digestion of other intracellular proteins – a function critical not only for metabolic regulation, but also for cell signal transduction.

DLDH accounts for only a small number of cases, and may well dwindle further as new tools are added the pathologist's diagnostic armamentarium.

Although there is certainly no clear relationship between clinical and pathological phenotype, ubiquitin positive, tau negative inclusions appear to be a disproportionately common histological pattern among patients with SD. By contrast, tau positive pathologies occur most commonly in the context of the behavioural and PNFA variants.

Dementia with Lewy bodies and Parkinson's disease dementia

Dementia with Lewy bodies (DLB; also known as 'dementia associated with cortical Lewy bodies' or 'diffuse Lewy body disease') and dementia associated with Parkinson's disease (Parkinson's disease dementia [PDD]) together constitute the second or third most common cause of dementia in later life in most series. These disorders appear to lie on a pathogenetic and clinical continuum. Although estimates vary widely, dementia probably occurs in at least 20–40% of patients with idiopathic Parkinson's disease. Risk factors for development of PDD include increasing age, duration of disease and motor disability (especially symmetric, akinetic-dominant with speech and axial involvement), diminished response to levodopa and levodopa-induced confusion, early visual hallucinations and mood disturbance.

Pathologically, both DLB and PDD are characterized by the formation of Lewy bodies: intracytoplasmic eosinophilic neuronal inclusions with a central core and pale halo, containing the protein α-synuclein aggregated with abnormally phosphorylated neurofilaments and ubiquitin. Lewy bodies are found in the neocortex, limbic cortices and subcortical nuclei and there is associated neuronal loss. Pathological subtypes of DLB have been categorized as brainstem predominant, limbic (transitional) or diffuse neocortical based on the predominant distribution of pathological changes. No neuropathological features that reliably separate DLB, PDD and Parkinson's disease without dementia have been identified, and the particular clinical phenotype is likely to depend on the pattern of spread of pathological changes in the brain. In individuals developing DLB in later life, pathological features of AD (senile plaques and neurofibrillary tangles) commonly coexist at postmortem: this has given rise to the concept of a 'Lewy body variant of Alzheimer's disease' that is intermediate between Alzheimer's and idiopathic Parkinson's disease, and distinct from a pathologically 'pure' form of DLB that may occur in younger patients.

The pathological determinants of cognitive dysfunction in association with DLB and PDD are complex. Although it is not a universal finding, a number of studies have found a correlation between the regional density of cortical Lewy bodies and cognitive dysfunction (in particular visual hallucinations), while conversely, dementia is uncommon in patients with parkin mutations that lack cortical Lewy body involvement. Lewy bodies have also been correlated with cortical Alzheimer's changes, and it has been suggested that the interaction of these factors predisposes to the development of dementia and modifies the clinical phenotype. However, the development of dementia in some patients with synuclein mutations that lack significant associated Alzheimer pathology suggests that this is not a critical factor. Disruption of ascending dopaminergic and cholinergic pathways gives rise to clinically significant deficiencies of these neurotransmitter systems that interact with intrinsic cortical pathology.

Unresolved issues of pathological classification notwithstanding, DLB and PDD remain clinically defined syndromes and together these diseases present characteristic clinical problems that justify their status as a distinct dementia category. According to the current revised McKeith guidelines, DLB should be diagnosed when dementia occurs before or concurrently with parkinsonism, and PDD when dementia develops in established Parkinson's disease. DLB is typically a sporadic disease of later life with an overall survival similar to AD; however, young adult, familial and rapidly progressive forms, although rare, are well-described.

Core features are progressive cognitive decline with fluctuating cognition, recurrent visual hallucinations and spontaneous parkinsonism. The cognitive profile is often dominated by executive, attentional and visuo-spatial disturbances. A history of some variation in cognitive function from day to day is common in many dementias; however, the fluctuations in DLB are more marked and often paroxysmal within a 24-hour period. They may manifest as drowsiness, decreased responsiveness or disorganization of speech or behaviour. Fluctuations may be profound and prolonged, and frank delirium with protracted confusion and hallucinosis may supervene. Visual hallucinations should be enquired about specifically: in DLB, they are generally animate, vivid, stereotyped and silent, and often emerge from background visual features or patterns under low-light conditions. Although it is a core diagnostic feature of DLB, parkinsonism is not recorded in a significant proportion of autopsy-proven cases, implying that the absence of extrapyramidal features does not exclude the diagnosis. Other characteristic features of DLB are marked neuroleptic sensitivity and REM sleep behaviour disorder, the occurrence of complex and bizarre (often violent) sleep-related behaviour because of acting of dream content (the result of abnormal restoration of muscle tone resulting from synuclein pathology in the region of the pontine tegmentum). Additional supportive features include recurrent syncope and falls, significant autonomic dysfunction, hallucinations in non-visual modalities, and early prominent delusions (including misidentification delusions such

as the Capgras phenomenon and topographical and other reduplicative paramnesias), apathy and depression.

PDD has a very similar neuropsychological profile to DLB and shares many other clinical characteristics. Visual hallucinations are common in PDD even after medication effects are taken into account. In contrast to spontaneously occurring visual hallucinations, drug-induced hallucinations in treated Parkinson's disease are often perceived as frightening or threatening and accompanied by paranoid delusions. REM sleep behaviour disorder is also a feature of PDD. Parkinsonism in both PDD and DLB may closely mimic that of uncomplicated idiopathic Parkinson's disease, although predominant axial involvement with postural instability, absence of tremor and limited response to levodopa are more common.

Certain investigations in DLB and PDD can help to support the clinical impression, although no diagnostic or disease-specific biomarkers have been identified. On structural brain MRI, mesial temporal structures tend to be relatively better preserved than in AD. Metabolic brain imaging typically shows reduced striatal dopamine transporter uptake, and cortical perfusion and metabolism are globally reduced, often with a posterior emphasis. Degradation of alpha rhythm in the EEG occurs as a non-specific marker of cortical degeneration.

No specific or disease-modifying therapies are currently available for DLB or PDD. Cholinesterase inhibitors modestly improve cognitive function, attention, alertness and behaviour in a substantial proportion of patients, and indeed may be more effective than in AD at a comparable disease stage. More particularly, these agents may help in the management of fluctuations, sleep disturbance, confusion and hallucinations. The side effect profile of the cholinesterase inhibitors in DLB and PDD is broadly similar to that in AD. The impact on extrapyramidal symptoms is variable: modest benefit is seen in some patients, but significant worsening of parkinsonism or dystonia does occasionally occur and patients should be monitored for this possibility. The evidence base in favour of particular cholinesterase inhibitors remains limited and the choice of agent should be tailored to the individual patient (e.g. the convenience of once-daily dosing with donepezil set against the shorter half-life and more flexible regimen of rivastigmine). Neuroleptic drugs should in general be avoided in DLB and PDD, in view of the potential to cause severe, prolonged and sometimes life-threatening extrapyramidal reactions. However, these drugs may sometimes be necessary for the management of agitation or hallucinations where behavioural strategies or cholinesterase inhibitors have failed. In this situation, a new generation agent such as quetiapine or aripiprazole should be introduced cautiously and titrated slowly to the smallest effective dose. Management of parkinsonism in both DLB and PDD follows principles similar to those in idiopathic Parkinson's disease, although dopamine agonists are generally avoided because of their higher incidence of psychiatric side effects. Levodopa may benefit motor symptoms less than in uncomplicated Parkinson's disease, and dopaminergic effects on cognition are variable. Special care is needed to avoid exacerbating hallucinations and psychotic symptoms; in practice, the balance between immobility and confusion is often very finely poised and difficult to strike.

Dementia with other movement disorders

Cognitive decline is a feature of a number of other extrapyramidal disorders (described in more detail in Chapter 5), and most commonly manifests as a subcortical dementia resulting from involvement of fronto-subcortical circuitry. Although diagnosis generally rests on non-cognitive features, the type and relative prominence of cognitive deficits may assist in the clinical differentiation of atypical parkinsonism and 'Parkinson's-plus' syndromes. Progressive supranuclear palsy (Steele–Richardson–Olszewski syndrome) is frequently accompanied by profound bradyphrenia and executive deficits, which may include perseverative responses, environmental dependency and utilization behaviours. The 'applause sign' is characteristic: when asked to clap three times as fast as possible after the examiner, the patient makes additional handclaps or may initiate applause. In contrast to other 'Parkinson's-plus' disorders, cortico-basal degeneration is distinguished by early prominent cortical deficits such as limb and bucco-facial apraxia, parietal signs and impaired speech production, which may be relatively focal or asymmetric, and which overlap with disorders in the FTLD spectrum. It is also characterized by alien limb phenomena of variable complexity. Although severe cognitive decline is an exclusion criterion for multiple system atrophy, many patients do have mild executive deficits and cognitive slowing.

Cognitive impairment is a core feature of Huntington's disease. Attentional deficits and behavioural disturbances often dominate early in the disease course, and patients frequently present via psychiatric services, especially where the family history is concealed or not recognized. Visuo-spatial deficits are also well documented. Deficits of emotion recognition may be present, even in presymptomatic carriers. Cognitive decline in Huntington's disease has been shown to correlate with caudate atrophy and frontal hypometabolism, consistent with a primary disruption of fronto-subcortical circuitry.

Cognitive dysfunction is common in the expanding group of inherited spinocerebellar ataxias (Chapter 16), and executive and verbal memory deficits, affective disturbances and personality change have all been described. The severity of cognitive decline varies with the underlying genetic abnormality and may be particularly evident in *SCA2* and *SCA17*. There is much interest in defining a cognitive and behavioural signature of cerebellar damage, but this is difficult because of the frequent co-occurrence of damage involving other neuronal systems.

Prion disease

Introduction and disease biology

The prion diseases, or transmissible spongiform encephalopathies, are neurodegenerative conditions that affect both humans and animals. The human prion diseases have been traditionally classified into the Creutzfeld-Jakob diseases (CJD), Gerstmann–Sträussler–Scheinker (GSS) disease, fatal familial insomnia and

kuru. Animal prion diseases include scrapie of sheep and goats, transmissible mink encephalopathy, chronic wasting disease of mule deer and elk, and bovine spongiform encephalopathy (BSE) which first appeared in the UK from the mid-1980s and rapidly evolved to a major epizootic estimated to have infected over two million UK cattle. BSE has since been reported from many countries. New animal prion diseases have since been identified, particularly of domestic and captive wild cats and ungulates. These diseases can be transmitted between mammalian species by inoculation or dietary exposure and the recognition of the novel human prion disease, variant CJD, from the mid-1990s onwards when experimental confirmation that it was caused by the same prion strain as BSE raised major public health concerns. While the number of human cases to date has been relatively modest, key uncertainties, notably with respect to major genetic effects on incubation period, allied with the widespread population exposure, suggest the need for caution.

Prions are transmissible agents with unique composition and properties, being apparently devoid of significant nucleic acid. Prion diseases are associated with the accumulation in the brain of an abnormal, partially protease-resistant, isoform of a host-encoded glycoprotein known as prion protein (PrP). The disease-related isoform, PrP^{Sc}, is derived from its normal cellular precursor, PrP^{C}, by a post-translational process that involves conformational change and aggregation. According to the 'protein-only' hypothesis, an abnormal PrP isoform is the principal, and possibly the sole, constituent of the transmissible agent or prion. PrP^{Sc} is hypothesized to act as a conformational template, promoting the conversion of PrP^{C} to further PrP^{Sc} by an autocatalytic process. In addition to public health concerns, prions have assumed much wider relevance in understanding neurodegenerative and other diseases involving accumulation of misfolded host proteins (protein-folding diseases).

Aetiological categories and classification of human prion disease

The human prion diseases are unique in having three distinct aetiologies (Table 7.6). They may occur sporadically, be acquired by dietary or iatrogenic exposure to prions, or inherited in an autosomal dominant fashion as a result of coding mutations in the prion protein gene (*PRNP*). Remarkably, Mendelian inherited forms of prion disease are also experimentally transmissible by inoculation of laboratory animals. The majority of recognized human prion disease occurs as sporadic CJD. The aetiology of

Table 7.6 Classification of human prion disease.

Aetiology	Phenotype	Frequency
Sporadic		
Unknown: random distribution worldwide; incidence of 1–2 per million per annum	Sporadic CJD: subacute myoclonic form and range of atypical forms; multiple distinct prion strains associated with distinct clinico-pathological phenotypes which includes sporadic fatal insomnia	~85%
Inherited		
Autosomal dominantly inherited conditions with high penetrance; all forms have germline *PRNP* coding mutations	Extremely variable: readily mimics familial Alzheimer's disease and other neurodegenerative conditions; over 30 mutations identified; includes Gerstmann–Sträussler–Scheinker disease, familial CJD and fatal familial insomnia	~10–15%
Acquired		
Iatrogenic infection with human prions via medical or surgical procedures: human cadaveric-derived pituitary hormones, tissue grafts and contaminated neurosurgical instruments	Iatrogenic CJD: typical CJD when direct CNS exposure; ataxic onset when peripheral infection	<5% (most from USA, UK, France and Japan)
Exposure to human prions via endocannibalism	Kuru	Unique to small area Papua New Guinea; major epidemic in 1950s with gradual decline since cessation of cannibalism
Environmental exposure (presumed dietary) to BSE prion strain	Variant CJD	Total to date ~200. Mainly in UK but now reported from a number of countries
Iatrogenic infection via blood transfusion from healthy donor infected with vCJD prions	Secondary vCJD	UK only to date

BSE, bovine spongiform encephalopathy; CJD, Creutzfeldt–Jakob disease; vCJD, variant CJD.

sporadic CJD is unclear but may arise from somatic mutation of *PRNP* or spontaneous conversion of PrP^{C} to PrP^{Sc} as a rare stochastic event. The alternative hypothesis, exposure to an environmental source of either human or animal prions, is not supported by epidemiological evidence.

Prion diseases show marked phenotypic variability. A major factor in explaining this diversity is the existence of distinct prion strains. Prion strains can be distinguished by differences in the biochemical properties of PrP^{Sc}. Prion strain diversity appears to be encoded by differences in PrP^{Sc} conformation and pattern of glycosylation. Four main types are seen amongst CJD cases, sporadic and iatrogenic CJD being of PrP^{Sc} types 1–3, while all variant CJD cases are associated with a distinctive PrP^{Sc} known as type 4 type (London classification). A similar type 4 PrP^{Sc} is seen in BSE and in BSE when transmitted to several other species. Such studies are allowing a molecular classification of human prion diseases although no internationally agreed classification has yet emerged and it is likely that additional PrP^{Sc} types or strains will be identified.

A common *PRNP* polymorphism at codon 129, where either methionine or valine can be encoded, is a key determinant of genetic susceptibility to acquired and sporadic prion diseases, the large majority of which occur in homozygous individuals. Heterozygosity is protective against developing sporadic and acquired prion disease and leads to increased age at onset in some forms of inherited prion disease. Codon 129 genotype also has a key role in determining clinicopathological phenotypes, in part via an effect on selection of particular prion strain types.

Sporadic prion disease

Creutzfeldt–Jakob disease

The core clinical syndrome of classic sporadic CJD is of a rapidly progressive multifocal dementia usually with myoclonus. The onset is usually in the 45–75 year age group with peak onset between 60 and 65 years. The clinical progression is typically over weeks progressing to akinetic mutism and death often in 2–3 months, most die in under 6 months. Prodromal features include fatigue, insomnia, depression, weight loss, headaches, general malaise and ill-defined pain sensations. Frequent additional neurological features include extrapyramidal signs, cerebellar ataxia, pyramidal signs and cortical blindness. About 10% of cases present initially with cerebellar ataxia.

Routine haematological and biochemical investigations are normal. There are no immunological markers and acute phase proteins are not elevated. Routine CSF examination is normal but 14-3-3 protein is usually elevated. However, it is also positive in recent cerebral infarction or haemorrhage and in viral encephalitis, and may also be elevated in rapidly progressive AD which may be difficult to clinically distinguish from CJD. CT or MRI is crucial to exclude other causes of subacute neurological illness but MRI has become increasingly useful in diagnosis of sporadic CJD, showing high signal in the striatum and/or cerebral cortex in FLAIR or DWimages (Figure 7.5). Cerebral and cerebellar atrophy may be present in longer duration cases. The EEG may show characteristic pseudoperiodic sharp wave activity which is very helpful in diagnosis but present only in around 70% of cases. Serial EEG is recommended to demonstrate this feature. Brain biopsy may be considered in highly selected cases to exclude treatable alternative diagnoses using appropriate CJD infection control precautions.

Neuropathological confirmation of CJD is by demonstration of spongiform change, neuronal loss and astrocytosis together with positive PrP immunohistochemistry. PrP amyloid plaques are usually not present in CJD. PrP^{Sc} can be demonstrated by immunoblotting of brain homogenates and is diagnostic of prion disease. PrP^{Sc} types 1–3 are demonstrated, distinct from type 4 which is exclusively seen in variant CJD. *PRNP* analysis is important to exclude pathogenic mutations even in the absence of a family history. Most cases of classic CJD are homozygous with respect to the common 129 polymorphism of PrP and MM is by far the most common genotype in classical subacute CJD.

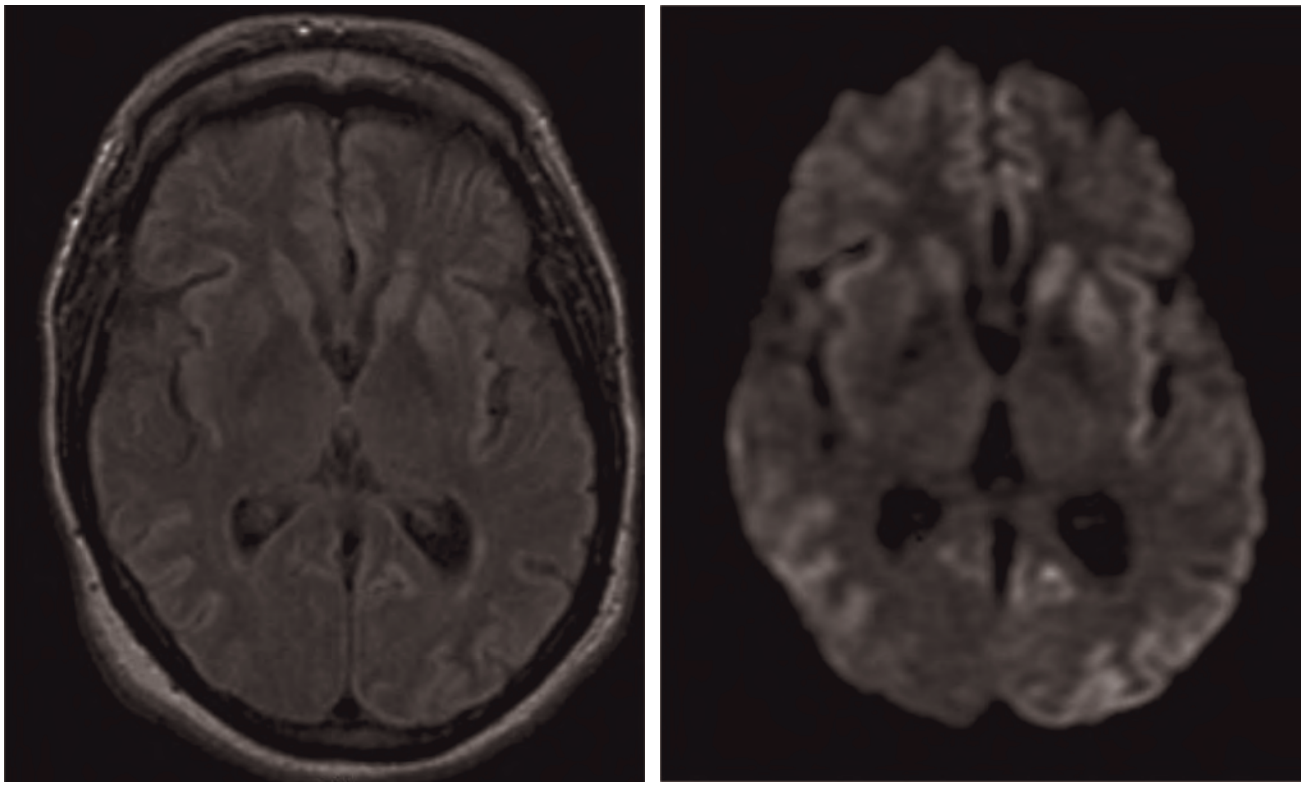
Atypical forms of Creutzfeldt–Jakob disease

Atypical forms of Creutzfeldt–Jakob disease are well recognized. Around 10% of cases of CJD have a much more prolonged clinical course with a disease duration of over 2 years. *PRNP* codon 129 genotype is often VV or MV, rather than the MM type usually seen in subacute myoclonic CJD. Around 10% of CJD cases present with cerebellar ataxia rather than cognitive impairment, so-called ataxic CJD, although this presentation should lead to a consideration of acquired prion disease (see below). Heidenhain's variant of CJD refers to cases in which cortical blindness predominates with severe involvement of the occipital lobes. The panencephalopathic type of CJD refers to cases with extensive degeneration of the cerebral white matter in addition to spongiform vacuolation of the grey matter.

Acquired prion diseases

Kuru

Kuru is now largely of historical interest. It reached epidemic proportions amongst a defined population living in the Eastern Highlands of Papua New Guinea and was the major cause of death amongst adult women and children in the affected region when first described by Western medicine in the 1950s. It was the practice in these communities to engage in consumption of dead relatives as a mark of respect and mourning. Males over the age of 6–8 years participated little in mortuary feasts, which is thought to explain the differential age and sex incidence. It is thought that the epidemic related to a single sporadic CJD case occurring in the region some decades earlier. Its gradual disappearance since the cessation of cannibalism in the late 1950s has allowed estimation of the range of incubation periods possible in human prion infection which may exceed 50 years. The mean clinical duration of illness is 12 months with a range of 3 months to 3 years. The dominant clinical feature is progressive cerebellar ataxia. In contrast to CJD, dementia is much less marked.



(a) (b)

Figure 7.5 Sporadic CJD: MRI demonstrates typical increased signal intensity in the caudate and putamen bilaterally and widespread increased cortical signal intensity involving the occipital, frontal, temporal and insula cortex on FLAIR (a) and DWI sequences (b). The cortical signal changes are more apparent on the DWI images.

Iatrogenic Creutzfeldt–Jakob disease

Iatrogenic transmission of CJD has occurred by accidental inoculation with human prions as a result of medical procedures. Such iatrogenic routes include contaminated neurosurgical instruments, dura mater and corneal grafting, and human cadaveric pituitary-derived growth hormone or gonadotrophin. The diagnosis is usually based on a progressive cerebellar syndrome and behavioural disturbance or a classic CJD-like syndrome together with a history of iatrogenic exposure to human prions, and may occur in any age group. Cases arising from intracerebral or optic inoculation typically manifest clinically as classic CJD, with a rapidly progressive dementia, while those resulting from peripheral inoculation, most notably following pituitary-derived growth hormone exposure, typically present with a progressive cerebellar syndrome. The incubation period in intracerebral cases is short (2–4 years for dura mater grafts) compared with peripheral cases (typically 15 years or more). EEG, CSF and MRI are generally less diagnostically helpful than in sporadic CJD. *PRNP* analysis is important to exclude pathogenic mutations. Brain biopsy may be considered in highly selected cases to exclude treatable alternative diagnoses. Diagnosis is confirmed by PrP immunocytochemistry or Western blot of brain tissue for PrP^{Sc} types 1–3.

Variant CJD

This was first described in 1996. Its occurrence initially in teenagers and young adults and distinctive neuropathology differentiated it from sporadic CJD. A link with BSE was confirmed by molecular and biological strain typing of prions.

The early features of vCJD are non-specific, often with behavioural and psychiatric disturbances and in some cases with sensory disturbance. Initial referral has frequently been to a psychiatrist and the most prominent feature is depression but anxiety, social withdrawal and behavioural change is frequent. Suicidal ideation is infrequent and response to antidepressants poor. Delusions, which are complex and unsustained, are common. Other features include emotional lability, aggression, insomnia and auditory and visual hallucinations. A prominent early feature in some is dysaesthesiae or pain in the limbs or face which is persistent rather than intermittent and unrelated to anxiety levels. A minority of cases have been noted to have forgetfulness or mild gait ataxia from an early stage but in most cases overt neurological features are not apparent until some months into the clinical course. In most patients a progressive cerebellar syndrome develops with gait and limb ataxia. Cognitive impairment then occurs with inevitable progression to akinetic mutism. Myoclonus is seen in most patients, and chorea is often present which may be severe

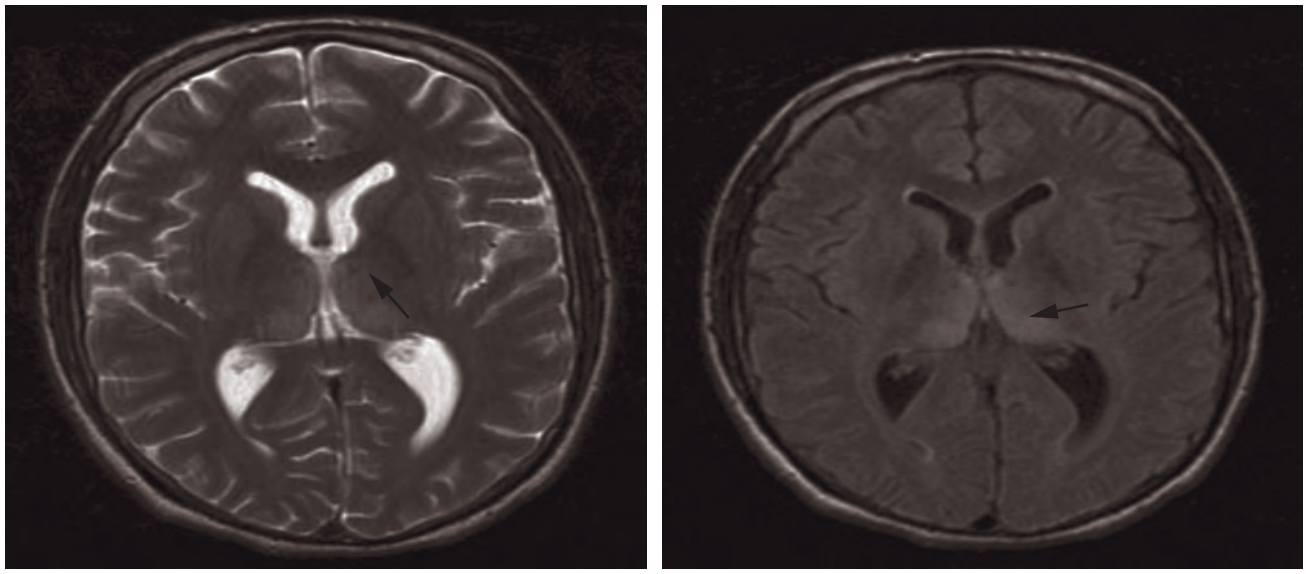


Figure 7.6 Variant CJD: MRI demonstrates symmetrical increased signal intensity in the pulvinar nuclei bilaterally (pulvinar sign) and dorsomedial thalami on T2 weighted (a) and FLAIR (b) sequences.

in some. Cortical blindness develops in a minority in the late stages of disease. Up-gaze paresis has been noted in some patients. Age at onset ranges from 12 to 74 (mean 28) years and the clinical course is relatively prolonged (median 14 months).

The EEG is abnormal, most frequently showing generalized slow wave activity, but without the pseudoperiodic pattern seen in most sporadic CJD cases. Neuroimaging by CT is either normal or shows only mild atrophy. The most useful non-invasive investigation is MRI, particularly the FLAIR sequence which demonstrates bilateral increased signal in the posterior thalamus (the pulvinar sign) in the large majority of cases (Figure 7.6). However, this sign appears as a late feature of the disease process and is not specific for vCJD; similar MRI appearances are described for example in sporadic CJD and paraneoplastic limbic encephalitis, both of which are important considerations in the differential diagnosis of patients with suspected vCJD. The absence of a pulvinar sign does not exclude a diagnosis of vCJD.

Tonsillar biopsy is a sensitive and specific diagnostic procedure for vCJD. Tonsillar PrP^{Sc} is uniformly present in clinically affected cases of vCJD but not in other forms of human prion disease. As infection of lympho-reticular tissues is thought to precede neuroinvasion, and indeed has been detected in archived surgical samples removed prior to development of vCJD, it is likely to allow firm diagnosis at the early clinical stage or indeed preclinically. A positive tonsil biopsy obviates the need for brain biopsy which may otherwise be considered in such a clinical context to exclude alternative, potentially treatable diagnoses. CSF 14-3-3 protein may be elevated or normal. *PRNP* analysis is essential to rule out pathogenic mutations, as the inherited prion diseases present in younger patients and may clinically mimic vCJD, and should be performed prior to tonsil biopsy. To date all clinical cases of vCJD have been of the *PRNP* codon 129 MM genotype. Whether vCJD will occur in other *PRNP* codon 129 genotypes at longer incubation periods remains to be seen and the VV and MV genotypes may result in a different disease phenotype which may involve propagation of distinct prion strains. Clinicians should therefore be alert to other manifestations of human BSE infection. Animal modelling using humanized transgenic mice also suggests that a sporadic CJD-like phenotype may result from BSE infection in the MM *PRNP* 129 genotype, raising the possibility that some cases of sporadic CJD may in fact be BSE related.

The neuropathological appearances of vCJD are striking and relatively consistent, generally allowing differentiation from other forms of prion disease. While there is widespread spongiform change, gliosis and neuronal loss, most severe in the basal ganglia and thalamus, the most remarkable feature is abundant PrP amyloid plaques in cerebral and cerebellar cortex. These consist of kuru-like, 'florid' (surrounded by spongiform vacuoles) and multicentric plaque types. Western blot analysis (molecular strain typing, see above) of brain tissue demonstrates PrP^{Sc} type 4 which is pathognomonic of vCJD.

Some of the features of vCJD are reminiscent of kuru, in which behavioural changes and progressive ataxia predominate. In addition, peripheral sensory disturbances are well recognized in the kuru prodrome. Kuru plaques are seen in around 70% of cases and are especially abundant in younger kuru cases. The observation that iatrogenic prion disease related to peripheral exposure to human prions has a more kuru-like than CJD-like clinical picture may well be relevant and would be consistent with a peripheral prion exposure.

Secondary (iatrogenic) vCJD

The prominent lymphoreticular involvement raised early concerns that vCJD may be transmissible by blood transfusion. Indeed, the tissue distribution is similar to that of ovine scrapie where prionaemia has been demonstrated experimentally. Since 2004, four transfusion-associated cases of vCJD prion infection have been recognized amongst a small cohort of now 23 surviving patients identified as having received blood from a donor who subsequently developed vCJD. The three clinical cases had the *PRNP* codon 129 MM genotype, while one patient, who died of an unrelated condition, was found to have prion infection at autopsy. This patient had the *PRNP* codon 129 MV genotype associated with relative resistance to prion disease. In each case transfusion was with a single unit of implicated red cells. The risk to recipients of blood from a silently infected donor appears very high. The incubation period in the clinical cases was 6–7 years. Clinical features and investigations are as for primary vCJD.

Inherited prion diseases

These are all adult onset autosomal dominantly inherited conditions associated with *PRNP* coding mutations (Figure 7.7). They were first classified as familial CJD and Gerstmann–Sträussler–Scheinker syndrome (GSS). Classic GSS is a chronic cerebellar ataxia with pyramidal features, with dementia occurring later in a much more prolonged clinical course than that seen in CJD. The onset of GSS is usually in either the third or fourth decades and characterized histologically by the presence of multicentric PrP-amyloid plaques. However, inherited prion disease kindreds show remarkable phenotypic variability, which can encompass both CJD-like and GSS-like cases as well as atypical cases which readily mimic other neurodegenerative conditions. Inherited prion diseases are a frequent cause of presenile dementia and a family history is not always apparent: *PRNP* should be analysed in all suspected cases of CJD, and certainly considered in all early onset dementia and in ataxias. Cases diagnosed by *PRNP* analysis have been reported that are not only clinically atypical, but also lack the classic histological features. Significant clinical overlap exists with familial Alzheimer's disease, fronto-temporal dementia, Huntington's disease, parkinsonian syndromes and ALS with dementia.

The identification of a pathogenic *PRNP* mutation allows not only molecular diagnosis of an inherited prion disease but also its subclassification according to mutation. Over 30 pathogenic mutations are reported in the human PrP gene and consist of two groups:

1 Point mutations within the coding sequence resulting in aminoacid substitutions in PrP or production of a stop codon resulting in expression of a truncated PrP; and

2 Insertions encoding additional integral copies of an octapeptide repeat present in a tandem array of five copies in the normal protein (octapeptide repeat insertion [OPRI]).

Notation for these diseases is 'Inherited prion disease (PrP mutation)', for instance:

- Inherited prion disease (PrP 6OPRI) or
- Inherited prion disease (PrP P102L).

The key clinical features in inherited prion disease are progressive dementia, cerebellar ataxia, pyramidal signs, chorea, myoclonus, extrapyramidal features, pseudobulbar signs, seizures and amyotrophic features, which are seen in variable combinations. The most frequent forms include PrP E200K, which may mimic subacute sporadic CJD (and in contrast to other inherited prion diseases often has a typical EEG), PrP P102L which may present as a progressive cerebellar ataxia or dementia, and insertional mutations which have a particularly variable clinical presentation, often with a long duration mimicking Alzheimer's disease. Fatal familial insomnia, usually associated with the D178N mutation, is characterized clinically by untreatable insomnia, dysautonomia and motor signs, and neuropathologically by

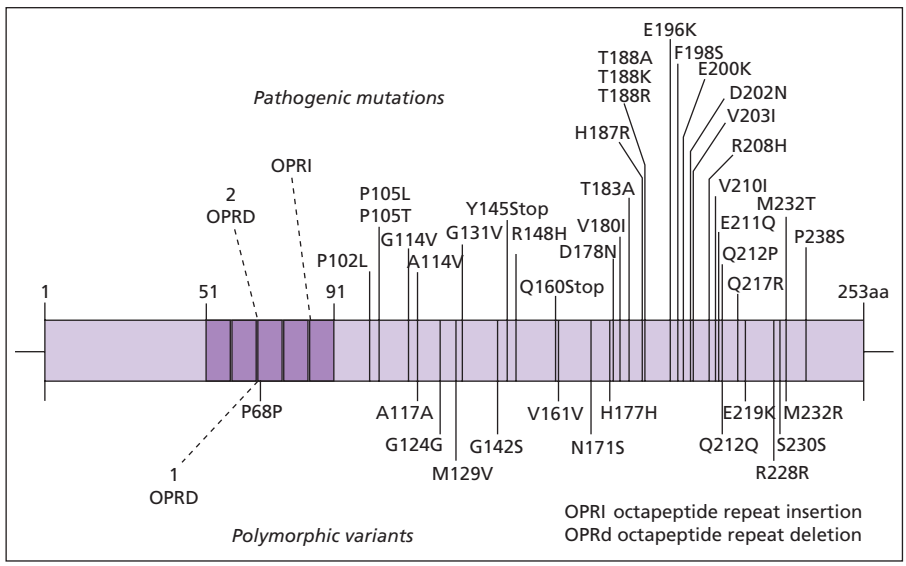

Figure 7.7 Pathogenic mutations and polymorphic variants in the prion protein gene.

selective atrophy of the anterior-ventral and mediodorsal thalamic nuclei. One variant, PrP P105L, presents as a progressive spastic paraparesis. Parkinsonism may be prominent in A117V and peripheral neuropathy occurs in E200K. Age at onset varies from the early twenties (seen often with insert mutations) to the seventies in some cases. The duration varies from less than a year to over 20 years.

Genetic counselling and presymptomatic testing

Direct gene testing allows unequivocal diagnosis in patients with inherited forms of the disease and presymptomatic testing of unaffected but at-risk family members, as well as antenatal testing. Most of the mutations appear to be fully penetrant; however, experience with some is extremely limited. Exceptions include E200K and D178N (fatal familial insomnia) where there are examples of elderly unaffected gene carriers. Genetic counselling is essential prior to presymptomatic testing and follows a protocol similar to that established for Huntington's disease. It is vital to advise both those testing positive for mutations and those untested but at-risk that they should not be blood or organ donors and that they should inform surgeons, including dentists, of their risk status prior to significant procedures, as precautions may be necessary to minimize risk of iatrogenic transmission.

Prevention and treatment

While prion diseases can be transmitted to experimental animals by inoculation, it is important to appreciate that they are not contagious in humans. Documented case-to-case spread has only occurred by cannibalism (kuru) or following accidental iatrogenic inoculation with prions. As discussed above, there is now evidence that vCJD prion infection is transmissible by blood transfusion. UK policy for some time has been to leucodeplete all whole blood and to source plasma for plasma products from outside the UK. A further possible route of transmission of vCJD is via contaminated surgical and medical instruments. Prions resist conventional sterilization methods and neurosurgical instruments are known to be able to act as a vector for prion transmission: several cases of iatrogenic transmission of sporadic CJD prions via neurosurgical instruments are documented. Recent epidemiological evidence suggests that classic CJD may also be transmitted by other surgical procedures. The wider tissue distribution of prions in vCJD together with the potential that significant numbers in the population may be silently infected has considerably increased these concerns. Effective products for prion-decontamination of surgical instruments are now available.

Certain occupational groups are at risk of exposure to human prions, e.g. neurosurgeons and other operating theatre staff, pathologists and morticians, histology technicians, as well as an increasing number of laboratory workers. Because of the prolonged incubation periods for prions following administration to sites other than the CNS, associated with clinically silent prion replication in the lympho-reticular tissue, treatments inhibiting prion replication in lymphoid organs may represent a viable strategy for rational secondary prophylaxis after accidental exposure. A short course of immunosuppression with high-dose oral corticosteroids in individuals with significant accidental exposure to human prions has been advocated.

All patients with or at-risk of developing prion disease should be counselled on infection control as described above for gene carriers. New diagnoses should be notified to the local consultant in communicable disease control who can assess if public health measures are necessary, notably if a patient has had recent surgery or donated blood prior to diagnosis.

All recognized prion diseases are invariably fatal following a progressive course. A variety of drugs have been tried in individual or small numbers of patients over many years. There is no clear evidence of efficacy of any agent. Useful websites are summarized in Table 7.7.

Vascular dementia and vascular cognitive impairment

Cerebrovascular disease (Chapter 4) is a major cause of cognitive impairment and dementia both in its own right and in association with AD ('mixed dementia'). Dementia has been estimated to occur in up to one-third of individuals within a year of stroke. Despite its frequency and importance, there is little consensus as to how 'vascular dementia' should be defined, whether in clinical or research settings. 'Vascular cognitive impairment' (VCI) may be a more appropriate catch-all term, because it reflects the broad range of clinical presentations including (in addition to clearly progressive cognitive decline) static or indolent cognitive syndromes and mild cognitive impairment on a vascular basis. In contrast to AD and other primary neurodegenerative disorders, VCI has been relatively little studied. The status of 'mixed' dementia is a particularly vexed issue. The frequent coexistence of vascular and Alzheimer changes presents serious practical challenges to the development and interpretation of treatment trials in both diseases, as well as complicating the interpretation of epidemiological studies suggesting common factors that may predispose to both Alzheimer's disease and VCI.

Pathologically, there are no absolute criteria for a diagnosis of VCI. A spectrum of changes of variable severity occurs. Atheromatous involvement of large vessels may be found, although small vessel disease is typically prominent. Vascular changes are accompanied by lacunar and sometimes larger infarcts, typically in watershed regions between large arterial territories. Microscopically, there is lipohyalinosis of small arteries and arterioles, rarefaction and cavitation of white matter (leuco-araiosis) resulting from the conjunction of nerve fibre degeneration, gliosis and demyelination, and scattered cortical microinfarcts. Foci of old haemorrhage and amyloid angiopathy may also be observed. Pathophysiologically, whereas lacunes are the result of completed infarction, incomplete ischaemia resulting from partial vessel occlusion or hypotension can give rise to white matter lesions. There is evidence that autoregulatory perfusion reserve is decreased in zones of white matter damage, which is probably compounded by labile blood pressure control and raised plasma viscosity in vascular disease. The blood–brain barrier breaks down in these areas, and extravasated plasma proteins and other factors may contribute to neurotoxicity. Metabolic brain imaging and diffusion tensor MRI can demonstrate white matter abnormalities extending beyond the zone of damage on conventional structural brain imaging, underlining the dynamic nature of the vascular lesion and helping to explain why the relation between structural damage and cognitive impairment is not straightforward.

The clinical picture of VCI is diverse, and a given cognitive phenotype can result from a spectrum of pathogenetic mechanisms, including atherosclerosis, thromboembolism, thrombophilia, haemodynamic insufficiency, haemorrhage, and specific metabolic and genetic arteriopathies. Executive and attentional impairments, behavioural changes (disinhibition or abulia) and cognitive slowing with relative sparing of memory are clinical features common to many forms of vascular damage. This reflects the relative vulnerability of cognitive processes that depend on distributed neural networks and subcortical structures and pathways: an essential theme in our current understanding of VCI. Traditionally, emphasis was placed on the cognitive effects of acute stroke affecting a single large arterial territory or the stepwise accumulation of cognitive deficits accompanying recurrent cortical strokes: 'multi-infarct dementia'. However, it is increasingly recognized that VCI comprises a number of other clinico-anatomical syndromes, defined according to distinct patterns of clinical and brain imaging findings. Vascular changes are very common on brain imaging of healthy elderly individuals, and determining that a particular cognitively impaired individual has VCI, rather than an alternative cause such as AD, may be difficult. Diagnostic instruments such as the Hachinski Ischaemia Score are available but are of limited value in clinical practice.

Discrete strategically located cortical infarcts that implicate the medial frontal lobe (anterior cerebral artery) or mesial temporal lobe (posterior cerebral artery) can have a disproportionate effect on executive function and memory respectively: such lesions may simulate the cognitive effects of more diffuse brain damage. Single strategic subcortical infarcts can lead to impairment of multiple cognitive functions by damaging functional circuitry linking the cortex with subcortical structures or by interrupting projection pathways to the cortex. Critical sites include the thalamus, basal ganglia, internal capsule, limbic circuit and upper brainstem.

More commonly, VCI results from diffuse involvement of cerebral white matter and subcortical nuclei caused by small vessel disease. This is the clinical entity known as Binswanger disease, a somewhat controversial term that has also been applied to the neuropathological substrate. These patients typically present with an indolent cognitive decline and lack a history of clinical vascular episodes; the syndrome may closely mimic primary degenerative dementias such as AD. Clinical clues often include fluctuating deficits, bradyphrenia and prominent dysexecutive features. Memory impairment is frequent, although it is more variable, more dependent on attentional factors and more responsive to cueing than in AD. On neurological examination there may be brisk facial and limb reflexes and a short-stepped wide-based apraxic gait or marche à petit pas. Other features may include parkinsonism and other extrapyramidal syndromes, urinary incontinence or pseudobulbar palsy. A history of vascular risk factors (especially hypertension) should be sought but is of limited discriminating value. Patients undergoing major surgery (especially cardiac bypass) and those with congestive cardiac failure and orthostatic hypotension are especially vulnerable. However, an identical picture can occur even with a paucity of conventional vascular risk factors, suggesting that as yet undefined genetic and other factors also influence the development of cerebral small vessel disease.

The diagnosis rests on brain imaging findings of extensive, typical peri-ventricular white matter changes which spare subcortical U fibres and the corpus callosum and lacunes in the deep grey matter. MRI is the preferred modality because of its greater sensitivity; however, white matter changes may arise from a variety of different mechanisms and care is needed not to misclassify prominent peri-vascular spaces, which have no pathological significance. Existing brain imaging criteria for subcortical ischaemic vascular dementia have not been prospectively evaluated and do not reliably distinguish cases of 'mixed' dementia: although diffuse atrophy accompanies white matter damage, disproportionate atrophy of mesial temporal structures is a marker of AD. Although cognitive dysfunction (and more specifically, executive and attentional deficits) correlates with cerebral atrophy and with more severe white matter involvement, there is no agreement regarding the threshold, extent or distribution of the vascular lesion load required to produce cognitive impairment. Also uncertain is the relationship to the rate of accumulation of vascular lesions on serial imaging, although the rapid appearance of new lesions raises concern regarding an atypical aggressive process such as vasculitis or an active embolic source.

While MCI on a vascular basis is well-recognized clinically, consensus diagnostic criteria that could form the basis of large-scale observational studies or therapeutic trials have yet to be

agreed. However, it is likely that conventional definitions of MCI that emphasize memory impairment will need to be modified to incorporate the early attentional and executive deficits that are clinical hallmarks of small vessel disease. Depression is an important consideration in such patients (as it is in all forms of VCI) because it is strongly associated with cerebral white matter disease and may amplify any cognitive deficit.

Although less common than ischaemic cerebrovascular disease, cerebral haemorrhage presents distinct diagnostic and management challenges, and multiple haemorrhages may simulate multi-infarct dementia. Hypertension is the key risk factor for most clinically significant cerebral haemorrhages; however, recurrent lobar haemorrhages are a marker for cerebral amyloid angiopathy. Pathologically, there is deposition of congophilic material (beta-amyloid peptide) in vessels of the cortex and leptomeninges, and there is a strong association with cerebral leuco-araiosis and cortical and subcortical microhaemorrhages. The origin of the vascular beta-amyloid is presently unclear. The extent of associated Alzheimer changes is variable, although these commonly coexist. Genetic factors influence the development of cerebral amyloid angiopathy: it is associated with ApoE epsilon-4 and epsilon-2, while the risk of cerebral haemorrhage is increased in association with the epsilon-2 allele. Rarely, cerebral amyoid angiopathy occurs on a familial basis with autosomal dominant inheritance, and various mutations leading to the deposition of specific amyloid proteins have been identified (Table 7.8).

A variety of other haematological, autoimmune, metabolic and genetic processes can cause VCI (Chapters 4 and 18). Clues to a process in one of these categories often lie in associated non-cognitive features, and they should be suspected in younger patients with a vascular phenotype but a paucity of conventional risk factors. The antiphospholipid antibody syndrome may produce dementia via ischaemic mechanisms and there may also be additional direct effects of the antibody on neural tissue. Cognitive impairment in sickle cell disease may reflect chronic hypoxia in addition to focal infarction. Of the genetic vasculopathies, CADASIL has attracted much interest recently as the culprit protein (a transmembrane receptor in smooth muscle cells coded by the *Notch3* gene on chromosome 19) appears to have a fundamental role in cell signalling, suggesting that this entity may be part of a broader spectrum of related disorders. Various presentations are possible, including psychiatric disturbance and acute encephalopathies, and a history of adult onset migraine is common. Brain MRI (T2 or FLAIR) characteristically shows involvement of white matter in the temporal pole and external capsule (Figure 7.8), unusual sites for conventional small vessel disease, and skin or muscle biopsy shows periodic acid–Schiff (PAS) staining of vessels and on electron microscopy granular osmophilic deposits adjacent to the basement membrane of arteriolar smooth muscle cells. The diagnosis is confirmed by screening the *Notch3* gene for known mutations; however, this is not straightforward as the gene is large and over 50 different mutations have been described.

Figure 7.8 CADASIL. MR FLAIR axial image showing typical hyperintense white matter changes in each temporal pole. Courtesy of Queen Square Imaging Centre.

The differential diagnosis of VCI is potentially very extensive, because it overlaps with the spectrum of diseases causing subcortical dementia with cerebral white matter change. These include multiple sclerosis, progressive multifocal leucoencephalopathy, HIV dementia, lymphoma, post-irradiation, post-traumatic and post-hypoxic states, hereditary leucodystrophies and rare familial forms of AD with presenilin mutations. This list can usually be rationalized based on the clinical context. On imaging grounds, associated cortical infarction and involvement of the deep grey matter and brainstem are pointers to a primary vascular aetiology. Investigation of the patient with suspected VCI should include, in addition to the standard investigations listed in Table 7.4, an assessment of other end-organ damage (especially ischaemic heart disease) which may dictate overall prognosis. Brain imaging is essential and MRI is generally more informative than CT. Assessment of the carotid circulation is indicated where there is large-territory ischaemia or other suspicion of a symptomatic stenosis. Thrombophilia or other haematological or metabolic screens may be indicated, especially in younger patients. EEG often shows non-specific bitemporal slowing but preserved alpha rhythm, unless AD or another cortical degenerative process has supervened. CSF examination is indicated in younger patients or where an inflammatory or infective process is suspected and brain biopsy may be required in exceptional cases where cerebral vasculitis is likely.

The management of VCI rests on primary and secondary prevention of further vascular damage, based on principles similar to those that hold for cerebrovascular disease in general (Chapter

Table 7.8 A clinical classification of young onset and inherited dementias.

Family history	EPS	PYR	Atax	PN	Other features	Useful investigations	Gene	Diagnosis

4), and symptomatic treatment of cognitive deficits. Control of hypertension and other vascular risk factors is a core management priority to prevent recurrent stroke. Antihypertensive treatment should be introduced cautiously in light of the evidence for impaired autoregulation in patients with subcortical ischaemic damage together with antiplatelet therapy. The benefit of statins on VCI is not clear, probably reflecting the weaker part played by cholesterol in cerebrovascular disease. Randomized controlled trials suggests that the cholinesterase inhibitors are likely to be of symptomatic benefit in vascular dementia, although this is a difficult issue to resolve partly because of the problem of associated AD and also to the relative lack of suitable outcome measures (which tend to emphasize memory rather than the executive or attentional functions that are more relevant to VCI).

Dementia in young adults

Dementia is very rare before the fifth decade: in young adults and adolescents, inherited errors of metabolism and other genetic disorders are over-represented and many of these present as a 'dementia-plus' syndrome. The cognitive profile frequently takes the form of a subcortical dementia with prominent behavioural and affective features, or even frank psychosis, which may be misinterpreted as a pseudodementia. As cognitive impairment in young adult life is often constitutional or the result of congenital brain damage or static insults in early life, it is always important to establish whether cognitive dysfunction is progressive: this depends on a detailed history of pregnancy, birth and early milestones, and physical, social and scholastic development in later childhood. Cognitive decline often occurs in the setting of more widespread neurological and systemic disturbance and diagnosis generally depends on additional clinical and laboratory findings (Chapter 18).

Effective treatments with the potential for prevention or reversal of deficits are available for some inborn errors of metabolism, such as Wilson's disease (Chapter 5) and the porphyrias (Chapter 18). This large and diverse group of conditions also includes the mitochondrial cytopathies (Chapter 9) and a bewildering array of storage disorders (Chapter 18), in which the absence or partial inactivity of an affected enzyme leads to accumulation of abnormal material. The storage diseases can be subclassified in various ways: for example, according to the type of material deposited (e.g. glycolipid, glycosaminoglycan, lipopigment, cholesterol metabolites, polyglycosans), the primary site of cellular deposition (white matter in leukodystrophies, cell bodies in neuronal storage diseases), or the subcellular organelle affected (lysosomes, peroxisomes).

Clinicians may find it more useful to adopt a pragmatic approach based jointly on the availability of a family history and cardinal clinical features. This is the approach outlined in Tables 7.4 and 7.8. Many of these disorders have autosomal recessive inheritance, and family history is therefore often unrevealing; a history of parental consanguinity may therefore be crucial. Other diseases show variable inheritance (e.g. the mitochondrial diseases, as components of the respiratory chain are encoded both by nuclear DNA and maternally inherited mitochondrial DNA; Chapter 9). The presence of pyramidal, extrapyramidal, cerebellar or peripheral nerve signs are key diagnostic clues and help to direct investigations. Additional features such as seizures, retinopathy or deafness further restrict the differential diagnosis while certain features (such as corneal Kayser–Fleischer rings in Wilson's disease, or tendon xanthomas in cerebrotendinous xanthomatosis), if present, are pathognomonic of particular conditions.

Despite recent progress in elucidating the genetic and molecular basis of many inborn errors of metabolism, diagnosis remains challenging. This is compounded by the protean nature of the diseases themselves. Genetic diagnosis is not practical in many cases (e.g. Wilson's disease and Niemann–Pick disease), both because of the limited availability of the relevant tests and the intrinsic heterogeneity of the causative mutations. Specialized processing of tissue samples is often required (e.g. muscle for respiratory enzyme analysis in mitochondrial disease; axillary skin for storage bodies in Kufs or Lafora body disease; fibroblast cultures in Niemann–Pick disease; Table 7.8). Despite much recent interest in disease-modifying therapies such as enzyme replacement or bone marrow transplantation in certain diseases (e.g. Gaucher's disease), the availability of such therapies remains limited, and cognitive deficits are unfortunately generally refractory to their effects. Accurate diagnosis is nevertheless of paramount importance in this group both for prognosis and genetic counselling.

In addition to genetically based disorders, non-degenerative acquired causes of dementia are also relatively more common in younger patients. The importance of this group lies in the potential for reversibility in many infective, inflammatory and acquired metabolic conditions.

Reversible causes of dementia

Although they are individually rare, many causes of dementia are potentially reversible and this group includes many diverse disease processes. A syndrome-based approach to the diagnosis of reversible dementias is presented in Table 7.9. Patients presenting with these syndromes demand particular vigilance to ensure that a treatable process is not overlooked. Rapid clinical evolution is a feature common to a number of diseases in this category. However, it is important to emphasize that many cases of dementia resulting from a reversible process do not present with such clinical clues: all patients with dementia should therefore be screened for treatable contributions to their cognitive decline.

Neoplasms and other space-occupying lesions

A variety of intracranial space-occupying lesions may present with insidious cognitive or behavioural decline. Potential causes include tumours, infectious lesions, chronic subdural haematoma and hydrocephalus. Cognitive and behavioural presentations are particularly associated with lesions in the frontal lobes, corpus callosum and midbrain. There may be associated features such as papilloedema or focal neurological signs, seizures, or systemic

Table 7.9 Diagnosis of some reversible dementia syndromes.

Syndrome/clinical features§	Candidate diagnoses	Relevant investigations
Intracranial space-occupying lesions		
Insidious behavioural change, frontal-executive dysfunction, may have papilloedema, focal neurological signs, seizures	Intracranial tumour (primary, CNS lymphoma, metastasis), esp frontal lobe, corpus callosum, midbrain*	*CT/MRI*: focal or multifocal space-occupying lesions Biopsy or resection of lesion
Constitutional disturbance, fever, other systemic evidence of infection, immunosuppression (esp HIV)	Brain abscess, cysts, other infectious lesions	May have serological, CXR or other findings; may require biopsy or resection of lesion
History of head trauma (often absent), coagulopathy, altered alertness	Chronic subdural haematoma	*CT*: subdural haematoma (may be isodense depending on age; may be bilateral)
History of meningitis, subarachnoid haemorrhage; gait apraxia, urinary incontinence, subcortical dementia	Hydrocephalus (any cause)	*CT/MRI*: findings of hydrocephalus (disproportionate ventricular enlargement) ± causative lesion
CNS vasculitis (various syndromes may occur)		
Rapid course, headache, fluctuation	Primary angiitis of CNS CNS lymphoma, esp intravascular	*EEG*: slowing of rhythms (non-specific) *MRI*: ischaemic lesions, signal abnormalities *CSF*: >3 cells, OCBs Brain biopsy
Systemic features of autoimmune/connective tissue disease (esp lupus, polyarteritis, Wegener's granulomatosis)	Vasculitis associated with systemic disorders	Inflammatory markers, serological and other investigations, tissue diagnosis (e.g. skin, kidney, lung)
Fever, other evidence of chronic infection (e.g. varicella zoster)	Vasculitis associated with infection	*CSF*: positive PCR May require brain biopsy
Limbic encephalitis		
Memory and behavioural disturbances, fluctuating alertness, confusion, temporal lobe seizures	VGKC Ab syndrome	*MRI*: abnormal mesial temporal signal *EEG*: temporal lobe spikes *Serum*: hyponatraemia (non-specific); VGKC titre *CSF*: OCBs
May have peripheral neuropathy, ataxia, hypothalamic dysfunction, brainstem signs	Paraneoplastic syndrome*	*CSF*: pleocytosis, OCBs Antineuronal antibodies (anti-Hu, anti-Ma2), systemic screens for malignancy incl whole body PET, CT
May have systemic features of autoimmune/connective tissue disease	CNS vasculitis (isolated or associated with systemic disorders)	*CSF*: pleocytosis May require brain biopsy Systemic serological and other investigations, other tissue biopsy (e.g. skin, kidney, lung) if indicated
Acute onset, may have fever, immunosuppression	Infectious encephalitis	*CSF*: pleocytosis; HSV, HHV6/7 PCR
Epilepsy		
Discrete episodes, fluctuating course, patchy retrograde amnesia	Temporal lobe epilepsy – Transient epileptic amnesia	*EEG*: epileptiform discharges (esp temporal lobe) *MRI*: abn mesial temporal signal, hippocampal damage
Refractory seizures increasing in frequency (may be epilepsia partialis continua), lateralized signs	Rasmussen encephalitis*	*EEG*: lateralized epileptiform discharges *MRI*: progressive atrophy and abnormal signal involving one cerebral hemisphere
Extrapyramidal syndromes		
Tics – motor stereotypies, psychiatric disturbances, may have precipitating factor (e.g. respiratory infection)	ABGA syndrome	*MRI*: basal ganglia signal change *Serum*: ABGA titre
Encephalitis lethargica: sleep disturbance, psychiatric disturbances, ocular abnormalities, parkinsonism, dyskinesias; may have precipitating factor (e.g. upper respiratory tract infection)	Encephalitis lethargica* (?post-infectious)	*MRI*: basal ganglia, thalamic, midbrain signal change *CSF*: OCBs *Serum*: ABGA may be positive
Chronic meningitis		
Uveitis, hypothalamic dysfunction, cranial nerve signs or polyradiculopathy, systemic features; often recurrent episodes	Neurosarcoidosis	*CXR*: various patterns *MRI*: w.m. lesions ± meningeal enhancement *CSF*: lymphocytic meningitis
Oral and genital ulcers, uveitis, rash, posterior circulation strokes, racial predilection (especially Turkish/Japanese)	Behçet disease	*MRI*: brainstem, basal ganglia lesions *CSF*: lymphocytic meningitis

Table 7.9 *Continued*

Syndrome/clinical features§	Candidate diagnoses	Relevant investigations
May have evidence of primary tumour; headache, confusion, cranial nerve and radicular signs	Carcinomatous/lymphomatous/leukaemic	*CT/MRI*: may have mass lesions *CSF*: cytology, immunophenotyping (may need several)
Immunosuppression (incl HIV), systemic features, may have cranial nerve signs, strokes; travel, occupational exposures	TB/fungal/'atypical' infectious agents	*CXR*: frequently abnormal *CT/MRI*: meningeal enhancement, may have hydrocephalus, mass lesions (tuberculoma) *CSF*: lymphocytic meningitis, AFB and fungal cultures, cryptococcal Ag
Tick bite/travel to endemic area, skin lesion, arthritis, may have radiculopathies/mononeuropathies/encephalomyelitis	Lyme disease (neuroborreliosis)	*Serum*: Lyme serology (may be negative) *CSF*: pleocytosis (may be absent), Lyme serology
Argyll Robertson pupils (light-near dissociation), strokes, dorsal column signs (tabes dorsalis), HIV infection	Neurosyphilis	*Serum*: treponemal serology *CSF*: pleocytosis, treponemal serology
Infectious syndromes with posterior hemisphere signs		
Adolescent or young adult, history of measles, rapid course, florid myoclonus and seizures	SSPE*	*EEG*: periodic burst-suppression *CSF*: OCBs (measles-specific Ab)
Immunosuppression/haematological malignancies, often hemiparesis, ataxia	PML*	*MRI*: confluent posterior w.m. changes *CSF*: JC virus PCR
Other infectious syndromes		
HIV risk factors, AIDS-related illnesses, advanced immunosuppression, gait disorder, seizures	HIV (AIDS–dementia complex)	*MRI*: confluent w.m. changes *Serum*: HIV serology, low CD4 count
Arthralgia, gut symptoms, facial movement disorder (oculomasticatory myorrhythmia), supranuclear gaze palsy, myoclonus	Whipple's disease of CNS	*CSF*: Whipple PCR Duodenal biopsy
Acquired metabolic disturbances		
History of poor nutrition, food faddism, vegan, features of malabsorption; specific features (e.g. Wernicke–Korsakoff, pellagra)	Nutritional deficiency states	Dietary assessment, nutritional and malabsorption (incl coeliac) screens, empirical therapy (e.g. thiamine)
Clinical features of endocrine dysfunction	Endocrinopathies	
Clinical features of organ failure; organ transplantation	Uraemia Hepatic encephalopathy Pancreatic encephalopathy Cardio-respiratory failure	Biochemical and metabolic screens, organ-specific imaging findings
Obesity, morning headaches, daytime somnolence, snoring	Obstructive sleep apnoea	Sleep study
Toxicological exposures		
Alcohol dependence, may have cerebellar ataxia, peripheral neuropathy, features of Wernicke–Korsakoff encephalopathy	Alcoholic dementia*	Co-morbidities: nutritional screens, liver function tests, brain imaging (exclude SDH)
History of heroin inhalation ('chasing the dragon'), parkinsonism, ataxia, corticospinal signs, subacute encephalopathy	Pyrolysate encephalopathy	*MRI*: diffuse w.m. increased signal sparing U fibres (esp posteriorly)
Polypharmacy, recent changes in therapy, culprit agents	Iatrogenic	Medication review
Suspicion of overt or covert poisoning (e.g. occupational/environmental, recreational drugs, self-harm), specific systemic features; specific neurological syndromes may occur (e.g. vasculitis with cocaine, amphetamines)	Environmental poisons (e.g. carbon monoxide, heavy metals, solvents, herbicides), illicit drugs	Specific urine and blood screens if available, other specific findings (e.g. blood picture, EMG)

* Limited potential for reversibility.

evidence of infection or primary tumour; however, such clues are often lacking and the detection of a process that may be amenable to surgical intervention is the single most important justification for brain imaging in all patients presenting with dementia. Biopsy or resection of the lesion is usually required for a definitive pathological diagnosis.

There are a number of other mechanisms besides focal cerebral damage by which neoplasms may produce cognitive dysfunction: metabolic disturbances associated with systemic cancers, paraneoplastic syndromes and meningeal infiltration. Cerebral lymphoma is notoriously protean, especially the intravascular variant which can closely mimic cerebral vasculitis and requires brain biopsy for diagnosis. Antineoplastic therapies may also be implicated in both acute and chronic cognitive decline, including cytotoxic drugs (especially methotrexate, or where multiple agents have been used) and cranial irradiation; these different modalities interact and show a dosage effect, and their delayed effects may be difficult to distinguish from tumour recurrence. Leucoencephalopathy and cerebral atrophy may manifest as a late decline in cognitive function up to several years post therapy. Cranial radiotherapy also predisposes to accelerated cerebral atherosclerosis and secondary tumours.

Epilepsy and dementia

There are a number of mechanisms by which seizures can be associated with cognitive decline and dementia. Seizures themselves may cause cognitive decline, and it is particularly important to identify covert temporal lobe seizures that may cause an amnesic syndrome similar to degenerative dementias such as AD. The syndrome of transient epileptic amnesia is characterized by fluctuations in cognitive function associated with episodes of anterograde amnesia and retrograde amnesia incorporating time periods for which the patient has essentially no recollection. Exacerbation of deficits following sleep is characteristic. Other clinical features of temporal lobe seizures often coexist but these are variable and indeed pure 'amnestic seizures' may occur. Temporal lobe spikes may be evident in the surface EEG; however, a prolonged recording may be required. There may be evidence of hippocampal damage on MRI. Although the pathophysiology is not understood in detail, ictal hippocampal paresis with inability to transfer events into long-term storage is a plausible mechanism.

Cognitive dysfunction (in particular, impaired attention and bradyphrenia) may develop in association with a number of anticonvulsant agents, including phenytoin, topiramate and valproate (the last may also cause a hyperammonaemic encephalopathy). The potential for cognitive deficits following surgical resections for intractable epilepsy (chiefly, temporal lobectomy) has long been recognized and must be taken into account during surgical planning and pre-operative studies of the lateralization of cognitive functions (especially language and memory).

A number of disorders predispose to the development of both cognitive dysfunction and seizures: examples include intoxications and drug withdrawal (notably alcohol), intracranial infections, head trauma, stroke, intracranial space-occupying lesions, cerebral vasculitis and degenerative dementias including AD (generally, later in their course). In such disorders, care is needed to distinguish the cognitive effects of seizures from the underlying disease process. Complex partial seizures frequently accompany limbic encephalitis, whether infectious, paraneoplastic or autoimmune. Certain epilepsy syndromes are integral to primary disease processes that also produce progressive cognitive decline: these include epilepsia partialis continua in Rasmussen encephalitis and progressive myoclonic epilepsy in neuronal storage diseases associated with inborn errors of metabolism (Table 7.8).

Limbic encephalitis

Limbic encephalitis is a subacute encephalopathy characterized by short-term memory impairment, confusion, alteration of consciousness, complex partial temporal lobe seizures and psychiatric syndromes. Limbic encephalitis may be caused by a variety of conditions which include:

- Paraneoplastic limbic encephalitis.
- Autoimmune limbic encephalitis with VGKC antibodies:
- Peripheral nerve hyperexcitability (PNH) absent +/– tumour;
- Peripheral nerve hyperexcitability present (Cramp fasciculation syndrome, Isaac's syndrome, Morvan's syndrome).
- Steroid responsive encephalopathy:
- With antithyroid antibodies (Hashimoto's encephalopathy);
- Without detectable antibodies.
- Inflammatory vasculopathy (CNS vasculitis, Susac's syndrome, lupus cerebritis, Sjögren's syndrome, antiphospholipid antibody).

Paraneoplastic limbic encephalitis (PLE) is associated with the subacute (>12 weeks) onset of antegrade memory impairment, temporal lobe seizures and psychiatric symptoms (particularly depression, aggressive psychosis, hallucination and personality change). There may be other associated constitutional symptoms resulting from the underlying cancer.

A number of tumours and associated antibodies are now recognized in this syndrome:

- *ANNA1 (anti-Hu)* bronchial small cell carcinoma;
- *Anti-Ma2 (anti-Ta)* testicular tumour;
- *CRMP5/(anti-CV2)* lymphoma, thymoma, bronchial small cell carcinoma;
- *ANNA3* bronchial small cell carcinoma; and
- *N type VGCC* bronchial small cell carcinoma, breast.

The primary tumours usually associated with PLE are small cell bronchial (50%), testicular (>20%) and breast (>13%). MRI shows non-enhancing increased signal in the mesial temporal lobes. The EEG shows diffuse slowing with epileptiform discharges and there is a CSF pleocytosis and elevated protein in >80%. Serum antineuronal antibodies are not detected in approximately 40% of cases of histologically proven PLE. The neurological presentation antedates the diagnosis of cancer in approximately 60% of cases and usually occurs in the absence of local or distant spread, emphasizing the importance of early diagnosis. Although extensive investigations for an underlying

tumour may be necessary, whole body fluoro-deoxyglucose position emission tomography imaging (FDG-PET) is sensitive in detecting occult underlying tumours.

The mechanism of PLE is unclear but is probably related to cell-mediated immunity developing against cancer cells with the underlying antineuronal antibodies probably being markers rather than directly pathogenic. PLE may improve following removal of the primary tumour or with immunosuppression (usually steroids) but there is often a considerable residual cognitive impairment and seizures may persist.

Autoimmune limbic encephalitis associated with antibodies that react to neuronal voltage-gated potassium channels (anti-VGKC Ab) without neuromuscular hyperexcitability is indistinguishable from paraneoplastic limbic encephalitis with subacute cognitive impairment, behavioural change, confusion, disorientation and temporal lobe seizures which are difficult to control. MRI shows high T2 signal in the mesial temporal lobes. The condition is frequently associated with hyponatraemia. There may rarely be an underlying malignancy (small cell carcinoma or thymoma). In some patients the condition may be associated with REM sleep behaviour disorder or seizures. Some patients respond to corticosteroids, plasma exchange or intravenous human immunoglobulin suggesting the antibody may have a direct pathogenic role.

Neuromyotonia (Isaac's syndrome)

In this condition neuromuscular hyperexcitability occurs with the presence of anti-VGKC Ab, the condition is associated with myasthenia gravis and underlying neuroplasms including thymoma and squamous cell carcinoma. The acquired neuromyotonia is characterized by involuntary rippling of the muscles with twitching and stiffness, myokymia in which there are waves of muscle twitching. Cramp fasciculation syndrome is probably a mild variant of neuromyotonia without fibrillations.

Morvan's syndrome

In Morvan's syndrome there is associated CNS involvement with severe insomnia, seizures, hyperhidrosis and encephalopathy. Autonomic hyperactivity may occur with labile hypertension, tachycardia and increased salivation. It occurs more frequently in men (9:1). Typically, patients with Morvan's syndrome present with subacute encephalopathy including confusion, hallucination and fluctuating cognition. EMG shows spontaneous muscle fibre activity with fasciculation, myokymia and neuromyotonic discharges and there may also be a mild sensory neuropathy. The MRI is usually normal but the EEG may show considerable slowing although seizure discharges are not present. Morvan's syndrome is also associated with thymoma but may develop after thymectomy. There may be symptomatic improvement in both neuromyotonia and Morvan's syndrome with immuno-modulatory therapy (corticosteroids, azathioprine, cyclophosphamide, plasma exchange and intravenous immunoglobulin).

Steroid responsive encephalopathy with autoimmune thyroiditis (Hashimoto's encephalopathy)

This is associated with the presence of thyroid autoimmunity (serum microsomal, peroxidase or antithyroglobulin antibody) often without clinical or biochemical evidence of thyroid dysfunction. The significance of this association is uncertain as there is no obvious relationship between phenotype and type or titre of antibody (see below). Many patients may develop hypothyroidism later in the course of the disease. The condition is more frequent in women (4:1) and presentation may be highly variable with seizures, psychosis and stroke-like episodes. Occasionally, there may be tremor, myoclonus or sleep disturbance. Investigation characteristically shows an elevation of CSF protein and abnormal EEG. The MRI is usually normal but there may be subcortical white matter changes. The condition is responsive to corticosteroids but prolonged treatment may be necessary.

Infective, metabolic, toxic and other causes of dementia

Cognitive dysfunction is a frequent accompaniment of infective, metabolic and toxic disorders, whether systemic or restricted to the CNS. The primary disorders are dealt with at greater length in Chapters 8 and 18: here, basic principles relating to their effects on cognition are summarized. In the majority of cases, cognitive decline is acute and manifests as a delirium; however, in a smaller proportion an insidious deterioration ensues which may be difficult to distinguish from more common degenerative causes of dementia. The exact pathophysiology of cognitive decline is poorly understood in many cases and probably multifactorial. The cognitive profile itself is rarely diagnostic, and indeed remains poorly characterized for many of the disorders in this large and diverse group. Posterior hemisphere signs may be prominent in some conditions, such as progressive multifocal leuco-encephalopathy and subacute sclerosing panencephalitis. However, most diseases in this group can produce a variable combination of behavioural (including neuropsychiatric) and executive deficits, often with bradyphrenia: the pattern of a subcortical dementia. General clues that one may be dealing with a disease process in one of these categories include an aggressive course, evidence of active systemic disease and younger age. Risk factor profiles based on ethnic or geographical origin (many of these diseases are more common in poorer populations), occupational, travel or sexual habits, clinical infection or infectious contacts, immunosuppression or toxic exposures may raise suspicion of a particular cause. Characteristic and discriminating clinical features and investigations for some of these diseases are summarized in Table 7.3.

Controversial entities

A number of conditions often listed as causes of dementia continue to arouse controversy, because of uncertainty regarding the pathogenetic mechanism or the validity of the association with cognitive decline.

In addition to its well-recognized acute effects on cognition and behaviour, alcohol has an established association with dementia and forms a high proportion of young onset cases in community-based series. However, it is often unclear to what extent cognitive decline in an individual patient is attributable to the toxic effects of ethanol per se versus associated factors such as malnutrition (in particular, thiamine deficiency and Wernicke–Korsakoff syndrome), concomitant drug use, hepatic encephalopathy and other associated medical conditions, head trauma or the interaction of multiple factors. Marchiafava–Bignami disease, a rare degeneration of the corpus callosum, was described initially in male Italian red wine drinkers but is likely to be the result of an uncharacterized nutritional deficiency or osmotic demyelination. On balance, it is likely that chronic heavy alcohol intake can itself produce a dementia that includes frontal deficits and difficulty with complex learning and which is accompanied by generalized cerebral atrophy. Improvement in cognitive function may occur with prolonged abstinence, although little information is available concerning the time course or extent of this. A variety of neuropathological changes have been described in alcoholics, including cortical neuronal loss and gliosis, cerebellar degeneration, and atherosclerosis; however, none could be considered pathognomonic.

Head trauma is linked with 'dementia pugilistica', a syndrome of cognitive deterioration, behavioural change and parkinsonism of variable severity that is observed in boxers and other individuals who have sustained significant repeated head injuries. Pathologically, dementia pugilistica shares many features with AD, and indeed head injury is a risk factor for later development of AD in epidemiological studies. The level of risk is influenced by the severity and tempo of the injury (greater with loss of consciousness and with repeated insults) and possibly ApoE status (greater in those with the epsilon-4 allele).

The association between dementia and common autoimmune disorders such as Hashimoto's thyroidopathy and coeliac disease is not straightforward. Such diseases may lead to cognitive deterioration secondary to a systemic disturbance such as hyperthyroidism or malabsorption. The key issue concerns the potential pathogenetic role of autoantibodies in causing cognitive decline in such disorders. Despite a growing literature on 'Hashimoto encephalopathy' its nosological status remains to be defined. This will require detailed clinico- and immuno-pathological correlation and ideally identification of an animal or other model in which the role of thyroid autoantibodies can be examined directly. In the absence of such confirmation, it is important to exclude other treatable processes (e.g. cerebral vasculitis) in all suspected cases of Hashimoto's encephalopathy.

Normal pressure hydrocephalus (NPH) is considered here insofar as it has been overdiagnosed in patients presenting with cognitive impairment. It is traditionally listed as a cause of reversible dementia, heralded by a clinical triad of gait apraxia, urinary incontinence and cognitive decline. However, the validity of the term has been criticised. NPH appears to be an idiopathic communicating hydrocephalus in a high proportion of cases, although it may follow arachnoiditis, subarachnoid haemorrhage or head trauma. Impaired CSF resorption at the arachnoid granulations is most often proposed as the pathogenetic mechanism. Supportive radiological features include ventricular enlargement that is disproportionate to the degree of gyral atrophy, occluded cortical sulci, prominence of the third and fourth ventricles with no macroscopic evidence of ventricular obstruction, and (on MRI) an aqueductal CSF flow void. The demonstration of normal CSF pressure and clinical improvement following removal of a diagnostic aliquot of CSF are put forward as additional criteria for the diagnosis. This can be supplemented by prolonged monitoring to document phasic increases in CSF pressure, CSF conductance studies or cisternography. Although the potential for improvement following surgical insertion of a CSF shunt has often been emphasized, the relationship between NPH and cognitive decline remains unclear. 'Pure' NPH is uncommon. Many patients diagnosed with NPH have changes of small vessel disease and/or AD at postmortem, and it has been shown that patients with AD may improve transiently following ventricular drainage (the mechanism is not clear). Patients with 'idiopathic' NPH, long-standing symptoms, established dementia, or radiological evidence of significant cerebral atrophy or cerebrovascular disease generally fail to improve following CSF shunting. The shunt procedure itself carries a significant risk of complications such as subdural haematoma in this population.

Management of dementia

Risk factor management

The greatest risk factor for development of dementia is age. However, there are several modifiable risk factors. Moderate exercise and a modest, rather than excessive, intake of alcohol reduce the risk of dementia as does modification of vascular risk factors: obesity, hypercholesterolaemia, diabetes, hypertension and smoking.

Co-morbidity

Delirium is often a harbinger of dementia and patients with dementia have a lower threshold for developing delirium and will take longer to recover than those who are cognitively normal. The usual causes apply, such as infection (usually involving the urinary or respiratory tract), metabolic/biochemical derangement, hypoxic/ischaemic damage or medication. These should all be excluded as a cause and treated actively if identified.

Depression is both an important treatable cause and compounding feature of dementia, occurring in up to 20% of individuals with AD, vascular dementia and DLB. Over 50% of patients with dementia experience depressive symptoms at some stage. Symptoms should be actively sought and treated in any patient at presentation and during the course of their illness.

Older tricyclics should be avoided because of their anticholinergic effects. Selective serotonin re-uptake inhibitors (SSRIs) are also preferable in FTD, as they may be effective in modifying the behavioural symptoms, in addition to any depressive symptoms. As in all patients, side effects should be looked for and response monitored.

Epileptic seizures occur in patients with dementia at a higher prevalence than among healthy elderly individuals. The incidence of seizures among patients with dementia varies with the aetiology of the dementing illness. In patients with AD, approximately 10–22% have at least one seizure. Seizures usually occur several years post diagnosis, in moderate to severe AD. There is an increased incidence in early onset AD, especially with *PS-1* mutation. The incidence of seizures in other dementing diseases is less clear. Diagnosis can be delayed by difficulty in description as a result of cognitive impairment. The potential cognitive adverse effects of some antiepileptic drugs must be taken into consideration, and the lowest effective dosage should be used.

The majority of patients with dementia are cared for in the community, usually in nursing homes. Approximately 30% of patients in UK nursing homes are receiving antipsychotic drugs, usually neuroleptics. In dementia, particularly DLB, these drugs can have catastrophic consequences; atypical antipsychotics should be used in preference. Even these are not free of the risk of increasing side effects and confusion, therefore treatment titration must be cautious. It is also important to remember the reported increase in stroke risk with risperidone and olanzepine.

Behavioural management

Coping on a daily basis with challenging behaviour is a major burden for the carer of a patient with dementia. In the early stages, the major behavioural changes are seen in FTD, but other disorders may also produce significant behavioural problems at some stage. The loss of insight seen in some diseases, combined with the change in personality and disinhibition, have a huge impact on the carer, causing strain on the relationship and loss of sense of control. Another problem apparent in mild dementia is significant anxiety, which also may exacerbate behavioural problems.

In more severe dementia, a multidisciplinary assessment is required for behavioural modification. This approach tends to be most successful in patients in nursing homes. Behavioural modification may be achieved by altering the environment, if there is an external precipitant, or by conditioning techniques with positive reinforcement. Strategies may improve performance, e.g. scheduled toileting, or prompted voiding can reduce urinary incontinence. Playing music during meals and bathing can reduce disruptive behaviour. Exercise, massage and pet therapy have all been used to reduce abnormal behaviours.

Hallucinations often occur at home in dimly lit surroundings (so-called 'sundowning') and improved lighting may help; as always, intercurrent infections and drugs should be considered as possible exacerbating factors.

Patients may become irritable or angry at being disturbed at times of washing, dressing or eating. A considered response is needed, with maintenance of a respectful friendly approach, removal of exacerbating factors and consideration of behavioural measures such as distraction or 'time out'.

Sleep cycle is often very disturbed – patients may be up all night and sleep all day. This can be extremely distressing for carers. It is important to exclude delirium, and to ensure structure and rewarding activities during the day. A routine should be established with a fixed bedtime, no stimulants and meal before sleep. If these fail, it is reasonable to provide a trial of medication, such as an anxiolytic.

Urinary and faecal incontinence may become a problem for multiple reasons: medical causes such as diabetes mellitus, or cortical loss of bladder control, reduced mobility; or cognitive causes such as poor recognition, disorientation or impaired planning. In addition to prompt treatment of medical problems such as urinary tract infections, simple physical measures can make a significant difference. Regular visits can reduce the likelihood of accidents; avoidance of bedtime drinks, labelling of the toilet to provide cues and the use of incontinence pads all help. Pharmacological therapies such as oxybutinin may help, but have the potential for worsening confusion and need to be monitored closely.

Safety

Patients with mild to moderate dementia usually function best in familiar surroundings. It is important to create an appropriate, safe and supportive environment to encourage optimal function. A home safety evaluation and appropriate modifications should be organized. For example, signs may be placed around the house to orientate patients.

Patients may become increasingly unstable on walking, yet be unaware of this because of their cognitive impairment. Wandering is a frequent problem, often associated with lack of stimulation and ensuing frustration. Behavioural measures such as increasing interaction, providing stimulation at day centres, encouraging exercise and increasing structure of the day may help. At times, locking doors is the only solution.

In patients with significant orobuccal apraxia, e.g. in progressive non-fluent aphasia, a feeding nasogastric tube, or even a percutaneous endoscopic gastrostomy, may be required. Patients and family may opt not to have this, but discussion is important. Broaching the subject early in the course of the illness, if swallow is involved, will enable the patient and carers to make an informed decision.

As dementia progresses, increasing supervision is necessary, eventually becoming continuous. This curtails the carer's ability to continue working, and progressively reduces their independence. Day care centres can provide release for the carers during the week and give structure to the patient.

The issue of fitness to drive creates enormous anxiety for the patient diagnosed with dementia, who perceives removal of a licence as a loss of independence. Driving for patients with frontal

impairment can be particularly difficult because of their lack of insight and poor judgement, and families often have difficulty in persuading patients to stop. In contrast, patients with AD often progressively curtail their driving activities as they realize they or their relatives feel unsafe. It is difficult to determine at what point an individual becomes sufficiently impaired to cease driving, and the relationship between the severity of dementia and driving abilities is complex. The UK driving licence law states that if at any time the licence holder becomes aware that he/she has a disability he/she must inform the driver and vehicle licensing authority (DVLA). The guidelines state that in general a patient able to attend to day-to-day needs, with adequate insight and judgement, and not disorientated in time or place may be fit to drive. A licence may be issued on a yearly basis with reassessment on each renewal. If in doubt, assessment at a mobility centre may be required; if serious doubt exists a medical adviser at the DVLA may require a test to be taken.

In practical terms, the issue must be discussed with the patient and family once a diagnosis of dementia is made. The patient should be reminded of their legal obligation to inform the DVLA. If the patient and family do not inform the DVLA, and the physician is concerned, then he/she can inform the DVLA directly. Each case is individual, and the discussion should include carers and the patient.

Caring for the carer

In the UK and USA, 33–60% of carers of patients with dementia are spouses, over 75% of whom are women. This profile, and the perception of the role of a carer, varies across cultures and socioeconomic groups. In most of the Western world, where the extended family is small or may not exist, the burden of caring can be very high, often focusing almost entirely on a single, often elderly individual.

Dementia leads to dependency and often to problem behaviours, with resultant strains on the carer. Compared to age-matched non-carer controls, carers have problems in several areas:

- Depression, stress, low self-esteem and poorer sense of well-being are common and are more severe in young onset dementia and if the premorbid relationship was ambivalent.
- Carers experience poorer physical health, with higher levels of chronic conditions, more prescription and GP attendances and poorer self-perception of health.
- Social isolation is frequent as carers have less time for themselves for hobbies and going out, and may have difficulty coping with social embarrassment caused by the patient's behaviour.
- The cost of nursing, respite care and lost earnings should not be underestimated, and often has a huge impact on quality of life, compounding the above factors.

This complex relationship requires both formal support from professionals and informal support from friends and relatives. The carer's needs change through the evolution of the illness and often continue after the death of the patient. Local support groups and national associations are extremely important in this regard.

Planning for the future and end of life issues

If no will is in existence, this should be discussed amongst the family. In order to make a will the patient needs to understand what they are doing and the effect it will have: what they have to leave, and who might make claims on it. Advanced directives concerning treatment should also be considered when patients are competent.

In the later stages of dementia the individual becomes totally dependent in activities of daily living, needing continuous nursing care. Profound loss of memory may lead to inability to recognize familiar surroundings or family and friends. Almost all comprehensible speech may be lost. There are particular issues that emerge at this stage, many with ethical implications, including whether to place the patient in institutional care. Important issues in any setting include:

- *Feeding* Swallowing may be difficult and good nutrition becomes a priority. Individuals at this stage need speech therapist assessment of swallowing, dietitian advice on nutrition and consultation with family as to when and if to institute feeding devices.
- *Medical treatment* Weight loss and immobility contribute to vulnerability to pressure sores and infection. Issues of withholding life-prolonging curative treatment, including cardiorespiratory resuscitation need to be discussed with the family.
- *Postmortem diagnosis and brain donation* Clinical diagnostic accuracy in patients with dementia is at best 70–80%. Postmortem neuropathological examination can provide an accurate diagnosis with potentially important aetiological information for familial diseases. Families often gain benefit from contributing to research from tissue donation. Examination of the brain and use of tissue, however, can only be performed with written informed consent from the next of kin, even in the case of a coroner's post mortem.

8 Infection in the Nervous System

Robin Howard, Hadi Manji

Infections involving the nervous system carry a high morbidity and mortality, particularly in developing countries where the burden of disease is great, diagnosis is difficult and limited resources mean that availability and access to treatment is poor. In the developed world, neurological infection is less frequent but continues to cause significant problems of diagnosis and management. Increasing global travel means unfamiliar organisms are encountered in unexpected settings; there is an increasing recognition that more familiar pathogens may manifest disease in varying patterns and settings and newer emergent pathogens have become important, particularly in the immunosuppressed patient.

Infections of the nervous system can be caused by viruses, bacteria, fungi or protozoa. They may affect the lining of the brain, CSF, brain parenchyma, spinal cord, nerve roots, peripheral nerve or muscle. Infections of the CNS may be divided into meningitis, encephalitis, focal suppuration or inflammation. In meningitis there is inflammation involving the pia and arachnoid mater and the subarachnoid space. Encephalitis is infection and inflammation within the brain parenchyma. Focal infection causes abscess formation within or immediately adjacent to the brain or spinal cord. These patterns may overlap and when infection involves the meninges, brain, spinal cord and nerve roots the descriptive compound terms are used: meningo-encephalitis, meningo-myelitis, encephalo-myelitis, meningo-radiculitis and meningo-encephalomyelitis. Neurological disturbances may also arise as a consequence of direct infection or from a secondary para-infectious immune-mediated mechanism.

The presentation of infections of the nervous system can be highly variable, ranging from acute fulminating meningitis or encephalitis leading to death within hours, to the development of disease many years after the initial infection. The spectrum of neurological manifestation is also highly variable, ranging from meningism and impaired consciousness, to signs of cortical and subcortical dysfunction, or involvement of the spinal cord, nerve roots, peripheral nerve or muscle.

Understanding of neurological infection has been advanced by new techniques of molecular diagnosis, in particular wider availability of polymerase chain reaction (PCR) assay to detect bacterial and viral nucleic acid in cerebrospinal fluid (CSF), and improved imaging of brain and spinal cord. There have also been many important recent advances in the development of new therapies targeted towards specific pathogens, such as antiretrovirus therapy, and in facing the challenges presented by increased antibiotic resistance of pathogens such as streptococcus, tuberculosis and malaria. Perhaps even more importantly, the global burden of infections of the nervous system has been greatly reduced by the development of effective strategies of prevention for conditions such as poliomyelitis, leprosy and malaria.

Bacterial meningitis

Bacterial meningitis is caused by a primary infection within the subarachnoid space that causes acute inflammation of the meninges (pia and arachnoid mater). It may be caused by a variety of organisms which vary in frequency according to the age of the host and other risk factors.

Epidemiology

The incidence of bacterial meningitis is 2–6/100,000 per annum with peaks in infancy, adolescence and the elderly. Common causes of bacterial meningitis by age and risk factors are shown in Table 8.1.

The incidence of *Haemophilus influenzae* type b and group C meningococcal (*Neisseria meningitidis*) meningitis has declined dramatically with the introduction of vaccination programmes.

Risk factors

A number of factors may contribute to the development of bacterial meningitis (Table 8.2).

ISBN: 978-1-405-13443-9

Neonates (<3 months)	*Escherichia coli*
	Group B streptococcus
	Listeria monocytogenes
Infant and child (>3 months)	*Streptococcus pneumoniae* (pneumococcus)
	Neisseria meningitidis (meningococcus)
	Haemophilus influenzae
Adults <50 (healthy and immunocompetent)	*Streptococcus pneumoniae*
	Neisseria meningitidis
Adult >50	*Streptococcus pneumoniae*
	Neisseria meningitidis
	Listeria monocytogenes
Skull fracture/post neurosurgery	*Staphylococcus epidermidis, Staph. aureus*
	Gram-negatives (*Klebsiella, Proteus, Pseudomonas, E. coli, Serratia, Acinetobacter*)
	Group A and D streptococci
	Streptococcus pneumoniae
	H. influenzae
Shunt associated	*Staph. epidermidis, Staph. aureus*
	Gram-negative organisms
	Rarely, streptococci spp, diphtheroids, anaerobes
CSF leak	Gram-negative organisms
	Streptococcus pneumoniae (pneumococcus)
Pregnancy	*Listeria monocytogenes*
Immunosuppressed (e.g. malignancy, alcohol, diabetes mellitus, septicaemia, UTI)	*Listeria monocytogenes*
	Gram-negatives
	Streptococcus pneumoniae
	Pseudomonas aeruginosa
	Group B streptococcus
	Staph. aureus
	Cryptococcus
Rarer causes	*Salmonella, Shigella, Clostridium, Neisseria gonorrhoea*

CSF, cerebrospinal fluid; UTI, urinary tract infection.

Table 8.1 Common causes of bacterial meningitis by age and risk factors.

Penetrating cranial trauma	
Foreign bodies within the CNS	CSF shunts predispose to staphylococcal meningitis
Defect in the immune system	Impairment of complement activation predisposing to the development of meningococcal meningitis
	Splenectomy or splenic dysfunction, as in sickle cell disease, associated with pneumococcal meningitis
	T lymphocyte dysfunction (HIV disease, chemotherapy or malignancy) predisposes to *Listeria monocytogenes* meningitis
Defect in the mucocutaneous barrier	Skull base fracture predisposes to pneumococcal meningitis

Table 8.2 Risk factors for the development of meningitis.

Pathogenesis

Bacterial infection reaches the CNS either by direct invasion, haematogenous spread or embolisation of infected thrombi. There can also be direct extension from contiguous structures via the diploic veins or erosion of an osteomyelitic focus. Also infection may be iatrogenic (e.g. following ventriculo-peritoneal shunt, intracranial pressure monitor or surgery).

In community-acquired meningitis the transmission of pathogenic bacteria occurs by respiratory droplets spread or close contact with a carrier. The process by which these bacteria gain access to the CNS is complex. Bacteria initially colonize the nasopharynx by attaching to epithelial cells using outer adhesive pili and membrane proteins. The risk of colonization of the respiratory epithelium is increased by damage caused by irritants such

as a preceding viral illness or cigarette smoke. Their capsular polysaccharides help to overcome host defence mechanisms including impairment of mucosal immunoglobulin A (IgA). The bacteria are carried across the epithelial cell into the intravascular space where they are relatively protected from the complement-mediated humoral response because of their polysaccharide capsule.

Bacteria that survive in the bloodstream gain access to the CSF via the choroid plexus epithelium or cerebral capillaries. They cross between endothelial cells by disrupting intercellular tight junctions or causing endothelial cell injuries. Once the bacteria reach the CSF they are in an immunologically privileged site because of the relatively minimal complement-mediated humoral response. Bacteria multiply rapidly within the CSF and bacterial wall components released by lysis induce an inflammatory process involving the meninges and brain substance. This, in turn, leads to increased permeability of the blood–brain barrier allowing further leakage of plasma proteins into the CSF and this contributes to the inflammatory and purulent exudates within the subarachnoid space. There is initially a temporary increase in cerebral blood flow leading to disruption of cerebral autoregulation and an increase in intracranial pressure. Worsening exudates infiltrate the arterial walls leading to intimal thickening and large vessel constriction, eventually culminating in cerebral ischaemia. The development of systemic shock leads to a reduction in systemic arterial blood pressure and, because of the impairment in cerebral autoregulation, a consequent reduction in cerebral blood flow which exacerbates the cerebral ischaemia or infarction. There may also be a secondary thrombosis of the major venous sinuses and thrombophlebitis of the cortical cerebral veins. Finally, the purulent exudate can obstruct the resorption of CSF by the arachnoid villi or the flow through the ventricular system leading to obstructive or communicating hydrocephalus with interstitial cerebral oedema.

Clinical presentation

Meningitis is characterized by the presence of fever, headache and neck stiffness. There is usually associated nausea, vomiting, photophobia and progressive lethargy, stupor or coma, and epileptic activity may develop. Meningitis may evolve as a fulminating illness over a few hours, particularly in children, but progression is variable and less commonly can be a progressive subacute infection worsening over several days. Meningism is characterized by the presence of neck stiffness on passive flexion and Kernig's sign becomes positive if neck and back pain is felt when the patient is in a supine position and the hip and knee are flexed. Brudzinski's sign is positive when flexion of the neck results in spontaneous flexion of the hips and knees when the patient is in a supine position. Seizures may be focal or generalized and may occur either at presentation or at any time during the course of bacterial meningitis in up to 40% of patients. They may arise from focal arterial or venous infarction, haemorrhage, localized cerebral oedema or as a consequence of systemic features including pyrexia, septicaemic shock, toxicity or other metabolic derangement. Meningitis may lead to vascular occlusion and subsequent infarction of the brain or spinal cord, progressive cranial nerve lesions and hydrocephalus secondary to impaired CSF absorption and obstruction. Organ failure, hearing loss and limb infarction may also occur.

Investigation

Bacterial meningitis is accompanied by an elevated white cell count and raised inflammatory markers. In the presence of septicaemia, platelet consumption may occur with loss of clotting factors. There may be associated hypocalcaemia, hyponatraemia and impaired renal function with metabolic acidosis. Imaging should be undertaken urgently to exclude mass lesions, hydrocephalus or cerebral oedema which are a contraindication to

Table 8.3 Comparison of cerebrospinal fluid (CSF) findings in different forms of meningitis.

	Normal	Acute bacterial	Viral meningitis	TB meningitis	Fungal meningitis

Table 8.4 Treatment of bacterial meningitis.

Neisseria meningitidis (meningococcus)	Benzylpenicillin (penicillin G) 2.4 g (iv) 4 hourly for 7 days or Cefotaxime 2 g (i.v.) 4–6 hourly for 7 days or Ceftriaxone 2 g (i.v.) 12 hourly for 7 days or Chloramphenicol 50 mg/kg 6 hourly or Ampicillin 2 g (i.v.) 4 hourly for 7 days
Streptococcus pneumoniae	Cefotaxime 2 g (i.v.) 4–6 hourly for 14 days or Ceftriaxone 2 g (i.v.) 12 hourly for 14 days or Penicillin G < 2.4 g (i.v.) 4 hourly for 10–14 days
Streptococcus pneumoniae – moderate resistance	Cefotaxime 2 g (i.v.) 4–6 hourly for 14 days or Ceftriaxone 2 g (i.v.) 12 hourly for 14 days
Streptococcus pneumoniae – resistant	Cefotaxime 2 g (i.v.) 4–6 hourly for 14 days or Ceftriaxone 2 g (i.v.) 12 hourly for 14 days *and* Vancomycin 1 g (i.v.) 12 hourly for 14 days
Haemophilus influenzae	Cefotaxime 2 g (i.v.) 4–6 hourly for 14 days or Ceftriaxone 2 g (i.v.) 12 hourly for 14 days or Ampicillin 2 g (i.v.) 4 hourly for 14 days or Chloramphenicol 50 mg/kg 6 hourly
Streptococcus group A & D	Cefotaxime 2 g (i.v.) 4–6 hourly for 14 days or Ceftriaxone 2 g (i.v.) 12 hourly for 14 days or Penicillin *and* gentamicin 3–5 mg/kg/day in divided doses, 8 hourly
Listeria monocytogenes	Ampicillin 2 g (i.v.) (4 hourly) for 3 weeks *and* gentamicin
Staphylococcus aureus – non-MRSA	Flucloxacillin 2 g (i.v.) 6 hourly for 4 weeks
Staphylococcus aureus – MRSA	Vancomycin 1 g (i.v.) 12 hourly for 4 weeks
Gram negatives (excluding *Pseudomonas*) i.e. *E. Coli, Klebsiella* and *Proteus*	Ceftriaxone 2 g (i.v.) 12 hourly for 3–4 weeks or Cefotaxime 2 g (i.v.) 4–6 hourly for 3–4 weeks or Meropenem 2 g (i.v.) 4–6 hourly *and* vancomycin 1 g 12 hourly for 14 days
Pseudomonas	Ceftazidime 2 g (i.v.) 8 hourly for 3 weeks and gentamicin 3–5 mg/kg/day in divided doses, 8 hourly or Meropenem 2 g (i.v.) 8 hourly for 4 weeks

lumbar puncture. The diagnosis of meningitis is made by blood culture, CSF analysis, staining and culture. However, there is a considerable risk that lumbar puncture may cause coning in the presence of cerebral oedema. Therefore, in the absence of imaging, lumbar puncture should be avoided if the patient has impaired consciousness or there are focal neurological deficits, signs of shock or bleeding diathesis, purpuric or petechial rash, prolonged focal seizures or signs of raised intracranial pressure or incipient herniation.

Gram staining of the CSF is positive for meningococcus in approximately 50% of patients with acute meningococcal meningitis. Blood cultures may be helpful but are unreliable. CSF tests may directly identify an organism and its nucleic acid or surface constituents by staining, culture or capsular antigen detection. PCR is particularly sensitive in CSF for *Streptococcus pneumoniae* and *Neisseria meningitidis.* The CSF findings in different forms of meningitis are summarized in Table 8.3.

In patients with severe meningitis, the first priority is to commence empirical antibiotic treatment, usually immediately after sending a blood culture. Primary care physicians are recommended to commence benzylpenicillin in any child suspected of having meningococcal meningitis before transfer to hospital although the benefit of this approach is uncertain. If the situation is less urgent it is preferable to undertake a lumbar puncture, if safe, and send CSF for staining and culture before antibiotics are commenced. Empirical therapy in the absence of staining and culture depends on age, immune status and any other risk factors. In healthy immunocompetent adults treatment should be initiated with a third generation cephalosporin (not penicillin because of potential pneumococcal resistance) with ampicillin if *Listeria* infection is considered possible. When there is the possibility of nosocomial infection (e.g. following surgery, trauma or in the presence of a shunt) ceftazidine is preferred because it is more active against *Pseudomonas* than other third generation cephalosporins. Vancomycin is also added to cover highly resistant staphylococcus. If there is penicillin or cephalosporin allergy, chloramphenicol should be given with vancomycin. Specific antibiotic treatment for acute bacterial meningitis is summarized in Table 8.4 but therapy depends on demonstration of appropriate microbiological sensitivities.

Specific causes of bacterial meningitis

Neisseria meningitidis (meningococcal meningitis)

This is a Gram-negative diplococcus. It is the most common identified cause of meningitis in children and young adults, with an incidence of 1–1.5/100,000. In the UK, meningococcal disease remains the leading infectious cause of death in childhood with a mortality of approximately 10%. It occurs throughout the year but the majority of cases are in the winter and early spring. Transmission occurs by droplet spread, particularly in close contact, and 5–10% of all adults are asymptomatic nasopharyngeal carriers of these pathogenic bacteria.

Meningococcus is classified into subgroups according to the immunoreactivity of the capsular polysaccharide. While there are at least 13 serogroups, most cases of meningococcal disease are caused by subgroups A and C for which a polysaccharide vaccine is effective. A vaccine has not been produced for subgroup B because the capsule polysaccharide is only poorly immunogenic in humans. In more recent years there have been increasing outbreaks of serogroup Y. Risk factors for meningococcal infection include close contact with carriers or infected individuals, low socio-economic status, poor housing and impairments of both humoral and cell-mediated immunity.

Clinical manifestations of meningococcal infection may develop within minutes or hours. In approximately 40% of patients there is isolated meningitis; 10% have septicaemia alone and the remainder a mixed pattern. Isolated meningococcal meningitis carries a better prognosis than meningococcal septicaemia or mixed picture. Clinically, fulminant meningitis is characterized by pyrexia, headache and meningism associated with nausea and vomiting, photophobia and progressive lethargy. In early meningococcal meningitis there is a diffuse erythematous macular papular rash which eventually develops into the characteristic petechiae found across the trunk and lower extremities in the mucous membranes, conjunctiva and occasionally on the palms and soles. These lesions should be distinguished from other infective disorders that cause a purpuric rash, including enterovirus meningitis and bacterial endocarditis. The development of meningococcal septicaemia is associated with progressive vasomotor disturbance culminating in profound hypotension, tachycardia and a rising respiratory rate indicating pulmonary oedema or raised intracranial pressure resulting from cerebral oedema.

Waterhouse–Friderichsen syndrome is a form of fulminant meningococcal disease, in which severe septicaemia is complicated by the development of bilateral haemorrhage into the adrenal glands and disseminated intravascular coagulation leading to the development of severe sudden febrile illness associated with septic shock, petechiae, purpura and coma.

Management (Table 8.4)

Patients with probable fulminant meningococcal meningitis should be treated immediately with parenteral benzylpenicillin (2.4 g) given intramuscularly or preferably intravenously because of uncertain absorption in patients with shock. If patients are allergic to penicillin they should be given ceftriaxone, cefotaxime or chloramphenicol and transferred immediately to the accident and emergency department. Antibiotics should be given prior to any diagnostic procedure if there is a petechial or purpuric rash or shock. If there is meningitis of uncertain aetiology or if the patient is allergic to penicillin it is preferable to give ceftriaxone 2 g i.v. stat, alternatively cefotaxime or vancomycin can be used.

Septicaemic shock should be treated with appropriate volume replacement, elective intubation and ventilation. Patients may require inotropic support and metabolic abnormalities, coagulopathy and anaemia should also be appropriately treated. In the presence of raised intracranial pressure it may be necessary to administer mannitol, muscle relaxation and appropriate intensive care nursing.

Contacts

Meningococcal meningitis is a notifiable disease in the UK and there is a high risk of family members developing the disease. All household close contacts should therefore be treated to eradicate nasopharyngeal carriage. It is recommended that rifampicin 600 mg 12 hourly should be given as prophylaxis for 2 days, ciprofloxacin 750 mg as a single dose is also effective.

Immunization

Meningococcal vaccination is currently available and contains polysaccharides to serogroups A, C, Y and W135. The beta serotype is antigenically identical to human brain and is therefore

poorly immunogenic. The vaccine induces protection for 3–5 years and may be of value in controlling outbreaks.

Outcome

The mortality is approximately 10% although this rises to 40% in those with meningococcal septicaemia coexisting with meningitis. Up to 20% may have neurological sequelae including hearing loss, loss of the limbs secondary to large vessel vasculitis and neurological disability resulting from cerebral ischaemia.

Streptococcus pneumoniae (pneumococcal meningitis)

This the most common cause of meningitis in adults over the age of 18 years with a case fatality rate of approximately 20%. The organism is a Gram-positive coccus; spread occurs by respiratory droplet infection. The primary site of colonization is the nasopharynx and the carrier state is common. *S. pneumoniae* meningitis is commonly caused by local extension from otitis media, or a paranasal source of infection, following a skull base fracture or sinus injury with dural tear. Other predisposing features include pneumonia, alcoholism, diabetes, immunodeficiency states (e.g. splenectomy, hypogammaglobulinaemia, HIV). Clinical presentation is similar to other forms of pyogenic meningitis but a coexisting pneumococcal pneumonia may be present. The course may be aggressive with rapid progression to coma and respiratory arrest. Residual neurological sequelae are common and occur in more than 35% including cerebral oedema, hydrocephalus, vasculitis, venous thrombosis, ventriculitis, labyrinthitis and spinal cord involvement.

Management

The treatment of pneumococcal meningitis has been complicated by the development of penicillin and cephalosporin resistant strains. Conventional treatment is with penicillin, ampicillin and ceftriaxone or cefotaxime but if penicillin-resistant pneumococcal infection is suspected then vancomycin should be added. However, vancomycin itself only crosses the blood–brain barrier poorly and therefore should not be used in isolation. At present, vaccination is inconsistent in inducing adequate immunity and does not include coverage for penicillin-resistant strains of *Pneumococcus*. Failure to improve despite antibiotic treatment implies either the development of cerebral complications, a persistent primary focus or an inadequate or inappropriate dosage of antibiotics. Adjuvant dexamethasone (10 mg 6-hourly i.v. for 4 days) improves the outcome and should be commenced before or with the first dose of antibiotics.

Haemophilus influenzae

This is a small Gram-negative coccobacillus. Prior to the introduction of *Haemophilus influenzae* type B (HiB) vaccination this was the most common cause of meningitis in children with a fatality rate of approximately 5% and permanent neurological damage in some 30% of cases. Meningitis occurs as a consequence of respiratory droplet spread and adults remain vulnerable to the non-encapsulated strains. Risk factors include otitis media, head trauma, previous neurosurgery or a CSF leak. Presentation may be with acute meningitis but an associated vasculitis may occur, leading to focal signs.

Management

The primary treatment of *Haemophilus influenzae* is ceftriaxone or cefotaxime because of the significant incidence of penicillin resistant strains in up to 40%. Chemo-prophylaxis is recommended as single doses for 4 days. Vaccination is recommended for all children with the first dose being given at 2 months.

Listeria monocytogenes

This is a beta haemolytic Gram-positive rod with 12 subtypes based on antigenic properties. It is an intracellular pathogen that lyses phagocytic cells before entering the bloodstream. The overall case fatality rate may reach 15%. Outbreaks are associated with contaminated food including soft cheese, unpasteurized milk and occasionally raw meat. Predisposing factors include pregnancy, advanced age or immunosuppression, and *Listeria* is particularly common in patients with malignancy, renal failure or following organ transplantation or steroid treatment. *Listeria* may cause a meningitis or meningo-encephalitis but seizures, disturbances of consciousness and movement disorders may also occur. A brainstem encephalitis develops in >10%, this presents with a prodromal phase followed by progressive ponto-medullary involvement with cranial neuropathy, pyramidal and sensory signs. The differential diagnosis of brainstem meningitis is listed in Table 8.5.

Management

Treatment is with ampicillin or penicillin for 3–4 weeks although gentamicin is often added to enhance bacteriocidal activity. If there is a penicillin allergy then co-trimoxazole (Septrin) is recommended but chloramphenicol and gentamicin should be avoided.

Group B streptococcus

Group B streptococcus is an important cause of neonatal sepsis and meningitis, it also causes purulent meningitis in adults with

Table 8.5 Differential diagnosis of brainstem encephalitis.

Virus	Enterovirus, EBV, CMV
	Tick-borne encephalitis
Bacterial	*Listeria, Mycoplasma*
	Coxiella, Legionella, Brucella
	Borrelia
Non-Infectious	Multiple sclerosis
	Sarcoidosis
	Acute disseminated encephalomyelitis
	Vasculitis
	Carcinomatous meningitis
	Fisher syndrome

CMV, cytomegalovirus; EBV, Epstein–Barr virus.

a case fatality rate of approximately 5%. Risk factors in neonates include premature birth or low birth weight, prolonged rupture of membranes, intrapartum fever or maternal group B streptococcus infection during pregnancy. In non-pregnant adults, group B streptococcal meningitis is associated with advanced stage diabetes, cirrhosis and systemic malignancy; it is usually acquired nosocomially. The treatment is with penicillin or ampicillin.

Gram-negative meningitis

Gram-negative meningitis (excluding *N. meningitidis*) may arise spontaneously, when the onset is often acute, and the condition follows an aggressive course. More commonly, Gram-negative meningitis may follow neurosurgical intervention when the development and progression is insidious and gradual. Nosocomial infection is usually caused by *Klebsiella* (approximately 40%), *Escherichia coli* (<30%) or *Pseudomonas aeruginosa* (<20%) with *Serratia*, *Enterococcus*, *Proteus* and *Salmonella* meningitis occurring less commonly. Meningitis may be associated with seizures, confusion and focal signs including cranial nerve palsies. The diagnosis is made on CSF culture but this is only helpful in <50% of untreated patients. The limulus lysate assay can detect endotoxin but is limited in sensitivity and has little clinical role. Treatment is with third generation cephalosporin (Table 8.4).

Gram-positive meningitis

Gram-positive meningitis excludes *S. pneumoniae*, but includes neonatal meningitis caused by streptococcus group B. Gram-positive meningitis usually results from a CNS shunt infection but may occur spontaneously in approximately 13% of community-acquired meningitis caused by *Staph. aureus* or streptococcus groups A, B and D. Gram-positive organisms are a common cause of nosocomial shunt infection, usually resulting from *Staph. aureus*, *Staph. epidermidis* or, less commonly, coagulase-negative staphylococci. Spontaneously occurring *Staph. aureus* meningitis may be predisposed by coexisting disease including diabetes mellitus, carcinomatosis, alcohol and intravenous drug abuse. It is usually associated with a focus of infection outside the CNS, e.g. endocarditis or osteomyelitis. The diagnosis is made on the basis of CSF staining and culture. Treatment depends on drug resistance. For fully sensitive staphylococcus, treatment with flucloxacillin is appropriate with vancomycin being used for methicillin resistant *Staph. aureus* (MRSA). There is a high mortality rate of <50% with >10% experiencing neurological sequelae.

Meningitis of unknown aetiology

The initial choice of antibiotic treatment depends on the age of the patient and any underlying risk factors. In the neonate in whom there is a possibility of group B streptococcal infection or *Listeria*, then ampicillin and ceftriaxone should be administered. For anyone over the age of 3 months, ceftriaxone is the preferred treatment; cefotaxime is an alternative. Vancomycin should be given if there is a significant risk of *Strep. pneumoniae* penicillin resistance. In those over 50 years, because of the incidence of *Listeria*, ampicillin is indicated. In patients who are allergic to penicillin or cephalosporins, chloramphenicol remains the drug of choice.

Focal CNS infection

Cerebral abscess

This is a focal suppurative (pus forming) infection occurring within the cerebral parenchyma. It develops as a result of contiguous spread of infection from paranasal sinuses, mastoiditis, otitis media, osteomyelitis or following postoperative and post-traumatic infections. Less commonly, it may arise as a result of haematogenous spread from distant sites including teeth and lungs. However, no cause is found in up to 20% of patients.

The causative agents depend on the underlying abnormality, and the age and immunological status of the patient. These are summarized in Table 8.6. Cerebral abscesses that arise from dental, frontal or ethmoid sinuses tend to involve the frontal lobe while those arising from the sphenoid sinuses or otitic infection particularly involve the temporal lobes. Cerebral abscesses

Table 8.6 Microbiological pathogens in brain abscesses.

Source	Pathogens
Paranasal sinuses, otitic, mastoiditis or dental infection	*Streptococcus* (esp. *Strep. milleri*) 60–70% Enteric bacteria (*E. coli, Proteus, Pseudomonas*) 20–40% *Bacteroides* Multiple organisms including *Listeria, Clostridium, Fusobacterium* and *Actinomyces*

HIV	*Toxoplasma gondii* *Mycobacterium tuberculosis* *Cryptococcus neoformans*

Figure 8.1 Multiple bacterial abscesses and ventriculitis in a 53-year-old woman with Gram-negative septicaemia (enhanced CT).

resulting from haematogenous spread tend to occur as multiple rather than single abscesses (Figure 8.1), often in the region of greatest blood flow, within the basal ganglia.

Clinical features

The peak frequency is 35–45 years but they can occur at any age. Although the characteristic onset is with the subacute or indolent onset of fever, headache, nausea, vomiting, seizures or focal neurological signs, there may be a more rapid onset of neurological symptoms suggesting a space-occupying lesion or cerebral infarction. Fever is variable and may be absent in up to 50% of patients usually those who are older; it tends to resolve rapidly with steroids. Rupture of an abscess into the ventricles may manifest as a severe headache and developing signs of meningism.

Investigation

Routine haematology and biochemistry usually shows an elevation of the erythrocyte sedimentation rate (ESR), white cell count and blood cultures are only positive in about 10%. Computed tomography (CT) scan may show a thin enhancing ring of uniform thickness with smooth margins which tends to be thicker nearer the cortex and thinner near the ventricles. Magnetic resonance imaging (MRI) with enhancement is more sensitive and will document the extent of surrounding oedema more accurately. Lumbar puncture is contraindicated in patients with mass lesions.

Prognosis

The prognosis depends on the clinical state of the patient. Survival is excellent for those fully alert and conscious but declines to 40% if they are unrousable at assessment. Intraventricular rupture carries a mortality of up to 80%.

Table 8.7 Antibiotic treatment of cerebral abscess.

Unknown source	Antistaphylococcal (flucloxacillin or vancomycin) + metronidazole ceftrioxone, ceftaxime (or chloramphenicol)
Streptococci or other Gram-positive (excluding staphylococcus)	Penicillin, ceftrioxone, ceftaxime
Streptococcus (resistant)	Vancomycin
Staph. aureus if MRSA	Vancomycin
Gram-negative organisms (excluding *Pseudomonas aeuruginosa*)	Ceftriaxone, ceftaxime
Pseudomonas aeruginosa	Ceftaxime
Bacteroides	Metronidazole

Treatment

Treatment is urgent, necessitating administration of appropriate antibiotic with surgical drainage or removal and control of cerebral oedema (Table 8.7).

Surgical intervention

Pus evacuation using modern image guidance techniques usually utilizing a mini-craniotomy is the optimum method and carries a low risk, provides a microbiological diagnosis and helps treat the patient. Simple pus aspiration is easier than abscess excision and carries a smaller risk of subsequent seizures but there is an incidence of recurrence even with modern antibiotics. The associated cerebral oedema should be treated appropriately with dexamethasone, hyperventilation and mannitol.

Subdural empyema

Subdural empyema occurs when an intracranial suppurative process develops between the dura and the arachnoid (Figure 8.2). This usually occurs as a consequence of ear or sinus infection, particularly involving the frontal ethmoid sinuses but it is also associated with cranial osteomyelitis, penetrating head trauma, neurosurgery, infection of the subdural effusion in childhood meningitis and, rarely, haematogenous spread.

Pathophysiology

Infection gains entry to the subdural space by direct extension through the bone and dura (e.g. ear and sinus infection, cranial osteomyelitis, penetrating head trauma) or by spread from septic thrombosis of the venous sinus particularly the superior sagittal sinus. Rarely, subdural empyema may result from metastases from infected lungs by haematogenous spread.

Causative agents

Infection is usually secondary to sinus disease from *Streptococci viridans* and aerobic streptococci (*Strep. milleri*) or bacteroides.

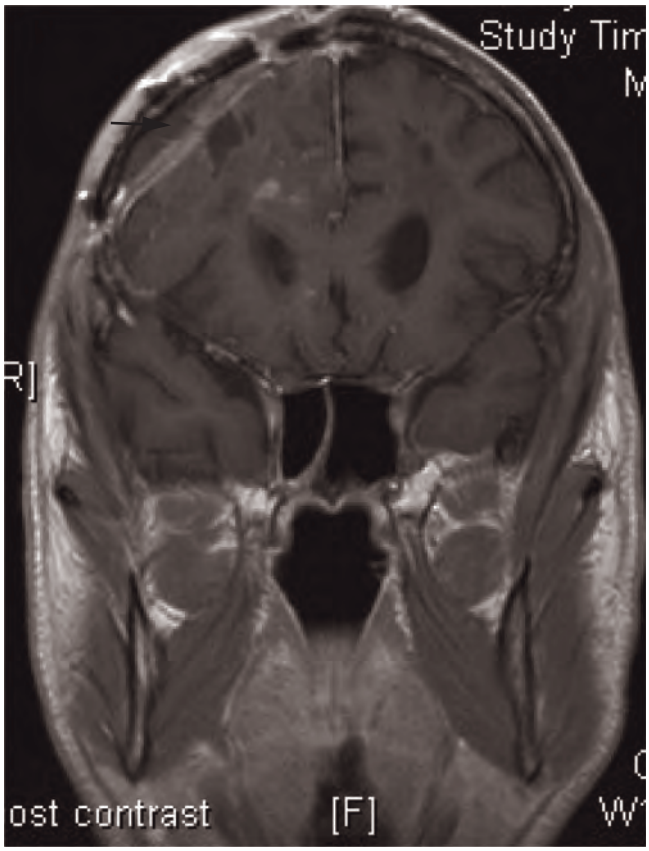

Figure 8.2 Large subdural empyema following previous craniotomy for grade II glioma (MRI T1W).

Figure 8.3 Extensive posterior epidural abscess (MRI T2W) (arrow).

Less often subdural empyema may be caused by *Staph. aureus* or *Enterobacter* species including *Proteus*, *Klebsiella*, *E. coli* and *Pseudomonas*. However, no organism is found in <50% of patients.

Clinically there is an acute onset with rapid progression to extensive hemispheric involvement or mass effect with tentorial herniation, occasionally a more gradual meningitis may evolve lasting up to 3 weeks. The onset is with pyrexia >80%, localized cranial pain, focal or generalized headache but meningism may develop and focal neurological deficits evolve into hemiparesis. Seizures occur in <50% of patients and there may be progressive obtundation. Venous extension of the infection may lead to the development of meningitis, brain abscess or septic intracranial venous thrombosis. CT scanning may fail to show the collection and the diagnosis is made on the basis of MRI scan with enhancement. The management is immediate surgical decompression with antibiotic cover although there is debate about whether to undertake craniotomy drainage or multiple burr holes. Because many patients with empyema contain a mixed culture of organisms, two or more antibiotic agents are required. For initial therapy where no information exists on the source of infection vancomycin, ceftriaxone and metronidazole are recommended and treatment should be continued for at least 4 weeks. The outcome of surgically treated subdural empyema and intracerebral abscess has been transformed by modern (image-guidance) surgical techniques and antibiotics.

Intracranial epidural abscess

Intracranial epidural abscess develops as a result of infection between the outer most layer of the meninges (dura) and the overlying skull. They are associated with cranial osteomyelitis complicating ear, sinus or orbital infection or neurosurgical intervention, infection is rarely metastatic. Epidural abscesses are commonly caused by *Strep. milleri.* The diagnosis and management are similar to subdural empyema. The onset is acute or more insidious after onset with localized cranial pain following generalized headache. The abscess may be accompanied by superficial subcutaneous infection and oedema. Patients develop focal or generalized seizures, focal neurological deficit or alterations in their mental state. Epidural abscess near the petrous bone affecting the V and VI cranial nerve may cause Gradenigo syndrome characterized by unilateral facial pain and lateral rectus weakness. Extension inwards across the dura, along the emissary veins leads to subdural empyema, meningitis, brain abscess or venous sinus thrombosis. Imaging may be normal. Epidural

abscesses can be managed by antibiotics alone, following the guidelines indicated above but larger abscesses require surgical drainage.

Spinal epidural abscess

Spinal epidural abscess is an infection of the epidural space of the spinal cord (Figure 8.3). It is usually caused by osteomyelitis or metastatic spread of infection from injuries to the back associated with skin wounds, bacteraemia or septicaemia. It may rarely occur following spinal surgery, lumbar puncture or epidural/spinal anaesthetic. Patients present with fever and back pain which may be severe and localized or radicular. There may be rapid progression with progressive spinal cord compression leading to paraparesis, sensory loss and sphincter involvement with localized spinal tenderness. Rarely, there may be a more chronic and indolent onset with a history suggesting a spinal cord neoplasm.

Staph. aureus is the most common cause of spinal epidural abscess in 50–90% of patients, although a few may be caused by aerobic streptococcus, Gram-negative bacilli and anaerobic organisms. CSF shows a clear pleocytosis but this is usually modest with <100 white cells/mm^3 and these may be both polymorphonuclear and lymphocytes. The protein is usually relatively high. Surgical treatment with laminectomy and drainage is indicated. There is a danger of vascular compromise to the cord causing infarction and permanent cord injury. Recovery may be slow with residual incomplete cord compression caused by formation of the fibrous and granulomatous reaction at the operative site.

Subdural spinal abscess

Subdural spinal abscess may be acute or chronic and caused by osteomyelitis or metastatic spread of infection and may be impossible to distinguish from the more common epidural infection. Presentation is similarly with fever, back and neck pain and rapidly developing signs of spinal cord compression. The onset is variable and may be over days or weeks. The causative agent is *Staph. aureus* in >50% of patients. A clue to the presence of subdural empyema comes from imaging, which tends to show that these lesions have a less sharp margin and a greater vertical extent than epidural abscess.

Spinal cord intramedullary abscess

Spinal cord intramedullary abscess is rare. It may present with a syringomyelia-like picture. The spinal cord is usually involved by direct spread from a contiguous abscess in the skin or if there is spinal dysraphism leading to an open track. Surgical drainage may be necessary.

CNS tuberculosis

Tuberculous meningitis

Mycobacterium tuberculosis is an aerobic non-spore forming bacillus which may be cultured and stained by Ziehl–Neelsen stain. Infection occurs by person-to-person droplet spread. The organism is inhaled into the lower portion of the lungs and there multiplies locally before disseminating through lymphatic and haematological spread into other organs. The decline in incidence of tuberculosis in Europe has led to a marked reduction in the incidence of tuberculous meningitis but unfortunately the condition is still frequent in developing countries and in patients who are immunosuppressed, particularly because of HIV. Tuberculous meningitis develops secondary to a caseating tuberculous focus adjacent to the CSF (Rich Focus). These usually develop following prior haematogenous dissemination of mycobacteria and in the absence of pulmonary tuberculosis. Parenchymal tuberculosis occurs as a result of haematogenous spread and may develop in the absence of pulmonary tuberculosis. Tuberculous meningitis is characterized by inflammatory meningeal adhesive exudates leading to a florid small and medium vessel vasculitis which culminates in occlusion of cerebral arteries and infarction (Figure 8.4a). There is also a disturbance of CSF flow because of impairment of absorption at the arachnoid villi and blockage at the aqueduct and fourth ventricular outlet. In tuberculous meningitis, vasculitis particularly affects the vessels at the base of the brain including the internal carotid, proximal middle cerebral and perforating vessels to the basal ganglia and internal capsule. Tuberculous meningitis was almost invariably fatal before the development of antituberculous chemotherapy. Table 8.8 summarizes factors of prognostic significance in the outcome of CNS tuberculosis.

Clinical manifestations

Tuberculous meningitis is often preceded by a prolonged prodrome of non-specific malaise, anorexia, low-grade fever, myalgia, photophobia and headache. The development of meningitis may be insidious, associated with worsening headache, nausea, vomiting, focal or generalized seizures and progressive impairment of consciousness. Cranial nerve palsies are common and often initially involve eye movements resulting from III, IV or VI nerve palsy. There may be facial weakness (VII), optic neuropathy (II), progressive hearing loss (VIII) and eventual bulbar involvement (X–XII). Fundal examination may show papilloedema,

Table 8.8 Poor prognostic factors in tuberculous meningitis.

Disease severity
Impairment of consciousness
Presence of neurological deficits, seizures or abnormal movements
Extremes of age
Coexisting miliary disease
CSF protein with spinal block
Very low CSF glucose
CT scan showing abnormalities
HIV positive, low CD4 count (below 22/mm^3)
Illness longer than 14 days

CSF, cerebrospinal fluid; CT, computed tomography.

optic atrophy or the presence of choroidal tubercles. Visual impairment may also develop because of involvement of the optic chiasm, tuberculomas compressing the optic pathways or optic nerve toxicity resulting from ethambutol. Other neurological signs include hemiparesis and hemiplegia as a consequence of vasculitic infarction or space-occupying tuberculomas. Movement disorders may be manifest as tremor, myoclonus, chorea, hemibellismus or dystonia and cerebellar ataxia may occur from direct involvement or vasculitic infarction. Cerebrovascular disease usually occurs in the distribution of the anterior circulation but may be posterior in distribution.

Diagnosis

The diagnosis of tuberculous meningitis or focal parenchymatous involvement may be clinically difficult. Tuberculin skin test is variable in its response and unreliable as there may be an anergy even in the presence of miliary tuberculosis. CSF examination is characterized by the presence of lymphocytic pleocytosis with a high protein and low glucose. The white cell count is usually 60–300/mm^3 and should not generally exceed 1000 but there may be a significant proportion of polymorphonuclear cells in the initial stages. The protein is generally elevated up to 1 g/L but may be greater than this particularly if there is a spinal block. There is also a low glucose concentration below 2.2 mmol/L and this is usually at least below 50% of the serum glucose.

CSF bacteriology

Direct examination of the CSF for acid–alcohol fast bacilli (AFB) requires the provision of large volumes of CSF and is experience dependent. AFB are only seen in up to 25% of cases with appropriate staining. CSF culture is the diagnostic investigation but requires up to 6 weeks and is therefore of only limited value in clinical practice. Culture is positive in up to 70% of cases and has the advantage of indicating drug sensitivities if the samples are taken before treatment has commenced. CSF PCR for tuberculosis is a sensitive technique but is limited in its specificity and is difficult to undertake. It is likely to play an increasingly important part in the diagnosis of tuberculous meningitis.

Radiology

Approximately 50% of patients with tuberculous meningitis may show evidence of previous tuberculosis on chest X-ray with up to 10% having miliary tuberculosis. CT brain scanning is commonly abnormal with marked enhancing exudate in the basal cisterns. There may also be hydrocephalus, parenchymal enhancement, evidence of cerebral infarction or cerebral oedema or focal tuberculoma. MRI is sensitive in showing meningeal enhancement, focal parenchymal abnormalities or the development of communicating or obstructive hydrocephalus.

Management of tuberculous meningitis

This is aimed at eradicating the causative organisms and management of the complications caused by the inflammatory response including hydrocephalus, vasculitis and raised intracranial pressure. The standard treatment of tuberculous meningitis is with an intensive primary phase of treatment followed by a continuation phase as summarized in Tables 8.9 and 8.10. Treatment should commence with isoniazid, rifampicin, pyrazinamide and ethambutol for 3 months and this should be followed by a 6-month continuation phase of treatment with isoniazid and rifampicin or pyrazinamide. There remains some debate about the duration of treatment.

Isoniazid and pyrazinamide are bacteriocidal and show good penetration through inflamed meninges, easily achieving therapeutic concentrations. Rifampicin, ethambutol and streptomycin have poorer penetration and achieve lower CSF concentrations.

Table 8.9 Treatment of tuberculosis. Initial phase using four drugs for 3 months.

Drug	Adult dose	Comment	Side effects
Isoniazid	<300 mg	Penetrates CSF freely and has potent early bacteriocidal activity Add pyridoxine to avoid peripheral neuropathy	Hepatitis, haemolytic anaemia, aplasticanaemia, peripheral neuropathy, optic neuritis, mania, fits
Rifampicin	450 mg (wt < 50 kg) 600 mg (wt > 50 kg)	Bacteriocidal but poor CSF penetration (10%)	Hepatitis, thrombocytopenia, headache, confusion drowsiness
Pyrazinamide	1.5 g (wt < 50 kg) 2.0 g (wt > 50 kg)	Bacteriocidal with good penetration	Hepatitis, anorexia, flushing
Fourth drug use one of:			
Streptomycin	<1 g/day	Neither penetrates CSF well in absence of inflammation (10–50%)	Avoid in pregnancy and renal impairment NM blockade
Ethambutol	15 mg/kg/day		Retrobulbar neuritis, peripheral neuropathy, confusion
Ethionamide	500–750 mg/day	Penetrates healthy and inflamed meninges but no evidence of advantage over other drugs	

CSF, cerebrospinal fluid; NM, neuromuscular.

All antituberculous treatment carries significant toxicity. Treatment with a fourth drug during the initial phase remains indicated given the poor ability of streptomycin and ethambutol to cross the blood–brain barrier.

There is an increasing incidence of tuberculosis caused by organisms resistant to conventional treatment. If this is suspected the initial treatment should include at least four drugs followed by a maintenance course of 9–18 months. An alternative aminoglycoside may be used during the initial phase (kanamycin, amikacin or capreomycin), ethionamide or moxifloxacin.

Corticosteroids

Steroids are indicated in the acute phase particularly if there is cerebral oedema, spinal block, severe tuberculous meningitis, spinal arachnoiditis or cerebral vasculitis.

Surgical intervention

Surgical intervention may be required in the presence of obstructive hydrocephalus that has not responded to medical treatment. This usually consists of an an external ventricular drain initially but may eventually necessitate a ventriculo-peritoneal shunt.

Table 8.10 Treatment of tuberculosis. Continuation phase using two drugs for 6 months.

Isoniazid	
Rifampicin	
Pyrazinamide	Achieve high CSF concentrations
Suspected or proven multidrug resistance:	
Aminoglycoside	Kanamycin, amikacin, capreomycin
Ethionamide	
Pyrazinamide	
Ofloxacin, moxifloxacin	

CSF, cerebrospinal fluid.

Outcome

The outcome of tuberculous meningitis has remained poor and the mortality is still >20%, with severe neurological sequelae occurring in up to 30% of survivors. Early drug treatment is essential particularly before the development of impaired consciousness and coma. Late neurological disability is predicted by the presence of extrameningeal tuberculosis, cranial nerve palsies, limb weakness and multiple neurological abnormalities.

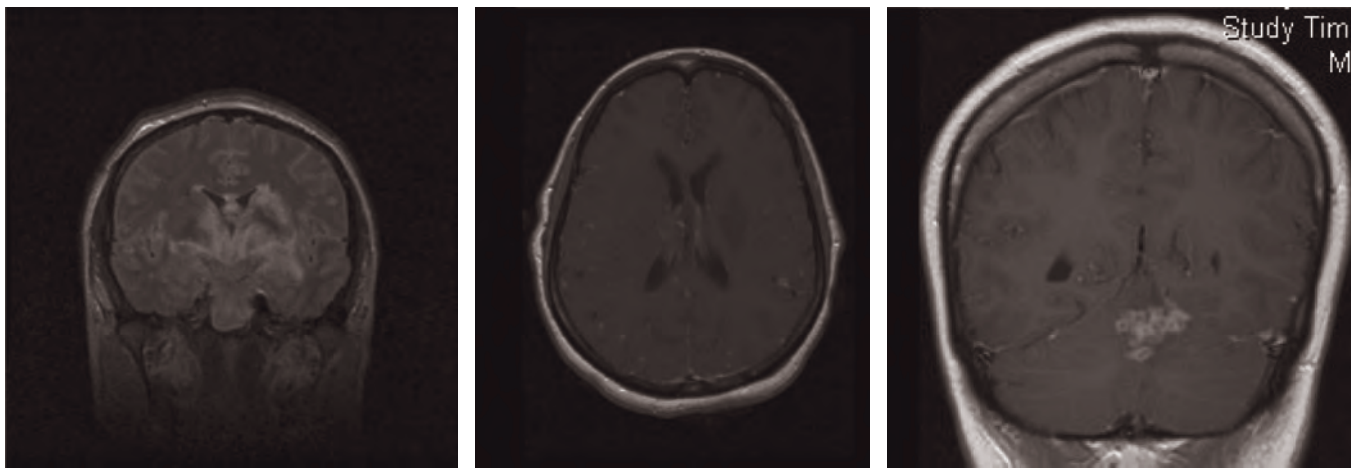
Parenchymal CNS tuberculosis

Tuberculous granuloma (tuberculoma)

Tuberculous granulomas can be found in the cerebrum, brainstem, cerebellum, spinal cord, subarachnoid or epidural space but are generally supratentorial; they may be multiple in up to two-thirds of patients and may coexist with tuberculous meningitis in up to 10% of patients. They present as space-occupying lesions with headache, intracranial hypertension, seizures and papilloedema. Imaging confirms the presence of an enhancing space-occupying lesion, occasionally with central calcification (Figure 8.4b and c). They usually resolve with conventional antituberculous treatment but occasionally surgical intervention is indicated.

Tuberculous abscess

Tuberculous abscess results from liquifaction of the central core of the tuberculoma. The lesions often enlarge and become multilocular and have mass effect associated with oedema. They tend to resemble pyogenic abscesses rather than tuberculomas and may be difficult to distinguish clinically. They do not always respond well to antituberculous chemotherapy and surgical excision may be necessary.



(a) (b) (c)

Figure 8.4 (a) Extensive vasculitis associated with tuberculous meningitis (MRI T1W). (b) Multiple tuberculomas (MRI T1W). (c) Multiple tuberculomas (MRI T1W).

Spinal tuberculosis (tuberculous spondylitis)

Tuberculosis may involve the spinal vertebral bodies, with a predilection for the anterior elements (Figure 8.5). In adults at least two contiguous levels and their intervening disc space are involved, particularly in thoracic and lumbar regions. Paraspinal soft tissue involvement is common and a paravertebral tuberculous abscess (Pott's abscess) may occur in up to 30% of patients with tuberculous spondylitis. Spinal collapse is also frequent and leads to cord compression and paraparesis.

Tuberculous spinal meningitis may be localized to the spinal cord. In this condition there is a gross granulomatous exudate in the subarachnoid space, which causes a vasculitic response in the spinal vessels, particularly the anterior spinal artery, culminating in ischaemia or infarction of the spinal cord. There may also be a progressive radiculopathy, myelopathy or transverse myelitis.

Figure 8.5 Anteriorly placed tuberculous abscess (MRI T1W) (arrow).

Intramedullary spinal cord tuberculous abscess or, rarely, tuberculoma may occur within the substance of the spinal cord mimicking a tumour. Tuberculous radiculomyelopathy or transverse myelitis often present acutely but may be slower in onset. They may be characterized by radicular pain, bladder disturbance or progressive paraparesis. CSF shows a high protein content with lymphocytic pleocytosis and a low glucose. MRI scan shows contrast enhancements surrounding the spinal cord and roots and often a diffusely increased intramedullary signal. Spinal cord disease is treated with prolonged standard antituberculous treatment and systemic steroids. If there is significant bone destruction, bracing and/or surgical decompression and stabilization may be necessary.

Syphilis

Syphilis is a chronic systemic infection caused by *Treponema pallidum*. The organism is a long slender coiled spirochete that is actively motile and sexually transmitted. It readily penetrates intact mucus membranes and abraded skin, rapidly reaching the bloodstream and lymphatics.

Syphilis is characterized by three stages:

1 Local primary chancre;

2 Secondary bacteraemic state with generalized mucocutaneous lesions; and

3 Tertiary stage characterized by involvement of the heart, bone, skin and CNS.

Primary syphilis usually develops within a few days of exposure but may be delayed up to 90 days. It is characterized by an ulcerated painless chancre at the site of inoculation with local lymphadenopathy. Manifestations of secondary syphilis usually develop 6–12 weeks after the chancre heals and consist of a characteristic generalized maculopapular rash involving the palms and soles which is associated with a diffuse generalized lymphadenopathy and constitutional symptoms including fever, weight loss and malaise. There may also be an associated proctitis, hepatitis, gastritis, nephrotic syndrome and iridocyclitis. Secondary syphilis is associated with neurological involvement characterized by meningitis and focal signs including multiple cranial nerve palsies, acute optic neuritis, sensori-neural hearing loss, aphasia, hemiplegia and focal epilepsy. The infection then becomes latent with a prolonged quiescent phase. Approximately one-third of untreated patients with latent syphilis develop tertiary disease and <10% develop symptomatic neurosyphilis.

Meningo-vascular syphilis

Meningo-vascular syphilis develops within 10 years of infection and is caused by an obliterative endarteritis and periarteritis associated with meningitis which may affect the brain or spinal cord. Progressive impairment of CSF absorption may lead to hydrocephalus, manifest as headache or confusion, there may be signs of focal cortical involvement including aphasia, hemiplegia, hemisensory disturbance or multiple cranial nerve palsies leading

to diplopia, vertigo and dysarthria. Spinal cord involvement in the form of a meningo-myelitis is characterized by the slow evolution of a spastic paraparesis with sensory disturbance in the lower limbs and bowel and bladder involvement. There may also be a more acute transverse myelitis with patchy cord involvement and anterior spinal cord artery occlusion may occur.

Tabes dorsalis

Tabes dorsalis occurs in 35% of those with neurosyphilis <10 years after primary infections. There is involvement of the posterior columns with diffuse infiltration and atrophic change. Symptoms include characteristic lightning pains in the legs which consist of sharp shooting paraesthesiae and pain and tabetic crises of episodic acute abdominal pain. The proprioceptive impairment leads to severely ataxic gait with a characteristic stamping of the foot. There is also impaired deep pain sensation with bladder, bowel and sexual dysfunction. Progressive posterior column impairment leads to the development of Charcot joints, a severe destructive arthropathy caused by repeated trauma, ulcers may develop around these joints. Cranial nerve abnormalities are associated with tabes including optic atrophy and pupillary abnormalities.

General paralysis

General paralysis is caused by direct invasion of the brain by spirochetes leading to frontal and temporal atrophy; it develops >15 years after the initial infection. There is a progressive cognitive impairment with memory loss and disintegration of personality and behaviour leading to severe dementia. This is associated with psychiatric disturbances including emotional lability, paranoia, delusions of grandeur and hallucinations. There may be a characteristic coarse tremor of the tongue and similar tremor of the extremities with pyramidal signs including hyper-reflexia. Pupillary abnormalities are characterized by the Argyll Robertson pupil in which the accommodation reflex is preserved but absent response to direct light.

Syphilis may be associated with HIV and progression to neurosyphilis may occur earlier.

Diagnosis

In primary and secondary syphilis, diagnosis is usually undertaken with dark field microscopy from skin and mucous membranes allowing direct visualization of the spirochete. The diagnosis of neurosyphilis depends on serological tests which may be either non-specific antigen tests (Venereal Disease Research Laboratory [VDRL] and rapid plasma reagin [RPR]) or specific treponemal tests (fluorescent treponemal antibody absorption, microhaemagglutination assay and the treponemal immobilization test). Specific treponemal tests are very reactive in secondary, latent and tertiary syphilis. They remain positive regardless of the disease stage and treatment. The presence of a positive VDRL on CSF examination may indicate neurosyphilis but there is a high incidence of false negative findings (particularly because of previous infection with yaws) and therefore the definite diagnosis depends on the presence of a positive serum treponemal test and a reactive CSF with pleocytosis, increased protein and IgG and possibly also oligoclonal bands. Co-infection with HIV also complicates the diagnosis as the CSF abnormalities may be unrelated to the neurosyphilis.

Treatment

Treatment of neurosyphilis is with benzylpenicillin 2.4 g given i.m. at weekly intervals for 3 weeks but the CSF penetration is variable and it may be necessary to continue for a longer period if the infection is incompletely cleared. As an alternative to parenteral treatment, amoxicillin 3 g 12 hourly can be given orally together with probenecid. If patients are allergic to penicillin, erythromycin 500 mg 6 hourly is recommended but tetracycline and ceftriaxone 2 g for 10 days are alternatives. Early treatment of syphilis may be associated with a Jarisch–Herxheimer systemic reaction which occurs because of the rapid destruction of treponemes and is characterized by sudden onset of severe systemic features including fever, chills, headache and tachycardia. All patients being treated for syphilis should be pretreated with prednisolone 60 mg for 24 hours. The CSF should be re-examined after treatment has been completed to show a fall in the pleocytosis and then at 6-monthly to 1-year intervals until the cell count and protein levels have returned to normal.

Lyme disease (neuroborreliosis)

Borrelia burgdorferi is a helical motile Gram-negative spirochaete. The substantial clinical differences between infections in the USA and Europe arise as a result of the differing strains – *B. burgdorferi sensu stricto* in North America and *B. garnii* and *B. afzelli* in Europe and Asia. The infection is a zoonosis in which the spirochaete is maintained in populations of large and small mammals, such as deer, field mice, as well as birds and spread by the ixodid tick. In Europe, Lyme disease is a significant problem in Germany, Austria, France, Switzerland and Sweden where the annual incidence maybe as high as 69/100,000. In the UK, the south-west regions are endemic areas. In North America most cases occur in the north-east and mid-Atlantic regions, with 15,000 cases reported each year. Lyme also occurs in Asia. Russian cases are well documented. Lyme disease affects all ages with time outdoors being the most significant risk factor, e.g. forest workers. A travel, occupational and social history with regard to hobbies such as shooting and rambling is therefore crucial. The infection occurs between May and September when the tick feeds, as they become inactive in cold weather.

Early neuroborreliosis – clinical features

Local infection

After a tick bite, 50–90% of patients develop the pathognomic skin lesion erythema migrans (EM), 7–10 days later. Typically, the lesion is not painful or pruritic and enlarges centrifugally over the ensuing days. The rash may be accompanied by systemic

Table 8.11 Clinical spectrum of Lyme disease.

Infection stage	Incubation period	Clinical features
Early local infection	<1 month	Erythema migrans, lymphocytoma cutis, flu-like illness, headache
Early disseminated infection	<3 months	Multifocal EM, arthritis, myalgias, myositis, cardiac (conduction block, pericarditis, myocarditis) conjunctivitis Meningitis, meningoencephalitis, cranial neuropathy (VII) acute painful radiculoneuropathy
Late stage	>3 months	Acrodermatitis chronica atrophicans Arthritis Keratitis, uveitis Chronic encephalomyelitis Chronic polyneuropathy ? Motor neurone disease like syndrome

EM, erythema migrans.

symptoms of malaise, fever, headache, meningism, arthritis and lymphadenopathy (Table 8.11).

Early disseminated infection

Haematogenous dissemination within a few days or weeks after the initial inoculation results in a number of complications – cardiac involvement occurs in 5–10% with conduction abnormalities such as complete heart block requiring temporary pacing. The neurological complications described at this stage are an aseptic meningo-encephalitis, cranial neuropathy and a painful radiculoneuropathy, which may all occur in combination. Although some of these early disseminated syndromes may resolve without therapy, 10% will go on to develop late chronic disease that is less responsive to antibiotic therapy, hence the necessity for early diagnosis and treatment. This pattern is similar to that found in neurosyphilis.

Cranial neuropathy

A facial palsy occurs in 50–75% of patients with early disseminated disease. Clues that may lead to the suspicion of Lyme disease related facial palsy are the occurrence of facial palsy during the summer months in endemic areas and associated systemic symptoms such as headache, meningism and arthritis. In one-third, the facial palsy is bilateral. This narrows the differential diagnosis to a limited number of conditions: Guillain–Barré syndrome (GBS), meningitis caused by e.g. HIV, chronic meningitic disorders such as sarcoidosis, malignant meningeal infiltration and amyloidosis. Involvement of the IIIrd, Vth, VIth and VIIIth cranial nerves has also been described.

Acute radiculoneuropathy

This complication is much higher in European Lyme disease compared to that found in North America. Patients present with severe radicular pain, which may affect the limbs or trunk resembling mechanical root pain. Weakness, sensory loss and areflexia develop over the next few days. When acute and severe, the clinical picture may resemble GBS although demyelination on neurophysiological studies is unusual in neuroborreliosis and CSF pleocytosis should raise doubts about the diagnosis of GBS. The differential diagnosis of such a painful radiculoneuropathy with a pleocytic CSF includes herpes zoster with or without a rash (zoster sine herpete), cytomegalovirus infection in the context of immunosuppression, malignant infiltration and sarcoidosis. Peripheral nerve vasculitis should also be considered. In patients with diabetes or those in whom this neurological syndrome may be the first manifestation, proximal diabetic radiculoplexoneuropathy (Bruns–Garland syndrome) and diabetic truncal radiculopathy have similar features.

Other syndromes

Anecdotal reports have described brachial and lumbosacral plexopathies similar to neuralgic amyotrophy (Parsonage–Turner syndrome). A number of patients with the clinical motor neurone disease (MND) phenotype and serological evidence of Lyme disease that have responded to antibiotics suggests that, at least in endemic areas, the diagnosis is worth considering.

Late neuroborreliosis – clinical features

A few untreated patients with early untreated Lyme disease may go on to develop a chronic disorder and, occasionally, this maybe the first presentation of neuroborreliosis. These include:

1 Acrodermatitis chronica atrophicans.

2 Chronic axonal neuropathy. Patients present with distal sensory, radicular involvement or restless legs. Neurological examination is unremarkable with only minor sensory abnormalities on examination. Neurophysiological abnormalities are consistent with a patchy sensory more than motor axonal neuropathy. The CSF is normal. Nerve biopsies are unhelpful but can reveal minimal changes of an axonal neuropathy.

3 Chronic meningitis, progressive myeloradiculopathy or encephalomyelitis.

4 Subacute encephalopathy.

Post Lyme syndrome

Despite effective antibiotic treatment, some patients complain of persistent symptoms of fatigue, myalgia, paraesthesias, memory difficulties and depression. The diagnosis of this post Lyme syndrome remains contentious because of the persistence of positive serological tests after appropropriate antibiotic treatment. Management of such patients is therefore focused on symptom control.

Diagnosis

The diagnosis of neuroborreliosis can be difficult for several reasons. The diagnosis remains clinical with laboratory support provided by serological tests and CSF examination. Features worth noting in the history are exposure in an endemic area, albeit brief, and the neurological syndromes are commonly associated with systemic symptoms. The American Academy of Neurology has produced practice parameters for the diagnosis of patients with nervous system Lyme disease (Table 8.12).

Culture is the gold standard but is difficult to achieve. Punch biopsy or aspiration of the EM lesion has the highest positive rates of 40–80%. Less than 10% of CSF cultures are positive reflecting the low density of organisms. Serology provides the basis for the laboratory support of the clinical diagnosis with a number of caveats:

1 The demonstration of positive antibody is evidence of exposure rather than active disease. Furthermore, these will remain positive even after adequate treatment regimens and cannot be used to assess treatment response.

2 Serology may be negative, especially in early disease because IgM antibodies take 2 weeks to develop and IgG antibodies 4–6 weeks after inoculation. Patients prescribed inadequate doses of antibiotics early in the course of the illness may remain antibody negative despite persistence of viable organisms.

Table 8.12 American Academy of Neurology guidelines for the diagnosis of nervous system Lyme borreliosis.

Diagnosis of definite nervous system Lyme disease requires:
1 Possible exposure (in wooded, brushy or grassy areas) to appropriate ticks in an area where Lyme disease occurs. A history of tick bite is not necessary
2 One or more of the following:
(i) Erythema migrans, the pathognomonic rash, or histopathologically proven *Borrelia* lymphocytoma or acrodermatitis
(ii) Immunologic evidence of exposure to *Borrelia burgdorferi* (e.g. positive serology)
(iii) Culture, histologic or PCR proof of the presence of *B. burgdoferi*
3 Occurrence of one or more of the following neurologic disorders after exclusion of other potential aetiologies. If CNS disease is suspected, CSF should be examined for intrathecal antibody production, culture or PCR
Causally related neurologic disease:
(i) Lymphocytic meningitis, with or without cranial neuritis or painful radiculneuritis
(ii) Encephalomyelitis
(iii) Peripheral neuropathy

CSF, cerebrospinal fluid; PCR, polymerase chain reaction.

3 False positive results may occur because of infections such as syphilis, ricketsial and bacterial infections and autoimmune disorders.

The current recommendation is to use a two-tier system for serodiagnosis – screening with an enzyme-linked immunosorbent assay (ELISA) or immunofluorescence assay (IFA) which is rapid and sensitive. Positive tests are followed up by a more specific Western blot analysis. Western blots are considered positive in acute disease if two of three selected bands are positive. In disease of longer duration five out of ten positive bands are required.

CSF examination is abnormal in most cases of neuroborreliosis – the exception being the chronic axonal neuropathy described above. There is usually a lymphocytic pleocytosis of up to a few hundred cells with an elevated protein level. The glucose is usually normal or slightly reduced. Intrathecal antibody production against *B. burgdorferi* is a useful indicator of infection; however, like blood serology, it may be a marker of past infection and remains positive after treatment. It is therefore necessary to assess CSF cytochemical parameters for evidence of active infection or a treatment response. PCR has proved disappointing with less than 50% of patients with meningitis demonstrating a positive response. As with serology, a positive PCR can be a marker of prior infection without viable organisms being present in the CSF.

Treatment

Although early disseminated neurological syndromes may resolve spontaneously, 10% go on to develop the late complications. The current recommendation is that early and late neurological and cardiological borreliosis be treated with intravenous third generation cephalosporins such as ceftriaxone 2 g o.d. for 2–4 weeks. Because it has not yet been determined whether a 2-week course is as effective as a 4-week course it seems reasonable to err on the side of caution. The alternative is another third generation cephalosporin cefotaxime 2 g 8 hourly. which is less convenient. Intravenous penicillin G 3–4 mU six times daily (18–24 mU/day), provided renal function is normal is another alternative. Oral or intravenous doxycycline 100 mg 12 hourly. was found to be effective for neuroborreliosis including meningitis in one European study and is an alternative. It maybe argued that facial palsy is a peripheral disorder and oral antibiotics will suffice. However, many patients have symptoms of meningism and the CSF is abnormal. It is therefore reasonable to consider lumbar puncture in patients presenting with facial palsy in endemic areas before deciding on the most appropriate treatment regimen.

Brucellosis

Brucellosis is a zoonotic infection caused by a Gram-negative non-motile non-encapsulated coccobacilli, *Brucella melitensis* and *B. abortis* (harboured in sheep and cattle, respectively). It is a granulomatous illness which may be acute or indolent. There is a non-specific prodrome with a variable and irregular (undulant) fever and flu-like symptoms of malaise, night sweats, arthralgia and myalgia. The development of lymphadenopathy and

hepatosplenomegaly may resolve or be followed by localized single organ infection. The nervous system is affected in up to 5% of patients; meningitis is the most common manifestation with meningism, confusion and impaired level of consciousness. Cranial nerve deficits occur as a consequence of granulomatous involvement at the skull base and facial weakness, sensori-neural hearing loss and visual impairment resulting from retrobulbar neuritis, papilloedema, optic neuropathy or ophthalmoplegia may occur. Brucella meningitis can lead to hydrocephalus and raised intracranial pressure. Brain and spinal cord abscesses can occur. There may be a granulomatous endarteritis or focal vasculitis causing stroke or myelitis, occasionally a radiculopathy and peripheral neuropathy may also occur. Blood cultures are positive in 50% of patients and CSF is positive in 25% on culture or standard agglutination tests. CSF shows an elevated protein with a lymphocytic pleocytosis and a low glucose; occasionally oligoclonal bands are present. MRI may show contrast enhanced inflammatory changes in the spinal cord or brain.

Brucella is treated by a variety of antibiotics including streptomycin, co-trimoxazole, tetracyclines, rifampicin or gentamicin. There is a high relapse rate with single drug treatment leading to drug complications. In particular, brucella meningitis should be treated with three drugs for 2–6 months and surgical drainage of brucella abscesses may be necessary.

Leptospirosis

Leptospirosis is caused by the aerobic spirochete *Leptospira* carried by rats. Although clinical manifestations vary in severity, presentation is gradual and non-specific with a flu-like illness, pyrexia, nausea, vomiting and myalgia. Systemic involvement may rapidly develop with chest and abdominal pain. Aseptic meningitis is characterized by headache, photophobia and meningism progressing to encephalopathy with seizures. Ocular features include conjunctival injection, optic neuritis and uveitis. In the most severe form of the condition (Weil disease) there is hepatic and renal impairment with a bleeding diathesis. Less commonly, leptospirosis may result in acute disseminated encephalomyelitis or cerebrovascular disease manifest as vasulitic ischaemia or haemorrhagic complications. Cranial neuropathy, peripheral nerve involvement including radiculopathy, mononeuritis multiplex and an axonal or demyelinating peripheral neuropathy may occur.

CSF in the meningitic state shows a mononuclear pleocytosis which is usually approximately 100/mm^3 but may rise to >10,000/mm^3. The protein concentration may also be elevated. The diagnosis depends on culture requiring special media and growth is very slow. Diagnosis can also be made by serology, complement fixation and specific agglutination tests.

The meningitic illness is usually self-limiting. *Leptospira* are sensitive to antibiotics during the initial febrile phase and treatment is with intravenous penicillin 6 mU/day or amoxicillin or erythromycin but there is a risk of Jarisch–Herxheimer reaction.

Leprosy

Leprosy is an extremely common condition worldwide, which occurs predominantly in Africa, South America, South-East Asia, Brazil, Mozambique, Nepal, India, China and Madagascar. It is caused by *Mycobacterium leprae* which causes granulomatous involvement of the peripheral nerves and skin. The organism is a Gram-positive rod which is an obligate intracellular acid-fast bacillus. It multiplies at cooler temperature and therefore favours distal parts of the human body. There is a prolonged incubation period ranging 2–5 years but this may be as long as 20 years. The organism has a predilection for Schwann cells associated with thinly myelinated axons. The infective risk of leprosy is relatively low but nasal transmission may occur and is followed by haematogeneous spread to preferential sites including skin, peripheral nerves, upper respiratory tract, anterior chamber of the eye and the testes.

The pattern of illness is determined by the host's immune response to the mycobacterial antigen. When there is an active cell-mediated immune reaction directed against *M. leprae*, tuberculoid leprosy develops that is restricted to a few peripheral nerves. However, a poor immune response leads to an extensive proliferation of bacilli, the so-called lepromatous leprosy. A proportion of patients also have borderline patterns with features of both tuberculoid and lepromatous. The World Health Organization (WHO) uses a simplified classification scheme that relies on clinical examination and skin scrapings, dividing cases into paucibacillary and multibacillary leprosy. Paucibacillary leprosy is defined as five or fewer skin lesions without detectable bacilli on skin smears whilst in multibacillary leprosy there are six or more lesions and skin smear may be positive. The risk of transmission from close contact is much greater in the multibacillary form.

Clinical features

Leprosy is characterized by hypoaesthetic skin lesions, thickened peripheral nerves and positive skin smear showing acid-fast bacilli.

The earliest skin lesions are mildly hypopigmented macules which may heal or evolve into tuberculoid or lepromatous appearances. In tuberculoid leprosy, there are single or few clearly demarcated asymmetrical hypopigmented or erythematous skin lesions which are hypoaesthetic and are scattered across the body with no obvious preferential areas. They have a sharp edge but vary in size. In lepromatous leprosy, there is a more diffuse involvement of the skin with extensive hypopigmented, nodular or maculopapular infiltration affecting the body, the skin of the face and the earlobes, with progressive loss of the eyebrows and eyelashes. There may be coarse thickening of the features, particularly the earlobes, nose and cheeks, giving rise to the characteristic pattern of leonine facies, and the larynx may also be involved. The testes become atrophic and gynaecomastia and sterility may develop. Visual impairment occurs because facial weakness and anaesthesia of the conjunctiva and cornea lead to corneal

ulceration and scarring culminating in exposure keratitis. There also may be an iridocyclitis and cataracts secondary to intraocular involvement by the bacilli.

Nerve involvement

In tuberculoid leprosy, there is involvement of the small superficial nerves in the cooler part of the body and at points where they are exposed, leading to pain on temperature, touch and pressure impairment over affected skin areas but thickening is less common. The most frequently affected peripheral nerves are as follows:

- Ulnar nerve;
- Posterior tibial nerve and sural (at the medial malleolous of the tibia);
- Common peroneal nerve – at the knee where it winds around the neck of the fibula;
- Median (at the wrist);
- Facial (crossing zygomatic arch);
- Trigeminal nerve involvement of ophthalmic division of the trigeminal nerve leading to corneal and conjunctival sensory loss, ulceration and blindness;
- Greater auricular (posterior triangle of the neck);
- Supraorbital; and
- Superficial radial (cutaneous at the wrist).

Lepromatous involvement of the peripheral nerves is insidious over many years. Peripheral nerve thickening affects sensory motor and autonomic nerves to a varying extent and may cause either a focal or diffuse mononeuritis multiplex or a progressive symmetrical distal peripheral neuropathy. Sensory impairment is more common than motor but there may be atrophy and weakness leading to claw hands or bilateral foot drop.

Borderline leprosy

There are features or both tuberculoid and lepromatous forms. Hyperanaesthetic skin lesions occur but they differ slightly in appearance from lepromatous leprosy. Borderline patients are particularly vulnerable to nerve damage and may develop severe deformities including trophic ulceration. The affected nerve trunk is often swollen and painful.

Primary neuritic leprosy

This is seen in India and Nepal. This presents as a peripheral neuropathy without the characteristic skin lesions and skin smears are negative for acid-fast bacilli. However, skin lesions develop later in the course of the illness. Neurological manifestations are caused by asymmetrical involvement of one or several peripheral nerve trunks and sensory changes develop before motor features. Isolated nerve thickening may occur.

Diagnosis

This is difficult and primarily clinical although nerve conduction studies show axonal loss and demyelination with focal slowing across thickening nerve segments suggesting segmental demyelination. There is loss of the sensory action potentials. A skin smear is used to assess the density of acid-fast bacilli – they are always found in the multi-bacillary form and occasionally in borderline disease. Skin biopsy is essential for diagnosis, correct classification and diagnosis when skin smears are negative. Nerve biopsy of a thickened sensory nerve (usually sural or radial cutaneous nerve) may also yield a diagnosis. The Lepromin test assesses the patient's cell-mediated immunity against *Mycobacterium leprae* and is strongly positive in tuberculoid leprosy but is negative in lepromatous leprosy; this test is of no value in patients who have received bacille Calmette–Guérin (BCG) vaccination or who have had previous subclinical disease. Serology tests use radioimmune assay (RIA) and ELISA assay based on the detection of antibodies to *M. leprae* antigen. The *M. leprae* genome has now been entirely sequenced and it is possible to detect the organism using PCR amplification in skin and nerve biopsies.

Management

Multi-drug therapy with a combination of rifampicin, dapsone and clofazimine is effective in both multi-bacillary and paucibacillary leprosy and nerve function does appear to improve with early treatment. The skin lesions in paucibacillary leprosy resolve within a year but in patients with multi-bacillary leprosy they persist for much longer but relapse rates are low. Dapsone is only slowly bacteriocidal and needs to be given daily. It is limited in its effectiveness and there is a high incidence of resistance if the drug is used alone. Side effects are rare but malaise, haemolytic anaemia and leucopoenia can occur. Rifampicin is a strongly bacteriocidal drug which is rapidly effective. Because of the slow rate of replication of *M. leprae* the drug need be given only once a month but resistance may occur on monotherapy. Clofazimine is weakly bacteriocidal but is highly effective in controlling lepromatous leprosy, particularly in suppressing the inflammation of erythema nodosum.

Patients with paucibacillary leprosy are generally treated with two drugs (rifampicin 600 mg/month and dapsone 100 mg/day) while those of multi-bacillary leprosy receive three drugs (rifampicin 600 mg/day, dapsone and clofazimine 50 mg/day and then 300 mg/month for 2 years). Treatment for paucibacillary leprosy requires 6 months while multi-bacillary leprosy should be maintained for at least a year and preferably two. However, all treated patients should be followed up for reactions or relapses for many years after completing treatment. The neuropathy is often treated with oral corticosteroids and 60% of patients are said to regain nerve function but this may take many months.

Immune-mediated (Lepra) reactions may develop in up to 30% of patients on treatment and may be associated with a slight shift towards lepromatous leprosy in previously untreated patients. There may be erythema nodosum, cropping of facial lesions and ocular involvement. Skin lesions may become erythematous, peripheral nerves painful and tender and sudden loss of function may occur. Patients should be treated with corticosteroids to control the serious effects of lepra reactions.

The social stigmas associated with deformity and scarring from leprosy remains a considerable worldwide problem despite extensive health education programmes run by WHO and other

community projects. Leprosy control has been integrated into general health services in endemic areas increasing access to diagnostic and treatment facilities.

Diphtheria

Diphtheria is now extremely uncommon in developed countries as a consequence of immunity induced by mass immunization with diphtheria toxoid. However, sporadic cases still occur and there is a risk that a decline in population immunity may render the individual at greater risk given that immunization does not necessarily confer life-long immunity. Diphtheria is caused by infection with *Corynebacterium diphtheriae*, an aerobic Gram-positive organism which does not disseminate in deep tissues or blood but rather causes local mucosal necrosis with the formation of a thick 'pseudomembrane' of fibrin, epithelial cells, bacteria and neutrophils affecting the skin and the throat. The toxin may disseminate leading to myocarditis and neurological complications. The incubation period is 1–7 days (usually 2–4 days) and infection is generally manifest as inflammation or pseudomembrane formation over the pharynx or skin. Systemic involvement caused by dissemination of the toxin leads to neurological complications characterized by cranial nerve involvement and peripheral neuropathy.

Palatal and posterior pharyngeal wall paralysis commonly follows pseudomembrane formation and is associated with progressive cranial neuropathy leading to bulbar weakness manifest as dysarthria, dyphagia and aspiration; ocular involvement may also occur. A mixed sensorimotor demyelinating peripheral neuropathy develops later in the course of the disease, often many months after the onset. There is usually proximal weakness extending distally with severe paralysis and areflexia. Diaphragm and respiratory muscle weakness may develop requiring tracheal intubation and prolonged ventilation. Distal sensory impairment affects all modalities and autonomic involvement is common, manifest as sinus tachycardia, postural hypotension and urinary retention. The diagnosis is initially clinical and confirmed by throat swabs, membrane sampling for *C. diphtheriae* and toxin detection.

Management

Treatment involves the immediate administration of diphtheria antitoxin to neutralize circulating toxin, antibiotic treatment against *C. diphtheriae* (penicillin or erythromycin) and supportive management of cardiac, respiratory, bulbar and secondary infective complications. It is essential to recognize that immunity can wane and booster immunization should be offered every 10 years. Contacts are at considerable risk and throat swabs should be collected.

Botulism

Botulism is caused by a highly potent neurotoxin elaborated by *Clostridium botulinum*, an anaerobic Gram-positive rod which survives in the soil by forming spores. There are eight antigenically distinct strains of toxin (A–G) but each strain of *C. botulinum* produces only a single toxin. In human botulism, the toxin is absorbed from the gastrointestinal tract and haematogenously disseminated before the toxin either binds irreversibly to the presynaptic membrane of peripheral neuromuscular and autonomic nerve junctions to inhibit acetylcholine release. Recovery depends on the sprouting of new nerve terminals.

Forms of botulism

- Infantile;
- Food-borne;
- Wound;
- Iatrogenic;
- Inhalation (possible bioterrorism).

The mean incubation period of food-borne botulism is 2 days. The onset is with an acute gastrointestinal illness with neurological symptoms. Classically, patients develop non-specific gastrointestinal symptoms, a descending flaccid paralysis, cranial nerve symptoms, autonomic disturbance and ventilatory failure but they remain afebrile with normal sensation. Wound botulism has a longer incubation period but the symptoms and signs are similar to food-borne botulism. This condition occurs as a result of subcutaneous injection (skin popping) of black tar heroin that has become contaminated with *C. botulinum* when being cut or diluted prior to street sale.

Clinical presentation

Patients are apyrexial but may have nausea, vomiting, anorexia and abdominal pain. Cranial nerve deficits develop early including blurred vision, diplopia, dysarthria, dysphagia, dysphonia, facial weakness, ptosis and external ophthalmoplegia with mydriasis occurring because of accommodation paresis. There is flaccid limb weakness affecting the arms more than the legs and progressive respiratory impairment and arrest. Autonomic involvement is characterized by a dry mouth, unreactive pupils, paralytic ileus, gastric dilatation, bladder distension, orthostatic hypotension and constipation. There is an important differential diagnosis, which includes Guillain–Barré syndrome and myasthenia gravis, which is summarized in Table 8.13.

Table 8.14 Management of botulism.

Supportive care	Patients should be admitted to ICU with close bulbar and respiratory monitoring Intubation and ventilation should be undertaken as necessary
Attempt to remove unabsorbed botulinum toxin	Controversial. In the absence of ileus and if ingestion is recent it is reasonable to induce catharsis or enemas
Antitoxin	Helpful particularly in type E botulism using the trivalent botulism antitoxin. This eliminates circulating toxin but does not remove botulinum toxin that has entered the neuromuscular junctions. The antitoxin therefore prevents worsening and should be administered as soon as possible, there is a risk of allergic reactions with equine antitoxins including urticaria and serum sickness
Wound treatment with débridement	Penicillin (care because lysing *Clostridium* botulism will release more toxin and potentially worsen the condition) Patients with wound infections should be treated with tetracyclines, metronidazole or chloramphenicol

Diagnosis

CSF and blood examination are normal. The *C. botulinum* may be isolated from the wound site, stool or food. The toxin is detected in serum, stool and food by bioassay using mice. The toxin is detected in two-thirds of food cases and 85% of wound botulism. Immunoassays to detect toxins in the stool and food are being developed but are not validated.

Neurophysiology

Nerve conduction studies are normal but repetitive stimulation shows a decremental response at low rates but an incremental response occurs at higher rates. Needle electromyography (EMG) confirms small polyphasic motor units and single fibre studies show jitter and block.

Management

The management of botulism is summarized in Table 8.14. The mortality of patients with food-borne botulism is approximately 10%, wound botulism 15% but the mortality for infant botulism is in the region of 5%.

Tetanus

Tetanus is rare in the UK but common worldwide and probably kills 500,000 adults per year.

Aetiology

Tetanus is caused by the neurotoxin tetanospasmin, elaborated by the anaerobic Gram-positive rod *Clostridium tetani*. This is a ubiquitous organism found in soil and faeces which persists as resilient spores capable of surviving many years and resistant to most disinfectants and boiling for up to 20 minutes. The spores germinate under appropriate anaerobic conditions. The toxin is produced in the wound and binds to peripheral motor nerve terminals before being transported via retrograde axonal transport into the spinal cord or brainstem, or both. The toxin ultimately migrates to the presynaptic terminals. It inhibits release of gamma-aminobutyric acid (GABA) and glycine, important inhibitory neurotransmitters. In the absence of the inhibitory influence of GABA and glycine, alpha motor neurones fire rapidly, producing rigidity. Preganglionic sympathetic neurones are also affected, resulting in increased catecholamine levels and sympathetic over-activity. Tetanospasmin can also produce weakness through blockade of acetylcholine release in a manner analogous to that of botulinum toxin.

Epidemiology

Tetanus occurs in neonates because of contamination of the umbilical stump. Children and adults may develop tetanus as a consequence of infected wounds, skin lacerations or as a consequence of intramuscular injections or drug abuse.

Clinical features

The incubation period varies from a few days to several weeks depending on the site of spore inoculation. There may be localized spasm and rigidity in the region of the wound. The onset may be with back pain, increased muscle tone and rigidity of the masseter muscles leading to trismus (lockjaw) and a similar rigidity of the facial muscles (risus sardonicus). There is a localized stiffness near to the injury with sustained rigidity of the axial muscles with involvement of the neck, back and abdomen and, in severe cases, reflex spasms and opisthotonus. Paroxysmal contractions of muscles appear in response to slight stimuli, and in severe cases are bad enough to cause limb fractures, tendon avulsion and rhabdomyolysis. Spasms of respiratory muscles lead to asphyxia, vocal cord obstruction and aspiration associated with increased bronchial secretions, hypersalivation and dysphagia.

Autonomic manifestations are common in severe tetanus with profuse sweating, hypersalivation and extreme hyperpyrexia. Fluctuations of blood pressure and heart rate are cardinal features and these may be followed by arrhythmias and circulatory failure. There may be transient glycosuria. There is also excessive bronchial secretion, gastric stasis, diarrhoea, acute renal failure and volume depletion.

Diagnosis

The diagnosis is made on the basis of history of the spasms and examination although the finding of *Clostridium tetani* in a wound guides the diagnosis.

Table 8.15 The management of tetanus.

Eradication of the causative bacterium	Debridement of the wound Antibiotics (metronidazole 500 mg q.i.d. for 7–10 days)
Neutralize any unbound toxin	Equine or human antitoxin are used but human immunoglobulin (100–300 mg IU/kg i.m.) is preferred because there is less anaphylaxis
Supportive therapy during the acute phase	Nursing in a calm, quiet environment with cardiorespiratory monitoring Fluid balance, nutrition and the control of muscle spasms with diazepam, midazolam Neuromuscular blockade with vecuronium
Vaccination	Primary childhood immunization programmes as five doses of combined DPT in the UK given at 2 months, 4 months, 6 months, 3–5 years and 13–18 years. Boosters are recommended every 10 years
Post injury wound care	Wounds associated with tissue necrosis infection or retained foreign bodies are important precipitant factors

DPT, diptheria, pertussis and tetanus.

Differential diagnosis

Strychnine is a competitive antagonist for glycine. Intake with poisoning is characterized by spasm and rigidity in the abdominal muscles. Dystonic drug reactions may also mimic the stiffness and involuntary truncal spasms of tetanus. Non-organic disorders may also be mistaken for tetanus.

Treatment

Treatment in the ICU has resulted in a marked improvement in prognosis for patients with tetanus but the mortality is still approximately 10%. Severe muscular rigidity may last for weeks, with assisted ventilation being required for up to 3–4 weeks. Complete recovery is typical, although mild painful spasms can persist for months. Management is summarized in Table 8.15.

Infective endocarditis

Infective endocarditis is caused by direct bacterial colonization of the endothelial surface of the heart, usually on the valves. Endocarditis affecting a native valve is usually associated with congenital, rheumatic or degenerative valve disease but occurs commonly in intravenous drug abusers. Endocarditis develops on prosthetic valves in up to 6% of cases over 5 years. Approximately 30% of patients with endocarditis have neurological complications and often these may be the presenting features. Most cases of native valve endocarditis are caused by *Strep. viridans*, *Strep. bovis* or *Staphylococcal aureus* with the latter being much more common in endocarditis amongst intravenous drug abusers in whom the right-sided valves are more often affected.

Clinical presentation is characterized by fever, systemic symptoms including weight loss and anorexia, new or changing heart murmurs or peripheral vasculitic signs including petechiae, splinter haemorrhages or Osler nodes. Neurological complications are common and brought about either by bacteraemia leading to meningitis, cerebritis or a parameningeal focus or by recurrent emboli which may be infective. Cerebral emboli commonly involve the anterior circulation and are frequently multiple with up to 10% being haemorrhagic. There is often a preceding transient ischaemic attack and concurrent systemic emboli are common. Septic emboli may cause cerebral infarction, meningitis or parenchymal abscess but they also lead to the development of mycotic aneurysms which occur when an infected arterial wall becomes weakened (Figure 8.6). They usually develop in distal arterial vessels and may also occur as a result of direct local spread. Mycotic aneurysms carry a high risk of rupture into the parenchyma and subarachnoid space leading to focal neurological deficits, meningism, declining consciousness and coma. Cerebral abscesses may be multiple and also lead to severe focal or generalized neurological deficits. Bacterial meningitis is common in endocarditis and carries a poor prognosis if severe. It may

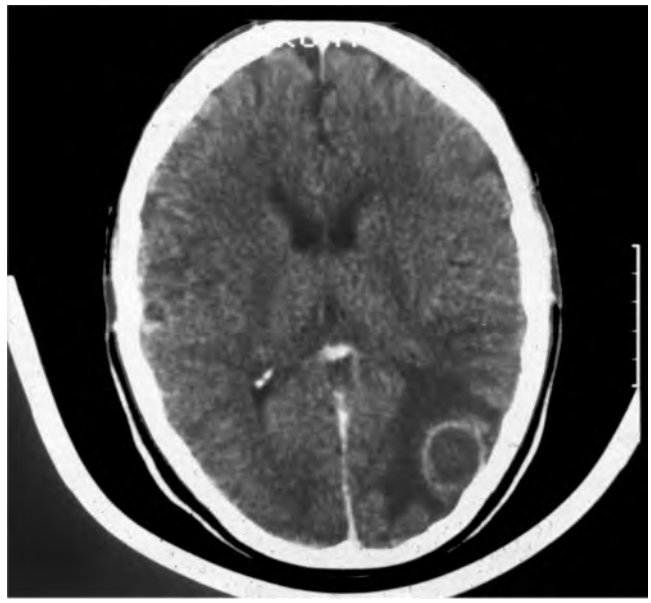

Figure 8.6 Mycotic aneurysm in *Streptococcus viridans* endocarditis (CT enhanced).

contribute to the development of cerebral vasculitis particularly in staphylococcal disease. Ocular involvement occurs rarely and is caused by involvement of the retinal vasculature, optic or cranial nerves or brainstem and may lead to central retinal artery occlusion, ophthalmoplegia or field loss.

The diagnosis should be considered in any patient with a focal or generalized neurological deficit and unexplained pyrexia. The diagnosis of endocarditis depends on appropriate cardiac imaging including transthoracic and transoesophageal echocardiography, investigation of neurological involvement includes serial blood cultures, urine microscopy for red cells, CT scan, magnetic resonance angiography (MRA) and CSF examination.

Treatment involves the urgent initiation of organism-specific antibiotics and depends on bacterial sensitivities and the underlying risk factors. Native valve *Strep. viridans* endocarditis is treated with benzylpenicillin (or ceftriaxone) and gentamicin in regimens varying 2–6 weeks depending on penicillin resistance. Longer courses are given for prosthetic valve *Strep. viridans* endocarditis and vancomycin is used if there is penicillin allergy. Native valve staphylococcal endocarditis requires a 6-week course of flucloxacillin or, if there is methicillin-resistant *Staph. aureus*, vancomycin is used. Prosthetic valve staphylococcal endocarditis usually requires the addition of gentamicin to flucloxacillin or vancomycin. The management of cerebral emboli and mycotic aneurysms is difficult. Anticoagulation should be avoided because of the high risk of haemorrhagic transformation. Neurosurgical intervention is rarely indicated and a conservative approach is usually justified depending on the size and location of the aneurysm. Despite advances in antibiotic management and supportive care, the prognosis of endocarditis once there is neurological involvement is poor, with mortality of 30–80%.

Viral disease of the nervous system

Viruses can cause a variety of diseases in the CNS. The most important are viral meningitis, encephalitis and encephalomyelitis.

Viral meningitis

Viruses causes an isolated aseptic meningitis characterized by symptoms and signs of meningeal irritation with a CSF pleocytosis in the absence of bacterial, fungal or parasitic infection. There is no parenchymatous brain or spinal cord inflammation. However, in most cases there is mixed meningo-encephalitic or encephalomyelitic involvement.

Aetiology

Non-polio enteroviruses are by far the most common cause of viral meningitis, these include coxsackie and echovirus strains. The main causes include:

- Enterovirus:
- Echovirus;
- Coxsackie A, B;
- Enterovirus 70, 71;
- Mumps;
- Measles;
- Herpes simple virus 2 (HSV-2);
- Varicella zoster virus (VZV);
- Epstein–Barr virus (EBV);
- Cytomegalovirus (CMV);
- Human herpes virus 6 (HHV-6);
- Arboviruses;
- HIV;
- Adenovirus;
- West Nile virus.

Viral meningitis is a relatively uncommon complication of systemic viral infection. Most viruses gain access to the body from the oropharynx. They are amplified (multiply) in lymphatic tissue, spread to the bloodstream (viraemia) and cross the choroid plexus or capillary endothelial cells to reach the CNS. Rarely, viruses may enter the CNS by direct transmission through axons.

Clinical features

In viral meningitis there may be a flu-like prodrome followed by the sudden onset of intense frontal headache, fever and neck stiffness associated with photophobia, malaise, myalgia and severe nausea and vomiting. Although there is pyrexia, neck stiffness and meningeal signs, patients are generally less unwell than those with bacterial meningitis. A pruritic rash, pleurodynia or myocarditis may be present. There is a wide differential diagnosis of aseptic meningitis which is summarized in Table 8.16.

Diagnosis

The peripheral white cell count is usually normal but may be increased or decreased and liver function may be abnormal. The CSF is clear and colourless with a normal to moderately elevated pressure, the cell count may be up to 1000 cells/mm^3, it is usually <300 and mononuclear lymphocytes predominate, although polymorpholeucocytes may be present, glucose is usually normal but may be slightly depressed and the protein is normal or mildly elevated.

Viral isolation

Viral isolation is undertaken from the throat, urine or stool and antibody studies are possible in serum or CSF. The detection of viral RNA or DNA is now undertaken using PCR in the serum or CSF. The prognosis in viral meningitis is good with spontaneous recovery usually occurring within 1–2 weeks. However, there may be residual deficits in up to 5% including malaise, fatigue, mild intellectual and language difficulties, seizures, isolated cranial nerve lesions and optic neuritis.

Management

The treatment is supportive care but it is necessary to admit the patient if there is a possibility of bacterial meningitis. Herpes virus meningitis can be treated with a variety of antiviral agents including aciclovir, famciclovir, valaciclovir, ganciclovir and

foscarnet. The only therapy of clinical use for enterovirus meningitis is immune serum globulin, but the new antipicorna viral agent pleconaril may have an important role.

Chronic and recurrent meningitis

Meningitis may be recurrent either because the patient is predisposed to repeated bacterial infection, recurrent non-purulent infection or because of a non-infective aetiology. Chronic meningitis may be defined as meningitis that persists for 4 weeks or more without showing any recovery. The condition often presents with a more encephalitic-like picture of progressive impairment of cognition and consciousness following a fluctuating course. Any of the conditions listed in Table 8.17 may cause a chronic meningitis or recurrent meningitis:

Chemical meningitis
Mollaret's meningitis

CMV, cytomegalovirus; EBV, Epstein–Barr virus; HSV, herpes simples virus; IVIG, intravenous immunoglobulin; VZV, varicella zoster virus.

Mollaret's meningitis

This is a rare condition in which recurrent episodes of pyrexia and meningism occur but may be separated by asymptomatic periods lasting days, weeks or months. The attacks resolve spontaneously with no residual deficit and they usually cease within a few years. During attacks the CSF shows a mild elevation in the protein and pleocytosis with characteristic monocytic cells. HSV types 1 and 2 have been isolated from the CSF.

Encephalitis

Encephalitis is acute infection of the parenchyma of the brain, usually caused by a virus, which results in a diffuse inflammatory process, often also involving the meninges. Most common viral infections can rarely lead to viral encephalitis. Encephalitis causes focal or multi-focal neurological deficits or seizure activity. Acute disseminated encephalomyelitis (Chapter 10) may occur as an immunologically mediated para-infectious phenomenon following a variety of infections or after vaccination.

Within the UK and North America, after the neonatal period, the most common severe forms of infectious encephalitis are those caused by:

- HSV-1;
- VZV;
- EBV;
- CMV;
- HHV 6 and 7;
- Enteroviruses;
- Adenoviruses;
- Influenza virus A and B;
- Arboviruses;
- *Mycoplasma pneumoniae*;
- HIV seroconversion.

Pathophysiology

There are several mechanisms by which viruses can cause encephalitis. Organisms that cause encephalitis require the ability to infect brain tissue (neurotropism) but not necessarily the ability to infect neurones (neuronotropism).They usually enter the CNS via direct haematogenous dissemination but may affect the brain via retrograde neuronal spread. Arbovirus encephalitides are zoonoses in which the virus life cycle takes place both in the biting arthropod and an invertebrate host. The virus is then transmitted by an insect bite and undergoes local replication in the skin before spreading to the brain and causing human encephalitis. Pathological examination shows involvement of the grey matter with perivascular inflammation, neural destruction, neuronophagia and tissue necrosis.

Incidence

In the USA, the annual incidence of viral encephalitis is between 3.5 and 7.4/100,000 of the population. In the UK, the reported incidence is lower. HSV is the most frequent cause but VZV, enterovirus and influenza A are also common. There remains considerable geographical variation and arbovirus encephalitis is common in the Americas and Asia.

Clinical features

The clinical manifestations of encephalitis are often most severe in infants and those over the age of 65. It is characterized by fever in 90% of patients. Seizures are common and help to distinguish acute infective encephalitis from acute disseminated encephalomyelitis. The presence of headache, pyrexia and meningism suggest leptomeningeal irritation while parenchymatous involvement leads to focal neurological signs including seizures and alteration of consciousness progressing to stupor and coma. More commonly, behavioural and speech disturbances develop and abnormal movements are associated with lesions in the basal ganglia and pituitary, involvement of the hypothalamus may cause hypothermia.

Diagnosis

In assessing a patient with suspected viral encephalitis it is essential to take a detailed history of travel and it is also important to note the season of onset, any contact with animals and any evidence of immunosuppression. CSF examination should be undertaken if possible. MRI appearances may be characteristic in herpes simplex encephalitis (see below) but are non-specific in other causes.

Herpes simplex encephalitis

The majority of cases of herpes simplex encephalitis (HSE) in adults are caused by HSV-1. Ten per cent are caused by HSV-2, usually associated with immuno-compromise or occurring in the neonate. Primary infection usually develops in the oropharyngeal mucosa before the virus is transported by retrograde transneuronal spread via the trigeminal nerve to establish latency in the olfactory bulb or trigeminal ganglion. Molecular analysis of paired oral and brain sites have indicated HSE can occur as the result of a primary infection, a reactivation of latent HSV in the trigeminal ganglion or reinfection by a second HSV. However, the presence of labial herpes has no diagnostic specificity to HSE. The herpes virus leads to inflammation, infection and necrotizing lesions particularly in the inferior and mesial temporal lobes which may also involve the orbital frontal cortex and limbic structures.

The onset of HSE is with fever, headache and alteration of consciousness which may develop gradually or rapidly over a matter of hours. The most common manifestations are personality change, dysphasia with progressive behavioural disturbance and occasional psychotic features. Less typical features include the development of hemiparesis or a visual field defect (particularly superior quadrantic). Focal or generalized seizures are often associated with olfactory or gustatory hallucinations.

Investigation

The MRI characteristically shows high signal areas of unilateral focal oedema on T2 images in the medial and inferior temporal

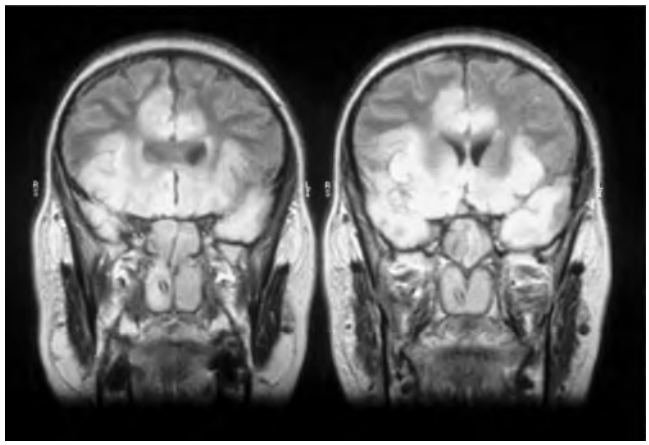

Figure 8.7 Fulminant herpes simplex encephalitis; extensive temporal lobe and diffuse parenchymal inflammation (MRI T2W).

lobes, extending into the insular cortex and frontal lobe; the changes may be extensive and midline shift may be present if there is significant vasogenic oedema (Figure 8.7).

The electroencephalogram (EEG) is characterized by periodic stereotyped, lateralized sharp and slow wave complexes occurring at regular intervals between 2 and 3 seconds. CSF is generally under an increased opening pressure and may show a mild to moderate lymphocytic pleocytosis of 5–500/mm^3; there may be a mild to moderate elevation in the protein (0.6–6 g/L) and a normal or mildly decreased glucose. In approximately 5% of patients CSF examination is normal. PCR examination of the CSF is sensitive and specific for the detection of HSV DNA. It should be positive after about 5 days of infection but clears again after 14 days of illness. PCR may also be used to guide the duration of treatment with aciclovir. PCR has also become increasingly valuable in the diagnosis of virus encephalitides from other causes such as CMV, VZV, influenza and enterovirus. Brain biopsy is now rarely undertaken but may be considered if diagnostic uncertainty remains.

Management

High-dose intravenous aciclovir (10–15 mg/kg body weight 8 hourly) reduces the mortality of HSE from 70% to 20%. It is also appropriate treatment for VZV-related CNS disease. In initial studies, treatment was continued for 10 days but it is now conventional to treat for 14–21 days or at least until the PCR has become negative. Occasionally, HSV may be resistant to aciclovir and foscarnet is indicated in this situation. Patients with HSE can develop seizures, which require specific treatment; corticosteroids may be of value if cerebral oedema develops and, occasionally, intracranial pressure monitoring and even surgical decompression may be necessary. Although high-dose aciclovir has reduced mortality from HSE, there is still a significant morbidity that may occur including severe memory impairment (up to 69%), personality behavioural changes (up to 45%), epilepsy (up to 25%) and dysphasia (up to 4%). Early treatment is essential for the reduction of morbidity, particularly before the development of impairment of consciousness.

Other causes of encephalitis

Other causes of encephalitis are summarized in Tables 8.18 and 8.19.

Varicella zoster virus

VZV is a large herpes virus. Primary infection causes chickenpox and secondary reactivation leads to dermatomal shingles or disseminated herpes zoster. Chickenpox (varicella) is a usually self-limiting exanthematous disorder which may be associated with pneumonitis or secondary bacterial infection. Neurological complications include a severe encephalitis, meningitis, myelitis and cerebellar ataxia. Rarely, an acute toxic encephalopathy or Reye syndrome may occur. In the elderly there is a high risk that post-herpetic neuralgia may develop, after the rash of shingles resolves. Involvement of the geniculate ganglion leads to ear pain, facial nerve palsy and herpetic lesions in the external auditory meatus (Ramsay-Hunt syndrome). Disseminated herpes zoster occurs particularly in the immunosuppressed. Herpes zoster may also be complicated by the development of a vasculopathy affecting both small and large vessels causing infarction. VZV may also cause encephalitis, myelitis, radiculopathy or a cranial neuropathy including optic neuritis. In VZV large vessel angiitis, steroids should be administered with aciclovir and the benefit of prolonged high-dose valaciclovir following aciclovir is currently being studied.

Cytomegalovirus

CMV is a ubiquitous herpes virus that only affects humans. The virus often persists in the throat following infection and may become latent for many years. Infection is usually transient and asymptomatic but it may cause cytomegalic inclusion disease in the newborn and neurological disease in the immunocompromised adult, particularly following organ transplant or in AIDS. In HIV-positive patients the most common complications are lumbo-sacral polyradiculopathy and retinopathy. Other forms of peripheral neuropathy may occur and encephalitis and myelitis are also associated with CMV.

Epstein–Barr virus

EBV is a lymphotropic herpes virus which, like all herpes viruses, may establish latency before being reactivated. It replicates in B cells, causes infectious mononucleosis and is associated with lymphoproliferative disorders – Burkitt and Hodgkin lymphoma, hairy cell leukaemia, lymphocytic lymphoma and nasopharyngeal carcinoma. Neurological complications include aseptic meningitis, encephalitis, acute cerebellar ataxia, cerebritis, transverse myelitis, polyneuropathy (including Guillain–Barré), mononeuropathy (including brachial plexopathy) and cranial nerve palsies (especially facial nerve). These may occur as a consequence of

Table 8.18 Viruses that may infect the CNS (excluding arboviruses).

Family of virus	Virus		
Herpes	HSV-1		
	HSV-2		
	VZV		
	CMV		
	EBV		
	HHV-6		Linked with meningoencephalitis, GBS and retinitis
			Occasionally found in CSF of patients with AIDS but significance unknown
Orthomyxovirus	Influenza		May present as a frontal lobe or limbic syndrome without disturbance of consciousness
			Guillain–Barré-like neuropathy, myelitis
	Avian flu A (H5N1)		Characterized by diarrhoea, seizures and progression to severe encephalopathy leading to coma and death
			CSF protein is elevated
Picornavirus	Enterovirus (non-polio)		Enterovirus infection is usually asymptomatic or manifest as an erythematous or maculopapular rash
	Coxsackie		Usually associated with a good prognosis but enterovirus 71 may present with herpangina, hand, foot and mouth disease, myoclonus, tremor and cranial nerve involvement
	Echo		
	Polio		May be complicated by acute flaccid paralysis or long-standing chronic meningo-encephalitis particularly in the young or patients who are immunosuppressed
			Enterovirus can be isolated from CSF faecal, throat and serum specimens
Paramyxoviruses	Mumps	Worldwide (Winter & Spring)	Usually starts several days after parotitis and usually resolves without sequelae except for occasional hydrocephalus due to ependymal cell involvement
	Measles	Worldwide (Winter & Spring)	Rash, myelitis, encephalitis
	Nipah virus	Asia (All year)	Rare. Contracted from pigs
			Presents with encephalitis and focal cerebellar or brainstem signs
		Direct transmission	Segmental myoclonus and systemic involvement, characterized by hypertension and tachycardia
			Encephalitis may be delayed for several months after exposure to the virus
			MRI shows increased signal in cortical white matter
Arenavirus	Lassa fever	Africa	
	Lymphocytic-choriomeningitis	Europe, America, Australia, Japan (usually winter)	
	Rabies		See text

CMV, cytomegalovirus; CSF, cerebrospinal fluid; EBV, Epstein–Barr virus; HHV, human herpes virus; HSV, herpes simple virus; MRI, magnetic resonance imaging; VZV, varicella zoster virus.

direct viral infection or as a parainfectious phenomenon. EBV causes <5% of viral encephalitis and is associated with impaired level of consciousness, seizures and focal deficits. Although recovery is usual, permanent deficit may occur with residual chorea and cognitive impairment.

Arboviruses (arthropod-borne viruses) (Table 8.19)
Specific arboviruses can be predicted on the basis of geographical location and the demographic pattern of infection. Subacute inoculation by mosquito or tick vector is followed by local tissue and lymph node replication, viraemia and finally invasion of deep soft tissues, organs and CNS. Arbovirus encephalitis predominantly affects cortical grey matter but it may also involve the brainstem and thalamic nuclei. Arboviruses can occasionally cause meningitis or meningo-encephalitis.

Rickettsial disease

Rocky Mountain spotted fever (RMSF) is caused by a minute polar staining bacillus that occurs in freshly laid eggs of infected ticks. A minimum of 6 hours attachment of the tick to the skin surface is required before the *Rickettsia* are transmitted. There is subsequent invasion and multiplication within endothelial smooth muscle cells leading to the development of a vasculitis. Severe RSMF is associated with encephalitis and systemic signs including purpura, hypovolaemia, hypotension, prerenal failure and cerebral and pulmonary oedema. Other rickettsial infections develop over 10–14 days and tend to be slightly less severe but are also associated with a purpuric rash and encephalitis. Treatment with doxycycline is given until the patient has been

Table 8.19 Arboviruses that may infect the CNS.

Alphavirus	Eastern Equine	Eastern & Gulf USA (Summer)	Severe, rapidly progressive, virulent encephalitis that affects children High mortality rate (<35%)
	Western Equine	Western USA (Summer)	Encephalitis, predominantly affects children Mortality rate <10%
	Venezuelan	South and Central America (Rainy season)	Occurs in large outbreaks but usually self-limiting and encephalitis is rare but neurological sequelae in <20%
Flavivirus	St Louis	USA (Summer)	Most common vector transmitted cause of aseptic meningitis in the USA Aseptic meningitis accounts for approximately 15% of all symptomatic cases Often asymptomatic and characterized by a mild febrile illness but severe encephalitic illness can occur in the older age group when mortality may rise to 20% Sequelae occur in 10% including memory loss chronic fatigue, sleep disturbance, headaches and occasional seizures Syndrome of inappropriate antidiuretic hormone secretion (SIADH)
	Japanese	Asia (Summer) Transmitted by mosquito bite	Affects children and young adults, most common arbovirus worldwide Non-specific prodrome but seizures are common. In adults, extrapyramidal involvement may occur with a transient parkinsonian-like syndrome, tremor, choreoathetotic head nodding or axial ridigidy and flaccid paralysis may occur due to damage of anterior horn cell Occasionally, JVE may present as a severe fulminant encephalitis characterized by fever, vomiting, convulsion and impaired consciousness leading to coma Mortality <50% with a high incidence of residual neurological sequelae MRI shows lesions in basal ganglia and thalamus Diagnosis by ELISA or PCR of serum and CSF or postmortem brain tissue Vaccination is possible with 3 doses of inactivated JVE
	West Nile	Africa, Asia Middle East (Summer) Transmitted by mosquito bite	Usually aymptomatic. May develop with a flu-like illness with incubation period of 3–15 days. Rash, arthralgia, hepatosplenomegaly and pancreatitis Neurological involvement in <15% – encephalitis, encephalomyelitis, aseptic meningitis or the development of an axonal or demyelinating polyneuropathy (resembling Guillain–Barre syndrome) Mortality ranges 12–14% – may be a residual flaccid weakness resembling poliomyelitis
	Far East	Eastern Russia (Summer)	Associated with partal epilepsy and high mortality (<20%)
	Central European	Central Europe	Tick-borne Flaccid proximal weakness
	Powessan	Canada (Summer & Autumn)	Tick-borne Severe encephalitis Residual cognitive impairment common High mortality
	Dengue	Tropics (SE Asia & Indian subcontinent)	Presents with severe influenza like illness or haemorrhagic fever Headaches, arthralgia and myalgia Less commonly this can give rise to encephalitis or encephalopathy and rarely transverse myelitis or polyneuropathy resembling Guillain–Barré syndrome Haemorrhagic form also causes intracerebral haemorrhage, hepatic failure and Reye syndrome-like illness Low risk of sequaelae and low mortality
	Murray Valley	Australia Mosquito borne	
	Kunijin	Australia	
	Rocio	Brazil	
	Russia	Russia Tick-borne	In cooler northern climates, flaviviruses transmitted by ticks rather than mosquito
Bunyavirus	La Crosse	Central USA	Predominantly a viral encephalitis of children which tends to be mild and self-limiting with a low mortality
Filovirus	Ebola	Africa	
	Marburg	Africa

afebrile for >2 days. Tetracycline and chloramphenicol are alternatives.

Polio and the post-polio syndrome

Despite a global policy aimed at eradication, pockets of wild polio still exist and there is a small incidence of vaccine-induced polio in infants and adults. Present policies are directed towards mopping up residual sources with the eventual discontinuation of routine immunization. Acute poliomyelitis is rarely encountered in the UK following its successful eradication; however, 'imported' poliomyelitis still occurs and it is necessary to distinguish acute poliomyelitis from other causes of acute flaccid paralysis (Table 8.20).

Poliomyelitis is caused by an enterovirus of high infectivity whose main route of infection is via the human gastrointestinal tract. There are three subtypes but, before the introduction of polio vaccine, type I accounted for 85% of paralytic disease. Epidemics of polio occurred, most commonly, during the summer months, in the temperate climates of the northern hemisphere and the incidence was greatest where children bathed together.

The incubation period is 7–14 days. The acute illness is characterized by minor flu-like symptoms, followed by a meningitic phase as the virus reaches the CNS. The onset of spinal poliomyelitis is associated with myalgia and severe muscle spasms and the subsequent development of an asymmetrical, predominantly lower limb, flaccid weakness which becomes maximal after 48 hours. A purely bulbar form, with minimal limb involvement, also occurs carrying a particularly high mortality rate because of vasomotor disturbances such as hypertension, hypotension and circulatory collapse, autonomic dysfunction, dysphagia, dysphonia and respiratory failure. Polio may also cause an acute encephalitis. Recovery from the acute infection can be slow and prolonged periods of rehabilitation are necessary for recovery of limb function, severe permanent impairment is common.

The virus is commonly isolated from the nasopharynx or the stool. In the absence of a viral isolate, serological diagnosis can be established by neutralization of sera against paired antigens of the three serotypes. PCR is now the technique of choice for serotypic identification of poliovirus and for differentiation of wild and vaccine-strain poliomyelitis.

Differential diagnosis (Table 8.20)

Acute flaccid paralysis is associated with infection by other enteroviruses including coxsackie virus A7 and enterovirus 71, tick-borne encephalitis and by flaviviruses including Japanese encephalitis and, more recently, West Nile virus. The differential diagnosis of asymmetric motor flaccid paralysis includes, Guillain–Barré syndrome, acute intermittent porphyria, HIV neuropathy, diphtheria and *Borrelia burgdorferi* (Lyme disease) infections.

Table 8.20 Causes of acute flaccid paralysis.

Infection
Viral
Enterovirus
Poliomyelitis (wild and vaccine associated)
Enterovirus 71, Coxsackie A
Flavivirus
Japanese encephalitis
West Nile encephalitis
Herpes virus
CMV
EBV
VZV
Tick-borne encephalitis
HIV-related (associated with opportunistic infections)
Other neurotropic viruses (e.g. rabies)
Borrelia
Mycoplasma
Diphtheria
Botulism
Neuropathy
Acute inflammatory polyneuropathy
Acute motor axonal neuropathy
Critical illness neuropathy

Prevention

Salk trivalent inactivated polio vaccine (IPV), introduced in 1956, is administered by injection and stimulates serum IgM, IgG and IgA, but not secretory IgA, immunity being induced by antibody transuding into the oropharynx. Sabin trivalent oral live attenuated polio vaccine (OPV) replaced the Salk vaccine in 1962; this is composed of live attenuated strains of polioviruses I, II and III grown in cell culture. The advantages over the Salk vaccine are that it is cheap; can be administered orally; and causes an active attenuated infection of the oropharynx and intestinal

endothelium stimulating local secretary IgA in addition to serum antibody production. Furthermore, the attenuated virus is excreted in the faeces leading to herd immunity. Complete immunization with OPV has, conventionally, included four doses routinely given at 2, 4 and 6–18 months, with a booster at 4–6 years.

Post-polio syndrome

Many patients with residual impairments following previous paralytic poliomyelitis develop new disabilities after a period of prolonged stability. These late changes include progressive muscular atrophy, weakness, pain and fatigue but most patients are aware of late functional deterioration manifest as impairment of activities of daily living, mobility, upper limb function and respiratory capacity. The new wasting and weakness is probably caused by distal degeneration of post-poliomyelitis motor units associated with age, overuse or disuse. Thus, new impairments often occur as a consequence of prolonged stresses on skeletal deformity and previously weakened muscles. The extent of the original limb, trunk, respiratory and bulbar weakness is an important factor in predisposing to the development of late functional deterioration. Although there are no adequate longitudinal studies, experience suggests that post-polio functional deterioration is not necessarily an ongoing process. Fatigue and reduced mobility, often may progress slowly or stabilize. The prognosis also depends on the nature of any underlying cause for the functional deterioration.

Subacute sclerosing panencephalitis

Subacute sclerosing panencephalitis is a progressive neurological condition associated with measles occurring at a young age (usually <2 years). The onset is usually in childhood at an average of 6–8 years, with a male : female ratio of 3 : 1 but the condition can occur in adults and can be triggered during pregnancy. The clinical course is highly variable but the onset is usually with behavioural and intellectual change developing over weeks or months. There is frequently a decline in school performance with withdrawal, hyperactivity and aggressive behaviours often with emotional lability. Motor signs progressively develop with dysarthria, incoordination and tremor. There is usually a progressive decline with periodic stereotyped attacks of myoclonic jerks and seizures. Higher functions deteriorate with worsening apraxia, visuo-spatial abnormalities and progressive language impairment. Profound disability is associated with choreathetosis, dystonia, persistent myoclonic jerking and autonomic instability with hyper-pyrexia, tachycardia and an abnormal respiratory pattern. There may be an associated choroido-retinitis pigmentosa and optic atrophy. The condition usually progresses over 1–3 years and 10% may survive for up to 10 years but a fulminate course with death in 3 months is seen in about 10% of patients. The condition is associated with early infection by measles virus which is an enveloped RNA virus and can be recovered from the CSF and brain in most patients. The diagnosis is based on the clinical pattern and characteristic bilateral synchronous and symmetrical periodic discharges occurring every 4–12 seconds on the EEG. There is also an associated slower background activity which becomes disorganized. An elevated measles virus antibody is found in serum and CSF. MRI shows focal or generalized high white matter lesions in frontal, temporal and occipital regions. There is no effective treatment.

Rabies

Rabies is a zoonosis of certain mammals endemic in all continents, it is caused by a lyssa virus which is inoculated into the tissue of a wound usually caused by a canine (usually dog) or bat bite. It may replicate locally in muscle cells or attach directly to nerve endings. It then enters the presynaptic nerve terminal and is carried in a retrograde direction. On reaching the CNS there is massive viral replication in neurones before transynaptic transmission of the virus occurs from cell to cell. Viral proteins accumulate in the cytoplasm appearing as inclusions (Negri bodies).

Clinical features

Clinical features develop up to 1–3 months after the bite. The onset is with a prodrome of fever, nausea, vomiting, chills, malaise, fatigue, insomnia and worsening encephalopathy before the development of pain, pruritus, paraesthesiae and fasciculation close to the bite site. Patients may develop furious rabies (80%) or paralytic rabies (20%).

Furious rabies is characterized by episodes of excitement and hyper-excitability fluctuating with periods of lucidity. Aggressive behaviour, confusion and hallucinations develop. Autonomic dysfunction is manifest as hypersalivation, sweating and piloerection. Patients develop severe muscle spasms of the throat, trunk and respiratory muscles triggered by the sight or sound or attempts to drink water (hydrophobia) or even by air (aerophobia). The spasms cause generalized extension, convulsions and opisthotonus with death usually occurring within 1 week of the onset of furious rabies as a consequence of cardiac arrhythmias, myocarditis and respiratory arrest. Paralytic rabies is less common than furious rabies and it may occur following vampire bat transmission; in patients who have been affected by attenuated virus; or following post-exposure vaccination. It is associated with an ascending paralysis leading to constipation, urinary retention, respiratory failure and an inability to swallow. Flaccid muscle weakness develops early in the course of the disease. Hydrophobic spasms may also occur and patients may go on to develop bulbar and respiratory muscle involvement but survive longer than classic furious rabies.

The differential diagnosis includes viral encephalitis, tetanus, post-vaccinal encephalomyelitis and Guillain–Barré syndrome.

Diagnosis

A CSF mononuclear pleocytosis develops, usually within the first week, but serum neutralizing antibodies are not present until the tenth day of the illness. Viral isolation is occasionally possible

from saliva, throat, trachea, CSF or brain biopsy and skin biopsy and immunofluorescent antibody techniques will demonstrate an antigen in the small nerves of the skin taken from the nape of the neck, often in a hair follicle. PCR detection of rabies virus RNA has also been demonstrated from the brain, saliva and CSF. Post-mortem virus isolation and brain cultures should be taken if possible.

Management

Management is supportive. Patients with acute rabies are treated with heavy sedation and adequate analgesia to relieve terror or pain. Acute interventional care may be necessary to manage cardiac arrhythmias, cardiac and respiratory failure, raised intracranial pressure, convulsions and fluid and electrolyte disturbances but only occasional reports of survival have been documented, usually in patients who had received rabies vaccine before the onset of symptoms. Vaccination before exposure is strongly recommended to travellers as it provides protection after unrecognized exposure and may simplify treatment. Post-exposure treatment is summarized in Table 8.21.

Prevention is achieved with careful attempts to eradicate rabies from dogs by vaccination, careful border control and preventing contact of domestic pets with wild animals. Pre-exposure immunization allows highly effective prevention and should be considered in individuals who are considered at high risk (e.g. vets, laboratory workers or those who handle imported animals) or those travelling to, living or working in endemic areas.

Table 8.21 Post-exposure treatment of rabies.

Examination of the biting animal
Ideally, the animal should be captured confined and observed for 10 days
If there is any clinical evidence of rabies, the animal should be killed and the brain examined for virus
Antigen detection in animals
Using fluorescent antibody techniques or cell culture (mouse inoculation)
Post-exposure prophylaxis
If there is any doubt about the possibility of rabies then post-exposure prophylaxis should be started immediately
Local wound care
Washed thoroughly with soap and water, debridement as necessary and tetanus prophylaxis
Active immunization
Using either human diploid cell vaccine or alternatively purified chick embryo cell culture vaccine in five doses given over 28 days. If infection occurs in a previously immunized individual only two booster doses are necessary
Passive immunization
Human rabies immunoglobulin should be given immediately before the vaccine. The wound should be infiltrated with the immunoglobulin and then a dose given intramuscularly

HTLV-1

HTLV-1 is a retrovirus that causes adult T-cell lymphoma/leukaemia and neurological involvement manifest as tropical spastic paraparesis and, less commonly, myositis and anterior horn cell involvement. HTLV-1 is a double-stranded RNA retrovirus with reverse transcriptase. Only a small proportion of people infected go on to develop neurological manifestations.

The virus is endemic in southern Japan, the Caribbean, South America and Africa. Risk factors for transmission of HTLV-1 include sexual contact, exchange of blood products and vertical transmission from mother to child (see also Chapter 15).

HTLV-1 associated myelopathy (TSP)

HTLV-1 associated myelopathy (tropical spastic paraparesis [TSP]) is a progressive inflammatory myelopathy evolving over many decades. The incubation period varies and may be years. Females are more commonly affected than males. Onset is variable but tends to be in the fourth or fifth decades; symptoms develop insidiously with a slowly progressive paraparesis predominantly affecting proximal musculature with brisk reflexes and extensor plantar responses. The lower limbs are overwhelmingly affected; bulbar muscles are not involved. Bladder dysfunction is manifest as urgency and incontinence; chronic retention and overflow may also occur leading to recurrent urinary tract infections; sexual dysfunction is common. There may be burning low back pain and painful dysaesthesiae in the legs. The myelopathy is occasionally associated with cerebellar ataxia. Examination shows mild to moderate progressive spastic pyramidal weakness which is more marked proximally. There is occasionally mild distal vibration sense absence to the ankles.

The major differential diagnosis is with primary progressive multiple sclerosis, hereditary spastic paraparesis (HSP) and primary lateral sclerosis. In TSP the brunt of pathological change is seen within the thoracic cord. The diagnosis is made on clinical grounds. HTLV-1 antibodies can be detected in serum and CSF using Western blot techniques. The CSF shows a mild lymphocytosis with elevated protein and local IgG synthesis. Oligoclonal bands are found that are specific for HTLV-1 core and envelope antigen. MRI shows peri-ventricular hyperintense lesions in many patients.

There is no effective treatment; transient benefit may be gained from steroids. The condition is relentlessly progressive, although the rate of evolution is variable.

Rarely, muscle inflammation is the only manifestation of HTLV-1 but it may accompany myelopathic or neuropathic features. Myalgia and progressive proximal muscle weakness develop over many months, occasionally associated with a dermatomyositis-like rash. The myositis is relentlessly progressive and does not respond to steroids. There have been no consistent reports of benefit from intravenous immunoglobulin (IVIG) or immunosuppression. Pathologically there is an inflammatory response with myofibre necrosis and regenerating fibres and mononuclear cell infiltrate.

HTLV I also causes both axonal and demyelinating neuropathies. Anterior and posterior uveitis have been described in association with HTLV-I. In these conditions the visual prognosis is good but there is a high relapse rate. A variety of other associations have been suggested, in particular between HTLV-I and cognitive impairment or other autoallergic conditions but these are unproven.

HTLV-II

HTLV-II is closely related to HTLV-I sharing 70% genomic homology. It is found in intravenous drug abusers and Native Americans but has not been clearly linked to any disease. HTLV-III was previously the term used for HIV-1 and HTLV-IV for HIV-2, but these terms have fallen out of usage. Recently, HTLV-III and HTLV-IV have been used to denote two newly characterized viruses of uncertain pathogenesis.

Progressive multifocal leucoencephalopathy

Progressive multifocal leucoencephalopathy (PML) is a rare condition in immunocompetent adults and is discussed in detail below in the context of HIV-related disease (see below).

Fungal infections

Fungi differ from bacteria by having a nucleus bounded by an organized membrane and a chitinous cell wall. They divide by mitosis, lack chlorophyll and are non-motile. Fungi exist in two forms: yeast and filamentous (hyphae and pseudohyphae). Yeasts are unicellular, multiply by budding and infections generally involve the CSF or meninges (Table 8.22). Filamentous fungi grow by extension of their hyphae, liberate spores and usually lead to parenchymous cerebral involvement. Fungal infections have increased because of the increased numbers of patients who are immunosuppressed due to HIV/AIDS, immunodeficiency or immunosuppression.

Fungi produce neurological disease by direct invasion, allergic phenomena and liberating toxins. Fungal meningitis generally develops insidiously over several days or weeks and is secondary to systemic mycosis elsewhere in the body. The CNS is seeded haematogenously either from a pulmonary or cardiac focus or secondary to direct spread from the sinuses or skull involving the subarachnoid space and leading to a basal meningitis. Fungal meningitis is characterized by meningism with subacute involvement of cranial nerves and an arteritis with thrombosis and cortical or subcortical infarction and micro-abscess formation.

Primary fungal pathogens include *Cryptococcus neoformans*, *Coccidioides immitis*, *Histoplasmosis*, *Blastomycoses* and *Paracoccidioides*. Secondary opportunistic pathogens are more common and occur with immune dysfunction, these include *Candida*, *Aspergillus* and *Mucormycosis*. *Cryptococcus*, *Aspergillus*, *Candida* and *Mucor* occur worldwide but *Histoplasmosis* and *Blastomyces* are generally confined to the Americas.

Risk factors

Fungal infection can occur as a consequence of direct inoculation of fungi followed penetrating trauma or neurosurgery. Cancer, chemotherapy and resulting neutropenia predispose particularly to *Candida* and *Aspergillus* meningitis and HIV to *Cryptococcus*, *Histoplasmosis* and *Coccidioides*. Other risk factors include:

- Pregnancy;
- Lymphoreticular malignancy including leukaemia and lymphoma;
- Diabetes;
- Organ transplantation;
- Severe burns;
- Connective and vascular disease; and
- Malignancy.

There is an extensive differential diagnosis of fungal meningitis summarized in Tables 8.16 and 8.17. The most import differential diagnoses are:

- Tuberculous meningitis;
- Granulomatous cerebral vasculitis (Churg–Strauss, Wegener's granulomatosis);

Table 8.22 Main fungal infections of the CNS.

Cryptococcus	Worldwide	HIV, cytotoxic drugs, HIV, RE malignancy	Granulomatous meningitis, hydrocephalus, raised intracranial pressure	Amphotericin B and flucytosine or fluconazole and itraconazole
Histoplasmosis	USA	HIV, steroids, organ transplant	Chronic basal meningitis or cerebritis Rarely, encephalitis or abscess	Amphotericin B, itraconazole or maintenance
Coccidiocoides	USA	HIV	Diffuse parenchymatous meningitis Meningoencephalitis Mass lesions	Amphotericin B followed by prolonged fluconazole maintenance
Candida	Worldwide	See text	Meningitis, vascular infiltration	Amphotericin B and flucytosine followed by fluconazole
Aspergillus	Worldwide	Neutropenia, immunosuppression	Cerebral abscess, diffuse granulomatous meningitis, vascular infiltration	Amphotericin B, debulking. Occ itraconazole
Mucormycosis	Worldwide	DM, malignancy		Ampohotericin B and surgical débridement

- Viral meningo-encephalitis;
- Sarcoidosis;
- Lymphoma;
- Carcinomatous meningitis;
- Partially treated bacterial meningitis;
- Other forms of chronic meningitis – lupus, sarcoid and idiopathic chronic meningitis.

The diagnosis of fungal meningitis is made on the basis of CSF examination which usually shows a mononuclear pleocytosis (20–500 cells/mm^3) with occasional predominance of polymorphonuclear cells especially in aspergillosis. The cell count may be reduced in immunosuppression. CSF staining and agglutinin testing is important in the diagnosis of *Cryptococcus* infection. In cultures *Candida* is identified in 2–3 days but dimorphic fungi such as *Histoplasma* may take several weeks to grow. Serology is occasionally helpful.

CT and MRI imaging may show meningeal enhancement and accompanying parenchymatous mass lesions, possibly with hydrocephalus. Meningeal biopsy is only occasionally of value.

True yeasts

Cryptococcus neoformans

Cryptococcus neoformans is an encapsulated yeast which is the most common pathogen causing fungal meningitis. It occurs in bird excreta and has a worldwide distribution. *Cryptococcus* characteristically occurs in patients with HIV, or who have received cytotoxic drugs or steroids and is also associated with sarcoid and reticulo-endothelial malignancy. Infection may remain dormant for many years or lead to immediate local pulmonary or disseminated infection.

Cryptococcus occurs as a result of inhalation of small yeast forms into the respiratory tract. There is an acute or subacute granulomatous meningo-encephalitis with meningism, headache and pyrexia, culminating in the progressive development of raised intracranial pressure due to hydrocephalus. There may be multiple cranial nerve palsies or focal neurological features including paraparesis, hemiparesis and ataxia. Visual impairment and cerebral infarction also occurs. The onset may be subacute over many weeks with cognitive impairment and dementia. The diagnosis is based on culture, direct observation with India ink staining, CSF fungal culture or crytococcal antigen testing which is both specific and sensitive. The CSF shows a variable lymphocytic pleocytosis.

The outcome of cryptococcal disease is variable. Untreated it tends to become disseminated and fatal within a few weeks but more often infection leads to persistently raised intracranial pressure with repeated lumbar puncture being necessary. It accounts for up to 20% of all AIDS-related deaths.

Cryptococcus is treated with an induction phase of intravenous amphotericin B and flucytosine. An alternative regimen is fluconazole or itraconazole for 8–10 weeks. Because of the high relapse rate in AIDS patients the third level of treatment using fluconazole 200 mg/day as a lifetime suppressive agent is recommended. Persistent raised intracranial pressure may need to be treated with recurrent lumbar punctures or ventriculoperitoneal (VP) shunt.

Histoplasmosis

Histoplasmosis usually manifests as a respiratory illness that resembles miliary TB. It is associated with AIDS, steroids and organ transplantation. In disseminated histoplasmosis, CNS involvement occurs in up to 20% of patients with a chronic basal meningitis or cerebritis. Less often there may be hydrocephalus, encephalitis, cerebral or spinal cord abscess. The diagnosis is made on the basis of CSF cultures positive in about 30%, microscopy is usually negative. CSF antigen detection is also possible but there is a high incidence of false positives. Treatment is with amphotericin B but relapses are common and maintenance with itraconazole is indicated. Similar chronic basal meningitis occurs with blastomycosis and actinomycosis.

Coccidiomycosis

Coccidiomycosis occurs particularly in the USA and is caused by air-borne spores. The onset is usually with a self-limiting flu-like illness and pulmonary infiltrates but the coccidioides may disseminate causing a chronic diffuse parenchymatous basal meningitis or meningo-encephalitis. Lytic skull and vertebral lesions occur and intracranial mass lesions may lead to communicating hydrocephalus. The diagnosis is made on the basis of culture and CSF positivity to complement fixation tests. Treatment is with intravenous amphotericin B given over a prolonged period of time followed by prolonged or lifelong treatment with fluconazole.

Pseudohyphae

Candida albicans

Candida albicans is a normal commensal but is the most common cause of fungal meningitis in neonates and young children.

Risk factors

- Neutropenia;
- Immunodeficiency (acquired in congenital shunt infection);
- Immunocompromised hosts;
- HIV;
- Organ transplants;
- Severe neutropenia;
- Diabetes;
- Severe burns;
- Use of total parenteral nutrition;
- Malignancy;
- Debility;
- Steroids and broad-spectrum antibiotics; and
- Postoperative neurosurgery.

Candidiasis may involve the lungs, heart, urogenital system and skin. There may be an acute meningitic illness with headache

and fever but diffuse infiltration occasionally leads to a small vessel thrombosis with microinfarcts particularly in the middle cerebral artery territory. There may also be haemorrhage from rupture of mycotic aneurysms. Rarely, there is a subacute onset where invasion of the subarachnoid space occurs. Patients may have an indwelling VPshunt or ventriculostomy in place and are often receiving prophylactic antibiotics.

The diagnosis is made on the basis of clinical features together with the CNS showing a mild pleocytosis and a low glucose. CSF staining has a low yield (up to 20%) but in nearly half of these cases the diagnosis can be confirmed by culture. The CSF can be examined for other products of candidal metabolism. The mortality has been reduced from 10% to 20% with the use of amphotericin B and flucytosine because of its synergistic action. Treatment should be continued for 6–8 weeks and shunt replacement may be necessary. The prognosis for candidiasis remains variable with a mortality rate of up to 30% in patients with HIV but generally about 10%.

True hyphae

Aspergillus fumigatus

Aspergillus fumigatus accounts for about 5% of CNS fungal infections and carries a poor prognosis. It is associated with prolonged neutropenia, immunosuppression and parenteral drug abuse. Aspergillosis occurs as a complication of sinusitis, otitis or mastoiditis. Manifestations include cerebral abscess, diffuse and granulomatous meningitis but there is direct hyphal invasion of the cerebral blood vessels with thrombosis, necrosis and haemorrhage, particularly involving the posterior circulation. Intracranial mass lesions also occur which may be solitary or, less commonly, multiple. Progressive vascular infiltration may lead to multiple mycotic intracranial aneurysms clinically manifest as encephalopathy, seizures and focal neurological deficit. Haematogenous spread occurs. The diagnosis is difficult as cultures are insensitive but the products of metabolism may show evidence of aspergillus. Treatment is both medical and surgical involving debulking and specific treatment with amphotericin B (0.7–1.0 mg/kg/day) but higher doses may be used although the treatment is not as effective as in *Cryptococcus*. In some circumstances, the addition of itraconazole 200 mg 12 hourly helps. The prognosis is poor often because of the poor host status and the lack of response to therapy.

Mucormycosis

Mucormycosis is a rare fungal infection which is associated with malignancy, diabetes, steroids, pregnancy or drug addiction. There may be malignant infiltration of cerebral vessels with hyphae commencing in the nasal turbinates and paranasal sinuses and spreading along the infected vessels to the retro-orbital tissue. Cavernous sinus or internal carotid artery thrombosis and involvement of the adjacent brain contribute to haemorrhagic infarction. Ocular involvement is manifest as central retinal and ophthalmic artery occlusion or optic nerve compression. Treatment is with rapid correction of hyperglycaemia and acidosis, surgical debridement and amphotericin B but the prognosis is poor.

Parasitic disease of the nervous system

For the parasitic causes of CNS lesions see Tables 8.23–8.25.

Neurocysticercosis

Neurocysticercosis is caused by infection of the human brain by the larvae of the *Taenia solium*. It is the most common cause of acquired epilepsy in most low income countries and of major importance worldwide.

Cysticercosis occurs when humans become the intermediate host in the life cycle of the pork tapeworm (*Taenia solium*) by ingesting its eggs from contaminated water, food or by spread from food handlers who harbour the adult parasites in their intestines. Eating infected pork in which the larval cysts or adult tapeworm may be ingested leads to adult tapeworm infection (taeniasis) but transmission does not occur because the infected pork does not contain the eggs that cause cysticercosis. If the eggs are ingested they hatch into oncospheres in the intestine, these cross the intestinal wall and enter the bloodstream being carried to the tissues where the larvae (cysticercus) develop. Cysticerci are vesicles consisting of a wall and scolex. The main target organs of the cysticerci are the eye, skeletal muscle and the nervous system where cysticerci may develop in the brain parenchyma, subarachnoid space, ventricular system or spinal cord. Parenchymatous cysts develop in the cerebral cortex or the basal ganglia

Paragonimiasis
Protozoa
American trypanosomiasis (Chagas disease)
African trypanosomiasis (sleeping sickness)

Table 8.24 Nematodes (roundworms).

Angiostrongyloides	Ingestion of raw or inadequately cooked shellfish or snails	Asymptomatic or associated with pruritus, abdominal pain. Neurological involvement is rare – may be chonic meningitis with headache, progressive cranial neuropathy, spinal cord involvement or retinal detachment CSF eosinophilic pleocytosis and raised protein. Larvae may be found in biopsy or the CSF Imaging shows meningeal enhancement with oedema and high signal in the basal ganglia Treatment is supportive
Strongyloides	Human intestinal infection Associated with poor sanitation Occurs on contact with the parasite in contaminated water or by direct penetration of the skin	Migrates via the venous circulation to the lungs and small intestine where it remains dormant for many years May subsequently reinfect the host and render them liable to secondary bacterial infection Affects the lungs and gastrointestinal tract but rarely may involve the CNS leading to encephalopathy, meningism and, rarely, vascular involvement including mycotic aneurysms, intracerebral haemorrhage or vasculitis Serum eosinophilia Larvae can be identified in stool, serum, CSF or peritoneal fluid Antibodies can be detected with immuno assay MRI shows atrophy and may show the presence of mycotic aneurysms or abscesses Treatment is with ivermectin (alternatives includes thiabendazole, albendazole or mebendazole)
Toxocara canis	Ingestion of parasites after contact with infected cats or dogs in whom the excreted eggs survive for many years	Endemic throughout the world The eggs hatch into larvae, which migrate to the liver and then to the viscera leading to an inflammatory response and granuloma formation Infection is usually mild and self-limiting but visceral larvae migrans may migrate to the lungs, liver, kidney, heart muscle, brain or eyes and ocular involvement can cause ocular neuritis and blindness. Cognitive impairment occasionally occurs with CNS involvement and there may be a dementia The diagnosis is difficult because the eggs are not excreted in the faeces Serum and CSF eosinophilia Antibody testing on CSF confirms the diagnosis Imaging may show subcortical and white matter disease suggesting a vasculitis Treatment is with diethylcarbamazine or alternatively mebendazole and albendazole

CSF, cerebrospinal fluid; MRI, magnetic resonance imaging.

Table 8.25 Cestodes (tapeworms).

Echinococcus (Hydatid disease)	The definitive host is canine Humans and sheep are infected by ingesting eggs excreted by infected animals and the source is usually water or vegetables contaminated by canine faeces After ingestion the parasite rapidly disseminates to the liver, lungs and vertebrae	Single hydatid cyst in the liver CNS involvement is also characterized by cyst formation causing compression of the brain or intracerebral blood vessels which may manifest as raised intracranial pressure with headache, nausea, vomiting and seizures and is generally difficult to distinguish from cysticercosis. The cysts may also cause compressive spinal cord lesions *Investigations* Elevated ESR, serum oesinophilia and positive immunophoresis testing Imaging confirms the presence of cysts (often multiple) of various sizes *Management* Surgical intervention is necessary to remove enlarged cysts with mass effect. Medical treatment is with albendazole
Sparganosis	Larval form of the tapeworm – contracted from contaminated water or eating undercooked fish	Invasion of the CNS occurs occasionally and there may be focal neurological features including seizures and hemiparesis *Investigations* Peripheral eosinophilia Parasite may be demonstrated in human tissue specimens. Immunofluorescent antibody techniques are sensitive and specific Imaging will show calcified lesions *Treatment* Praziquantel – only moderately successful and surgical excision of the parasite may be necessary

ESR, erythrocyte sedimentation rate.

because of the relatively high blood flow to these areas. Subarachnoid cysts may be larger and lodge within the cortical sulci or the CSF cisterns at the base of the brain. They may also involve the subdural space, the sellar region, the eye and the spinal cord. Cysticerci elicit a mild inflammatory response when they enter the nervous system and either remain viable for many years or enter into a process of degeneration that ends with their death. Following death, cysticerci undergo progressive involution in which the cyst is surrounded by a thick collagen capsule and adjacent brain parenchyma develops astrocytic gliosis and diffuse oedema. This progresses to granuloma formation and then calcification and astrocytic change when the oedema subsides. Cysticerci in the meninges induce an intense inflammatory response in the subarachnoid space with formation of a dense exudate leading to leptomeningeal thickening which may cause hydrocephalus or occlusion of the vessel lumen and cerebral infarction.

Clinical features

Infection is commonly asymptomatic. Epilepsy is the most common presentation – the seizures are usually generalized tonic–clonic or simple partial but can occasionally be complex partial. Focal signs may develop and hydrocephalus is commonly manifest as intracranial hypertension. Cognitive function may be impaired. Intrasellar cysticerci present with visual field loss and endocrine disturbances from pituitary involvement while ocular cysticerci cause decreased visual acuity or visual field loss. Spinal cord involvement is characterized by root pain or motor and sensory deficits that vary according to the level of the lesion. Massive infection of striated muscle may lead to generalized weakness associated with progressive muscle enlargement.

Neuroimaging

Plain films may show cigar-shaped soft tissue calcification or direct visualization of cysticerci in the anterior chamber of the eye or in muscles. In countries where neurocysticercosis is prevelant, small <1 cm brain lesions are often regarded as neurocysticercosis cysts unless proved otherwise. CT scan may show viable cysts which appear as hypodense rounded cystic lesions which may enhance after administration of contrast. The scolex can occasionally be seen as a hyper-intense dot in the interior of the cyst. Degenerating cysts appear as contrast enhancing rings on FLAIR MRI sequences (Figure 8.8). There may be hydrocephalus and abnormal enhancement of the leptomeninges is characteristic. Cysticerci should be distinguished from lesions of tuberculosis which tend to be larger and to have mass effect. The differential diagnosis also includes tuberculoma and tumours, particularly glioma.

Stool examination may reveal the ova of *Taenia solium*. Serological investigations including enzyme-linked immunoelectrotransfer blot with purified glycoprotein antigens (Western blot) can be undertaken on serum or CSF. Cysticerci outside the nervous system may be noted subcutaneously on X-ray or by muscle biopsy.

Management

There remains uncertainty about the value of medication in the treatment of neurocysticercosis because many of the clinical manifestations are brought about by the effects of established deficit caused by calcified cysts rather than active lesions. In most patients a single enhancing lesion may disappear spontaneously. However, current evidence favours treatment in patients with viable intraparenchymal or extraparenchymal parasites. This is both symptomatic and anti-parasitic treatment. Albendazole (<15 mg/kg/day for 1 month) has a greater effect on killing parasites but praziquantel has also been widely used. There is considerable variability in the dose and duration of treatment. A single course of albendazole or praziquantel will kill 60–85% of viable brain cysts leading to a faster radiological resolution of the cysts. Corticosteroids are indicated in the presence of encephalitis

CSF, cerebrospinal fluid.

angiitis or chronic meningitis that causes progressive entrapment of the cranial nerves. Antiepileptic medication may need to be life-long. Ventricular shunting to resolve hydrocephalus may be necessary but this is associated with a high level of shunt malfunction.

Trematodes

See Table 8.26 for trematodes.

Schistosomiasis (bilharzia)

Schistosomiasis occurs in up to 300 million people worldwide. There are five forms but CNS involvement occurs particularly with *Schistosoma mansoni*, *S. haematobium* and *S. japonicum*. Infection is acquired from water where there is poor sanitation or water supply. The larva invades the skin and migrates into the venous system. Subsequent spread depends on the species involved. The eggs of *S. japonicum* cause 60% of all schistosomal brain infections while *S. mansoni* tends to be confined to the spinal cord and *S. haematobium* can involve brain or cord. Eggs enter the CNS and cause a granulomatous response which walls off the invading parasite. The granulomas expand, become exudative and necrotic, involving vascular walls as well as local tissue.

The onset is with an acute pyrexia with urticarial swelling, myalgia, eosinophilia and bloody diarrhoea. Neurological involvement occurs in <5% of patients and develops after weeks or months when the eggs migrate through the vascular system to the brain or spinal cord. Mass lesions may be produced by expanding granulomas leading to raised intracranial pressure or erosion of vessel walls culminating in intracranial haemorrhage. Spinal cord involvement may be caused by granuloma formation and transverse myelitis can occur although cauda equina and conus syndromes are also characteristic.

Diagnosis is made by detection of the eggs in stool, urine or tissue biopsy. Antibody detection, using ELISA, is possible but this is not reliable. CT scan shows single or multiple hyperdense lesions caused by granuloma formation, which is inflammatory and surrounded by oedema with variable contrast enhancement.

Treatment

Treatment is conventionally with praziquantel, which is effective against all schistosome species and curative for <90% of patients. If patients continue to excrete the eggs then it is necessary to have a further course of treatment. Alternative treatments include niridazole or artemether, which kills immature migrating larvae and is synergistic with praziquantel. Steroids are used for lesions if there is extensive surrounding oedema and large granulomas may need to be excised surgically.

Protozoa

American trypanosomiasis (Chagas disease)

American trypanosomiasis (Chagas disease) is caused by *Trypanosoma cruzi*, which is endemic in South and Central America. Infection occurs secondary to contact with raduviid bug, ingesting guinea pig excretia, blood transfusion or organ transplantation. Larval eggs are taken through the site of pruritic skin lesions. The larvae then mature and are transported by the bloodstream to distant sites. They divide intracellularly before rupture of the cell releases the infectious parasite and inflammatory substances.

Chagas disease has an onset with malaise, myalgia, headache and anorexia. There is unilateral or bilateral periorbital oedema (Romana's sign). Cardiac failure and intestinal involvements are common. Meningo-encephalitis may occur in a minority of patients depending on the severity of infection and extent of host immune response. The diagnosis is made by CSF demonstration of trypanosomes. Serum antibody detection tests are sensitive and specific for acute and chronic forms. MRI scanning may show one or more ring enhancing lesions involving the grey and white matter. Acute Chagas disease can be eradicated by benzonidazole or nifurtimox but chronic infection remains symptomatic and is difficult to clear.

African trypanosomiasis (sleeping sickness)

African trypanosomiasis (sleeping sickness) occurs in humans in two forms: *Trypanosoma brucei gambiense* (West African) and *Trypanosoma brucei rhodensiense* (East African). The condition is widespread throughout sub-Saharan Africa. The vector of both species is the tsetse fly which feeds from infected animals. A superficial chancre forms at the site of the bite and the parasite larvae migrate, via the bloodstream, to the lymphatic vessels before maturing and reproducing. There is then a secondary spread of mature forms to the lymph nodes, spleen, liver, heart, endocrine system, eye and CNS leading to a host immune response and meningo-encephalitis.

West African trypanosomiasis is slow or indolent in onset and characterized by rash, intermittent fever and lymphadenopathy. Involvement is episodic. The East African form is more aggressive with behavioural disturbance, psychiatric manifestations including anxiety agitation and manic and uncontrolled behaviours. Sleep disruption occurs with day–night reversal and uncontrolled urges to sleep. The condition progresses to motor disturbances including ataxia, rigidity, akinesis and progressive pyramidal signs but meningism is rare. Visual involvement includes optic neuritis, optic atrophy and papilloedema. Death occurs as a result of coma, secondary infection or cardiac involvement. The diagnosis of trypanosomiasis can be made by direct observation in wet preparations of stained blood, CSF or biopsy. However, antibody and PCR tests are unreliable. MRI may show focal high signal abnormalities.

The treatment is suramin and pentamidine but this is not suitable if there is CNS involvement when melarsoprol or eflornithine are recommended.

Toxoplasma gondii

Toxoplasma gondii is an intracellular protozoan which is widely distributed. Invasion occurs as a result of ingestion of uncooked meat. *Toxoplasma* may invade multiple organs but in immunocompetent individuals infection is generally asymptomatic or associated with a mild mononucleosis-like illness with lymphadenopathy and a non-specific systemic illness. However, severe disease may occur in the immunocompromised patient and this is discussed below.

Malaria

Malaria is the most important parasitic disease of humans and it is estimated that >5% of the world population has been infected. Each year >500 million cases of malaria occur worldwide, 90% of these are in Africa or South-East Asia and the condition accounts for 200 million deaths per year.

Malaria is caused by four parasitic protozoa of the genus *Plasmodium*: *P. vivax*, *P. falciparum*, *P. ovale* and *P. malariae*. It is only *P. falciparum* that can cause severe generalized disease and in particular cerebral malaria. The protozoa is transmitted by the female *Anopheles* mosquito which feeds at night-time although, rarely, transmission may also be transplacental or from contaminated needles. Infection is initiated by sporozoites injected in the bite of the mosquito. The protozoa undergoes a complex life cycle in the human host in which the sporozoites mutiply within hepatocytes, producing thousands of multinucleated merozoites which enter the red blood cells and become mature forms (trophozoites and schizonts) before rupturing and releasing further merozoites. In falciparum malaria the red blood cells become distorted and excessively adherent binding to endothelial cells and causing sequestration, clumping and eventually vascular obstruction within the cerebral vessels. There is also an associated suppression of haemopoiesis leading to anaemia, thrombocytopenia and hepatosplenomegaly.

Plasmodium vivax, *P. ovale* and *P. malariae* are either asymptomatic or cause recurrent episodic fever of varying severity. In *P. falciparum* malaria, clinical manifestations depend on the load of parasite and the immune state of the host. Onset is with a flu-like illness, headache, fever and muscle aches. There are often paroxysms of rigor and shivering in between the pyrexia with extensive diaphoresis and hypothermia. Cerebral malaria is manifest by the onset of coma often heralded by focal or generalized seizures. Raised intracranial pressure develops rapidly, leading to possible brainstem herniation; in addition, vascular engorgement leads to the development of cerebral arterial occlusion, aneurysms or intracranial haemorrhage. A subacute syndrome or diffuse symmetrical encephalopathy may also occur associated with brainstem signs, eye movement abnormalities, pyramidal signs or extrapyramidal movements including choreoathetosis and myoclonus. Retinal haemorrhages are characteristic. Severe malaria is also associated with generalized systemic involvement including renal and hepatic failure, hypoglycaemia, bleeding diathesis, circulatory collapse and pulmonary oedema.

Diagnosis

The diagnosis of cerebral malaria is made on thick blood films and a light microscopy ensuring that large amounts of blood are available and a minimum of 100 fields are observed. Thin film assessment allows species recognition. Newer antigen tests are now available based on recognition of the HRP-2 antigen of falciparum. PCR techniques are specific and sensitive to plasmodium, but do not give an estimate of the parasite load.

Coma occurring in patients with cerebral malaria carries a fatality rate of up to 20% when appropriately treated and is invariably fatal if untreated. Complications include cerebral or dural venous thrombosis and cortical infarction. The management of acute malaria depends on the infecting species, the severity of parasitaemia, the pattern of clinical involvement and potential drug resistence.

Acute management

Acute management of cerebral malaria involves supportive care with appropriate attention to ventilation, fluid balance, renal

Table 8.27 Antimicrobial treatment for malaria.

Plasmodium *P. malariae* *P. ovale* *P. vivax*	Chloroquine and primaquine
Chloroquine sensitive *P. falciparum*	
Chloroquine resistant *P. falciparum*	Quinine sulphate and tetracycline (alternative to tetracycline is sulfadoxine and pyrimethamine or amiodaquine or doxycycline)
Multi-drug resistant *P. falciparum*	Mefloquone or artesunate or sulfadoxine and pyrimethamine or proguanil and atovaquone
Severe complex multi-drug resistant *P. falciparum* (particularly if mefloquine resistant)	Quinine dihydrochloide

function and seizures. *P. falciparum malariae*, *P. ovale* and *P. vivax* should be treated with a standard course of chloroquine over 48 hours. In severe cases it may be necessary to treat with an intravenous infusion of chloroquine. Primaquine may be added to eradicate the exerythrocytic forms and prevent relapses (Table 8.27).

Because chloroquine-resistant *P. falciparum* is widespread, treatment of mild infections is with oral quinine sulphate followed by doxycycline or clindamycin to eradicate remaining asexual forms. Alternatives include mefloquine or co-artemether. Severe *P. falciparum* should be treated in intensive care with intravenous quinine sulphate and meticulous attention to fluid balance, renal and cardiac function. Alternative treatments for *P. falciparum* or cerebral malaria include quinidine, artemether or artesunate.

Prevention

Although the complete genome of the *Anopheles* mosquito and *P. falciparum* has been sequenced, this has not yet led to new therapy and therefore traditional prophylaxis is still mandatory. Recommendations concerning appropriate prophylaxis vary depending on the characteristics of malaria and drug resistance in particular areas.

Whipple's disease

Whipple's disease is a multi-system disorder that usually presents with systemic and gastrointestinal features before neurological involvement develops. However, the condition may occasionally present with neurological features or these may be the only manifestation. Patients usually develop weight loss in association with gastrointestinal disturbance including abdominal pain, diarrhoea and steatorrhoea. Joint pain occurs as a consequence of a seronegative migratory arthropathy. There may be a low grade chronic pyrexia and the development of lymphadenopathy, splenomegaly and hyperpigmentation. Cardiac involvement may include endocarditis, constrictive pericarditis and culture negative endocarditis.

CNS involvement occurs in up to 40% of patients, often late in the course of the disease. The most common manifestation is slow onset of cognitive change including memory loss, behaviour and personality change which may evolve into frank dementia. Ocular involvement is also frequently seen with inflammatory changes causing retinitis or uveitis but there may also be papilloedema and progressive optic atrophy. Supranuclear vertical gaze palsy may occur in association with the characteristic movement disorders of oculo-masticatory myorhythmia in which there is an associated repetitive movement of the masticatory muscles that persists during sleep or oculofacial skeletal myorhythmia that involves the facial and other musculature. Seizures and myoclonus occur in up to one-quarter of patients in whom there is neurological involvement and there may also be a progressive ataxia. Rarely, the level of consciousness may be affected with progressive obtundation and even coma. Thalamic involvement causing polydipsia, hyperphagia, insomnia or hypersomnia is described.

The condition is caused by a Gram-positive bacillus *Tropheryma whippelii.* This is a slow-growing organism which is ubiquitous. It is identified in biopsy of the jejunal mucosa which shows macrophages filled with Periodic acid – Schiff (PAS) positive intracellular inclusions which contain the organism. Similar staining may be seen in biopsies of lymph nodes, heart valves and cerebral tissue and in the CSF. Diagnostic PCR assay for *T. whippelii* are increasingly used to establish and confirm the diagnosis of Whipple's disease. CSF is characterized by pleocytosis with an elevated protein. MRI may show diffuse high signal on T2 weighted images particularly affecting the frontal cortex, basal ganglia and peri-ventricular white matter but the hypothalamus and cortex may also be involved. Occasionally, mass lesions may develop with ring enhancement. There may also be diffuse atrophy or focal abnormalities and, occasionally, hydrocephalus.

Management remains unsatisfactory. Conventionally, patients have been treated with parenteral penicillin and streptomycin followed by long-term tetracycline. Relapses occur and the outlook for recovery with neurological involvement is particularly poor. Newer recommendations suggest more intense and vigorous treatment is indicated in the presence of neurological involvement because of the likelihood of clinical relapses. Treatment should be with penicillin G and streptomycin in an induction phase with ceftriaxone maintenance followed by 6-month cyclical therapy with co-trimoxazole, doxycycline and cefixime. Although antibiotics are usually given for 1 year it has been increasingly argued that with neurological involvement treatment should be given indefinitely because of the high likelihood of relapse when therapy is stopped.

Neurological disorders resulting from HIV

It is now more than 25 years since the onset of the HIV/AIDS pandemic. Although it was soon apparent that the CNS was frequently involved with opportunistic infections, it was subsequently recognized that patients developed complications from the HIV genome itself such as dementia, myelopathy and neuropathy. With the introduction of highly active antiretroviral therapies (HAART) since 1997 the incidence of opportunistic infections and tumours, as well as the HIV-related complications, have drastically reduced. This group of patients now present with problems resulting from drug side effects such as neuropathy, a metabolic syndrome that may predispose to cerebrovascular disease and complications arising as a complication of immune reconstitution. In addition, because of the greater longevity, patients with HIV are now prone to the same disorders associated with ageing found in the non-infected population.

HIV is neuroinvasive (with invasion occurring early in the course of the infection), neurovirulent (causing a neuropathy, myopathy, myelopathy and encephalopathy) but not particularly neurotrophic. The virus is rarely isolated from the neurones of the peripheral or central nervous systems and productive infection is usually found within the associated inflammatory infiltrate, predominantly in macrophages and microglia.

Basic principles

As a result of immunosuppression, the clinical presentations may be atypical. For example, only one-third of patients with cryptococcal meningitis develop classic features of meningism. A low threshold for investigation with CT/MRI and lumbar puncture is necessary.

Because all areas of the neuro-axis in an HIV infected individual may be affected by different aetiological agents, the principle of 'Occam's razor' may not be applicable. For example, a patient may have a mass lesion in the brain resulting from toxoplasmosis, a concurrent HIV-related myelopathy and a drug-induced neuropathy.

Dual infections are relatively common and this possibility must be borne in mind when assessing a treatment response. For example, patients may have meningitis resulting from *Cryptococcus neoformans* and *Mycobacteria tuberculosis*.

At seroconversion, a glandular fever-like illness occurs in 70% of cases. In 10%, this may be associated with neurological symptoms and signs – aseptic meningo-encephalitis, acute disseminated encephalomyelitis (ADEM), transverse myelitis, polymyositis, brachial neuritis or a cauda equina syndrome. Guillain–Barré syndrome has also been described at seroconversion and during the asymptomatic phase of HIV infection although the CSF shows a significant pleocytosis in contrast to the findings in HIV-negative patients where CSF examination is usually acellular with a high protein.

During the asymptomatic phase of HIV infection, when there is no evidence of immunosuppression clinically and the CD4 count is above at least 350 cells/mm^3, there is no evidence of neurological symptoms or signs. This has been ascertained by a number of large cohort serial studies using clinical, neurophysiological, neuroradiological and neuropsychological methods of assessment. However, prior to the introduction of HAART, in up to 5% of cases HIV dementia was the AIDS defining diagnosis. HIV infection should therefore be considered in the differential diagnosis in any young patient presenting with cognitive impairment.

HIV infection may be associated with a vasculitis or a thrombophilic state with anticardiolipin antibody and lupus anticoagulant and therefore enters the differential diagnosis of young stroke.

CSF examination may be abnormal because of HIV infection per se even in the asymptomatic immunocompetent stages. These include a mild lymphocytic pleocytosis, an elevated CSF protein and oligoclonal bands. Conversely, as a result of HIV-induced immunosuppression, patients with meningitis or encephalitis may have normal CSF indices. The diagnosis of neurological disorders therefore relies on specific tests on the CSF such as the detection of cryptococcal antigen (by latex agglutination – CRAG), culture or using PCR techniques.

Serological studies, e.g. in toxoplasmosis, are unhelpful in making a diagnosis as used in immunocompetent cases as there is no diagnostic fourfold rise in IgM and IgG titres.

In patients who have not received HAART, the CD4 count is a useful guide in attempting to determine the specific aetiologies of opportunistic infections and tumours. For example, toxoplasmosis and cryptococcal meningitis occur with CD4 counts below 200 cells/mm^3; CMV retinitis, encephalitis and polyradiculopathy occur below 50 cells/mm^3. Complications resulting from *Mycobacteria tuberculosis* may occur at earlier stages when the CD4 count may be 350 cells/mm^3. In HAART exposed patients, these guidelines are less robust because even if there is a rise in the CD4 count, these lymphocytes may not be fully competent as some antigen-specific clones will have been lost.

Opportunistic infections and tumours in HIV

Toxoplasma gondii

Toxoplasma gondii is an obligate intracellular protozoan, whose definitive hosts include members of the cat family with humans acting as intermediate hosts. Human infection occurs by ingestion of oocytes in cat faeces and the ingestion of tissue cysts in undercooked meat. Variations in dietary habits explain the differing seroprevalence rates worldwide – 90% in French adults compared to 50% in the UK. Symptomatic toxoplasmosis is usually caused by reactivation of latent infection in immunosuppressed individuals. The risk of an HIV-infected patient who is seropositive for IgG *T. gondii* antibody developing toxoplasmosis is around 25%.

Toxoplasmosis is the most common cause of mass lesions in the CNS of HIV patients even in developing countries where

tuberculosis is rife. Reactivation occurs when the CD4 count drops below 100–200 cells/mm^3. The clinical presentation is with headache, confusion and/or seizures in association with hemiplegia, dysphasia and visual field defects. Other clinical features include: a variety of movement disorders (choreoathetosis, dystonia and hemiparkinsonism); psychiatric illness such as depression and personality change resulting from frontal lobe pathology; brainstem syndromes and a rapidly progressive diffuse encephalitis. Rarely, the spinal cord may be involved with a myelitis or a cauda equina syndrome.

A definitive diagnosis of *Toxoplasma* encephalitis can only be made by brain biopsy. With increasing experience and pragmatism, it is now standard practice to treat any HIV-infected individual with a low CD4 count and mass lesions on imaging with anti-*Toxoplasma* therapy. A response, clinically and radiologically, confirms the diagnosis. Although negative blood serology makes the diagnosis less likely, this may still occur in up to 17% of cases. These latter cases are a result of impaired antibody synthesis with increasing immunosuppression and the occasional primary infection. It is useful therefore to document *Toxoplasma* serology at the time of HIV diagnosis. On imaging studies, preferably MRI, *Toxoplasma* lesions have a predeliction for the grey–white interface and the basal ganglia. There is normally mass effect with surrounding oedema with patchy enhancement. A single lesion or peri-ventricular lesions are more likely to be caused by primary CNS lymphoma, the main differential diagnosis that occurs with a similar clinical presentation and at similar low CD4 counts.

Response to treatment is seen in 90% of patients by the second week of treatment. It is prudent to re-image even if there is clinical improvement because it is not rare for some lesions to improve and others, such as those due to *M. tuberculosis*, to enlarge making it necessary to consider biopsy. The radiological improvement generally lags behind the clinical improvement. Patients who are HIV infected and who are seropositive for IgG against *T. gondii* should be offered primary prophylaxis with 980 mg co-trimoxazole (trimethoprim and sulfamethoxazole) when the CD4 count drops below 200 cells/mm^3. This also offers protection against *Pneumocystis jirovecii*.

Primary CNS lymphoma

Primary CNS lymphoma (PCNSL) is the second most common cause of mass lesions in adults and the most common in children with AIDS. Histologically, this is a high grade, non-Hodgkin B-cell lymphoma (Chapter 20). The Epstein–Barr virus is causally linked to PCNSL, with the identification of the viral DNA incorporated into that of the neoplastic cells.

The common presenting symptoms are headache with focal neurological deficits, altered level of consciousness and seizures. Brain imaging reveals enhancing mass lesions with surrounding oedema. These are similar to those found in toxoplasmosis. PCNSL is more likely to present with a single lesion than toxoplasmosis and is also more likely to invade the ventricular walls. Studies using thallium-201 single photon emission computed tomography (SPECT) suggest that it may be possible to differentiate between an abscess and a tumour with the former having little uptake compared with high uptake of the mitotically active lymphoma. CSF analysis is usually not performed because of raised intracranial pressure but when possible the identification of EBV by PCR is useful diagnostically with a sensitivity of 50–100% and a specificity of 94%.

There is no effective therapy for PCNSL and most patients succumb within 2–3 months. Radiotherapy may increase survival times by a few months. However, recent data suggest that treatment with HAART can also improve survival times.

Progressive multifocal leucoencephalopathy

Progressive multifocal leucoencephalopathy (PML) is caused by the reactivation of the JC virus (JCV; the initials of the patient from whom the virus was first isolated), a common polyoma virus, which infects 75% of the general population. As the virus is frequently excreted in the urine of healthy individuals, primary infection is postulated to occur via the urine–oral route.

Because impaired cell-mediated immunity is the major predisposing factor for the development of PML, prior to the AIDS epidemic, the condition was occasionally encountered in patients with lympho-proliferative disorders, sarcoidosis and those treated with immunosuppressive drugs, e.g. after transplant operations and systemic lupus erythematosus (SLE). HIV-induced immunosuppression currently accounts for 85% of cases of PML. Prior to HAART, 5% of AIDS patients developed PML with CD4 counts usually below 100/mm^3. However, after the introduction of HAART, PML has remained more prevalent than expected and this may be related to increased activation of JCV by the HIV proteins. The underlying pathology results from replication of the virus within the oligodendrocytes causing lysis and demyelination. It is unclear whether PML results from reactivation of the virus in the CNS following immunosuppression or if it is a result of invasion of the CNS by infected lymphocytes from the peripheral circulation.

The clinical presentation is with a progressive subacute focal deficit which may be hemiparesis, hemianopia or ataxia. Cognitive dysfunction is usually associated with focal neurological signs. Lesions adjacent to the cortex may occasionally result in dysphasia and seizures. Spinal cord involvement has not been described. In contrast to other more common causes of focal lesions found in HIV infected patients such as toxoplasmosis, there are usually no symptoms or signs of systemic infection or raised intracranial pressure. A cerebellar syndrome with only cerebellar atrophy on MRI scans may occur, pathological studies show JCV infection of the granular cells (JCV granule cell neuronopathy).

Cranial CT shows hypodense lesions. MRI shows large single or multiple lesions involving white matter, with scalloping at the grey–white interface; the parieto-occipital and frontal lobes are most commonly affected. The affected areas are low signal on T1 weighted images and hyperintense on T2 weighted sequences. This may help distinguish PML from HIV dementia. There is no

mass effect but contrast enhancement may be seen and has been identified as a good prognostic marker.

Early in the AIDS epidemic the diagnosis was only possible by brain biopsy with the histological demonstration of demyelination, enlarged oligodendrocyte nuclei with JCV inclusion particles and bizzare enlarged astrocytes. Prior to the HAART era, JCV DNA could be isolated from the CSF by PCR with a sensitivity of 75% and a specificity of 99%. Since HAART, the sensitivity seems to have dropped to 58% perhaps because of decreased viral replication. The yield can be increased to 85% with repeated CSF examination in PCR negative cases but stereotactic brain biopsy may be necessary.

The treatment of PML in patients with HIV is two-pronged: improving the underlying immunosuppression with HAART and anti-JCV therapy. Institution of the former has resulted in fourfold improvement in survival, with some patients' neurological status stabilizing or improving. A number of drugs such as cytosine arabinoside (araC) given intravenously or intrathecally have anti-JCV activity but have not been shown to be of benefit. Alpha interferon has been used because of its antiviral and immune-enhancing effect in a pre-HAART retrospective open-labelled observational study. About one-third of patients showed some neurological benefit, with some also showing radiological improvement. The anti-CMV drug cidofovir, when used in conjunction with HAART, also increases neurological improvement or stability when compared to HAART alone and led to faster clearance of the virus from the CSF but this finding has not been consistent. Furthermore, cidofovir has a number of serious side effects – nephrotoxicity resulting from a dose-dependent renal tubular acidosis, neutropenia and ocular hypotonia.

Cryptococcal meningitis

In patients infected with HIV, meningitis caused by the fungus *Cryptococcus neoformans* occurs in 10% of patients with advanced HIV disease, usually when the CD4 count falls below 100 cells/mm^3. The incidence has fallen significantly since the introduction of HAART. *C. neoformans* is ubiquitous in the environment and is commonly found in the soil and in the excreta of pigeons. Pulmonary infection, usually asymptomatic, occurs by inhalation followed by haematogenous spread to the meninges.

The clinical presentation is usually with headache which initially maybe mild, fever and drowsiness. Only 30% of individuals present with features of meningism – photophobia, neck stiffness and a positive Kernig's sign. In 20% of cases there may be extra-neurological involvement with diffuse pulmonary infiltrates, lobar consolidation or cavitating lesions on chest X-ray, skin lesions (small papules which resemble molluscum contagiosum) and infection of the urinary tract.

Brain imaging may be normal or may reveal hydrocephalus, cryptococcomas, dilated Virchow–Robin spaces which are filled with the fungal organisms, and basal meningeal enhancement. Measurement of the serum cryptococcal antigen is a useful screening test in those with mild symptoms and, if positive, necessitates imaging and CSF examination. At lumbar puncture, CSF pressure is frequently elevated. In most cases there is a moderate mononuclear pleocytosis, an elevated protein and a low glucose; however, in 25%, the CSF maybe normal. The diagnosis is established by the identification of India ink positive hypae in 75% and the detection of cryptococcal antigen in 95% of cases. A number of poor prognostic markers have been identified:

- CSF opening pressure >25 cm CSF;
- Altered mental status;
- CSF cryptococcal antigen titre >1 : 1024;
- CSF white cell count <20 cells/mm^3; and
- Hyponatraemia.

Amphotericin B with or without flucytosine is the treatment of choice, but in patients with mild disease without any of the poor prognostic markers fluconazole maybe considered. Acute treatment should be continued until the CSF culture is sterile which may take 4–6 weeks, following this, secondary prophylaxis should continue with fluconazole. HAART should be commenced on complete recovery if the patient was not already receiving this. However, if HAART is started too soon there is a risk of developing the immune reconstituition inflammatory syndrome (IRIS).

Raised intracranial pressure, unrelated to hydrocephalus, should be managed aggressively, as it may result in visual loss, by repeated lumbar puncture with high volume CSF removal and, if required, by the placement of a lumbar or ventricular drain. Acetazolamide may also be used as an adjunct.

Cytomegalovirus infection

CMV infections of the nervous system occur when the CD4 counts are very low – usually below 50 cells/mm^3 and usually associated with CMV disease elsewhere in the body. Prior to HAART, CMV retinitis was the most common cause of blindness in this group of patients. Typically, patients present with painless visual loss. Fundoscopy shows extensive haemorrage and necrosis with the so-called ketchup and cheese appearance. CMV encephalitis presents with a rapidly evolving encephalopathy with focal deficits often involving the brainstem. Imaging studies have shown a range of abnormalities including a peri-ventriculitis, non-enhancing hypodense lesions resembling PML and, rarely, single or multiple enhancing mass lesions. CMV lumbosacral polyradulopathy presents subacutely with back pain and progressive weakness of the legs with sphincter involvement. Imaging studies may be normal or show thickened nerve roots. CSF examination, which is essential to exclude other causes of a polyradiculopathy such as syphilis and lymphomatous infiltration, shows a polymorphonuclear pleocytosis which is unusual in a viral infection, an elevated protein and low glucose. CMV DNA can be isolated from the CSF by PCR. CMV has also been associated with a mononeuritis multiplex, usually in the context of CMV elsewhere such as a retinitis. The diagnosis is confirmed by sural or superficial peroneal nerve biopsy.

Herpes varicella zoster

Although dermatomal zoster (shingles) is common in the HIV population, occasionally patients may progress to a severe

myeloradiculopathy. After dermatomal zoster, especially involving the trigeminal nerves, VZV involvement of the small cerebral vessels can present with a granulomatous angiitis. The clinical presentation is with headache, progressive focal neurological deficits and seizures. MRI shows multiple T2 abnormalities on T2 weighted images. The CSF is diagnostic with the identification of viral DNA by PCR. Treatment is with high-dose aciclovir and corticosteroids.

Herpes simplex

Herpes simplex type 2 has been rarely associated with a rapidly progressive myelitis in those presenting with back pain, progressive leg weakness and sphincter disturbance. MRI shows an oedematous cord. The diagnosis is confirmed by the identification of viral DNA in the CSF.

Neurological complications directly resulting from HIV

HIV enters the nervous system early in the course of infection. The evidence for this includes the neurological seroconversion illness, the presence of CSF abnormalities in asymptomatic immunocompetent individuals and the presence of HIV DNA in brain pathological studies of asymptomatic HIV-infected patients who died from other causes. In one case of iatrogenic HIV transmission caused by a blood product given intravenously, the patient died 15 days after the accident from an unrelated cause. HIV DNA was identified in the brain (Table 8.28).

The mechanism of viral entry into the CNS remains controversial because the blood–brain barrier is an effective physical and metabolic barrier. The most accepted current theory is the Trojan horse mechanism, which proposes that HIV viral entry through the blood–brain barrier occurs via infected macrophages from the peripheral circulation. The choroid plexus, which resides outside the blood–brain barrier, is another potential site of viral entry because the choroid capillary endothelial cells are freely permeable with the stromal cells containing monocytes and macrophages.

Within the brain, infection is localized primarily within the microglial cells and macrophages which are derived from peripheral blood monocytes. HIV does not infect neuronal cells even though neuronal cell death is an important aspect of the neuropathology of HIV dementia. There is some evidence suggesting there is a low level of astrocyte infection; this may be important because the astrocytic foot processes are an integral part of the blood–brain barrier and a low level of infection may be enough to disrupt functioning of the tight junctions between the endothelial cells. Although demyelination is also a feature of HIV brain disease, infection of the oligodendrocytes has rarely been reported.

The neurovirulence of HIV occurs later in the course of the disease when immunosuppression develops and HIV acts like an opportunistic infection. It remains uncertain if this is a result of activation of the virus seeded in the nervous system early in the course of disease or trafficking of new HIV viral species from the peripheral circulation, or both. There is no doubt that since the introduction of HAART, the incidence of HIV dementia has reduced suggesting that suppression of HIV in the peripheral circulation has a crucial role (Table 8.29).

Table 8.28 Neurological complications in HIV-1 infection.

Caused by HIV
Peripheral neuropathy
Distal sensory peripheral neuropathy
Inflammatory demyelinating neuropathy (GBS and CIDP)
Vasculitic neuropathy
Diffuse inflammatory lymphocytosis syndrome
HIV associated dementia
Vacuolar myelopathy
HIV polymyositis
Opportunistic infections
Toxoplasmosis gondii – abscesses, encephalitis
Cryptococcal neoformans – meningitis
Mycobacterium tuberculosis – meningitis, abscesses, tuberculoma, myeloradiculopathy
Cytomegalovirus – encephalitis, retinitis, lumbosacral polyradiculopathy, vasculitic neuropathy
JC virus – progressive multifocal leuco-encephalopathy
Herpes varicella zoster – encephalitis, CNS vasculitis, myelitis
Herpes simplex – encephalitis, myelitis
Tumours
Primary CNS lymphoma (EBV-related)
Metastatic systemic lymphoma
Cerebrovascular disease
HIV-associated thrombophilia
Cardioembolic – endocarditis, infectious and marantic
Vasculitis – HIV-associated, infectious (varicella zoster)
Drug-related complications
Peripheral neuropathy
ARV drugs (ddC, ddI, d4T)
Other drugs (thalidomide, isoniazid, dapsone)
Myopathy (AZT)

ARV, antiretroviral; CIDP, chronic inflammatory demyelinating polyradiculoneuropathy; EBV, Epstein–Barr virus; GBS, Guillain–Barré syndrome.

HIV-associated dementia (HIV encephalopathy, HIV associated cognitive motor complex, AIDS dementia complex)

This subcortical dementia occurred in 15% of AIDS patients prior to the introduction of HAART but the incidence has now been reduced by 50%. Risk factors for the development of HIV-associated dementia (HAD) include: low CD4 counts, increasing age, anaemia, systemic symptoms, injection drug use and female sex. Host genetic factors such as the E4 isoform for apolipoprotein E may also be a predisposing factor. The pathological features of HAD are an HIV encephalitis (HIVE), usually

Table 8.29 Peripheral nerve complications in HIV infection.

HIV related
Axonal neuropathy (distal sensory peripheral neuropathy)
Demyelinating neuropathy (GBS and CIDP)
Vasculitic neuropathy
Diffuse inflammatory lymphocytic syndrome
Lower motor neurone syndrome (resembling MND)
CMV related
Lumbosacral polyradiculopathy
Vasculitic neuropathy
Drugs
Antiretroviral drugs (ddI, ddC, D4T, ?protease inhibitors)
Isoniazid (treatment of TB)
Thalidomide (treatment of mouth ulcers)
Dapsone (treatment and prophylaxis of toxoplasmosis and *Pneumocystis jirovecii*)
Vincristine and vinblastine (treatment of KS and lymphoma)
Paclitaxel (Taxol) (treatment of KS)
Others
Syphilis (polyradiculopathy)
Metastatic NHL
Ganglionitis
Autonomic neuropathy

CIDP, chronic inflammatory demyelinating polyradiculoneuropathy; CMV, cytomegalovirus; GBS, Guillain–Barré syndrome; KS, Kaposi sarcoma; MND, motor neurone disease; NHL, non-Hodgkin lymphoma; TB, tuberculosis.

at the grey–white interface, suggesting haematogenous dissemination. The hallmark for HIVE is the presence of microglial nodules which are a fusion of HIV infected and non-infected macrophages. Most infection is demonstrated in the basal ganglia, the brainstem and the deep white matter areas. Other pathological features include leuco-encephalopathy and areas of neuronal cell loss, especially in the hippocampal areas and the frontal and temporal lobes. Because neuronal cells are rarely affected, the pathophysiology of HAD probably results from the release of inflammatory cytokines such as tumour necrosis factor, quinolinic acid and platelet-activating factor by activated macrophages.

The clinical features of HAD in the early stages may be mild with symptoms of poor concentration, mental slowing and apathy which may mimic a depressive disorder. Later, as the syndrome progresses, more specific cognitive changes with memory loss and personality change develop. These occur in association with motor changes such as impaired dexterity and gait problems which result from the associated vacuolar myelopathy and peripheral neuropathy. Examination may show impaired pursuit and saccadic eye movements, generalized hyperreflexia, cerebellar and frontal release signs. Investigations are indicated to exclude other causes – MRI typically shows evidence of atrophy with diffuse white matter changes on T2 weighted images. The CSF shows non-specific cytochemical abnormalities but must be examined to exclude conditions such as neurosyphilis, CMV and PML. The CSF viral load correlates with severity of dementia but is not sensitive enough for diagnostic purposes. Formal neuropsychological assessments typically reveal abnormalities in the following cognitive domains – psychomotor speed, attention, frontal lobe function and verbal and non-verbal memory.

Pre-HAART, the mean survival rate for patients with HAD was 12 months. With the introduction of HAART, some patients may improve, some remain static and some with virological non-response may continue to deteriorate. A minority of patients with evidence of viral suppression in the peripheral circulation may continue to deteriorate as a result of 'compartmentalization' with a high viral load in the CSF which will necessitate a change in HAART regimen. There is concern regarding the ability of the currently available antiretroviral drugs to penetrate the blood–brain barrier, particularly the protease inhibitor drugs. The following drugs seem to have the best penetration: stavudine, zidovudine, abacavir, lamivudine, efavirenz, nevirapine and indinavir (Table 8.30). However, to date no one HAART regimen has proved superior to another in the treatment of HAD suggesting that it is the suppression of viral replication in the peripheral circulation that is crucial.

HIV-related vacuolar myelopathy

Clinically significant vacuolar myelopathy affects up to 10% of patients with AIDS usually in patients who also have HAD. The condition is characterized by a slowly progressive spastic paraparesis, sphincter disturbance and a sensory ataxia resulting from posterior column involvement. There is no sensory level. Pathological specimens demonstrate a vacuolar degeneration of the white matter within the thoracic spinal cord similar to that seen in subacute degeneration of the cord resulting from vitamin B_{12} deficency. Although B_{12} levels are usually normal, it is possible that a methylation defect is responsible because S-adenosylmethionine is reduced in the CSF of patients with vacuolar myelopathy. This degeneration is not specific to AIDS and has been described in other immunodeficient states and malignancy. As with the other complications of HIV, significant productive HIV infection is not found. However, there is evidence of macrophage activation and increased levels of cytokines. MRI shows increased signal in the white matter tracts on T2 images or may be normal. CSF examination is necessary to exclude viral myelitis resulting from herpes zoster, herpes simplex and CMV although these myelitides tend to be much more acute. Co-infection with HTLV-1, which has a similar mode of transmission to HIV, merits consideration. There is no specific treatment apart from HAART. A small study using 3 g methionine showed some limited benefit but results of larger studies are awaited.

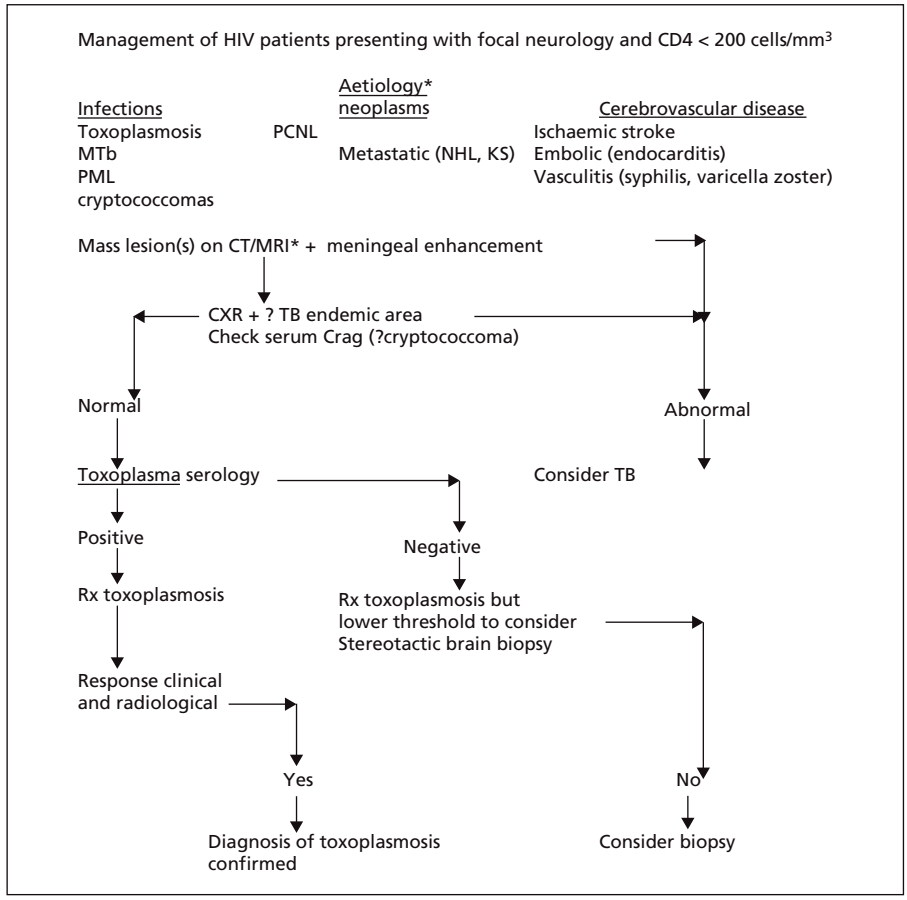
HIV-related neuropathy

The most common peripheral nerve disorder encountered because of HIV is distal sensory peripheral neuropathy (DSPN). The prevalence rate pre-HAART was estimated at 35% and at

Table 8.30 Drug treatment regimens for the common HIV-related CNS infections.

TOXOPLASMOSIS	
Acute phase (for 6 weeks)	**Side effects**
First line therapy	
Pyrimethamine loading dose	Marrow suppression
(100 mg p.o. for 3 days, then 75 mg/day)	
+	
Sulfadiazine 6–8 g/day p.o./iv	Rash
	Nephrotoxicity
+	Marrow suppression
Folinic acid 15 mg/day	
Second line therapy	
Clindamycin 600–900 mg/day p.o./iv instead of sulfadiazine	Rash, diarrhoea
Maintenance treatment*	
Pyrimethamine 25–50 mg/day	
+	
Sulfadiazine 2–4 g/day	
+	
Folinic acid 10 mg/day	
Clindamycin 600 mg/day instead of sulfadiazine	
CRYPTOCOCCAL MENINGITIS	
Acute phase therapy for 4–6 weeks or until CSF culture negative	
Amphotericin B 0.7–1.0 mg/kg/day (via central line)	Nephrotoxicity
+/–	Anaemia, hepatitis
Flucytosine 100–150 mg/kg/day p.o.	Marrow suppression
In milder cases:	
Fluconazole 400 mg iv/p.o.	Rash, hepatitis
*Maintenance treatment**	
Fluconazole 200–400 mg/day p.o.	
CYTOMEGALOVIRUS INFECTION	
Acute phase therapy	
Ganciclovir 5 mg/kg every 12 hours for 14–21 days	Anaemia, leucopenia, thrombocytopenia
or	
Foscarnet 60 mg/kg 8-hourly for 14–21 days	Renal failure
	Leucopenia
Maintaince treatment*	
Ganciclovir 5 mg/kg every 24 hours	
or	
Foscarnet 90–120 mg/kg/day	

Table 8.30 *Continued*



CT, computed tomography; CXR, chest X-ray; KS, Kaposi sarcoma; MRI, magnetic resonance imaging; MTb, *Mycobacterium tuberculosis*; NHL, non-Hodgkin lymphoma; PCNL, primary CNS lymphoma; PML, progressive multifocal leucoencephalopathy.

* Consider stopping maintenance treatment if after highly active antiretroviral therapy (HAART) is started the CD4 remains >200 cells/mm^3 for >6 months.
MRI preferred as more sensitive.

If there are signs of raised intracranial pressure, treat with dexamethasone 4 mg q.d.s. initially. Once the patient is stable, gradually tail off. Improvement on steroids may be because of reduction of cerebral oedema or partial response of lymphoma to corticosteroids.

At least 2 weeks may be necessary to assess for a response to anti-*Toxoplasma* therapy. In some cases, if no urgency, monitor for 4 weeks with repeat MRI.

necropsy 95% of patients had sural nerve pathological abnormalities. The underlying pathology in DSPN is one of a dying back axonopathy with secondary demyelination. Increased numbers of macrophages are found in the dorsal root ganglia and within the peripheral nerves. HIV RNA is rarely detected in the peripheral nerves and the pathophysiological mechanisms for the development of DSPN are those for HAD, i.e. neurotoxicity of viral proteins such as Gp 120 and tat as well as a bystander effect of neurotoxic cytokines released by activated macrophages.

Risk factors for the development of DSPN include age, higher viral load and lower CD4 counts. Patients with other risk factors for neuropathy such as diabetes, excess alcohol intake and genetic neuropathies are more vulnerable. The presentation is with 'painful, burning, numb feet'. Patients also complain of paraesthesiae, dysaesthesiae and allodynia but the upper limbs are rarely involved. Examination may reveal limited weakness, often confined to the intrinsic foot muscles. The reflexes may be normal, depressed or absent. There is characteristically impaired sensation to pain and temperature but subsequently other modalities are involved. Nerve conduction tests (NCTs) may be normal or show mild axonal abnormalities. Thermal thresholds are abnormal indicating small fibre involvement. Punch skin biopsies with the assessment of epidermal nerve fibre densities are increasingly being utilizsed in diagnosis and treatment trials of DSPN. In atypical cases where, for example, there is more extensive weakness with foot drop or significant upper limb involvement clinically or on NCTs, CSF examination and nerve biopsy should be considered to exclude vasculitis, demyelinating neuropathies and lymphomatous infiltration.

The treatment of DSPN is symptomatic – only lamotrigine and recombinant human nerve growth factor have been shown to be effective in relieving the pain of DSPN in randomized placebo controlled trials. Gabapentin, although often used, has only been shown to be effective in small trials. Amitriptyline, although not proven to be effective in placebo controlled trials, has a role in individual patients starting at low doses. Mexiletine, acupuncture and topical capsaicin have not shown benefit.

Diffuse inflammatory lymphocytosis syndrome

Some patients respond to HIV infection by developing diffuse inflammatory lymphocytosis syndrome (DILS), a syndrome characterized by a persistent circulating CD8 lymphocytosis with visceral lymphocytic infiltration particularly affecting the salivary glands. An uncommon form of HIV-associated neuropathy is seen in DILS which is eminently treatable with antiretroviral drugs and corticosteroids. This multisystem disorder resembles Sjögren syndrome, although anti-Ro/SS-A and anti-La/SS-B antibodies are absent. Patients present with salivary gland enlargement, xerostomia, keratoconjunctivitis sicca, uveitis and lymphocytic pulmonary, gastrointestinal and renal involvement. The peripheral nerve complications present with a painful sensorimotor neuropathy which may be symmetrical or asymmetrical. Neurophysiological studies show an axonal neuropathy although rare cases of demyelination are reported. The CD4 counts are variable but the CD8 counts are consistently high, resulting in a low CD4:CD8 ratio. The diagnosis is confirmed at nerve biopsy.

Toxic neuropathy for antiretroviral drugs

The nucleoside reverse transcriptase inhibitors (NRTIs) didanosine (ddI), zalcitabine (ddC) and stavudine (d4T) have all been shown to cause a dose-dependent peripheral neuropathy but an association with lamivudine (3TC) is not well documented. Mitochondrial toxicity from inhibition of the DNA polymerase enzyme may be the underlying mechanism for the neuropathy and the same mechanism may also account for the other side effects of this class of drug – pancreatitis, fulminant hepatic failure, lactic acidosis and lipodystrophy. More recently, protease inhibitors (PI) have also been implicated in the drug-related neuropathies. The clinical presentation of toxic neuropathy for antiretroviral drugs (TNA) is similar to that seen with DSPN. The drug-related neuropathies are, however, more likely to be painful, have an abrupt onset and progress rapidly. After stopping the appropriate drug, there may be a paradoxical worsening of neuropathic symptoms over a period of 4–8 weeks (coasting). An improvement of symptoms may occur in some patients but a number may be left with underlying DSPN which has been unmasked by the TNA.

As with DSPN, the management of this group of patients can be difficult. The development of this painful sensory neuropathy is a significant cause of morbidity and poor drug compliance. If the patient is on a neurotoxic drug, the issue of stopping it needs to be discussed with their HIV physician. In practice, this maybe a difficult decision if there has been a good virological response and the CD4 count has risen significantly as lowering the drug dosage risks the possibility of viral drug resistance. Treatment is otherwise symptomatic. One small study has shown acetylcarnitine improves neuropathic pain scores and epidermal skin nerve fibre densities.

HIV-associated myopathy

An immunologically mediated polymyositis may occur at seroconversion or during the asymptomatic phases of the disease. As with non-HIV patients, the subacute illness manifests with proximal weakness and myalgia, an elevated creatine phosphokinase and myopathic changes on EMG studies. The disorder is usually steroid responsive. The inflammatory infiltrates found on muscle biopsy are similar to HIV – negative polymyositis, except there is a reduction of CD4 positive cells. Zidovudine, an NRTI introduced in 1986, causes a mitochondrial myopathy. Muscle biopsies show ragged red fibres and muscle mitochondrial DNA levels are significantly depleted. Patients improve when the drug is stopped. This complication in now rare since the drug doses have been reduced from 1000–1500 mg/day to 600 mg/day.

Immune reconstitution inflammatory syndrome (IRIS)

A consequence of HAART is that the recovery of CD4 T lymphocytes leads to recovery of memory T cells. This has led to the development of so-called immune restoration or immune reconstituition syndrome. This has been defined as the 'paradoxical deterioration of clinical or laboratory parameters including imaging studies, despite a favourable response of the HIV surrogate markers, (i.e. viral load and CD4 count) to antiretroviral therapy (ART)'. A total of 10–25% of patients on ART may develop IRIS, which may occur days to months after starting ART but usually within the first 2 months. IRIS maybe subdivided into three categories:

1 Infectious IRIS caused either by ongoing or latent infection.
2 Sarcoid-like IRIS with granulomatous lesions in the lungs.
3 Autoimmune IRIS with patients developing disorders such as SLE, polymyositis and rheumatoid arthritis.

Neurological IRIS has been described with *Mycobacteria tuberculosis* causing meningitis and abcesses; CMV with the development of vitritis, uveitis and cystoid macular oedema; HIV itself has caused a demyelinating leuco-encephalopathy. IRIS-induced cases of PML demonstrate gadolinium enhancement on MRI and, of those cases that have been biopsied, inflammatory infiltrates. The management of IRIS consists of treating any identified infection and corticosteroids for the inflammatory component. The question of whether to stop or continue ART is difficult. If there is a life-threatening complication such as a mass lesion within the brain, it would seem prudent to stop the drugs at least for a short period.

Conclusions

Since the onset of the AIDS epidemic, tremendous strides have been made in unravelling the immunobiology of HIV; the development of the antiretroviral drugs which have made HIV a chronic

medical disorder rather than an inexorably fatal one; identifying and treating the opportunistic complications with better diagnostic and therapeutic options. However, these benefits have not to date reached the areas of the world most affected by the epidemic. From the neurology point of view, DSPN continues to pose problems. Although the incidence of HAD has declined, as a result of increased longevity, the prevalence has increased. There is concern from pathological data on patients who have died while on HAART about ongoing low-grade inflammation in the brain. IRIS has also proved difficult to diagnose and manage.

9 Nerve and Muscle Disease

Michael Lunn, Michael Hanna, Robin Howard, Matthew Parton, Mary Reilly

Neuromuscular diseases have traditionally been overlooked, underdiagnosed and poorly treated when compared with neurological diseases with greater visibility (e.g. Parkinson's disease or epilepsy), social impact (such as the dementias) or which pose a threat for survival (e.g. brain tumours or meningitis). However, neuromuscular disorders are diverse and extremely common, possibly accounting for up to 40% of neurological diagnoses. They may lead to significant disability or death. The accurate and early diagnosis of a cause may lead to effective treatment, reduction in disability and improved quality of life.

This chapter provides a comprehensive summary of disorders of peripheral nerve, neuromuscular junction, muscle and the anterior horn cell.

Peripheral nerve disorders

An understanding of the many peripheral nerve disorders relies upon a comprehension of the complexities of the macro- and micro-anatomy of peripheral nerves, their molecular biology, immunology and pathophysiology. Much of this is beyond the scope of this chapter but a short synopsis is provided below.

Macro-anatomy of the peripheral nerve

Peripheral nerves are bundles of axons, Schwann cells, elaborated myelin and the supporting cellular tissues whose primary purpose is to communicate neural information between the CNS and peripheral sensory or effector structures (e.g. muscles, sweat glands, blood vessels). In very simplified terms, the peripheral nervous system (PNS) functions via a series of reflex arc circuits with efferent and afferent arms controlled from above by the CNS (Figure 9.1).

Neurology: A Queen Square Textbook Edited by Charles Clarke, Robin Howard, Martin Rossor and Simon Shorvon © 2009 Blackwell Publishing Ltd.
ISBN: 978-1-405-13443-9

The anatomy of the major nerve trunks and their connections has been known for more than 500 years, even if there was little understanding of their function (Figure 9.2). The PNS consists of 10 of the 12 cranial nerves and the spinal roots, becoming the peripheral nerves, exiting from the spinal cord. Knowledge of basic peripheral neuroanatomy, physiology and immunology is the key to understanding the pathophysiology of diseases affecting peripheral nerves.

Upper limbs

The brachial plexus is formed from the anterior rami of the spinal roots from C5 to T1 (Figure 9.3). Within the course of the brachial plexus, axons originating from these cervical roots are rearranged and exit in major and minor nerve branches to supply sensory, motor and autonomic inputs and outputs to the upper limb and shoulder girdle (Table 9.1(a); Figure 9.4). Many find the localization of processes affecting the brachial plexus or cervical roots difficult but it is simplified by an understanding of the anatomy. The identification of affected muscle groups and sensory territories assist.

The major nerves leaving the brachial plexus are the musculocutaneous, median, ulnar and radial nerves (see below and Figure 9.4). Each nerve has its innervated muscles (although there are occasional anatomical variations).

Lower limbs

The lumbosacral plexus is formed from the ventral rami of L1–S4 nerve roots (Figure 9.6). The upper (or lumbar) part of the plexus gives rise to the obturator and femoral nerves. The lower part of the plexus gives rise to the sciatic nerve which is regionally organized and later divides into the tibial and common peroneal nerves at the knee. As with the brachial plexus, some smaller nerves exit the plexus directly (e.g. the genitofemoral and lateral cutaneous nerve of the thigh). The major nerves of the lumbosacral plexus innervate individual muscles as indicated in Figure 9.6 (Table 9.1(b)). An ability to identify which muscles or areas of skin innervation are affected on clinical and neurophysiological examination and correlate this to the anatomical innervation is

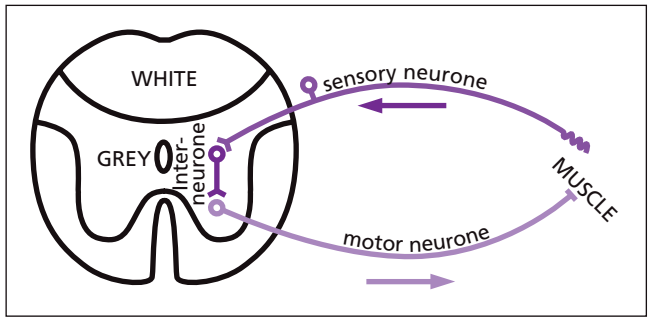

Figure 9.1 The spinal reflex arc is the foundation of peripheral nerve function. Although highly stylized, peripheral stimuli enter the arc along the afferent limb and exit to effector organs along the efferent limb. Responses may be modified by synaptic connections along this pathway.

central to being able to make successful peripheral nerve diagnoses (Figures 9.5 and 9.7).

Micro-anatomy of the peripheral nerve

Each peripheral nerve comprises a collection of neurones and their bundles of axonal processes, supporting cells, blood vessels, connective tissue and other elements including cells of the immune system (e.g. macrophages and mast cells). An axon and its supporting cells (an axon–Schwann cell unit) are often referred to as nerve fibre. A fascicle is a group of nerve fibres with associated endoneurial elements enclosed in ensheathing perineurium. A nerve is a collection of fascicles surrounded by supportive and protective epineurium. Apart from post-ganglionic neurones of the autonomic nervous system, all PNS axons have a CNS extension or origin where the axonal and support matrix characteristics are different.

Peripheral nerve compartments

The peripheral nerve is divided into distinct compartments easily visible when cross-sectioned nerves are examined under the light microscope (Figure 9.8). The compartmentalization of the peripheral nerve provides several layers of protection able to resist physical and immunological attack. Axons are protected from most immune reactions that might otherwise interfere with effective electrical impulse transmission.

The outer layer of epineurium is composed of loosely packed collagenous connective tissue containing adipocytes, fibroblasts, collagen and mast cells and serves to provide tensile strength and resist impact and trauma. The perineurium is a tight sleeve of flattened cells separated by collagen within the epineurium, and surrounds each individual nerve fascicle. The specialized flattened fibroblasts, connected by occlusive tight junctions, form

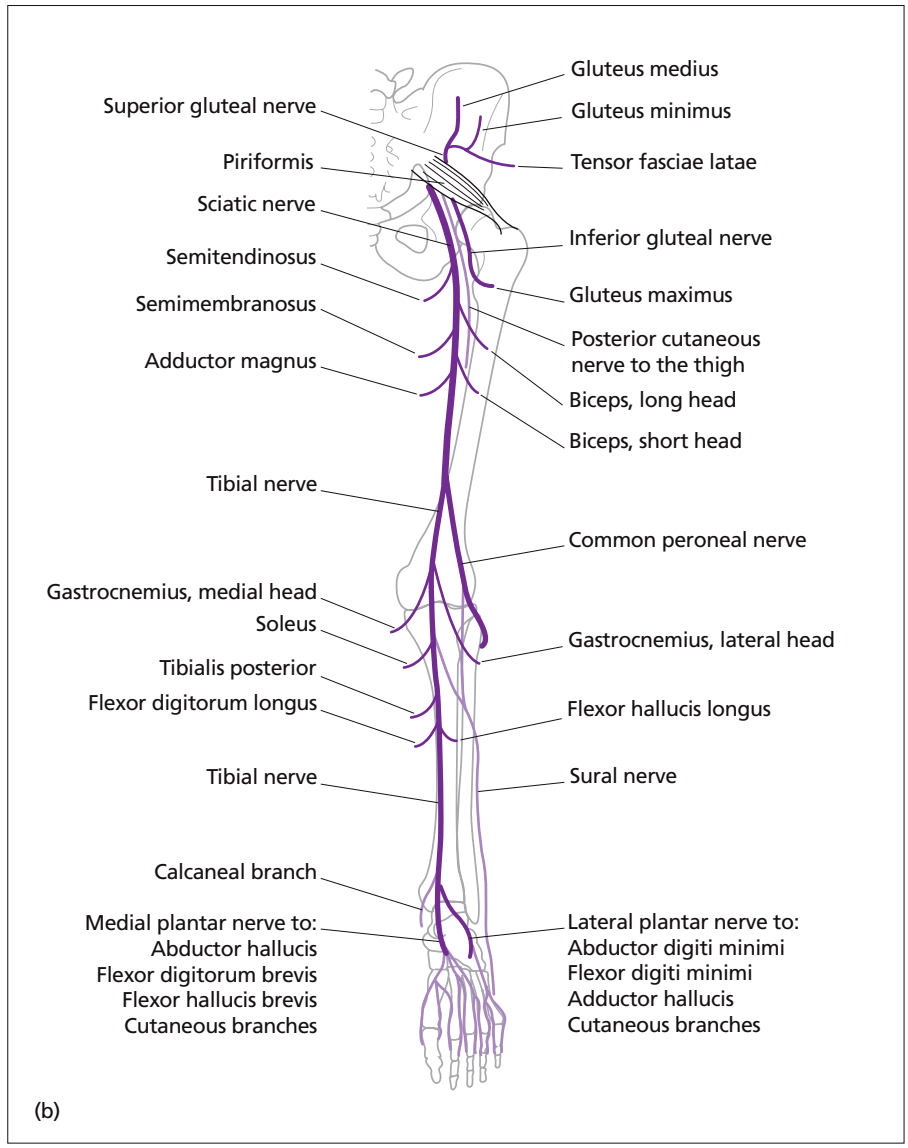

Figure 9.7 *Continued* (b) Posterior aspect of the lower limb. (From *Aids to the Examination of the Peripheral Nervous System*, 4th edn. London: W.B. Saunders, 2000 with permission, courtesy of Dr M. D. O'Brien.)

an effective barrier to diffusion of macromolecules between the epineurium and endoneurium.

The endoneurium is a tissue space containing connective tissue, axon–Schwann cell units, pericytes, fibroblasts, macrophages and mast cells. The blood vessels in the endoneurium have a specialized endothelium also impermeable to macromolecules. There is no endoneurial lymphatic drainage. The endoneurial space is bathed in endoneurial fluid, the composition of which betrays the specialized protection afforded to this space. The electrolyte composition is that of extracellular fluid to enable electrical nerve conduction but the protein and immunoglobulin content is some 250 times less than that found extracellularly. The fluid is under positive pressure. This unique set of characteristics is possible because the perineurium and the specialized endoneurial endothelium form a blood–nerve barrier (BNB) that is relatively impenetrable to cells and macromolecules under normal conditions. Any active transcellular traffic of essential substances through the perineurium and into the endoneurium probably occurs in pinocytotic vesicles.

Immunology

The peripheral nerves are isolated behind the BNB which provides relative protection from circulating immune factors and perturbations of homeostasis. Not only is the endoneurium physically protected from outside attack, but it is also relatively deficient in the immunological machinery with which to make an internal immunological response. A few macrophages constitutively displaying major histocompatibility complex

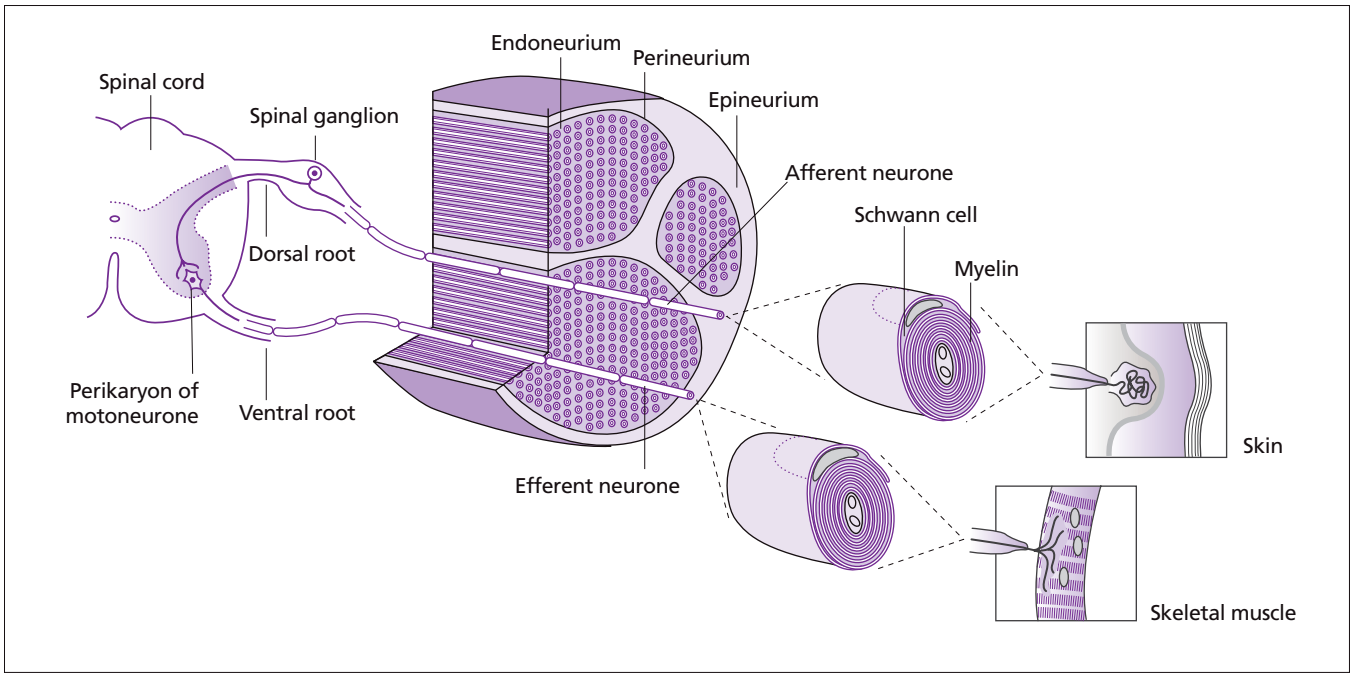

Figure 9.8 Cross-section of a normal nerve. Axons are associated with Schwann cells which in some cases elaborate myelin. Neurones are gathered in fascicles limited by a peri-neurial sheath. The endoneurium also contains supporting stromal cells, endoneurial vessels and, in health, low numbers of immune cells including resident macrophages and mast cells. Fascicles are grouped into nerves limited by the epineurium.

(MHC) Class II are found within the endoneurium and Schwann cells do not usually express MHC markers. Only very limited T-cell traffic occurs into and out of the endoneurium under normal conditions. Restricted access and egress of cells and molecules, raised endoneurial pressure, low constitutive MHC expression and limited patrol by cells of the immune system all contribute to antigen sequestration in the PNS and the relative BNB.

The physical characteristics of the BNB are not the same throughout the PNS. The barrier is relatively deficient at the trigeminal and dorsal root ganglia (DRG), the motor nerve terminals and the sensory endings. MHC Class II expression is up-regulated at the DRG as a result of continuous immune stimulation because of the physical deficiency and the need to patrol more effectively for invading pathogens. In some neuropathies these are the preferred sites for immune attack and development of pathology.

Pathophysiology of the peripheral nerve

All PNS axons are ensheathed by Schwann cells and the Schwann cells are, in turn, invested by a continuous layer of basal lamina. Schwann cells surrounding smaller axons (0.5–1.5 μm) do not elaborate myelin and one Schwann cell may surround several unmyelinated fibres (a Remak bundle). Those surrounding axons of larger calibre (1–20 μm) wrap a single axon only and form a tightly compacted multi-lamellar myelin sheath. Myelin is a lipid-rich specialized extension of the Schwann cell membrane in the PNS (and of oligodendrocytes in the CNS). Although broadly similar in structure, PNS differs from CNS myelin in its molecular composition (Chapter 2).

The pathophysiological mechanisms that result in peripheral neuropathies are almost as diverse as the number of peripheral nerve diagnoses. However, the patterns of damage at a microscopic level are few. Axonal degeneration occurs distal to a site of nerve transection (which may be physical, inflammatory or vascular; and focal, multifocal or diffuse). Axonal degeneration can also occur as a distal dying back phenomenon especially in toxic and metabolic neuropathies. In many inflammatory neuropathies segmental demyelination occurs which may result in conduction failure but not necessarily subsequent axonal degeneration. Remyelination (with thin myelin, short internodes and onion bulbs) may occur, restoring adequate clinical nerve function. Axonal regeneration occurs less consistently and over distances of centimetres only.

Diseases of the peripheral nerve

Diseases of the peripheral nerve can be genetic or acquired. The acquired neuropathies may be primary or secondary to other conditions. The initial clinical approach is similar in all peripheral nerve disorders.

General approach to peripheral nerve disease

History

Patients with peripheral nerve disease complain of sensory disturbance, muscle weakness or wasting (and sometimes fasciculation) and/or symptoms referable to the autonomic nervous system.

Sensory disturbance may be numbness or hypoaesthesia (a term that does not have a correlate in many languages), pain, pins and needles (parasthesiae), heightened sensation (hyperaesthesia), prolonged painful responses (hyperpathia) or abnormal unpleasant sensations perceived from innocuous stimuli (allodynia) or combinations (e.g. a 'painful numbness'). Abnormal sensations are often described in colourful terminology such as like walking on shards of broken glass or sponges or as if limbs were wrapped in cotton wool, hot boots or gripped in a vice. Pain may have a number of qualities that can help the physician. For example, lancinating or shooting pain often associates with large fibre involvement and in the context of an apparent inherited neuropathy may suggest an abnormality in the *SPTLC-I* gene (see below). Burning or stinging pain associates with small fibre involvement. The site of onset and subsequent progression help to differentiate the length dependent sensory neuropathy from the patchy multiple mononeuropathy or dermatomal radiculopathy.

Weakness may be described in terms of handicaps ('I can no longer run for a bus' or 'I can no longer do up my zip fastener') or disability ('My foot flaps' or 'I cannot lift my arms'). The pattern of such deficits helps to point to polyneuropathy, multiple mononeuropathies or radicular involvement. Weakness should always be differentiated from fatigue.

Autonomic disturbances may be missed through lack of recognition of their importance (diarrhoea or bladder dysfunction) or social embarrassment (impotence) by the patient, only compounded by a doctor's unwillingness to enquire. More than infrequent postural hypotension with presyncope or syncope is seldom innocuous. Nocturnal diarrhoea, urinary hesitancy or urgency, impotence and reduced sweating or tearing often require a proactive line of questioning and should be taken seriously if answered in the affirmative.

The tempo of symptom onset is definitive in some conditions and highly useful in the diagnosis of others. In the inflammatory neuropathies accurate determination of the time to the nadir of a first episode distinguishes between Guillain–Barré syndrome (GBS), subacute and chronic inflammatory demyelinating polyradiculoneuropathy (CIDP) and subsequently determines the selection of treatment. Likewise, a progressive sensory neuropathy with autonomic involvement that has evolved over 7 years is unlikely to be amyloid or paraneoplasia. Furthermore, relapses and remissions (whether spontaneous or following treatment) may favour one diagnosis over another (e.g. CIDP over GBS or an inflammatory neuropathy over a metabolic cause).

The pattern of weakness or sensory loss is a clue to the site of pathology and often to a pathogenic mechanism. Establish the pattern as symmetrical, asymmetrical, focal, multifocal, monomelic or upper or lower limb predominant and any transition from one to another (e.g. multi-focal to symmetrical in vasculitides).

Cranial nerve involvement is important to identify as some conditions have a predilection for one or more cranial nerves (e.g. sarcoidosis and Sjögren's syndrome). Phrenic nerve and diaphragmatic involvement may be disclosed with a history of orthopnoea, early morning headaches or daytime somnolence. A failure to recognize this may lead to a silent and unnecessary death.

Parts of the history, which at first sight may not seem relevant either to the patient or the doctor, are sometimes more important than the reported symptom complex itself. Other concurrent or previous diseases should not necessarily be assumed at face value and should be chased down and checked. For example, a diagnosis of 'asthma', so often reported, when established as relatively recent in an older person may give the clue to Churg–Strauss syndrome or if misattributed to lung disease may give the clue to cardiac involvement in amyloidosis.

An extensive multi-generational family history including details such as consanguinity, non-paternity, early infant death or adoption is crucial to identifying reduced penetrance or recessive disorders. In genetic disorders, careful probing of early and developmental history will often establish a relevant history of symptoms pre-dating the apparent onset of the condition (lack of interest in sport or numbness of the feet after wearing high heels) by a decade or more.

In all situations, exposures to other agents through sex, travel, insect, animal, toxin or drug exposures, should be sought. A systematic and thorough search for other systemic clues should be made, enquiring about skin and nails, joints, sicca symptoms, weight loss and appetite, masses, eyes and other body systems not covered by previous enquiry.

Examination

On inspection the examiner is looking for classic deformities such as pes cavus (Figure 9.9) or other indicators of diagnosis such as amputations, ulceration, wasting (or prominent lack of wasting in conditions with conduction block), trophic skin changes and fasciculations. Tremor occurs in demyelinating disease. Thickened nerves (Figure 9.10; Table 9.2) may be visible, but should be sought and palpated for. Common sites are the ulnar, superficial radial, greater auricular, sural and peroneal.

Examination of the gait can identify both subtle abnormalities of the PNS such as mild distal weakness, or associated features (e.g. ataxia or dystonias). Romberg's sign is of limited use but may be illuminating in sensory neuronopathies. Tone is usually normal or apparently 'reduced'. A careful and correctly performed quantitative motor examination (see O'Brien, *Aids to the Examination of the Peripheral Nervous System,* 2000) is crucial to identify the pattern of root, plexus, nerve or muscle and CNS involvement. Some neuropathies are predominantly or entirely motor (Table 9.3) but most will involve both motor and sensory modalities. Reflex loss may be variable and may evolve (e.g. GBS). Careful documentation of sensory loss in each modality using

Figure 9.9 The typical lower limb appearances of CMT1A with distal wasting, pes cavus and clawed toes.

Figure 9.10 Great auricular nerve thickening in leprosy. (From Forbes CD, Jackson WF. *A Color Atlas and Text of Clinical Medicine*. Aylesbury: Wolfe Publishing, 1993, with permission from Elsevier.)

vibration, proprioception, pain, temperature or tickle and light touch may again illuminate disease patterns and pathogenesis. These may be the only findings in some purely sensory neuropathies (Table 9.4).

A subsequent general examination should be thorough but tailored and include close inspection of fundi, skin, nails, joints, testes, breasts and a search for palpable nodes or organomegaly as well as a structured systems examination.

Table 9.2 Causes of thickened nerves.

Hypertrophic Charcot–Marie–Tooth diseases (especially CMT1A and HNPP)
CIDP
Neurofibromatosis
Refsum's disease
Leprosy
Infiltration (lymphoma/secondary deposits)
Amyloidosis
Acromegaly
Perineuroma and other rare primary tumours

CIDP, chronic inflammatory demyelinating polyradiculoneuropathy; CMT1A, Charcot–Marie–Tooth disease type 1A; HNPP, hereditary neuropathy with liability to pressure palsies.

Table 9.3 Motor neuropathies.

Inherited
Distal hereditary motor neuropathies
Spinal muscular atrophy
SMN: chromosome 5q; recessive
Bulbo-spinal muscular atrophies (Kennedy X-linked, recessive, dominant)
Tay–Sachs (hexosaminidase A deficiency): chromosome 15; recessive
Acquired
Motor neurone disease (progressive muscular atrophy) – sporadic/hereditary
Monomelic atrophy (Hirayama) and other idiopathic focal motor neurone disorders
Inflammatory
Acute motor axonal neuropathy
Multifocal motor neuropathy with conduction block
Distal lower motor neuropathy associated with anti-GM1 IgM paraprotein
Paraneoplastic motor neuropathy (breast/lymphoma)
Brachial amyotrophy
Metabolic and medical
Diabetic amyotrophy
Porphyria
Post-asthmatic amyotrophy (Hopkins syndrome)
Infective
Poliomyelitis, West Nile virus, Central European encephalitis
Toxins
Lead, dapsone, botulism, tick paralysis
Compressive neuropathies (motor branches)
Differential diagnoses
Neuromuscular junction disorders: myasthenia gravis, Lambert–Eaton myasthenic syndrome
Myopathies: distal myopathies; myotonic dystrophy; inclusion body myositis

Scores

The quantification of the examination findings by their incorporation or translation into one of the many available scoring systems is useful for documenting levels of impairment, disability and handicap at a point in time and following patients over the course of their disease or treatment. The use of standardized and validated scales is also useful in combining and comparing data

in clinical trials. Commonly used scales are the MRC Scale (for assessment of power, Chapter 3), the Overall Neuropathy Limitation Score, the Modified Rankin Scale, the 10-metre walk time, the Walk-12 and the SF36.

Neurophysiology

A neurophysiological examination should be regarded as an extension of the clinical examination. If it is not performed by the examining physician then it should be performed with detailed communication between the two practitioners to ensure that problems and specific issues can be addressed and clarified. Conduction block may be particularly difficult to identify.

Nerve biopsy

A nerve biopsy should be sought only after careful consideration of the other options available to achieve a diagnosis. Biopsies are generally of sensory nerves, and usually a sensory nerve identifiably and recently affected; a neurophysiologically normal nerve should not be biopsied. The biopsy should be performed with informed patient consent; complications, especially of biopsy site pain, are not infrequent. The nerve biopsy should be performed by someone competent and experienced, as crush or diathermy artefact is easily caused and may render the biopsy uninterpretable. At least 4 cm should be excised for examination.

Table 9.4 Sensory predominant neuropathies.

Inherited
Hereditary sensory and autonomic neuropathies
Acute intermittent porphyria
Fabry's disease
Acquired
Neuronopathies
Paraneoplastic (anti-Hu)
Sjögren's syndrome
Toxic (pyridoxine, *cis*-platinum)
HIV
Idiopathic inflammatory
Copper deficiency
Metabolic and deficiency states
Diabetic
Renal failure
Thiamine deficiency, pellagra, Cuban neuropathy (Strachan syndrome)
Toxins
Alcohol, chemotherapy agents (especially platinums), metronidazole, nitrofurantoin, thalidomide, thallium, mercury, phenytoin
Infectious agents
Herpes zoster
HIV
Leprosy
Focal compressive (e.g. meralgia paraesthetica, plantar nerves)
Small fibre neuropathies
Idiopathic distal sensory axonal neuropathy
Others: myelopathies, tabes dorsalis, B_{12} deficiency

Staining and examination should again be carried out in consultation with a trained nerve histopathologist. Generic and specific tincturic and immunohistochemical stains can be used to identify or exclude suspected pathologies and special preparation of parts of the specimen for electron microscopy or teased fibre studies should be requested and discussed beforehand.

Inherited neuropathies

The inherited neuropathies can be divided into those in which the neuropathy is the sole or primary part of the disease and those in which the neuropathy is part of a more widespread neurological or multi-system disorder (Table 9.5). The first group includes Charcot–Marie–Tooth disease (CMT). CMT is the most common inherited neuropathy affecting approximately 1/2500 in the Caucasian population, and usually presents with a length dependent sensory motor neuropathy. Most of the other neuropathies in this group are either genetically related to CMT (e.g. hereditary neuropathy with liability to pressure palsies) or can present in a similar fashion (e.g. hereditary sensory and autonomic

Table 9.5 Classification of the inherited neuropathies.

Neuropathies in which the neuropathy is the sole or primary part of the disease
Charcot–Marie–Tooth disease
Hereditary neuropathy with liability to pressure palsies
Hereditary sensory and autonomic neuropathy
Distal hereditary motor neuropathy
Hereditary neuralgic amyotrophy
Familial amyloid polyneuropathy
Neuropathies in which the neuropathy is part of a more widespread neurological or multi-system disorder
Disturbances of lipid metabolism, e.g.
Leuco-dystrophies
Lipoprotein deficiencies
Phytanic acid storage diseases
α-Galactosidase deficiency
Cerebrotendinous xanthomatosis
Porphyrias, e.g.
Acute intermittent
Hereditary coproporphyria
Variegate
Amino lavulinic acid dehydrase deficiency
Disorders with defective DNA, e.g.
Ataxia telangiectasia
Xeroderma pigmentosum
Cockayne's syndrome
Neuropathies associated with mitochondrial diseases
Neuropathies associated with hereditary ataxias, e.g.
Friedreich's ataxia
Spinocerebellar ataxias
Miscellaneous

neuropathy [HSAN] and distal hereditary motor neuropathy [dHMN]). This group also includes hereditary neuralgic amyotrophy (HNA) which presents with recurrent brachial plexus lesions and familial amyloid polyneuropathy (FAP), a disease in which neuropathy (often including autonomic neuropathy) is the cardinal feature although other systems can be involved (e.g. heart).

The second group is a very large varied group of disorders that usually also involve the CNS (e.g. leucodystrophies, spinocerebellar ataxias) or where systems other than the nervous system are significantly involved (e.g. mitochondrial disorders and porphyrias). Many of these disorders have been covered elsewhere in this book and will not be dealt with in this section which will concentrate on the first group where the neuropathy is the sole or primary part of the disease.

Charcot–Marie–Tooth disease and related disorders

CMT disease is a group of neuropathies that are clinically and genetically heterogeneous. They are also referred to as hereditary motor and sensory neuropathies (HMSN) although CMT is now the more commonly used term. CMT is characterized clinically by distal muscle wasting and weakness, reduced reflexes, impaired distal sensation and variable foot deformity, and neurophysiologically by a motor and sensory neuropathy. There is a wide variation in the age of onset and the severity of CMT, the variation depending to a large extent on the underlying genetic defect. Traditional clinical classifications differentiate between CMT (which has both motor and sensory involvement; Table 9.6), HSAN (more sensory and autonomic and less motor; Table 9.7) and dHMN (only motor; Table 9.8). Certain forms of CMT and HSAN are very difficult to distinguish clinically. Some recently described causative genes for axonal CMT also cause forms of dHMN. Therefore, the same phenotypes may be caused by different genes and the same gene may cause different phenotypes. Technology is not yet advanced enough to allow the rapid screening in an individual patient of all genes identified so far. Therefore, a classification system (Table 9.6) based on clinical features of neurophysiology and neuropathology as well as the genetic cause, when known, is the most useful current classification for the practising clinician.

An approach to the diagnosis of CMT and related disorders

1 *Is the neuropathy hereditary?* Where a patient attends with an obviously affected family member or there is a positive family history, a genetic neuropathy is likely. Unfortunately, many patients are from small families (especially UK, USA and North European) and extensive family histories are not available. Furthermore, rates of non-paternity in Western societies are at least 10%. Factors that may help the clinician decide that the neuropathy in 'sporadic' patients is hereditary include:

(a) A long, slowly progressive history.

(b) The presence of foot deformity such as pes cavus in an adult patient (Figure 9.9).

(c) The absence of positive sensory symptoms in patients with clear sensory signs.

(d) In the demyelinating forms of CMT (CMT1), neurophysiology can be very useful in distinguishing hereditary from acquired neuropathies as the motor conduction velocities are usually uniformly slow in the common hereditary neuropathies.

2 *Classifying the neuropathy*. Is the neuropathy most compatible with CMT, hereditary neuropathy with liability to pressure palsies (HNPP), HSAN or dHMN?

(a) CMT is numerically the most likely diagnosis.

(b) CMT is a motor *and* sensory neuropathy although the patients may not have sensory symptoms and sometimes no sensory signs (the most sensitive sensory sign is a reduction in distal vibration sensation).

(c) Because dHMN (Table 9.8) can be indistinguishable clinically from CMT it is often necessary to perform a neurophysiological examination to differentiate between these two conditions. The sensory action potentials (SAPs) should always be involved (reduced or absent) in CMT and normal in dHMN.

Table 9.6 Classification of Charcot–Marie–Tooth (CMT) disease.

Type	Gene/locus	Specific phenotype
Autosomal dominant CMT1 (AD CMT1)		
CMT1A	Dup 17p (PMP22)	Classic CMT1
	PMP22 (point mutation)	Classic CMT1/DSD/CHN
CMT1B	MPZ	CMT1/ DSD/CHN/CMT2
CMT1C	LITAF	Classic CMT1
CMT1D	EGR2	Classic CMT1/DSD/CHN
CMT1	NEFL	CMT2 but can have slow MCVs in CMT1 range +/– early onset severe disease
Hereditary neuropathy with liability to pressure palsies (HNPP)		
HNPP	Del 17p (PMP-22)	Typical HNPP
	PMP-22 (point mutation)	Typical HNPP

Table 9.6 *Continued*

Type	Gene/locus	Specific phenotype
X-linked CMT1 (CMT 1X)		
CMT1X	GJB1	Males CMT1 (+/– patchy MCVs)/females CMT2
Autosomal recessive CMT1 (AR CMT1)		
CMT4A	GDAP1	CMT1 or CMT2 usually early onset and severe / vocal cord and diaphragm paralysis described / rare AD CMT2 families described
CMT4B1	MTMR2	Severe CMT1/facial/bulbar/focally folded myelin
CMT4B2	MTMR13	Severe CMT1/glaucoma/focally folded myelin
CMT4C	KIAA1985	Severe CMT1/scoliosis/cytoplasmic expansions
CMT4D (HMSNL)	NDRG1	Severe CMT1/gypsy/deafness/tongue atrophy
CMT4E	EGR2	CMT1/DSD/CHN phenotype
CMT4F	Periaxin	CMT1/more sensory/focally folded myelin
CCFDN	CTDP1	CMT1/gypsy/cataracts/dysmorphic features
HMSN Russe	10q22–q23	CMT1
AR CMT1	PMP22 (point mutation)	Classic CMT1/DSD/CHN
AR CMT1	MPZ	CMT1/DSD/CHN/CMT2
Autosomal dominant CMT2 (AD CMT 2)		
CMT2A	KIF1Bβ	Classic CMT2
CMT2A	MFN2	Classic CMT2/more progressive/optic atrophy
CMT2B	RAB7	CMT2 with predominant sensory involvement and sensory complications
CMT2C	12q23–q24	CMT2 with vocal cord and respiratory involvement
CMT2D	GARS	CMT2 with predominant hand wasting/weakness or dHMN-V
CMT2E	NEFL	CMT2 but can have slow MCVs in CMT1 range +/– early onset severe disease
CMT2F	HSP27	Classic CMT2 or dHMN-II
CMT2G	12q12–q13.3	Classic CMT2
CMT2L	HSP22	Classic CMT2 or dHMN-II
CMT2	MPZ	CMT1 or CMT2
CMT2 (HMSNP)	3q13.1	CMT2 with proximal involvement
Autosomal recessive CMT2 (AR CMT2)		
ARCMT2A	LMNA	CMT2 proximal involvement and rapid progression described/also causes muscular dystrophy/cardiomyopathy/lipodystrophy
ARCMT2B	LINKAGE	Typical CMT2
ARCMT2	GDAP1	CMT1 or CMT2 usually early onset and severe/vocal cord and diaphragm paralysis described/rare AD CMT2 families described
X-linked CMT2		
CMT 2X	Xq24–q26	CMT2 with deafness/mental retardation
Dominant intermediate CMT (DI-CMT)		
DI-CMTA	10q24.1–25.1	Typical CMT
DI-CMTB	DNM2	Typical CMT
DI-CMTC	YARS	Typical CMT
Hereditary neuralgic amytrophy		
HNA	SEPT9	Recurrent neuralgic amyotrophy

AD, autosomal dominant; AR, autosomal recessive; CCFDN, congenital cataract with facial dysmorphism and neuropathy; CTDP1, CTD phosphatase 1; Cx32, connexin 32; Del, deletion; DMN2, dynamin 2; Dup, duplication; EGR2, early growth response 2; GARS, glycyl-tRNA synthetase; GDAP1, ganglioside-induced differentiation-associated protein 1; HSP 22, heat shock 22 kDa protein 8; HSP 27, heat shock 27 kDa protein 1; LITAF, lipopolysaccharide-induced tumour necrosis factor; LMNA, Lamin A/C; KIAA1985, KIAA1985 protein; KIF1Bβ, Kinesin family member 1B-β; MFN2, Mitofusin 2; MPZ, myelin protein zero; MTMR2, myotubularin-related protein 2; MTMR13, myotubularin-related protein 13; NDRG1, N-myc downstream-regulated gene 1; NEFL, neurofilament, light polypeptide 68 kDa; PMP-22, peripheral myelin protein 22; PRX, periaxin; SEPT9, septin 9; RAB7, RAS-associated protein RAB7; YARS, tyrosyl-tRNA synthetase.

Table 9.7 Classification of the hereditary sensory and autonomic neuropathies (HSAN).

Type	Inheritance	Gene/locus	Specific phenotype
HSAN I	AD	SPTLC1	Mainly sensory, sensory complications Occasionally motor early, males more severe
CMT2B	AD	RAB7	Sensorimotor, sensory complications, no pain
HSAN 1	AD	3p24–p22	Sensory, cough, gastroesophageal reflux
HSAN II	AR	HSN2	Severe sensory complications, mutilations Onset first two decades
HSAN III	AR	IKBKAP	Familial dysautonomia or Riley–Day syndrome Prominent autonomic, absence fungiform papillae of the tongue
HSAN IV	AR	NTRK1	Congenital insensitivity to pain with anhydrosis (CIPA) with severe sensory involvement, anhydrosis, mental retardation Unmyelinated fibres mainly affected
HSAN V	AR	NTRK1	Congenital insensitivity to pain with mild anhydrosis No mental retardation Small myelinated fibres mainly affected
HSAN V	AR	NGFB	Congenital insensitivity to pain, minimal autonomic No mental retardation Mainly unmyelinated fibres affected
Channelopathy associated insensitivity to pain	AR	SCN9A	Congenital insensitivity to pain

AD, autosomal dominant; AR, autosomal recessive; HSN2, HSN2 gene; IKBKAP, IκB kinase complex-associated protein; NGFB, nerve growth factor beta gene; NTRK1, tyrosine kinase A receptor; SCN9A, sodium channel 9A; SPLTC1, serine palmitoyltransferase, long chain base subunit-1.

Table 9.8 Classification of the distal hereditary motor neuropathies (dHMN).

Type	Inheritance	Gene/locus	Specific phenotype
HMN I	AD	Unknown	Juvenile onset dHMN
HMN II	AD	HSP27	Adult onset typical dHMN/CMT2F
HMN II	AD	HSP22	Adult onset typical dHMN/CMT2L
HMN III	AR	11q13	Early onset, slowly progressive
HMN IV	AR	11q13	Juvenile onset, diaphragmatic involvement
HMN V	AD	GARS	Upper limb onset, slowly progressive/CMT2D
HMN V	AD	BSCL2	Upper limb onset, +/– spasticity lower limbs
HMN VI	AR	IGHMB2	Spinal muscle atrophy with respiratory distress (SMARD1), infantile onset respiratory distress
HMN VII	AD	2q14	Adult onset, vocal cord paralysis
HMN VII	AD	DCTN1	Adult onset, vocal cord paralysis/facial weakness
HMN/ALS4	AD	SETX	Early onset, pyramidal signs
HMN-J	AR	9p21.1–p12	Juvenile onset, pyramidal features, Jerash

BSCL2, Berardinelli–Seip congenital lipodystrophy gene; DCTN1, dynactin1; GARS, glycyl-tRNA synthetase; HSP 22, heat shock 22 kDa protein 8; HSP 27, heat shock 27 kDa protein 1; IGHMB2, immunoglobulin μ binding protein 2; SETX, sentaxin.

(d) The neuropathy of HNPP is usually easily distinguished from CMT as the patient normally has a history of recurrent pressure palsies but later accumulates neurological deficits. The neurophysiological findings are usually patchier in HNPP than in the common forms of CMT1.
(e) Most forms of HSAN (Table 9.7) have more sensory and autonomic involvement and less motor involvement than CMT. The presence of neuropathic pain makes HSAN1 more likely and is a useful differentiating feature.

Charcot–Marie–Tooth disease

CMT disease is the most common of the hereditary neuropathies. The classification of CMT is in a state of constant flux reflecting the rapid advances in the identification of the underlying

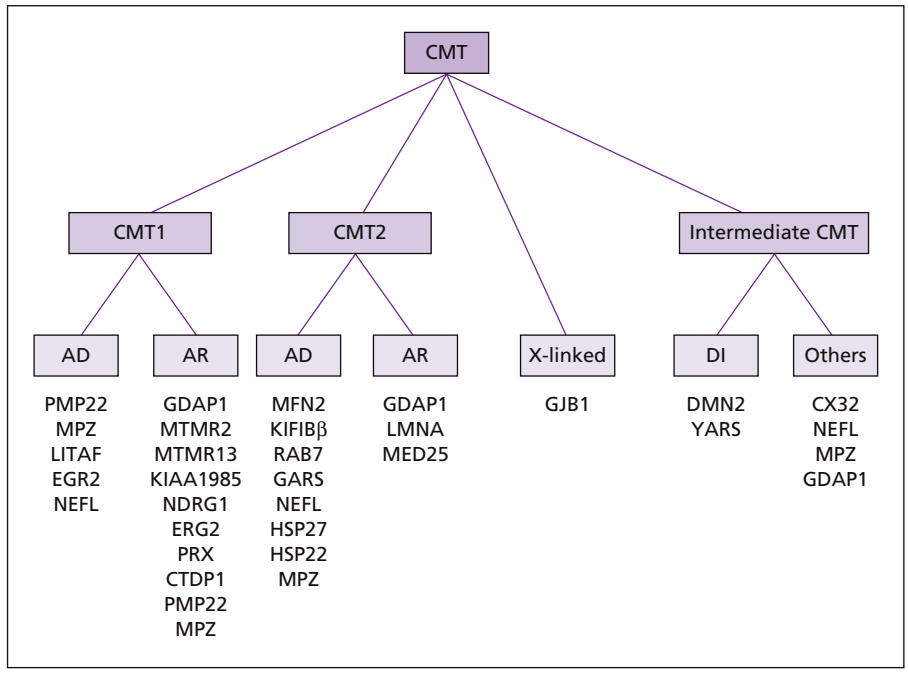

Figure 9.11 Current known causative genes for Charcot–Marie–Tooth (CMT) disease. AD, autosomal dominant; AR, autosomal recessive; CTDP1, CTD phosphatase, subunit 1; DI, dominant intermediate; DMN2, dynamin 2; EGR2, early growth response 2; GARS, glycyl-tRNA synthetase; GDAP1, ganglioside-induced differentiation-associated protein 1; GJB1, gap junction protein, beta 1; HSP 22, heat shock protein 22 kDa protein 1; HSP 27, heat shock protein 27 kDa protein 8; KIAA1985, KIAA1985 protein; KIF1Bβ, kinesin family member 1B-β; LITAF, lipopolysaccharide-induced tumour necrosis factor; LMNA, lamin A/C; MED25, mediator of RNA polymerase II, subunit 25; MFN2, mitofusin 2; MPZ, myelin protein zero; MTMR2, myotubularin-related protein 2; MTMR13, myotubularin-related protein 13; NDRG1, N-*myc* downstream-regulated gene 1; NEFL, neurofilament, light polypeptide 68 kDa; PRX, periaxin; PMP-22, peripheral myelin protein 22; RAB7, RAS-associated protein RAB7; YARS, tyrosyl-tRNA synthetase.

causative genes (Figure 9.11). Despite the rapid genetic advances the most useful method of classification for clinicians is a combination of clinical presentation, neurophysiology and inheritance pattern.

CMT is classified as either demyelinating (CMT1) if the median (or ulnar) nerve motor conduction velocity (MCV) is <38 m/s or axonal (CMT2) if the median MCV is >38 m/s (Table 9.5). The concept of an intermediate form of CMT with median MCVs in the intermediate range (25–45 m/s) has been around since the 1970s and although sometimes out of favour it can be helpful in directing genetic diagnosis.

The inheritance pattern may not be clinically obvious until a genetic diagnosis has been established as de novo autosomal dominant (AD) mutations, autosomal recessive (AR) mutations and other factors may obscure it. In most UK, north European and US populations where there are few consanguineous marriages, about 90% of cases of CMT are either AD or X-linked; the social background of the population should always be taken into account.

Autosomal dominant CMT1

Classic CMT1

The most common form of CMT in most populations is AD CMT1 and most patients present with a 'classic CMT' phenotype in the first two decades with motor symptoms in the lower limbs, e.g. difficulty walking or foot deformity. On examination, they have evidence of distal wasting and weakness and hyporeflexia affecting the lower limbs to a greater extent than the upper limbs. Distal sensory loss and foot deformity are frequent findings. Neurophysiologically, the median MCVs are <38 m/s and the SAPs are either reduced or absent. Nerve biopsies are no longer necessary to make the diagnosis but if performed show a demyelinating neuropathy with classic onion bulbs (Plate 9.1).

If there is a clear family history of AD inheritance, or if the patient is apparently 'sporadic', then the most likely diagnosis is CMT1A secondary to duplication of the peripheral myelin protein 22 gene (*PMP22*). In a European population this duplication accounts for 70% of all CMT1 cases. Mutations in the *PMP22* gene can also cause CMT1A but a wider spectrum of phenotypes is described.

CMT1B is less common and is caused by mutations in the myelin protein zero gene (*MPZ*). Patients may present with the classic CMT1 phenotype but are more likely to present with either a more severe, early onset form of CMT1 or a much milder, late onset form of CMT with median MCVs in the axonal range. As a result *MPZ*-related CMT can be classified as intermediate CMT.

Mutations in *EGR2* and *LITAF* are very rare and account for less than 1% of cases each and have no particular distinguishing features. Mutations in *NEFL* (neurofilament light polypeptide) were originally described as a cause of CMT2. Some patients with *NEFL* mutations have median MCVs in the demyelinating range and so *NEFL*-related CMT could be classified as intermediate CMT.

Severe CMT1 (HMSN III, Dejerine–Sottas disease, congenital hypomyelinating neuropathy)

The severe cases of CMT1 used to be called HMSN III in older classifications and were subdivided into Dejerine–Sottas disease (DSD) and congenital hypomyelinating neuropathy (CHN) depending on the underlying pathology. They usually present in

the first decade with very slow MCVs and a more severe neuropathy than classic CMT1. It was thought that most of these cases were recessive but we now know they are usually secondary to de novo dominant mutations in the three genes that commonly cause CMT1 (*PMP22*, *MPZ*, *EGR2*). Mutations in these three genes, which cause the DSD/CHN phenotype, can also occasionally be inherited in an autosomal recessive fashion (Table 9.6).

Hereditary neuropathy with liability to pressure palsies

HNPP is an autosomal dominant condition usually caused by a deletion of the same portion of chromosome 17 duplicated in CMT1A. Point mutations in *PMP22* can also rarely cause HNPP. Most patients with HNPP present with episodic recurrent pressure palsies, although atypical presentations have been described. Diagnostically, an important point is that although patients may present with only one nerve clinically involved at a particular time, there is always a more generalized patchy demyelinating neuropathy neurophysiologically. Screening for the chromosome 17 deletion is therefore not warranted in isolated pressure palsies that do not have electrophysiological abnormalities outside the clinically involved nerve.

X-linked CMT1

The X-linked form of CMT1 is caused by mutations in the gap junction β1 gene (*GJB1*) which codes for connexin 32 (Cx32). This is the second most common form of CMT. Over 300 mutations have been described in *GJB1*. Males are more severely affected than females. The MCVs in affected males are usually in the demyelinating range. Conversely, the MCVs in the females are usually in the axonal range but can be in the demyelinating range. Connexin 32 related CMT is therefore another form of intermediate CMT.

Patients (especially males) can have a rather patchy neuropathy both clinically and neurophysiologically with less uniform conduction slowing, differences in conduction velocities between nerves (e.g. ulnar and median) and more pronounced dispersion than that seen with AD CMT1. This can lead to difficulties in diagnosis in patients without a family history and occasionally to patients being diagnosed with CIDP leading to unnecessary immunosuppressive therapy. CNS involvement is occasionally seen and is usually mild (extensor plantars, mild deafness, abnormal brainstem evoked potentials).

Autosomal recessive CMT1

In communities where consanguinity is high AR CMT may account for 30–50% of all CMT cases. There are now 10 genes described that can cause AR CMT1 (including the three genes *PMP22*, *MPZ* and *EGR2* that more commonly cause AD or de novo dominant CMT1). Unfortunately, there is no one gene that is a major cause of AR CMT1 which makes the diagnosis difficult for the clinician presented with a patient with presumed AR CMT1. Further confusion arises as AR CMT1 is called CMT4 in the genetic literature and hence the various forms of AR CMT1 are also classified as CMT4A, CMT4B, and so on.

Although no one algorithm is suitable for the diagnosis of AR CMT1, there are some simple clinical rules that can be used to aid diagnosis:

1 As a general rule, AR forms of CMT have an earlier onset and are more severe than AD cases. They usually start as a length dependent neuropathy but are more likely to progress to involve the proximal muscles and to result in loss of ambulation than AD patients. Associated clinical features, the ethnic background of patients and specific neuropathological features can aid the diagnosis (Table 9.6).

2 Neurophysiology may be difficult, as in severe cases all the nerves may be unexcitable. In these cases nerve biopsies can be particularly useful. Biopsy is also useful in AR CMT1 in general as specific features in nerve biopsies may make a particular genetic diagnosis more likely. This is the major diagnostic use for nerve biopsy in genetic neuropathies.

3 Specific phenotypes in AR CMT1 (CMT4) are recognized:

(a) CMT4A secondary to mutations in *GDAP1* is usually an early onset progressive neuropathy and can be associated with diaphragmatic and vocal cord involvement. Mutations in *GDAP1* can also cause AR CMT2 making *GDAP1*-related CMT another intermediate form of CMT.

(b) Nerve biopsies showing focally folded myelin are characteristic of CMT4B1 (*MTMR2* mutations) and CMT4B2 (*MTMR13* mutations) although this finding has also been described with *MPZ* mutations and in CMT4F secondary to periaxin mutations.

(c) Severe and early scoliosis is seen with CMT4C because of mutations in the *KIAA1985* gene. Patients with mutations in this gene also have characteristic nerve biopsy features including basal membrane onion bulbs and multiple cytoplasmic processes of the Schwann cells of unmyelinated axons.

(d) Three forms of AR CMT1 are largely confined to patients of Balkan Romany origin. CMT4D secondary to *NDRG1* mutations is characterized by a demyelinating neuropathy with a high incidence of deafness. Tongue atrophy has also been described in this form of CMT. Another form of AR CMT1 seen in this Romany population is CCFDN (congenital cataract, facial dysmorphism and neuropathy syndrome) secondary to *CTDP1* mutations. The gene for the third form of CMT in this population, HMSN Russe, has not been identified yet.

(e) A phenotype ranging from a severe DSD type phenotype to a milder neuropathy with mainly sensory involvement is seen in CMT4F secondary to periaxin mutations.

To summarize, although there are many different genes identified as causing AR CMT1 careful phenotyping of the patients together with consideration of the ethnic background can help guide the genetic diagnosis.

Autosomal dominant CMT2

The true prevalence of CMT2 is not known. However, any adult presenting with a long-standing mild axonal neuropathy without an obvious family history and where an acquired cause has not

been identified may have a CMT2 but this is difficult to prove. Eight causative genes for AD CMT2 have been described (Table 9.6). These still account for only about 25% of the total cases of AD CMT2 and until all the causative genes for CMT2 are identified, we will not know the true prevalence of this condition.

Autosomal dominant CMT2 can be divided into three different groups by phenotype which can be used to direct genetic testing.

1 Most patients with AD CMT2 present with the 'classic CMT' phenotype, indistinguishable from AD CMT1. The neurophysiology revealing an axonal sensorimotor neuropathy distinguishes between the two. Nerve biopsies are rarely performed in patients with AD CMT2 as a non-diagnostic axonal neuropathy is usually described. The major cause of the classic phenotype are mutations in mitofusin 2 (*MFN2*) causing CMT2A. Mutations in this gene account for approximately 20% of all cases of AD CMT2 in all populations tested so far. Furthermore, approximately 20% of the mutations are de novo, explaining why so many of these patients have normal parents. Patients with mutations in *MFN2* can also present early and with a more severe phenotype with fairly rapid progression to proximal muscle involvement and loss of ambulation. Occasionally, patients may have brisk reflexes. Mutations in *MFN2* also cause axonal CMT with optic atrophy (HMSN VI in previous classifications). In patients with classic AD CMT2 and no mutation in *MFN2* both *MPZ* and *NEFL* should be screened as they can cause this phenotype. Two recently described heat shock protein genes (*HSP27* and *HSP22*) may also rarely cause the classic CMT2 phenotype. These two genes are of additional interest as they can also cause a purely motor phenotype, dHMN type II (Table 9.8; i.e. same gene, different phenotype).

2 The second phenotype seen with AD CMT2 has much more sensory involvement than is usually seen with CMT. These patients have been described as having an 'autosomal dominant inherited neuropathy with prominent sensory loss and ulceromutilating features'. They were originally classified as CMT2B. Presentation is in the second or third decade with typical motor CMT features but also severe sensory complications including ulcerations, osteomyelitis and amputations. The causative gene for CMT2B is *RAB7*. The presentation of these patients is also very similar to patients with HSAN1 secondary to mutations in the *SPTLC1* gene (Table 9.7; i.e. different genes, same phenotype). Patients with *SPTLC1* mutations usually have less motor involvement at presentation and also lancinating pain, an unusual feature in hereditary neuropathies. Sometimes conduction velocities can be in the demyelinating range and males are often severely affected. There remain other families with this phenotype who do not have mutations in either *SPTLC1* or *RAB7*, suggesting other unidentified genes can also cause this phenotype.

3 The third phenotype seen with AD CMT2 is upper limb predominant CMT2, classified as CMT2D. Patients were originally described presenting with wasting and weakness of the small muscles of the hand (onset can also be unilateral and misdiagnosed as thoracic outlet syndrome) with much later involvement of the distal lower limb muscles. Interestingly, as with mutations in *HSP27* and *HSP22*, some of these patients had no sensory involvement and were classified as dHMN type V (Table 9.8). CMT2D and dHMN V have now been shown to be allelic. The causative gene is *GARS*. Some patients with the dHMN V phenotype (no sensory involvement) have also been described to have mutations in the *BSCL2* gene which usually causes Silver syndrome (spastic legs and distal amyotrophy of the upper limbs) but can present in 33% of cases with just amyotrophy of the upper limbs. Other families have been described with this phenotype that do not have mutations in either *GARS* or *BSCL2*.

Autosomal recessive CMT2

There are only two causative genes for AR CMT2 (Table 9.6). Mutations in lamin A/C (*LMNA*) cause AR CMT2A. Moroccan and Algerian families were reported with this phenotype. Most patients present in the second decade with a severe CMT phenotype including proximal muscle involvement although some patients have been reported with a milder phenotype. Lamin A/C mutations have been associated with a wide spectrum of phenotypes including Emery–Dreyfuss muscular dystrophy, cardiomyopathy, Dunniugan-type familial partial lipodystrophy and many others.

The second form of AR CMT2, AR CMT2B, has only been described in one Costa Rican family and the gene for this has yet to be identified. The phenotype of AR CMT2B is milder than seen with the other AR CMT2 genes and is more like classic CMT2.

Mutations in *GDAP1* have been described above as a cause of AR CMT1 (CMT4A) but they can also cause AR CMT2 with a similar severe early onset phenotype which can include vocal cord paresis.

X-linked CMT2

One X-linked form of CMT2 has been described linked to Xq24-Q26, but no gene has been identified for this.

Dominant intermediate CMT

It is increasingly recognized that many forms of CMT can present with MCVs in the intermediate range as discussed above. These include patients with X-linked CMT resulting from *GJB1* mutations, patients with AD CMT caused by *MPZ* or *NEFL* mutations and patients with AR CMT caused by *GDAP1* mutations. In addition to these forms of intermediate CMT, two genes have recently been described (*DNM2* and *YARS*) that cause classic CMT with intermediate MCVs and these have been classified as dominant intermediate CMT (Table 9.6).

Hereditary sensory and autonomic neuropathy

HSAN are much rarer than CMT but many of the genes for these disorders have been identified (Table 9.7).

Generally, these disorders are characterized by prominent sensory and autonomic involvement and less motor involvement than CMT. The sensory involvement can be severe and result in

mutilating injuries. Education of the patients to try to prevent these complications is crucial.

HSAN1 secondary to *SPTLC1* mutations has already been described above. This disease is more appropriately termed HSN as there is usually no autonomic involvement. All other forms of HSAN are rare. HSAN II is an early onset, autosomal recessive, severe sensory neuropathy with prominent sensory complications and is caused by mutations in the *HSN2* gene.

Riley–Day syndrome is a distinct autosomal recessive neuropathy seen in Ashkenazi Jews and characterized by mainly autonomic involvement but it also involves the PNS, particularly the sensory nerves. The causative gene is the *IKBKAP* gene. Presentation is often in infancy or childhood with poor feeding, swallowing difficulties and recurrent chest infections.

HSAN IV and V are both AR neuropathies characterized by congenital insensitivity to pain. HSAN IV (also called congenital insensitivity to pain with anhydrosis [CIPA]) presents with a severe sensory neuropathy, anhydrosis and mental retardation and is caused by mutations in the *NTRK1* gene, a receptor for nerve growth factor. HSAN V is similar but without the mental retardation or significant anhydrosis. This phenotype has been described with both *NTRK1* mutations and also with *NGFB* mutations. A recent development in the hereditary sensory neuropathies has been the identification of homozygous mutations in the gene (*SCN9A*) for the voltage-gated sodium 1.7 channel ($NA_v1.7$) in a form of HSAN resembling type V and termed channelopathy-associated insensitivity to pain.

Distal hereditary motor neuropathies

The dHMNs are a complex group of disorders (Table 9.8) also referred to as distal spinal muscular atrophies (distal SMA). Forms that resemble CMT are discussed above.

Distal HMN II is the classic form of AD dHMN and is caused by mutations in the *HSP27* and *HSP22* genes. These patients present with classic CMT but without any sensory involvement. Distal HMN I (no gene identified) is a similar AD disorder but with earlier onset. There are many other forms but the genes are only known for a few of these. Mutations in *GARS* and *BSCL2* cause dHMN V as described above.

Distal HMN VI is an unusually severe AR form of dHMN that presents in infancy with respiratory and distal limb involvement (called spinal muscle atrophy with respiratory distress type 1 [SMARD1]) and is caused by mutations in the *IGHMBP2* gene.

Mutations in dynactin (*DCTN1*) cause one of two forms of dHMN type VII, which is characterized by vocal cord paralysis and progressive weakness and atrophy of the face, hands and legs. Another very similar form, also called dHMN VII with vocal cord paralysis has been mapped to a different locus.

Finally, missense mutations in sentaxin (*SETX*) can cause a form of dHMN with pyramidal features. Nonsense mutations in the same gene cause autosomal recessive ataxia oculomotor apraxia type 2 (AOA2).

As can be seen in Table 9.8, there are other forms of dHMN described for which no causative genes have yet been identified.

Hereditary neuralgic amyotrophy

HNA is an autosomal dominant condition caused by mutations in the Septin 9 gene and characterized by recurrent episodes of typical brachial neuritis. The attacks are characterized by pain, weakness and sensory disturbance in the brachial plexus distribution. These attacks are indistinguishable from sporadic brachial neuritis but are recurrent, often starting in childhood.

Importance of a genetic diagnosis in CMT and related disorders

A major issue throughout the world is the lack of availability of testing for the rarer genes causing CMT and related disorders. Many countries offer routine diagnostic testing for the common CMT1 (chromosome 17 duplication, *PMP22*, *MPZ*, *Cx32*) and CMT2 (*MFN2*) genes. Most of the other genes are only available through research laboratories.

An accurate genetic diagnosis is extremely important for these patients. There are obvious benefits including diagnostic testing for other family members, accurate genetic counselling and prognosis, predictive and antenatal testing but an accurate diagnosis also prevents patients from having invasive diagnostic tests, e.g. nerve biopsies and lumbar punctures. In certain situations where inflammatory neuropathies are being considered a genetic diagnosis can prevent a trial of potentially dangerous immunosuppressive therapy.

The era of treatment for genetic neuropathies is here. The first therapeutic trials in CMT have just begun (ascorbic acid for CMT1A) and it seems likely that any treatments developed (at least at the trial stage) will be gene specific, making the case for an accurate genetic diagnosis even more convincing.

Familial amyloid polyneuropathy

FAP is an autosomal dominant condition first described in Portugal in 1952. The amyloidoses are characterized by deposition of a fibrillar β-pleated protein in the extracellular space of many organs. Only AL (light chain) amyloidosis and FAP cause a generalized neuropathy with autonomic involvement. AL amyloid is discussed below. Within the familial amyloidoses there are three different forms of FAP classified by the constituent amyloid-forming protein: transthyretin (TTR), apolipoprotein A-1 (Apo A-1) and gelsolin.

Transthyretin-related familial amyloid polyneuropathy

Clinical features

The cardinal clinical features of TTR-related FAP are of a sensory motor peripheral neuropathy usually with autonomic involvement, a cardiomyopathy and to a lesser extent vitreous involvement. Other systems can be involved. Over 80 mutations in TTR have been described, the most common of which is the index Met30 point mutation. Clinical features do not always correlate well with a specific mutation.

Patients with TTR Met30 usually present with painful dysaesthesia in the lower limbs progressing to a severe mixed polyneuropathy. Early there is greater small fibre susceptibility giving rise

to lack of pain and temperature sensation, but eventually all sensory modalities are involved. Mutilating injuries can occur. Later motor involvement is universal, with upper limb involvement occurring months to years after lower limb manifestations. Carpal tunnel syndrome as a presenting feature is rare in TTR Met30. Autonomic involvement occurs frequently and can be severe and early.

Neurophysiological studies confirm an axonal neuropathy although SAPs may be normal early in the course of the disease, reflecting the mainly small fibre involvement. Cardiac involvement is common, presenting as an arrhythmia, heart block or heart failure, and amyloid deposition results in abnormal echocardiographic appearances. Vitreous involvement is more common in Swedish than Portuguese TTR Met30 patients and may be the presenting feature. Kidneys and, more rarely, pulmonary or bone involvement also occur.

Other common mutations include TTR Tyr 77 and TTR Ala 60. FAP TTR Tyr 77 has a high incidence of carpal tunnel syndrome but absent vitreous involvement. FAP TTR Ala 60 is mainly seen in patients of Irish descent and typically presents in the sixth decade with more prominent small and large fibre sensory loss than TTR Met30. Cardiomyopathy is a major and commonly a presenting feature.

CNS involvement in FAP TTR is very rare and, although postmortem studies have shown leptomeningeal amyloid deposition, this is usually asymptomatic. Oculoleptomeningeal amyloidosis (OLMA) is associated with TTR point mutations. The clinical features vary even within a kindred and include vitreous opacities, progressive dementia, stroke, subarachnoid haemorrhage, ataxia, hydrocephalus, seizures, spasticity and episodes of fluctuating consciousness often with focal neurological signs. The hallmarks of the CNS disease are meningeal enhancement of the brain and spinal cord on MRI and a raised CSF protein.

Pathology

The pathological changes in the PNS are similar in FAP and AL amyloidosis. The amyloid in the PNS appears as extracellular, amorphous, eosinophilic deposits, which are found both diffusely in the endoneurium and epineurium and surrounding endoneurial and epineurial blood vessels. They are also present in sensory and autonomic ganglia. In milder cases there is predominant loss of small myelinated and unmyelinated axons; at later stages larger myelinated fibres are also lost. The pathology is predominantly one of axonal degeneration with some regenerative activity. Segmental demyelination has also been described. Congo red staining has apple green birefringence under polarized light and under electron microscopy (EM) rigid 10–15 nm fibrils are seen (Plate 9.2).

Diagnosis

The most important step in the diagnosis of TTR-related FAP is having a clinical suspicion. It should always be considered in patients with a family history and a neuropathy and/or cardiomyopathy, carpal tunnel syndrome or vitreous deposits. The diagnosis should also be considered in patients with an unexplained small fiber neuropathy especially with autonomic involvement or a cardiomyopathy regardless of family history. Neurophysiologically, the neuropathy is an axonopathy and has no specific features.

The diagnosis of amyloid can be made by direct examination of biopsy material from rectum, peripheral nerve, heart, subcutaneous fat or other tissue depending on the presentation. Congo red staining with apple green birefringence under polarized light is the primary examination. Immunohistochemistry with monoclonal antibodies against TTR or the λ or κ light chains differentiates TTR amyloid from light chain amyloid but the method is neither 100% sensitive nor specific. Light chains should be sought by immunofixation in urine and serum if AL amyloid is suspected and the antibodies to TTR are negative.

Sequencing of the TTR gene is widely available for genetic testing and confirmation of a histopathological diagnosis. Predictive testing remains difficult because of uncertainties about the penetrance of certain mutations.

Once the diagnosis is made the extent and stage of the disease must be assessed by iodine-123 labelled serum amyloid protein scan, especially if liver transplantation (see below) is being considered.

Treatment

Ninety per cent of TTR is produced in the liver. Until the early 1990s the treatment of TTR-related FAP was limited to symptomatic treatments and rehabilitative measures. Since then liver transplantation has been used in the treatment of TTR-related FAP. More than 700 liver transplants have been performed for TTR-related FAP worldwide. The consensus is that liver transplantation halts or slows the progression of TTR-related FAP in most Met30 patients. The 1-year survival has improved from 70% to 90% and a preliminary 10-year survival of 73% following transplant has been reported. There is concern that patients with mutations other than Met30 do not do as well.

Although liver transplantation is the first treatment for TTR amyloidosis and should be considered in affected patients, it is associated with a significant mortality and other safer and more effective treatments are being researched but none is in routine use to date.

Prognosis

The average life expectancy for patients with untreated TTR-related FAP is about 10 years but varies with ethnicity, mutation and treatment. This figure is likely to improve further as the optimum conditions and timing for liver transplantation are determined and as newer genetic and chemotherapeutic treatments are developed.

Apolipoprotein A-1 related FAP

One type of FAP, originally described in an Iowa kindred, has been shown to be associated with deposition of a variant apolipoprotein A-1. The phenotype is similar to that of FAP TTR Met30 except for a higher incidence of renal amyloidosis and severe gastric ulcer disease.

Gelsolin-related FAP

Gelsolin amyloidosis was first described in a Finnish kindred. This usually presents in the thirties with corneal lattice dystrophy caused by amyloid deposition in the corneal branches of the trigeminal nerve. This is followed by a progressive cranial neuropathy. The facial nerve is the most common cranial nerve involved with the upper fibres as manifested by forehead muscle weakness initially being affected. Other cranial nerves may also be affected including the vestibulocochlear, hypoglossal and trigeminal with varying clinical manifestations. Peripheral nerve and autonomic involvement is usually mild.

The fibril protein in this type of amyloidosis is an abnormal fragment of a plasma protein, gelsolin, a calcium-binding protein that fragments actin filaments.

Acquired neuropathies

The acquired peripheral nerve diseases are a diverse group of conditions with a variety of pathogenic mechanisms. Some are primary peripheral nerve disorders affecting a single system. Many are disorders with multi-system dysfunction such as the neuropathies associated with diabetes, autoimmune diseases or toxic exposures. The inflammatory neuropathies, in their various guises, constitute the largest group of peripheral nerve disorders.

Inflammatory neuropathies

The inflammatory neuropathies (Table 9.9) are a diverse group of peripheral nerve disorders linked by their presumed immune-mediated pathogenesis. They are characterized pathologically by inflammatory infiltration of the peripheral nerves associated with destruction of myelin and/or axons. The inflammatory neuropathies are typified by the idiopathic demyelinating neuropathies, both chronic and acute, and the closely related neuropathies associated with paraproteinaemia. However, vasculitic, infectious and parainfectious, paraneoplastic and more recently diabetic plexopathy, amongst others, are included. Some of these may be thought of as primary disorders of the PNS (e.g. GBS and CIDP) and others secondary to a systemic immune process with subsequent

Table 9.9 Inflammatory neuropathies.

ACUTE

Guillain-Barré (GBS) variants

Acute inflammatory demyelinating polyradiculoneuropathy
Acute motor axonal neuropathy
Acute motor sensory axonalneuropathy
Fisher syndrome and other regional variants
- Pharyngeal-cervical-brachial
- Paraparetic
- Facial palsies
- Pure oculomotor

Functional variants of GBS
- Pure dysautonomia
- Pure sensory GBS
- Ataxic GBS

INTERMEDIATE

Subacute inflammatory demyelinating polyradiculoneuropathy

Vasculitic neuropathies (may present acutely, subacutely or chronically)

Primary vasculitis
- Polyarteritis nodosa
- Churg–Strauss syndrome
- Microscopic polyangiitis
- Wegener's vasculitis
- Non-systemic vasculitic neuropathy
- Giant cell arteritis

Systemic autoimmune diseases with associated vasculitis
- Rheumatoid arthritis
- Systemic lupus erythematosus
- Sjögren's syndrome
- Mixed connective tissue disease

Other vasculitis
- Diabetic and non-diabetic lumbosacral plexopathy

Other inflammatory neuropathies
- Serum sickness
- Infections (hepatitis B and C, HIV, Lyme disease), leprosy
- Malignancy (small cell lung cancer, lymphoma, leukaemia, renal and adenocarcinomas)
- Chemotherapy

Paraneoplastic
- Subacute sensory neuropathy/neuronopathy – small cell lung carcinoma and anti-Hu Abs
- Other paraneoplastic tumour–antibody syndromes

CHRONIC

Chronic inflammatory demyelinating polyradiculoneuropathy
Multifocal motor neuropathy with conduction block
Multifocal acquired demyelinating sensory and motor neuropathy
Chronic relapsing axonal neuropathy
Chronic ataxic sensory neuronopathy

CHRONIC, WITH PARAPROTEINAEMIAS

Monoclonal gammopathy of undetermined significance
Multiple myeloma
Solitary plasmacytoma
Lymphoma or chronic lymphocytic leukaemia
Waldenström's macroglobulinaemia
POEMS syndrome
Cryoglobulinaemia
Cold agglutinin disease

involvement of the peripheral nerves (e.g. the neuropathy associated with vasculitis and the connective tissue diseases).

Acute neuromuscular weakness and the inflammatory neuropathies

Acute neuromuscular weakness may be caused by disease of muscle, neuromuscular junction, peripheral nerve, roots or the CNS. The distinction between these sites of pathology can largely be made on clinical grounds, with supportive investigations where necessary (Chapters 3 and 19).

A differential diagnosis of acute inflammatory neuropathies exists (Table 9.9). By far the most common of these is GBS. The acute infectious neuropathies (poliomyelitis, diphtheria, HIV, tick paralysis) are dealt with in Chapter 8 and paraneoplastic neuropathies in Chapter 20.

Guillain–Barré syndrome and its variants

GBS is the most common cause of acute neuromuscular weakness in the developed world following the near eradication of polio, but certainly occurs worldwide. The incidence is about 1–2/100,000 population. There is no sex difference. It affects all ages including children and infants but is more frequent in older age groups. In some populations a seasonal variation in the incidence is reported coinciding with the seasonal incidence of predisposing infections (Table 9.10). In the developed world GBS is synonymous with acute inflammatory demyelinating polyradiculoneuropathy (AIDP) but axonal variants (occurring in 3–5% of cases in the developed world) are far more common in China, Japan and Mexico (see below).

Symptoms and signs

The diagnosis of GBS remains a clinical one, supported by investigations which may be normal in the early stages of disease. Patients present with a progressive ascending sensorimotor paralysis with areflexia, affecting one or more limbs and reaching a nadir in less than 4 weeks. Patients who progress beyond this time or present with 'recurrent GBS' are reclassified into subacute or chronic inflammatory demyelinating neuropathies (SIDP/CIDP, see below). Pain, cranial nerve involvement and autonomic disturbances with arrhythmias and labile blood pressure are often features. Papilloedema may occur, which if unrecognized and untreated may lead to blindness. A clinical diagnosis of GBS should be questioned if there is persistent asymmetrical weakness, bladder or bowel involvement or a sensory level suggestive of spinal cord pathology. Furthermore, the presence of a known toxin, HIV, diphtheria or tick exposure or neoplasia broadens the differential. In the first few days the examination may be normal and reflexes retained. However, some patients may progress to tetraparesis and require ventilation in as little as 48 hours and vigilance for either scenario is important. Functional variants exist with acute pure autonomic failure, pure sensory neuropathy and pure ataxic neuropathy described. Recognized regional variants (Table 9.9) are associated with particular serum antiganglioside antibodies (see below).

Table 9.10 Infections predisposing to Guillain–Barré syndrome.

Campylobacter jejuni
Cytomegalovirus
Mycoplasma pneumoniae
Epstein–Barr virus
HIV
Haemophilus influenzae

Investigations

Cerebrospinal fluid. In GBS the CSF is acellular or should contain <10 cells/mm^3. Ten per cent of patients have cell counts of 10–50 cells/mm^3 but these do not persist for more than a few days. Cell counts >50 cells/mm^3 should stimulate a search for an alternative diagnosis. Note that intravenous immunoglobulin (IVIG) can stimulate an aseptic meningitis and may provoke increased cell counts (as well as falsely raised CSF protein levels). CSF protein is usually raised for 4–6 weeks but may be normal in the first 7 days of illness and may also remain normal in a greater proportion of the regional variants (e.g. Fisher syndrome) than typical GBS. CSF pressure is typically normal but raised levels of CSF pressure and protein contribute to papilloedema.

Nerve conduction studies. In the correct clinical context, abnormalities of nerve conduction studies suggestive of patchy proximal and distal demyelination are highly suggestive of GBS. Nerve conduction tests may be normal in the first few days of illness. Typical changes of slowed motor nerve conduction velocities, with prolonged F-wave and distal motor latencies with largely preserved amplitudes are typical. Conduction block may be demonstrated. Early on the lower limb sensory action potentials are relatively preserved but they are later lost and electromyographic (EMG) evidence of denervation may emerge. Inexcitable nerves are common in severe cases and are unhelpful in diagnosis. Axonal changes without evidence of slowing are found in acute motor axonal and acute motor and sensory axonal neuropathies (AMAN and AMSAN) and these may indicate a worse prognosis.

Blood tests. Blood tests are unhelpful in the context of the diagnosis of GBS. However, they importantly serve to exclude major biochemical disturbances that may mimic GBS, identify coexistent disorders that may complicate treatment (e.g. renal failure and IVIG), and point to conditions that may cause a GBS-like illness (systemic lupus erythematosus [SLE], HIV, malignancy). All patients should have urea and electrolytes, calcium, magnesium, liver and thyroid function, full blood count, erythrocyte sedimentation rate (ESR), vitamin B_{12} and folate and antinuclear antibodies (ANA) checked.

Ten per cent of patients will have abnormal liver function tests, possibly the result of viral (Epstein–Barr virus [EBV] or cytomegalovirus [CMV]) hepatitis. Hyponatraemia occurs in a

proportion of patients caused both by syndrome of inappropriate antidiuretic hormone (SIADH) or an excess of atrial natriuretic factor.

Antiganglioside antibodies. Antiganglioside antibodies are frequently requested but seldom help in diagnosis. They are sometimes found more commonly associated with one or other of the regional GBS variants. In the acute neuropathies only IgG antibodies are of relevance. IgG anti-GQ1b antibodies are found in 90–95% of cases of Fisher syndrome and also a substantial proportion of cases of GBS with ophthalmoplegia. Anti-GD1a and anti-GalNAcGD1a antibodies are associated with AMAN. IgG anti-GM1 antibodies associate with more severe disease. Anti-GM2 antibodies sometimes follow CMV infection and seem to be associated with a predominantly sensory neuropathy. Ganglioside species share epitopes and therefore more than one antiganglioside activity is commonly found.

Campylobacter stool testing and serology. Serological testing with acute and convalescent serum may confirm seroconversion following infection with any of the infectious agents implicated in GBS causation. Stool should also be cultured for Campylobacter species. Its identification also has public health implications.

Lung function testing. Forced vital capacity (FVC) should be measured and recorded immediately on presentation and at least every 4 hours thereafter (more frequently if necessary) until the patient has begun to recover. Elective intubation should be considered if the FVC falls below 15 mL/kg.

Cardiac monitoring. A 12-lead ECG should be recorded and the patient monitored for arrhythmia and blood pressure fluctuations until stabilized and improving.

Nerve biopsy. Sural nerve biopsy is seldom helpful as much of the pathology in GBS is proximal and changes may take days to weeks to develop. In severe, unusual cases or cases unresponsive to treatment sural nerve biopsy may be helpful to exclude alternative diagnoses.

Variants of GBS

AMAN and AMSAN form a spectrum of axonal GBS. Although responsible for only 3–5% of cases of GBS in the western hemisphere, axonal variants may constitute up to 50% or more of GBS cases in China and South America. Here GBS occurs in seasonal summer outbreaks and is closely associated with *Campylobacter jejuni* infection. Anti-GD1a, GalNAcGD1a and GM1 antibodies occur frequently. The pathology involves direct macrophage attack on the axolemma resulting in profound axonal degeneration.

Limited and regional variants of GBS are shown in Table 9.9. Individual variants are rare but the combined incidence rate of all variants is about 7–13% of the incidence of GBS. Fisher syndrome, the triad of ataxia, areflexia and ophthalmoplegia is the most common variant accounting for between one-third and half of variant cases. There is a frequent association with *C. jejuni* infection. Up to 95% of cases are associated with anti-GQ1b antibodies. Fisher syndrome seldom progresses to require supportive or therapeutic treatment. Occasionally, a Fisher/GBS overlap syndrome or GBS with ophthalmoplegia may progress to full-blown weakness and thus it should be monitored and treated like GBS.

Other limited and regional variants are rare. The pharyngo-cervico-brachial variant involves predominantly the bulbar and upper limb musculature with weakness and areflexia but sparing the lower limbs. Anti-GT1a antibodies (sometimes cross-reacting with GQ1b) are often found. The pathophysiology is predominantly axonal. Paraparetic lower limb variants have been described as having pure motor and pure sensory or sensory ataxic forms. Acute dysautonomia has more recently been recognized in this group of conditions. It presents with profound postural hypotension and impaired sweating, impotence and bladder and bowel dysfunction. Antibodies to the nicotinic, ganglionic acetylcholine receptor have been described associated with this condition which improves with immunotherapy.

Pathogenesis

The infectious agents associated with GBS probably all display ganglioside-like epitopes on their surface. Immune responses to these epitopes cross-react with gangliosides displayed on nerve cells resulting in immune attack.

The pathogenic hallmark of typical GBS is macrophage-mediated attack of either the Schwann cell or the axolemma resulting in demyelination or axonal degeneration. The BNB becomes inflamed and leaky allowing for the ingress of activated T cells, IgG and complement. IgG and activated complement is found on actively degenerating cells. The inflammatory milieu stimulates up-regulation of MHC Class II receptors and antigen presentation by endoneurial cells including Schwann cells, promoting endoneurial damage.

Treatment

General treatment

1 Respiratory monitoring is essential. Elective endotracheal intubation may be life-saving with early conversion to tracheostomy for comfort and prevention of complications.

2 Cardiac monitoring in a high dependency unit setting should be performed in all patients while the diagnosis is being confirmed and until recovery begins. Arrhythmias and blood pressure fluctuations should be treated appropriately. Persistent or severe bradyarrhythmias may require the insertion of a pacemaker.

3 Anticoagulation (low molecular weight heparin), pressure stockings and calf massage devices as prevention against deep venous thrombosis (DVT) should be used routinely.

4 Fluid balance, nutrition and electrolyte monitoring. A nasogastric tube may be necessary for feeding, which may need to be supplemented. Hyponatraemia is more often brought about by

excess atrial naturetic factor (ANF) (with loss of salt *and* water) than SIADH.

5 Physiotherapy should start immediately with hand and foot splints to prevent contractures.

6 Excellent nursing care of the paralysed patient prevents many complications associated with immobility and recumbency (pneumonia, pressure sores, DVT) and should be the central point of all care. Detection and treatment of issues related to pain, emotion, continence, nutrition and mouth care are crucial.

Specific treatment

Plasma exchange was the first GBS treatment shown to have substantial benefit. It halves the need for ventilation, hastens recovery and improves outcome at 1 year if administered within 4 weeks of onset. Usually 4–5 3-L exchanges are given over the course of 10 days. More practically, IVIG 2 g/kg over 5 days is as effective as plasma exchange and more likely to be completed as it has fewer complications. No additional benefit has been shown for following plasma exchange with IVIG. No trial has been performed to examine the benefit of a second dose of IVIG 14 days after the first in cases of minimal or delayed response. Steroids are not indicated in the treatment of GBS.

Pain may be severe. Treat with combinations of high-dose anticonvulsants (gabapentin, pregabalin, carbamazepine) and tricyclic antidepressants or selective serotonin re-uptake inhibitors (SSRIs), in conjunction with opiates (e.g. fentanyl). Epidural anaesthesia is sometimes helpful.

Outcome

Despite many advances in therapeutics and intensive care, GBS remains a severe illness. Poor prognostic factors include advanced age, axonal degeneration in the context of AIDP and if the patient is ventilator-dependent or bed-bound at the nadir of the illness. Even with the best medical care 5–8% of patients die and about one-third are left with significant disability. The remainder make a good recovery and have few residual symptoms. Fatigue is an under-recognized and poorly treated residual outcome.

Chronic inflammatory neuropathies

The chronic inflammatory neuropathies include the idiopathic and those associated with other diseases, e.g. the paraproteinaemias and the vasculitides (Table 9.9). Although the latter group, especially the vasculitides and paraneoplastic disorders, may present more acutely and progress more rapidly, they are included here for convenience.

Chronic inflammatory demyelinating polyradiculoneuropathy

CIDP is an acquired, treatable, demyelinating PNS disease characterized by progressive or relapsing proximal and distal weakness of the limbs with sensory loss and/or cranial nerve involvement reaching a nadir in more than 8 weeks with absent or reduced reflexes in all limbs. Prevalence estimates vary at 1.2–7/100,000 population. Unlike GBS there are no known predisposing infections.

Symptoms and signs

The diagnosis of CIDP is clinical, supported by electrophysiological, CSF and other tests (see below) and the exclusion of other causative pathologies.

Patients with CIDP present with a progressive or relapsing limb weakness or numbness which may have an asymmetrical onset. Parasthesiae are common. Limb and back pain occurs but if prominent should stimulate a search for alternative causes especially vasculitis, lymphoma or infection. As with all demyelinating conditions a tremor may be prominent. Autonomic and bladder or bowel involvement is distinctly unusual. 'Recurrent GBS' should be classified as CIDP. Unusual forms can occur including monomelic paralysis, lower limb variants and sensory ataxic forms.

The clinical signs mirror the presentation. Proximal and distal weakness with areflexia and a distal sensory loss are normal and tremor occurs frequently. Wasting is not evident until late in untreated disease. Progression to respiratory involvement and need for ventilation occurs rarely.

A careful general examination is crucial to identify systemic causes or contributing factors (e.g. malignancy, pre-existing CMT, SLE and other connective tissue diseases, diabetes or alcohol).

Investigations

The European Federation of Neurological Sciences and the Peripheral Nerve Society have published criteria for essential and supportive investigations.

1 *Nerve conduction studies.* Clear demonstration of demyelination in at least two nerves is mandatory for a definite diagnosis of CIDP if no other supportive criteria are employed. Demyelinating features of reduced motor conduction velocity, prolonged distal motor latencies or proximal F-waves or conduction block or dispersion, all in the presence of relatively preserved compound muscle action potentials are acceptable. Later in the condition axonal degeneration may supervene.

2 *CSF.* The CSF protein is raised in 90% of cases. A CSF white cell count of >10 mm^3 should prompt a search for alternative causes.

3 *MRI.* Nerve root enlargement and/or enhancement with gadolinium is often seen. Most commonly imaged areas include the cervical and lumbosacral regions. MRI findings are now included in the supportive criteria for the diagnosis.

4 *Nerve biopsy.* A diagnosis of CIDP does not always require a nerve biopsy as the clinical presentation, neurophysiology and other less invasive paraclinical investigations are usually sufficient to make a diagnosis. Furthermore, complications include a 10–30% risk of permanent dysaesthesia at the biopsy site and other routine surgical complications of wound healing and infection. Although the sural nerve is the most commonly biopsied, a suitable nerve should be selected on the basis of symptoms and electrophysiological findings; only very rarely should an electrically 'normal' nerve be biopsied.

Biopsies contain reduced numbers of myelinated nerve fibres with evidence of active demyelination or previous onion bulb

formation (Plate 9.3). Endoneurial macrophage activity is usually increased and endoneurial T cells are present in increased numbers. Unequivocal diagnostic findings in the correct clinical context are macrophage-associated demyelination on EM, evidence of demyelination or remyelination in five fibres by EM or demyelinated segments of at least 20 fibres in teased preparations.

5 *Blood tests.* There are no diagnostic blood tests for CIDP. Full blood count, ESR, B_{12} and folate, urea and electrolytes, glucose, liver and thyroid function tests, immunoglobulins, protein electrophoresis and immunofixation and ANA should be requested as an initial screen to rule out other conditions.

6 *Exclusion of other conditions.* Exclusion of other causative or contributing conditions is essential. Coexistent CMT disease should be considered and genetic tests requested as necessary.

CIDP variants

Multi-focal motor neuropathy with conduction block

Multi-focal motor neuropathy with conduction block (MMNCB) is a progressive immune-mediated demyelinating motor neuropathy which often begins asymmetrically in the upper limbs. Weakness in the distribution of individual nerves, often with prominent cramps but without wasting or fasciculation, and patchy reduced reflexes are the most usual signs. Wasting and fasciculation can occur later which causes confusion with motor neurone disease. Subjective sensory symptoms can occur but no more than minor disturbance of vibration sense at the ankle is acceptable on examination. Cranial nerve or respiratory involvement are extremely rare and upper motor neurone, sphincter or marked bulbar involvement exclude the diagnosis. The prevalence of MMNCB is about 10% of that of CIDP. Men are more often affected than women.

Both IgG and IgM antibodies to ganglioside GM1 are described in the serum from 30–80% of patients, rarely as a paraprotein. CSF protein should not be raised to >1 g/L. The hallmark of the condition is the demonstration of multi-focal conduction blocks at sites other than common sites of compression. Extremely thorough neurophysiological assessment may be necessary to identify them.

MMNCB was originally described in 1988 as a subtype of CIDP but it may be a distinct entity as illustrated by its dramatically different response to immunosuppressive therapy including worsening with steroids (see below).

Multi-focal acquired demyelinating sensory and motor neuropathy

Multi-focal acquired demyelinating sensory and motor neuropathy (MADSAM), previously called Lewis–Sumner syndrome, has similarities to CIDP and MMNCB. It may respond to treatment with IVIG.

Sensory ataxic CIDP

This rare inflammatory disorder presents with profound sensory ataxia and may be caused by inflammatory involvement of the dorsal root ganglia. HIV, paraneoplasia, Sjögren's syndrome, copper deficiency and pyridoxine toxicity should be excluded.

Distal acquired demyelinating sensory neuropathy

Many cases of distal acquired demyelinating sensory neuropathy (DADS) are associated with an IgM paraprotein.

Chronic relapsing axonal neuropathy

Chronic relapsing axonal neuropathy (CRAN) is a rare entity that has an uncertain position in the nosology of CIDP.

Treatment of typical CIDP

Treatment should be commenced as soon as possible in patients who warrant it after discussion of the risks and potential benefits with the patient. The first line treatments for CIDP are either oral steroids (although various regimens are used, 1 mg/kg given for 2 months and then slowly tapered is common) or IVIG (0.4 g/kg for 5 days repeated at 4–6 weeks and then as necessary according to the response). Both steroids and IVIG have been shown to be better than placebo and there is no clear difference between IVIG and steroids. Steroids should be co-prescribed with a bisphosphonate to protect against bone loss, and gastric pharmacoprotection should be considered. IVIG is a blood product and patients should be made aware of and consented for the risks. If IVIG or steroids are contraindicated or ineffectual then plasma exchange should be considered.

Other immunosuppressants have been tried in CIDP but cyclophosphamide is the only one to have shown promise.

MMNCB, MADSAM and possibly motor-predominant CIDP may deteriorate with steroids and therefore steroids should be avoided in these conditions.

Outcome

CIDP is a chronic progressive or relapsing disease. About 80% of patients will respond to treatment. Where patients fail to respond to treatment an occult paraprotein should be sought annually.

Over half (54%) of patients require assistance to walk or are bed-bound at some stage of their illness; 13% of patients require assistance to mobilize or are bed-bound at any one time. Over 50% require continuous treatment to maintain stability.

Paraproteinaemic neuropathies

Neuropathies associated with a paraprotein occur more often than by chance alone. The prevalence of a paraprotein in the serum at the age of 50 is approximately 1%, rising to 3% aged 70. Some 30–70% of patients with a paraprotein have a demonstrable peripheral neuropathy. Conversely, of a group of patients with no other identifiable cause for their neuropathy, 10% have a paraprotein. Most neuropathies are associated with 'benign' paraproteinaemias (monoclonal gammopathies of undetermined significance [MGUS]). Although IgG paraproteins account for 61% of all paraproteins, IgM MGUSs are over-represented in association with neuropathies and in many the MGUS is thought to be implicated in causation. Neuropathies associated with

malignant gammopathies are more often caused by compressive lesions, direct infiltration or amyloidosis.

If a paraprotein is discovered in the serum it should be fully investigated with a full clinical examination, search for urine light chains, a skeletal survey and a bone marrow aspirate and trephine to establish whether it is benign or malignant. The differential diagnosis of gammopathies associated with neuropathy is shown in Table 9.9.

Neuropathies associated with IgM paraproteins

The neuropathy associated with IgM paraproteins is most frequently demyelinating. About 50–70% of the paraproteins react with the peripheral nerve epitope displayed by myelin-associated glycoprotein (MAG). A κ light chain is most frequent although IgMλ anti-MAG paraproteins do occur. The clinical picture associated with anti-MAG antibodies is relatively homogeneous. A slowly progressive distal sensorimotor neuropathy with a variable degree of ataxia and prominent tremor is typical. Men are affected more than women, with a mean age of onset of 59 years. The neurophysiological features are demyelination with characteristic prominent distal slowing. Nerve biopsy (not required for diagnosis) shows characteristic widening of the myelin lamellae (Plate 9.4).

There is good evidence to indicate that anti-MAG IgM paraproteins are pathogenic. The evidence for the pathogenesis of other IgM paraproteins is less robust even though other serum activities to specific epitopes are reported. Thus, when IgM paraproteins occur in conjunction with CIDP-like and axonal neuropathies they are treated accordingly (see below).

Neuropathies associated with IgG and IgA paraproteins

The neuropathy associated with an IgG or IgA paraprotein is most often a chronic symmetrical predominantly sensory neuropathy similar to CIDP, but the presentations are much more heterogeneous than for IgM. People with IgG and IgA MGUS neuropathy often have less weakness and relatively more sensory involvement, both clinically and neurophysiologically, than do people with idiopathic CIDP. Electrophysiologically the neuropathies are either demyelinating or axonal/mixed neuropathies in approximately equal numbers. Debate continues about whether a patient with an IgG MGUS and otherwise typical CIDP justifies a separate diagnosis.

Neuropathies associated with lymphoma/CLL/Waldenström's macroglobulinaemia

Neuropathy may be the presenting feature of a malignant gammopathy. A progressive painful neuropathy is common. Axonal and demyelinating large fibre and small fibre involvement occur. Several pathogenic mechanisms have been described including direct antibody attack on the nerves, immunoglobulin deposition, cryoglobulinaemic vasculitis, cold agglutinin activity, amyloid deposition, increased serum viscosity and ischaemia and direct infiltration by malignant cells (neurolymphomatosis).

POEMS syndrome

Polyneuropathy, organomegaly, endocrinopathy, M-protein and skin changes constitute the POEMS syndrome, a rare haematological paraneoplastic disorder in which the cytokine vascular endothelial growth factor (VEGF) is strongly implicated in the pathogenesis. All five clinical features are not always present at presentation. The minimal criteria to establish the diagnosis are the presence of a demyelinating and axonal polyneuropathy associated with an IgA or IgG monoclonal gammopathy, the light chain being almost always λ, and at least two of eight other features: sclerosing plasmacytoma, endocrinopathy, skin changes (of which glomeruloid haemangiomas are specific to POEMS), organomegaly, Castleman disease, generalized oedema, papilloedema or thrombocytosis. Ultrastructural identification of uncompacted myelin lamellae on the peripheral nerve biopsy is also a strong argument in favour of the diagnosis.

Cryoglobulinaemic neuropathy

See vasculitis below.

Neuropathies associated with multiple myeloma, solitary myeloma and other malignant plasma cell dyscrasias

The neuropathies associated with a malignant plasma cell dyscrasia are heterogeneous. They should be managed in conjunction with a haematologist.

Treatment of paraproteinaemic neuropathies

Because the neuropathy associated with paraproteinaemia is often mild and only slowly progressive treatment may not be required. The level of paraprotein and the neuropathy should be monitored as there is a risk of approximately 1% per year of malignant transformation of the B-cell clone. Treatments are aimed at reducing the amount or activity of antibody in the serum. IVIG has short-term benefit in IgM paraproteinaemic neuropathies. Rituximab is showing promise as an effective treatment. Plasma exchange, steroids, chlorambucil, azathioprine, cyclophosphamide, α-interferon, fludarabine and cladribine have all been used with variable success. For IgG and IgA paraproteinaemic neuropathies those with a slowly progressive distal axonal polyneuropathy tended to show a poor response to immunotherapy. Patients with a sensorimotor demyelinating neuropathy tend to respond better. In POEMS syndrome, specific treatment of osteosclerotic bone lesions may improve the other features of the syndrome, especially the neuropathy. Autologous bone marrow transplantation has been effective in some.

Acquired amyloid neuropathy

In AL (light chain) amyloidosis the constituent amyloid protein is derived from monoclonal immunoglobulin light chains secondary to multiple myeloma, malignant lymphoma or Waldenström's macroglobulinaemia, or to a non-malignant immunocyte dyscrasia. Amyloid develops in approximately 15% of patients with myeloma and less frequently in other malignant B-cell disorders.

The amyloid is more commonly derived from λ than κ light chains.

Clinical features

The incidence of AL amyloidosis is 5.1–12.8 per million. Light-chain amyloidosis occurs predominantly in later life, two-thirds between the ages of 50 and 70. It may present with non-specific symptoms such as malaise, fatigue and weight loss or with system specific symptoms, the most common being nephrotic syndrome, congestive cardiomyopathy, peripheral neuropathy (sometimes with autonomic involvement) and hepatomegaly. Associated features include purpura, oedema, hepatosplenomegaly and macroglossia.

Patients with neuropathy present with an acquired length dependent sensory loss with prominent small fibre involvement. Pain is often burning, especially nocturnally, or lancinating stabs. Autonomic involvement including distal limb anhydrosis, orthostatic hypotension, difficulty in voiding urine, and erectile and ejaculatory difficulty tends to be an early manifestation. Diarrhoea and gastroparesis may be prominent but whether this is related to direct gut wall or autonomic infiltration is uncertain.

On examination, nerves may be thickened, pain and temperature are selectively involved and autonomic involvement is often evident (including pupillary involvement).

Pathology

The pathological features of AL amyloidosis are similar to those already described in the section above on pathology of transthyretin-related FAP.

Diagnosis

Histological confirmation of amyloid deposition in nerve, rectum, abdominal fat or other tissue with Congo red is described above. Immunohistochemical staining for λ or κ light chains has a sensitivity of only 50%.

Once the diagnosis of AL amyloidosis is made it is necessary to screen for a paraprotein. Protein electrophoresis will detect a paraprotein in serum or urine in about 50% of patients where it is present. Immunofixation of serum and urine should be routinely performed and quantification of free light chains detects abnormality in 92% of patients. If all of the above techniques are used the sensitivity is 99%.

Bone marrow aspirate with a trephine biopsy and detailed systemic investigation should then be undertaken to assess the degree of other organ involvement, especially renal, cardiac and gastrointestinal. A serum amyloid protein scan identifies and quantifies tissue deposits in many tissues but not peripheral nerve.

Treatment of amyloid neuropathy

Symptomatic treatments for pain, autonomic symptoms and the neuropathy can be tried as outlined above for TTR-related FAP. Extensive cardiac or renal involvement may merit organ transplantation. Chemotherapeutic regimens of different intensity are available to treat patients diagnosed at different stages of their disease. It is very important that patients are treated by centres with expertise in amyloidosis as regimes are continually being researched and updated.

Prognosis

Prior to recent advances in treatment a median survival time of 35 months for patients with acquired amyloid peripheral neuropathy compared to 16 months for those without neuropathy was typical although longer survival is reported. Death was usually because of involvement of systems other than the peripheral nerves.

With treatment the outcome is better; a recent review reported that 22% of patients survived more than 10 years.

Vasculitic neuropathies

The vasculitic neuropathies are uncommon but are some of the most devastating treatable peripheral neuropathies. The principal pathology is vascular inflammation in the vessels of the vasa nervorum with fibrinoid necrosis and occlusion of the vessel leading to nerve infarction. The early recognition, diagnosis and appropriate treatment can prevent considerable morbidity. They can be classified into systemic or non-systemic and then into primary or secondary causes (Table 9.9).

Symptoms and signs

Sequential progressive painful sensorimotor mononeuropathies presenting over days or weeks is typical of the presentation of vasculitis. Lower limb nerves tend to be affected first. Progression to confluence occurs, especially in polyarteritis nodosa (PAN) and Wegener's granulomatosis, and more slowly in some of the secondary vasculitides. Systemic involvement may present as fever, weight loss, myalgia, fatigue and night sweats or as organ-specific symptoms of rash, wheeze or shortness of breath, haematuria and arthritis or arthralgias.

Primary vasculitides

1 *Churg–Strauss syndrome.* Up to 80% of patients with Churg–Strauss syndrome present with a neuropathy. Fever, pulmonary infiltrates, late onset asthma, skin rash and eosinophilia are often all present. Antineutrophil cytoplasmic antibody (ANCA) is positive in up to 70%.

2 *Wegener's granulomatosis.* This is a midline necrotizing vasculitis associated with a positive c-ANCA in 90% of patients. A neuropathy occurs in up to 40% of patients and may be confluent.

3 *Polyarteritis nodosa*. True PAN is rare. It affects muscular arteries and arterioles only and is ANCA negative. Neuropathy occurs in 75% of cases and presents quite frequently as a painful symmetrical picture. Hepatitis B infection is often associated and implicated in the genesis.

4 *Microscopic polyangiitis.* This is an overlap syndrome in which neuropathy occurs in 50–60% of cases. p-ANCA is often positive.

Secondary vasculitides

1 *Rheumatoid arthritis* (RA). The most common neuropathy associated with RA is a slowly progressive distal symmetric sensory neuropathy, many of which are asymptomatic. This is not vasculitic. Vasculitic neuropathies occur more often in late seropositive disease.

2 *SLE.* This may present with a multiple mononeuropathy with vasculitis on nerve biopsy. However, a CIDP or GBS-like illness also occurs.

3 *Infection.* Hepatitis C is strongly associated with the presence of type II (mixed) cryoglobulinaemia. This is associated with a painful asymmetric multiple mononeuritis. The treatment is that of hepatitis C with ribavarin and interferon, although there are a number of case reports of vasculitis occurring in association with treatment per se.

Vasculitis directly attributable to HIV occurs in <1% of cases. More frequent is a vasculitis secondary to coexistent hepatitis B (see above), CMV or lymphoma.

Non-systemic vasculitides

1 Non-systemic vasculitic neuropathy usually has a more subacute or chronic course, but again with multiple mononeuropathies. Systemic symptomatic features are absent, except occasionally weight loss or fevers. No other organ involvement is identified on investigation. The prognosis and response to treatment are more favourable than with systemic forms.

2 Diabetic lumbosacral plexopathy (diabetic femoral neuropathy, Bruns–Garland syndrome, diabetic amyotrophy). There remains controversy about the classification of this entity but there it seems to be a monophasic vasculitis.

Investigation of vasculitic neuropathies

1 *Haematological and biochemical investigation*. Routine investigations should include full blood count, ESR, urea and electrolytes, C-reactive protein (CRP), liver and thyroid function, glucose (+/− HbA1c), ANA, ANCA, rheumatoid factor and RA latex, complement, serum protein electrophoresis and immunofixation, cryoglobulins (transfer to the laboratory at 37°C), hepatitis B and C. Consider requesting anti-ENA (extractable nuclear antigen), anti-CCP (cyclic citrullinated peptide), serum ACE (angiotensin converting enzyme), HIV testing and Lyme serology.

The urine should be examined for red cell casts and Bence-Jones proteinuria.

2 *Radiology.* A chest X-ray should be performed.

3 *CSF* is not usually helpful in vasculitic neuropathies. It should be performed to rule out differentials including HIV, carcinomatosis, lymphoma and Lyme disease.

4 *Neurophysiology*. Patchy asymmetric sensorimotor axonal damage is typically found with evidence of acute or subacute denervation on EMG. Demyelinating neuropathies are sometimes found but should point to alternative or additional pathologies.

5 *Nerve biopsy.* Patients with vasculitis are likely to need treatment with high dose, potentially toxic immunotherapies for a considerable time. A biopsy-proven diagnosis can usually only be made before treatment commences and it will reassure both physician and patient about their treatment. A biopsy of skin, liver, kidney or lung might be alternatives. If a nerve biopsy is performed, a recently affected sensory nerve should be selected. Biopsy of the superficial peroneal nerve and the underlying peroneus brevis muscle increases the chances of diagnosis over biopsy of the superficial peroneal nerve alone.

Patchy axonal fibre loss with active axonal degeneration is frequently seen in vasculitides. The diagnostic hallmarks of T-cell infiltration into vessel walls with destruction of the elastic lamina and fibrinoid necrosis with vessel occlusion (Plate 9.5) are seen less frequently. Biopsies should be carried out by an experienced surgeon and interpreted by a histopathologist with specific experience in peripheral nerve disease.

Treatment

The vasculitides are a treatable group of disorders because of the ischaemic pathology; missing the opportunity to treat early may result in permanent irrecoverable peripheral nerve lesions. Randomized controlled trial evidence for specific therapeutic regimens does not exist.

Non-virus-associated vasculitis

Treatment is usually required, except in mild or non-progressive cases (usually non-systemic vasculitic neuropathy) and usually urgently. The key to treatment is the initial induction of remission followed by a maintenance phase. Oral steroids at a dose of 1–2 mg/kg or pulsed methylprednisolone (monthly courses 1 g/day for 3–5 days with 1 mg/kg oral prednisolone between) are usual. Wegener's granulomatosis and microscopic polyangiitis often require a more aggressive treatment course than Churg–Strauss or the non-systemic vasculitides. However, each case should be judged on its merits. Furthermore, there is good retrospective evidence that the addition of additional agents to the remission regimen improves the rate of remission, disability at 1 year and the rate of relapse even in non-systemic vasculitis. Cyclophosphamide is the most commonly used agent. Oral cyclophosphamide (2 mg/kg/day) is traditionally used; however, many clinicians now prefer to use monthly pulsed intravenous cyclophosphamide (10–15 mg/kg, maximum 1 g per dose and modified by age and renal function) with prehydration and mesna cover for 6 months because of its reduced side effect profile.

Many agents have been used for maintenance which usually covers the tail of oral steroids and continues to 2 years depending upon outcomes and patient tolerance. Methotrexate, azathioprine, mycophenolate and leflunomide have all been shown to be beneficial in case reports. Rituximab is useful in cryoglobulinaemic and lymphoma-associated vasculitis and has shown promise in other primary vasculitides resistant to first line interventions.

Virus-associated vasculitis

Hepatitis B associated PAN responds to a short (2-week) induction course of steroids followed by a 6 months of antiviral treatment, either interferon-2α or lamivudine. Hepatitis C cryoglobulin associated vasculitis is treated with pegylated interferon-2α with ribavarin, although neuropathy has on occasion been induced when this regimen is used to treat hepatitis C alone. Plasma exchange is traditionally used alongside the treatment for both viruses to clear circulating immune complexes but is of no demonstrable benefit.

Outcome

Untreated vasculitis has a very poor outcome. In most types of vasculitis induction and maintenance treatment is associated with partial or complete recovery in about 50% of patients over months to years. Non-systemic vasculitis has much the best prognosis.

Other acquired peripheral nerve disorders

Endocrine disorders

Diabetes

Neuropathies occur extremely frequently in association with diabetes and, after leprosy, diabetes is the most common cause of neuropathy worldwide. Many neuropathies are asymptomatic or minor. Most occur later in the course of the disease; the prevalence of neuropathy is 50% after 25 years. The risk of neuropathy increases with duration of disease, poor control, height, male sex and with other cardiovascular risk factors constituting the 'metabolic syndrome'. Diabetic neuropathies can be classified as in Table 9.11.

Distal symmetric sensory neuropathy

Distal symmetric sensory neuropathy (DSSN) is the most common of the diabetic neuropathies. It presents with a slowly progressive 'glove and stocking' sensory loss which may be painful. Small fibre symptoms may also be present. With severe neuropathy, neuropathic Charcot joints may be present (Plate 9.6).

It is rarely necessary to perform a sural nerve biopsy on someone with apparently uncomplicated DSSN. Many of the biopsy features are non-specific but reduplication of basement membranes (Figure 9.12) and other endothelial alterations are commonly found.

The pathophysiology is poorly understood but relates to prolonged periods of hyperglycaemia increasing flux through the polyol pathway. Increased metabolic and oxidative stresses result in advanced glycated end-products in nerve.

There is no effective treatment but progress of the neuropathy can be largely arrested with aggressive diabetic control, although this is only achieved in about 25% of patients. Pain can be treated with antiepileptic and antidepressant medication.

Autonomic neuropathies

These occur in both type I and II diabetes but are often most severe in type I. Diabetes is the most common cause of autonomic neuropathy in the West. Up to 75% of men have impotence. Gastrointestinal motility disorders are common with constipation and nocturnal diarrhoea. Subclinical cardiovascular autonomic involvement is common with sympathetic and parasympathetic cardiac denervation demonstrated by fixed high heart rates. Postural hypotension is demonstrable in more than 40% of patients but is seldom symptomatic.

Vasculitic plexopathies

The most common plexopathy is the diabetic lumbosacral plexopathy (also known as diabetic femoral neuropathy, diabetic amyotrophy, lower limb asymmetric motor neuropathy or Bruns–Garland syndrome). It presents with asymmetric aching pain in the buttock, hip or thigh followed by progressive weakness and wasting affecting the hip flexors and quadriceps. The knee jerks are lost but sensory loss is unusual unless there is a coexistent DSSN. Patients present with a progressive history of asymmetric leg ache or pain followed by weakness and wasting mostly in the femoral compartment. Usually, dramatic weight loss and the appearance of diabetes or worsening of its control are prominent.

Table 9.11 Classification of diabetic neuropathies.

Distal symmetric sensory neuropathy (DSSN)
Autonomic neuropathies
Vasculitic plexopathies and thoracolumbar radiculopathies (amyotrophies)
Focal and multifocal mononeuropathies

Acute reversible hyperglycaemic neuropathy
Insulin neuritis and hypoglycaemic neuropathies
Neuropathies associated with diabetes, e.g. CIDP

CIPD, chronic inflammatory demyelinating polyradiculoneuropathy.

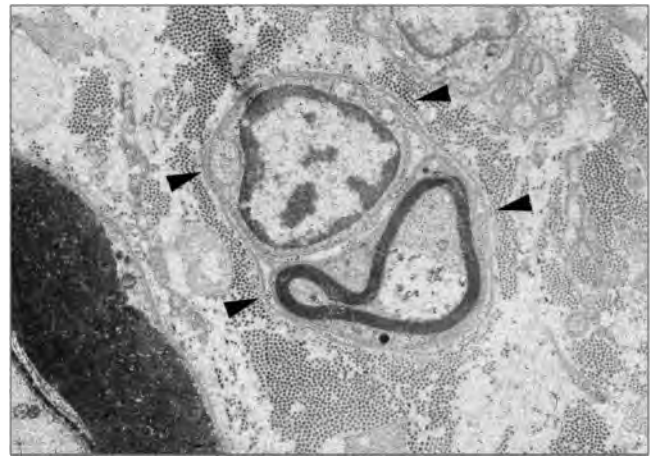

Figure 9.12 Diabetic nerve demonstrating reduplication of the basal lamina (arrows) around a Schwann cell and myelinated nerve fibre (case of DSSN).

Cervical plexopathies and thoracolumbar radiculopathies have also been described. These probably have the same pathogenesis.

Nerve conduction studies show radicular neurogenic changes in the quadriceps muscles. Pathological studies have suggested that this is a microvasculitis.

Regaining tight control of the diabetes is the basis of treatment. Both IVIG and pulsed intravenous and oral steroids have been anecdotally been said to be of benefit. However, spontaneous recovery (which is sometimes complete) may occur over 18–24 months without any treatment.

Focal and multifocal mononeuropathies

Individual mononeuropathies including carpal tunnel syndrome and peroneal neuropathies are more common in diabetes than in the healthy population because nerves are more susceptible to the mechanical effects of compression.

Cranial nerve palsies, most commonly pupil-sparing 'microvascular' IIIrd nerve palsies, are not uncommon. The VIIth and VIth nerves may also be affected.

Small fibre neuropathy

See below.

Acute reversible hyperglycaemic neuropathy

In patients with uncontrolled hyperglycaemia, an uncomfortable mainly lower limb sensory neuropathy can develop acutely. Nerve conduction is slowed. The symptoms resolve with reversal of the hyperglycaemia.

Insulin neuritis

Rarely, an acute painful neuropathy may develop after the introduction of insulin, leading to rapid normalisation of glycaemic control. There is scant evidence to support a pathology but a pre-existing diabetic neuropathy may be unmasked with sudden relative hypoglycaemia. Prognosis is good if insulin therapy is continued.

Neuropathies associated with diabetes (e.g. CIDP)

CIDP, but not GBS, is more common in diabetics than the otherwise healthy population. Severe proximal and distal diabetic neuropathy should be investigated for supra-added CIDP.

Hypoglycaemia

Recurrent and severe hypoglycaemia, as occurs in insulinoma, results in a distal symmetric sensorimotor neuropathy. Distal painful parasthesiae are usually prominent. Correction of the hypoglycaemia by treatment of the insulinoma results in improvement of the sensory symptoms but not the motor.

Hypothyroidism

Frank hypothyroidism is associated with a sensory axonal neuropathy in a substantial number of cases. Carpal tunnel syndrome occurs frequently as a presenting feature.

Acromegaly

Unrecognized and untreated acromegaly is now unusual. Most commonly weakness is caused by myopathy. CTS is common as are other entrapment neuropathies partly through hypertrophy of nerves. A distal predominantly sensory axonal neuropathy also occurs.

Toxic, nutritional and metabolic peripheral neuropathies

Toxic neuropathies

Peripheral nerve is relatively sensitive to the effects of systemic toxins (Chapter 18). The number of implicated drugs, chemicals and neurotoxins is too numerous to discuss each individually (Table 9.12). The reader is referred to http://www.neuro.wustl.edu/neuromuscular for a discussion of individual toxins.

If toxin exposure is suspected a full history and examination should be performed and a sample of the toxin should be retrieved if possible. Serum and urine specimens should be collected and, for acute poisoning, an Acute Poisons Unit consulted.

Most toxins cause axonal neuropathies, some of which have motor or sensory predominance. Fewer toxins cause demyelination. Frequently, the severity of the neuropathy is dose related. Removal of the source of the toxin may result in recovery which may be complete. Some agents 'coast' (i.e. the neuropathy tends to continue to worsen) for several weeks or months after removal of the toxin. Heavy metal poisoning may require specific treatment (e.g. lead, mercury and thallium) and toxins (e.g. α-latrotoxin, botulinum toxin) may benefit from antitoxin therapy. Prolonged supportive therapy in ITU may be required (e.g. botulism, tick paralysis).

Nutritional

Vitamin deficiencies occur through inborn errors of metabolism (e.g. vitamin E deficiency, methylcobalamin deficiency; Chapter 18), limited dietary intake (vegan/vegetarian diet, alcoholism) or failure of absorption (post-ileal resection, pancreatic failure, coeliac disease). Deficiencies may therefore be isolated or combined. Neuropathies are invariably axonal some associated with pain or ataxia and many with CNS involvement. Replacement of deficient vitamins by supplementation or providing an alternative metabolite can halt and sometimes improve the neuropathy.

Multi-vitamin malabsorption syndromes

1 *Coeliac disease.* Coeliac disease is associated with a typical length-dependent sensory neuropathy, sometimes with pain. As well as the systemic disease features, coeliac has also been associated with seizures, ataxia, myopathy, headaches and vitamin A deficient night-blindness. Causation is difficult to prove except in the latter.

2 *Inflammatory bowel disease.* Occasionally, a neuropathy occurs proportionate to the severity of the illness. Vitamin B_{12} deficiency through terminal ileal malabsorption is common.

3 *Cuban epidemic neuropathy* (Strachan's syndrome). Strachan's syndrome was described in prisoners of war. Cuban epidemic neuropathy occurs in patients of Afro-Caribbean origin and is

Table 9.12 Toxic neuropathies. After http://www.neuro.wustl.edu/neuromuscular

Axonal			Demyelinating	Mixed
Sensory	**Sensory and motor**	**Motor**		
Bortezomib	Acrylamide	β-bungarotoxin	Buckthorn	Amiodarone
Chloramphenicol	Alcohol (ethanol)	Botulism	Chloroquine	Ethylene glycol
Dioxin	Allyl chloride	Dimethylamine borane	Diphtheria	1,1′-Ethylidinebis [tryptophan]

Statins	Thallium			
Thalidomide	Trichloroethylene			
	Tri-ortho-cresyl phosphate			
	Vacor (PNU, a rat poison)			
	Vinca alkaloids			

very similar. It is thought to be caused by deficiencies in B vitamin and sulphur compounds. It typically occurs between 25 and 65 years of age with no sex predominance. Risk factors include tobacco and cassava consumption. The neuropathy is distal, axonal, sensory and often painful and occurs with an optic neuropathy presenting as central scotomata. Early treatment with B and multivitamin preparations can lead to resolution of the neuropathy although visual field defects may persist.

4 *Post gastroplasty/gastrectomy.* Patients may become malnourished through severely reduced dietary intake, diversion, bypass or resective procedures and sometimes vomiting. Copper and selenium deficiency may occur. Polyneuropathy, mononeuropathies (especially carpal tunnel), radiculopathies and myelopathies are all described.

Vitamin deficiencies

1 *Vitamin B_1* (beri-beri). Beri-beri presents with an acute or chronic length dependent sensorimotor axonal neuropathy primarily affecting the legs. Burning feet with lancinating pains are common as is autonomic involvement in severe disease. Wernicke–Korsakoff syndrome, cerebellar degeneration and cranial nerve palsies also occur as well as the systemic features of beri-beri (heart failure, oedema and weight loss).

2 *Pyridoxine* (vitamin B_6). In excess, pyridoxine typically causes a neuropathy/neuronopathy syndrome. Deficiency causes a length-dependent polyneuropathy. Users of isoniazid, penicillamine and hydralazine as well as alcoholics, the elderly and the malnourished are all at risk and should be supplemented appropriately.

3 *Vitamin B_{12}.* The causes of B_{12} deficiency are legion and all neuropathy blood profiles could include the measurement of B_{12} and folate. Symptoms are compounded by central and peripheral involvement. Deficiency may be long-standing and chronic. Nitrous oxide dental anaesthesia may unmask it. Typically, large fibre modality distal sensory loss begins first and motor involvement occurs later. Corticospinal tract involvement may lead to

pyramidal weakness and extensor plantar responses. Treatment with vitamin B_{12} may stabilize or improve the neuropathy but seldom improves the central involvement.

4 *Vitamin E.* Deficiency states cause a distal axonal neuropathy associated with cerebellar and posterior column involvement. Plantar responses may be extensor.

Metabolic neuropathies

Porphyrias

Acute intermittent porphyria (AIP), coproporphyria, variegate porphyria and δ-amino-levulinate dehydratase porphyria cause neurological syndromes. The most common is AIP.

AIP typically occurs in attacks, affecting women more than men. Abdominal pain and constipation reflect the sympathetic and parasympathetic involvement which can cause great management difficulties with additional cardiovascular instability. The neuropathy is motor and sensory and may be severe enough to result in respiratory failure and require ventilation.

Nerve conduction studies typically show axonal degeneration with denervation and small sensory potentials.

Treatment of attacks is with haem arginate or haematin and supportive measures to treat pain, constipation and weakness (including ventilation).

Uraemic neuropathy

Renal failure, uraemia and dialysis are all associated with a multifactorial neuropathy. Up to 60% of patients have a subclinical neuropathy. Symptoms and signs are of a length dependent sensory axonal neuropathy occasionally with pain and prominent itching. Recovery from renal failure or renal transplantation may improve or reverse the symptoms.

Critical illness neuromyopathy (Chapter 19)

The existence of a severe critical illness neuropathy in the absence of a myopathy is controversial. Most patients who have a period of intensive care will have a mild distal sensory neuropathy following it. However, some patients have a severe proximal and distal weakness, sometimes affecting ventilation and weaning because of a myosin loss myopathy. This is most common in sepsis, dialysis-dependent renal failure and myasthenic crises as well as severe ITU episodes. On examination patients may be profoundly weak (including neck flexors), have absent reflexes and they often have distal sensory loss. Small compound muscle action potentials (CMAPs) are found on electrophysiology because of muscle inexcitability rather than axonal loss. Myosin is depleted in muscle biopsy specimens. Treatment is supportive.

Small fibre neuropathies

Small fibre neuropathies (SFN) are an increasingly recognized and symptomatically troublesome group of disorders with diverse causation. There are no studies of the epidemiology of SFN. This is largely because of the lack of a satisfactory definition for SFN and standardized methods of investigation and detection. A reasonable definition is 'a neuropathy characterized by positive (spontaneous or stimulus-induced) or negative sensory symptoms caused by dysfunction of Aδ or C fibres with or without autonomic abnormalities as assessed by specific neuropathological or electrophysiological tests'. Asymptomatic small fibre involvement may also occur in certain conditions.

The list of causes of SFN is increasing (Table 9.13). Unfortunately, perhaps 50% or more small fibre neuropathies have no identifiable cause.

Table 9.13 Small fibre neuropathies.

Familial burning beet
Systemic amyloidosis

EBV, Epstein–Barr virus; HAART, highly active antiretroviral therapy; MGUS, monoclonal gammopathies of undetermined significance; SLE, systemic lupus erythematosus.

Symptoms

Small fibre neuropathies most often present with positive sensory symptoms of pain (often burning, pricking or aching) in the feet. Sometimes the symptoms also affect the upper limbs. Pain may be spontaneous or stimulus evoked. It is often worse at night, may interfere substantially with sleep, and can be relieved temporarily by walking or immersing the feet in cold water. Lancinating pain and paraesthesiae are usually indicative of additional large fibre involvement.

An association with restless legs syndrome is not uncommon. Significant autonomic disturbances are uncommon in idiopathic small fibre neuropathy and most often mild. Prominent orthostatic hypotension, faecal urgency, diarrhoea (especially nocturnal) and incontinence, urinary difficulties, impotence and sweating abnormalities should all prompt a search for diabetes, amyloid, vasculitis or a hereditary cause.

Signs

The allowable clinical signs in SFN vary between authors. Usually there is reduced temperature and pain sensation in the distal feet. Otherwise there should be no muscle wasting or weakness, deep tendon reflexes should be present and bedside vibration and proprioception should be normal.

Investigation

Causation should be sought with appropriate blood tests and chest X-ray. Standard nerve conduction tests are normal. Thermal threshold testing (especially warm thresholds which correlate well with intra-epidermal nerve fibre densities) is a low resolution but effective method to confirm the diagnosis. Other tests are being developed (contact heat evoked potentials [CHEPs], laser evoked potentials [LEPs], measurement of cutaneous silent periods and axon reflex flare responses) but are yet to be fully validated or widely used. Skin biopsy is a useful, largely painless, site specific and minimally morbid procedure to quantify intraepidermal nerve fibre density with high diagnostic efficiency and predictive value. Sural nerve biopsy does not form part of the investigation of small fibre neuropathy.

Treatment

No treatments are yet available to treat or reverse small fibre neuropathy. Erythropoietin has shown promise in limited *in vitro* scenarios. Treatment is largely symptomatic and trials of gabapentin, pregabalin, sodium valproate, topiramate and opiates all demonstrate some benefit. Tricyclic antidepressants, duloxetine, oxcarbazepine and others are often tried. Enzyme replacement is helpful for the small fibre neuropathy in Fabry's disease.

Idiopathic axonal neuropathy

Despite best practice the cause of at least 25% of neuropathies remain undiagnosed. These are largely a group of slowly progressive but usually non-disabling axonal and small fibre neuropathies. Careful history-taking, examination and sometimes the ability to examine 'unaffected' relatives improves diagnosis. Over the coming years many of these conditions will be diagnosed more successfully.

Focal and compressive neuropathies

Focal neuropathies are the result of local damage to individual nerve trunks. They may be single or multiple; the occurrence of more than one pressure palsy should stimulate a search for a predisposing cause. Damage occurs most frequently because of compression, usually as the nerve passes through a tissue tunnel (bone, ligament, aponeurosis, muscle), or against an underlying surface at an exposed site (e.g. the peroneal nerve as it passes around the head of the fibula). Compression may also occur with prolonged abnormal postures (e.g. radial paralysis in the 'Saturday night palsy'). Diabetes, HNPP and alcohol overuse render nerves susceptible to the effects of otherwise non-damaging pressure.

The pathogenesis of focal compressive nerve dysfunction is probably multi-factorial and in experimental studies the mechanisms of acute and chronic compression have been shown to differ. At sites of acute compression endoneurial fluid, axonal contents and subsequently myelin are squeezed down the pressure gradient at the edge of the compression, resulting in nerve intussusception and subsequently Wallerian degeneration. In chronic compression, focal demyelination is found with alterations in nodal structure suggestive of a 'myelin slippage' secondary to stretching. In addition, endoneurial ischaemia may occur and contribute to focal pathology. The transperineurial venous plexus may be easily compressed as it obliquely exits the perineurium resulting in increased endoneurial tissue pressures, reduced blood flow and alteration in the endoneurial metabolic microenvironment. Over the longer term, impaired axonal transport may result in reduced distal trophic support. Furthermore, a nerve that becomes tethered at a site of inflammation can become further damaged; the inability of the nerve to glide during limb movement results in more nerve stretching.

Compression palsies cause signs in the motor and sensory distribution distal to the site of compression. Symptoms may occur both proximal and distal to the site. The reader is referred to diagrams of neuromuscular innervation at the beginning of this chapter (Figures 9.3–9.6). The most common focal neuropathies affect the median (carpal tunnel syndrome), ulnar and common peroneal nerves. Many other nerves may be affected producing a variety of syndromes, many with colloquial names (e.g. orator's [anterior interosseous] and claw [ulnar] hand, waiter's tip and Saturday night [radial] palsy in the upper limb and toilet seat [sciatic], strawberry and turnip picker's and hoeing [peroneal] palsies in the lower limb). These are not always entirely 'typical' as anatomical variations may vary muscle and cutaneous innervation (e.g. Martin–Gruber anastomoses between median and ulnar nerves). Lesions of any other individual nerve trunk are possible and result in motor and/or sensory signs in the distribution of their innervation. The most common are the lateral cutaneous nerve of the thigh (resulting in meralgia paraesthetica), sciatic,

Table 9.14 Other focal neuropathies.

Colloquial terminology	Sites of compression	Weakness	Sensory loss
Upper limb			
Median nerve			
Carpal tunnel syndrome (CTS)	Wrist (carpal tunnel)	Opponens pollicis, abductor pollicis brevis, flexor pollicis brevis, lumbricals	Palmar skin of thumb, digits II, III (and lateral IV)
Circle sign	Anterior interosseous nerve (below elbow)	Flexor pollicis longus and flexor digitorum profundus (median) – the circle sign	None
Orator's hand	Bicipital aponeurosis (elbow), or Ligament of Struthers (above elbow)	Median innervated flexors (profundus/ superficialis) and pollicis + pronators quadratus and teres	Palmar + CTS loss
Ulnar nerve			
Guyon canal syndrome	Guyon canal at wrist	Interossei and abductor digiti minimi (variable)	Distal superficial ulnar (variable)
'Claw hand'/tardy ulnar palsy/cubital tunnel syndrome	Elbow	As above + flexor carpi ulnaris, flexor digitorum profundus (ulnar)	Medial surface of palm and digits V and IV
Radial nerve			
Waiter's tip palsy	Upper arm/axilla	Triceps (strong in proximal lesions), brachioradialis, wrist and finger extensors	Superficial radial territory of hand (snuff box)
Tourniquet palsy Saturday night palsy Crutch palsy (sometimes with ulnar and median = *triad* neuropathy)			
Wartenberg syndrome Cheiralgia paraesthetica	Wrist	None	
Axillary nerve	Axilla or humeral head	Deltoid	Skin over deltoid
Suprascapular nerve			
Pitcher's neuropathy	Suprascapular notch or ligament	Supra- and infraspinatus weakness (often painful)	None
Long thoracic nerve			
Rucksack palsy Long thoracic neuropathy	Shoulder or lateral thoracic wall	Serratus anterior	None
Brachial plexus			
Neurogenic thoracic outlet syndrome	C7 transverse process, anterior scalene muscle, fibrous band	C8 root > T1 root hence thenar > hypothenar muscles	Ulnar border of hand, forearm and arm
Lower limb			
Sciatic nerve			
Toilet seat palsy	Gluteal compression	Hamstrings and all muscles below knee	Tibial and common peroneal territories (latter more common if partial)
Yoga paralysis Catamenial sciatica (with endometriosis)	Sciatic notch	May also involve superior/inferior gluteal nerve	? + posterior cutaneous nerve of thigh
Peroneal nerve			
Strawberry picker's, (olive) harvester's, turnip picker's or hoeing palsy	Popliteal fossa, lateral fibular head and fibular tunnel	Tibialis anterior, extensor hallucis longus, extensor digitorum and peronei	Lateral lower leg and dorsum of foot
Anterior (tibial) compartment syndrome	Tibial compartment	Tibialis anterior, extensor hallucis longus, extensor digitorum	Interspace and dorsum of digit I and II
Anterior tarsal tunnel syndrome	Ankle	None	Interspace and dorsum of digit I and II

radial, long thoracic, 'tarsal tunnel' (distal tibial [posterior] and peroneal [anterior] neuropathies) and femoral neuropathies.

History, examination and investigation follow similar principles to those outlined above. These are outlined with their colloquial terminology in Table 9.14. For more detailed descriptions the reader is referred to Stewart (2000).

Median nerve compression and carpal tunnel syndrome

Median nerve compression between the flexor retinaculum of the wrist and the bones of the carpus is referred to as carpal tunnel syndrome (CTS) and is the most common of the median compression palsies. The prevalence has been estimated at more than 6% of the population.

Compression in the more proximal upper limb occurs more rarely. Median nerve compression in the axilla usually co-occurs with radial and ulnar nerve involvement and is most commonly caused by traumatic or surgical injury, or unusual compressive forces (e.g. crutches or heavy sleep through intoxication). In the upper arm trauma is the most common insult and the median nerve may be affected in isolation. At the elbow the median nerve is susceptible to numerous injuries (Table 9.15). Compression at the elbow or more proximally leads to inability to pronate the forearm and flex the distal phalanx of thumb and index finger (orator's hand). Numbness affects the palm as well as the distal fingers.

Carpal tunnel syndrome

Carpal tunnel syndrome is three to eight times more common in women than men. It most commonly affects both hands, usually the dominant hand first. There are many recognized causes of CTS (Table 9.16). Numbness, paraesthesiae and pain in the hand and sometimes in the more proximal arm, often occurring at night, are the most common presenting complaints. When the pain is intermittent, shaking the hand or wrist relieves the symptoms and is a relatively reliable sign of compression at the wrist (more reliable than Phalen's, Tinel's or other provocative signs). If not treated, sensory symptoms become permanent and weakness and wasting of the thenar eminence may become apparent.

Examination

Compression of the median nerve at the wrist typically results in weakness of abductor pollicis brevis, opponens pollicis, first and second lumbricals and sometimes flexor pollicis brevis and sensory disturbance on the palmar skin of the thumb, second, third and half the fourth digit. There are many anatomical variations. The palmar cutaneous branch arises proximal to the flexor retinaculum and does not pass through the carpal tunnel. Occasionally, the motor branch may pierce the retinaculum and may escape compression but be damaged during surgery.

Investigation

Nerve conduction studies are required to confirm the diagnosis as demonstration of the clinical symptoms and signs is not 100% reliable. About 5% of studies are thought to be falsely negative, but a negative study should provoke a search for an alternative diagnosis (C6/7 radiculopathy, thoracic outlet syndrome or thalamic infarction). Where anatomical variants or structural

abnormalities of the wrist are considered MRI can be most helpful in assisting both diagnostician and surgeon. The yield from haematological and biochemical testing where no pathology is detected on thorough clinical examination is low.

Treatment

There is evidence of variable quality that non-surgical interventions including oral steroids, ultrasound, yoga and carpal bone mobilization are effective in the short term for symptom relief. There is no benefit from the use of non-steroidal anti-inflammatory drugs or diuretics. Local steroid injections may provide short-term relief. Surgical decompression gives the most satisfactory clinical relief (90–95% success) in both the short and long term (3% recurrence rate) and is associated with minimal risks. Results are better if symptoms have been present for less than 3 years. Endoscopic release has few advantages over open procedures and is more often associated with failure.

Ulnar nerve compression

The ulnar nerve can also be damaged anywhere along its course from the brachial plexus to the hand. The most common site of damage is at the elbow. Here the nerve is exposed to trauma, pressure and stretching as it passes the medial epicondyle through the ulnar groove and then deep to the flexor aponeurosis under flexor carpi ulnaris. Other causes reflect the causes of median neuropathy (Table 9.17). An extensive differential diagnosis of conditions mimicking ulnar neuropathy exists (Table 9.18).

Table 9.18 Conditions mimicking ulnar neuropathy.

Cord lesions/myeloradiculopathy
Syringomyelia
Hirayama monomelic atrophy
Amyotrophic lateral sclerosis
C8/T1 radiculopathy
Thoracic outlet syndrome
Lower brachial plexus lesions (trauma/infiltration/radiation/post sternotomy)
Brachial neuritis (neuralgic amyotrophy)
Multi-focal motor neuropathy with conduction block

Symptoms

Numbness and tingling affecting the fourth and fifth digits of the hand are the most frequent presenting complaints. Deep pain may be felt proximal to the nerve. Weakness of hand grip appears later but may be the only symptom in some. The elbow may be identified as a site of previous damage, trauma or pressure and occasionally sensitivity of the ulnar nerve at the elbow is reported.

Signs

Accurate clinical localization of ulnar neuropathies is essential to guide exploration and treatment. Weakness of first dorsal interosseous and abductor digiti minimi in the hand is most common. Motor branches and the distal superficial cutaneous branches all

pass through Guyon's canal; signs confined only to this territory could result from compression at the wrist or more proximally. Sensory loss should not extend above the wrist; the medial cutaneous nerve of the forearm emerges from the brachial plexus. Weakness of the flexor digitorum profundus to the fourth and fifth digits or flexor carpi ulnaris puts the lesion at the elbow or above. Involvement of the palmar skin of the medial border of the hand or the dorsal skin of the affected fingers excludes compression in Guyon's canal at the wrist. Additional weakness of median nerve innervated muscles (see above) suggests alternative diagnoses. The presence of a thickened nerve at the elbow suggests inflammatory, hereditary, tumourous or lepromatous involvement.

Treatment

Effective treatment of ulnar neuropathies usually involves surgical intervention. Conservative measures aimed at educating the patient to avoid leaning on the elbow, nocturnal splinting and diffusing pressure with sheepskin elbow pads may all assist. Surgery should be offered to all patients who have sensory and motor signs consistent with the diagnosis, especially if there is clear worsening. Patients with sensory signs only should be closely reviewed to detect signs of progression – most will remit. In late severe cases with weakness, wasting and sensory loss surgical intervention may not be beneficial but tendon transfer procedures may help hand function. Surgical approaches involve removing compressing structures (e.g. masses) if appropriate, and thereafter releasing and mobilizing the nerve to a greater or lesser extent. Transposition of the nerve is associated with greater risks of peri-operative damage and thus extensive exploration and release may often be the most appropriate intervention.

Other ulnar neuropathies

Ulnar neuropathies at other sites are identified by careful history-taking, examination directed at ulnar nerve innervation and more widely in the neck, chest and upper limb and neurophysiological 'inching studies' (inch by inch). Imaging (both MR and ultrasound) will be more widely used to identify abnormalities in other sites than the elbow.

Common peroneal neuropathies

Isolated lesions of the peroneal nerve are the third most common of the mononeuropathies. The common peroneal nerve is most liable to damage as it winds laterally around the knee and fibula head. It then passes through the fibular tunnel (a fibrous arch derived from peroneus longus) before dividing into superficial and deep peroneal nerves (Figure 9.7).

Symptoms

Complete common peroneal lesions cause a foot drop with inability to evert the foot or extend the toes and a characteristic high-stepping and audibly slapping gait. The sensory loss covers the lower half of the lateral part of the leg and dorsum of the foot, sparing the sural nerve territory. The history may or may not reveal an obvious cause (Table 9.19). A history of focal pain elsewhere in the leg or other systemic symptoms should prompt a search for a local or systemic cause.

Table 9.19 Causes of common peroneal nerve palsy.

Pressure
Leg crossing
Prolonged crouching (e.g. childbirth, 'strawberry pickers' palsy, yoga)
Lithotomy stirrups
Plaster casts
Peri-operative/ITU
Anterior (fibial) compartment syndrome

Knee dislocation
Popliteal fossa lesions
Baker's cyst, haematoma, DVT
Nerve tumours
Neuroma, schwannoma, lymphoma
Diabetes
Leprosy
Vasculitis
Idiopathic

DVT, deep venous thrombosis.

Signs

The site of the lesion may be clear from the history or obvious site of damage from examination. However, the variability of innervations in the leg, and common occurrence of partial nerve lesions of the sciatic, lumbo-sacral trunk or multiple radiculopathies, means that an electrical study is often crucial for localizing the site of damage and directing further investigation and treatment.

Investigation

Nerve conduction and EMG studies enable localization of any lesion from root (often L5) through the lumbosacral trunk and sciatic nerve to the more distal branches of the superficial and deep peroneal nerves. Although plain radiographs, CT and arteriography have diagnostic use in specific scenarios, MRI scanning has greatest utility in demonstrating intrinsic and extrinsic mass lesions (both tumours and inflammatory) of the nerve.

Treatment

Acute trauma with nerve transection or compartment syndromes are surgical emergencies and intervention to explore and relieve pressure and/or repair the nerve is indicated. Where an identified episode of prolonged nerve compression is identified avoidance of further injury and watchful waiting are appropriate. Most lesions recover. Lesions that progress or fail to recover, or lesions

associated with other structural abnormalities should be surgically explored.

Plexopathies

The two major nerve plexuses are the brachial and lumbosacral. Lesions of a plexus cause complex post-ganglionic motor and sensory deficits in the distribution of part or all of the plexus. The reader is referred to the anatomical diagrams (Figures 9.3 and 9.6) to assist with identifying and localizing involvement. Causes are shown in Table 9.20. Many of these are common to both plexuses. Some, e.g. neuralgic (brachial) amyotrophy and diabetic lumbosacral plexopathy have a predilection for one or the other.

Hereditary brachial plexopathy (Septin)
Hereditary neuropathy with liability to pressure palsies (chromosome 17p11.2 deletion)

CIDP, chronic inflammatory demyelinating polyradiculoneuropathy; MMNCB, multi-focal motor neuropathy with conduction block.

Acute brachial neuritis

Parsonage and Turner described this entity also known as neuralgic amyotrophy in 1948. Typically, acute deep aching pain occurs spontaneously and affects the neck, shoulder and upper arm in a diffuse pattern. This may last from hours to 2 weeks or more and is followed by focal wasting and weakness, most commonly in the distribution of nerves originating from the upper plexus (deltoid, serratus anterior, supraspinatus and infraspinatus and biceps). Muscles in the distributions of the lower plexus may also less commonly be affected. Sensory symptoms occur in about one-third of patients and signs in about two-thirds, most often sensory loss in the territory of the axillary nerve. Prolonged pain, bilateral involvement, structural or mass lesions on examination should prompt a search for an alternative cause.

The cause of brachial neuritis remains uncertain. Occasional rapid recovery and the finding of conduction block point to demyelination as an initial mechanism but clearly axonal degeneration swiftly follows. Rare pathological reports of inflammatory nerve lesions exist. Associations with immunizations, infections, trauma, surgery, pregnancy and childbirth, intravenous heroin and vasculitides point to an immune mechanism. Steroids, although sometimes useful for pain, usually fail to alter the outcome. Other analgesics (including opioids) are usually necessary. About 90% of patients with a typical brachial neuritis will recover in 3 years. Raraly, a similar condition affects the lumbosacral plexus.

Anterior horn cell diseases

Many motor nerve diseases principally affect the anterior horn cell body; these are usually neurodegenerative (e.g. motor neurone disease) or hereditary (e.g. spinal muscular atrophy). However, there is a broad differential diagnosis (Table 9.21).

Motor neurone disease

Motor neurone disease (MND) is a progressive neuronal degenerative disease that leads to severe disability and death. There is considerable variability in presentation, clinical course and prognosis. The condition is divided into several different clinical subtypes. Amyotrophic lateral sclerosis (ALS) is the most common and is characterized by upper and lower motor neurone involvement of the bulbar, upper and lower limb territories; presentation with predominantly or exclusive bulbar weakness is referred to as progressive bulbar palsy (PBP). In primary lateral sclerosis (PLS) there is exclusively upper motor neurone involvement and progressive muscular atrophy (PMA) involves only lower motor neurones.

Amyotrophic lateral sclerosis

The onset of ALS is usually with focal wasting and weakness affecting contiguous limb muscles more commonly in the upper limbs. Occasionally, there may be severe isolated wasting and weakness of individual limbs (e.g. flail arms). Other patients may present

with progressive dysarthria. Rarely, there may be selective involvement of respiratory muscles leading to respiratory failure.

ALS is characterized by the progressive development of wasting, fasciculations, cramps, weakness, spasticity, brisk reflexes and extensor plantar responses. Limb involvement is more often distal than proximal and leads to weakness of the hands or bilateral foot drop. Patients may complain of clumsiness or impaired mobility. Bulbar involvement is characterized by dysarthria, tongue wasting, fasciculations, slow movement, brisk jaw jerk, sialorrhoea and dysphagia. Patients complain of difficulty speaking or occasionally hoarseness which usually precedes swallowing difficulties. Clear fluids tend to aspirate causing the patient to cough after drinking. Hypersalivation becomes difficult to clear and leads to the development of drooling and dribbling. Pseudobulbar involvement is also associated with pathological emotional lability in which there is excessive uncontrolled laughter or crying.

Fasciculation is variable but may be prominent after exercise. It is well seen in the tongue and across the back. Head droop may be an early feature because of weakness of the neck extensors and paraspinal muscles. Progressive respiratory muscle weakness may lead to exertional dyspnoea but selective diaphragm weakness will cause breathlessness on lying flat and progressive hypoventilation. Increasing limb and truncal weakness causes worsening immobility and self-care. Bulbar weakness leads to increasing difficulty with communication and eventual anarthria with worsening dysphagia. Sleep disturbance is common and multi-factorial related to difficulty turning in bed, periodic limb movements, hypersalivation and inability to clear secretions, difficulty with communication, emotional lability and depression. Sensory, ocular and bladder symptoms are unusual.

Progressive bulbar palsy

PBP is restricted to bulbar musculature at presentation and during the initial progression. Subsequent spread to the cervical regions and then more generally is common after months. PBP constitutes about 15–20% of cases of MND and is associated with a poor prognosis with a median survival of 2 years.

Flail arm/leg syndrome

Progressive isolated wasting and flaccid weakness of an arm or leg may be the presenting feature in up to 10%. Upper motor neurone features develop later. This form of the condition is considerably more common in males and carries a better prognosis than ALS, with median survival of 57 months.

Primary lateral sclerosis

This is an exclusively upper motor neurone form of MND which occurs in about 5% of patients. Lower motor neurone features may develop in a minority after 5–10 years. The condition develops at an older age and may be slow in its progression. A survival of 20 years is relatively common. Bladder symptoms are common but bulbar involvement occurs later and is less severe.

The hemiplegic variant of Mills is a rare presentation with mixed upper and lower motor neurone signs occurring on one side of the body.

Aetiology

MND can be associated with genetic or acquired factors or may occur sporadically (Table 9.22).

Genetics

Between 5% and 10% of cases of ALS are familial (FALS) and most have an AD pattern of inheritance. In approximately 20% of patients with FALS the genetic defect is a mutation on chromosome 21 in the gene for copper/zinc superoxide dismutase (*SOD1*). More than 100 mutations of the *SOD1* gene are now known. There is a small incidence of *SOD1* mutation occurring in sporadic MND. *SOD1* mutation screening is available, but counselling is important before predictive testing can be

undertaken and genetic screening for predictive testing is not performed routinely. Mutations in several other chromosomal loci have now been described in patients with autosomal recessive inheritance.

Environmental

There is a 50–150 fold increase in the incidence of MND in the Western Pacific. The condition differs pathologically from sporadic ALS because dementia and parkinsonism frequently coexist. Furthermore, unlike sporadic ALS, the pathological findings are characterized by the presence of neurofibrillary tangles. It seems likely this form of the condition is related to a toxin, possibly from the cycad seed.

Lymphoproliferative disease

An association between MND and lymphoproliferative disorders has been reported. PLS may rarely occur as a paraneoplastic disease associated with antineuronal antibodies.

Diagnosis of MND

Routine haematology and biochemical screening is usually normal. Creatine kinase (CK) may be mildly or moderately elevated. Underlying lymphoproliferative, infective, endocrine or toxic causes should be excluded. Hexosaminidase A should be checked in the young and ANA in late presentation. Genetic analysis may include *SOD1* and *SMN* in the predominantly lower motor neurone presentation.

Investigation

Neurophysiology is essential in establishing the diagnosis and severity of MND and excluding the differential diagnoses (Tables 9.21 and 9.22). Sensory nerve action potentials (SNAPs) are normal and motor conduction velocities should be >70% of normal. There must be no conduction block. Needle EMG shows neurogenic changes of denervation and reinnervation. There is considerable variability in EMG findings and extensive sampling of bulbar, cervical, thoracic and lumbosacral muscles may be necessary. MRI is important to exclude structural or inflammatory conditions which may mimic MND. MR imaging may show high signal in the descending pyramidal tracts indicating Wallerian degeneration. Positron emission tomography (PET) imaging has shown cortical changes, particularly in patients with cognitive impairment.

Incidence and prognosis

The annual incidence is 1.5–2/100,000 and the prevalence approximately 4–8/100,000. Males are more commonly affected than females (1.5 : 1). The incidence increases with age with a mean age of onset of 63 years.

The natural history of MND is variable and occasional prolonged periods of stability may occur. Patients with PBP have the worst prognosis because of the risk of aspiration with a median survival of 2–2.5 years. In ALS the mean disease duration is 3–4 years. Over 50% of patients die within 3 years and 90% within 5 years of the first symptom. In PLS a survival of 20 years is relatively common. In general, rapid rate of progression, early respiratory or bulbar symptoms and increasing age are adverse prognostic indicators, while exclusively upper or lower motor neurone syndromes and young age are associated with a better prognosis.

Management

Telling the patient the diagnosis

The communication of the diagnosis is a major and potentially devastating life event which must be handled with great sensitivity. All too often patients complain that the diagnosis has been given in a hurried, off-handed and inappropriate manner. The diagnosis should be explained by a senior physician, in a quiet and private room, with a carer present. The consultation should be sensitive. The patient should be provided written comprehensible information, and a follow-up appointment within a few weeks. Ongoing follow-up should be supervised by a single named doctor, in close liaison with the GP and community services. The diagnosis and details of the information given to the patient and the management plan must be communicated to the GP without delay.

Principles of management

The management of MND involves the coordination of multidisciplinary care with a team that will include the patient's own GP and primary care team, occupational and physiotherapists, clinical nurse specialists, support and social workers and the palliative care team. The supervising neurologist or physician should coordinate a continuum of care for each patient from diagnosis to the terminal phase of the disease. Each member of the team will have an individual role. In the UK *The Motor Neurone Disease Association (MNDA)* employs a network of Regional Care Advisors (RCA). These individuals act as a point of contact for people with MND and their carers, and help to point to the provision of pieces of equipment such as splints, communication aids, which may be needed. They also provide a telephone helpline and are able to contribute to the support of relatives and carers following the death of the patient. Important websites are listed in Table 9.23.

Pharmacotherapy

Riluzole inhibits glutamate release and is the only drug which has been shown to increase survival in MND. Riluzole prolonged survival by 3 months after 18 months administration with little or no effect on functional deterioration in two clinical trials. It is usually well tolerated with occasional nausea and fatigue. The drug should be discontinued if liver function tests exceed five times the upper limit of normal. Many patients look to other possible treatments and antioxidants (vitamins C and E) and creatine are in common use. Acupuncture, reflexology, chiropractic and massage may contribute to the individual's personal feeling of well-being.

Respiratory management

Respiratory impairment is common and may develop because of respiratory muscle weakness, impaired bulbar function and obstructive sleep apnoea (OSA) or defects in central control. It should be anticipated in all patients with a diagnosis of MND. Dyspnoea may be caused by infection, pulmonary embolus or airway obstruction from mucus plug or inhaled pharyngeal contents. Prompt use of antibiotics should be supplemented with physiotherapy. Annual influenza vaccination should be undertaken. Nocturnal hypoventilation and OSA present as daytime hypersomnolence, lethargy, morning headaches, poor concentration, depression, anxiety and irritability with or without snoring and restless sleep with abnormal movements.

FVC reflects respiratory muscle strength, and serial measurements may be useful in predicting the onset of respiratory failure and non-invasive ventilation is often initiated when FVC is <50% of predicted. Other markers of impending respiratory failure include maximal inspiratory and expiratory mouth pressures and maximum sniff nasal pressure. Polysomnography, diaphragmatic EMG and phrenic nerve conduction studies may provide useful additional information.

Respiratory support can provide symptomatic relief and increase life expectancy. These benefits must be balanced against the demands on carers, practical problems of administration, the risk of iatrogenic problems, and distressing and unwanted prolongation of life in the terminal stages of MND. Many of these difficulties can be avoided by early and careful discussion with patients and their carers. Elective ventilatory support is usually administered non-invasively (NIV), initially during sleep. NIV allows speech, oral feeding and leads to fewer respiratory infections. However, it may not be desirable in patients with severe bulbar weakness, facial abnormalities or where aspiration has already occurred. Some patients require ventilatory support for increasing periods and may choose to undergo tracheostomy. Tracheostomy carries a significant risk of complications and considerable difficulties in domiciliary management. There remains a concern that tracheostomy may lead to prolonged survival in the face of severe disability. Many patients will decide to use NIV support if their respiratory function deteriorates and is symptomatic. The provision and supervision of respiratory support should be through a specialist MND centre.

Management of bulbar weakness

Bulbar palsy is one of the most distressing features of MND. Weakness of tongue, pharynx and facial muscles results in slow eating, choking, drooling, dysarthria and dysphonia. Sialorrhoea is generally managed with anticholinergic agents including atropine or amitriptyline taken orally, hyoscine (scopolamine) transdermally or glycopyrronium bromide subcutaneously. Side effects are common in the elderly. Antimuscarinic agents render secretions viscid whereas β-blockers have been reported to reduce secretions without increasing tenacity. A portable home suction device and cough enhancement techniques may be helpful. Unilateral parotid gland irradiation and parotid botulinum toxin injection have also been used.

Dysphagia

The management involves speech and language therapy assessment of swallow and advice on techniques to ease mastication and prevent aspiration.

Nutrition

Patients with dysphagia may have inadequate calorific and fluid intake, leading to accelerated weight loss and dehydration. The initial management of dysphagia in ALS includes modification of food and fluid consistencies while ensuring maximal calorific intake. Percutaneous endoscopic gastrostomy (PEG) should be considered as an alternative or supplementary route for nutrition, hydration and medication. PEG should be undertaken before FVC falls below 50% of predicted as it is more successful, improves survival and is less complicated at this early stage. Radiologically inserted gastrostomy (RIG) tubes do not require sedation or endoscopy and are preferable in patients with respiratory compromise.

Communication

Progressive dysarthria is common and speech may become severely impaired or lost within a short time. Simple techniques for improving the intelligibility of speech include reducing background noise and facing the speaker. Writing is often an excellent alternative to speech if limb function is preserved. There are a variety of other aids ranging from pointing boards to computerized speech synthesizers.

Limb dysfunction

Musculoskeletal pain is common and may respond to antispasticity agents, NSAIDs and stronger analgesics including opiates. Skin pressure pain caused by immobility may also occur. Cramps are usually nocturnal and may respond to quinine sulphate, diazepam, carbamazepine or phenytoin. Stiffness may be caused by spasticity or muscle or joint contracture. Tizanidine and baclofen may help with the pain of spasticity.

Cognitive impairment in ALS

MND is associated with both mild frontal lobe impairment and also a more severe form of fronto-temporal dementia. Cognitive impairment occurs most often in patients with PBP who may show changes in character, personality and behaviour. However, this is difficult to assess because of the speech disturbance, motor retardation associated with pseudobulbar palsy and the obvious distress, anxiety and frequently depression. Fronto-temporal dementia is characterized by disinhibition, loss of insight and social awareness, impulsivity, reduced speech output with echolalia and eventual mutism. In the late stages there may also be anxiety, agitation, apathy and even delusions. There are characteristic pathological changes including frontal temporal neuronal loss, gliosis and spongiform change.

Psychological factors

Depression and anxiety often follow the diagnosis of MND. The drugs of choice are SSRIs. Anxiety may require specific drug therapy. This may be short-term treatment with benzodiazepines or amitriptyline. If aggression and disinhibition occur with cognitive impairment, phenothiazines may be necessary and psychiatric support is often helpful. Emotional lability may be distressing for patient and carers and may be eased by amitriptyline or an SSRI.

Other symptoms

Insomnia is common in MND. If sleep remains disturbed after relief of pain then amitriptyline is preferable to hypnotics for sedation. Constipation is treated by dietary modification, ample fluid intake and aperients.

With severe pyramidal involvement bladder frequency and urgency may occur requiring oxybutinin.

Terminal care

Palliative care should be introduced before the terminal stages of MND. Home care teams and day centres may offer respite care in parallel with home carers. Close liaison between GP, community health care and hospice teams and palliative care physicians is essential.

Terminal care often involves alleviating psychological distress and the symptoms of bulbar weakness and respiratory failure. Patients may experience a frightening sensation of choking because of episodes of laryngospasm. Benzodiazepines and agents to dry secretions may be helpful but laryngospasm usually resolves spontaneously. Oral, subcutaneous or intravenous morphine may be indicated to relieve dyspnoea, anxiety, pain or other distress. The effectiveness of sedatives such as diazepam, midazolam or chlorpromazine in reducing anxiety in the terminal stages outweighs any depressive action of the drugs on respiratory function.

The 'Breathing Space Kit', provided by the Motor Neurone Disease Association in the UK, contains medication which can be used by the carer, nurse or GP for the emergency treatment of acute episode of respiratory distress which often occurs in the terminal stages. These include diazepam, diamorphine, chlorpromazine and hyoscine.

Carers

Following the death of an MND patient the family and carers will require bereavement support. This may be provided by the palliative care team but continuing domiciliary support may also be necessary.

Spinal muscular atrophy

Spinal muscular atrophy (SMA) represents a group of predominantly autosomal recessive disorders characterized by degeneration of anterior horn cells and bulbar nuclei. After cystic fibrosis, SMA is the second most common autosomal recessive disease of childhood (1/6000–10,000 live births). There are four clinically distinct types (Table 9.24).

1 *SMA Type I:* infantile SMA (Werdnig–Hoffmann disease);
2 *SMA Type II:* intermediate SMA;
3 *SMA Type III:* juvenile SMA (Kugelberg–Welander disease);
4 *SMA Type IV:* adult onset SMA.

Table 9.24 Summary of spinal muscular atrophy (SMA).

Condition	Genetic association	Clinical features
SMA Type I (infantile, Werdnig–Hoffman)	5q13 (SMN gene)	see text
SMA Type II (intermediate)	5q13 (SMN gene)	
SMA Type III (juvenile, Kugelberg–Welander)	5q13 (SMN gene)	
SMA Type IV Adult onset	Variable (AR or AD)	
X-linked arthrogryposis multiplex (X-linked infantile SMA)	Xp11.3–q11.2	Hypotonia, areflexia, multiple congenital contractures. Death in infancy
Diaphragmatic SMA (HMN III, IV)	11q13	Distal limb weakness
SMARD (HMN VI)	1GHMB2	Diaphragm weakness, death in infancy
Distal SMA (HMN V)	7p15 (GARS)	Often sporadic, predominantly upper limb

GARS, glycyl-tRNA synthetase; HMN, hereditary motor neuropathy; SMARD, SMA with respiratory distress type 1; SMNgene, survival motor neurone gene.

There are also rarer variants affecting bulbar, limb girdle, musculature and diaphragm with various patterns of inheritance (nomenclature tends to vary).

Genetics and aetiology

The most common types of SMA are associated with defects in ribonucleic acid (RNA) processing. Spinal muscular atrophy types I–III and some of type IV (95% of the total SMA cases) are associated with reductions in the product of the survival motor neurone (*SMNI*) gene (chromosome 5q11.2–5q13.3). The *SMNI* gene encodes a protein involved in RNA metabolism and the severity of the phenotype correlates with the level of SMNI protein. In the majority of patients it is functionally absent and survival depends on the expression of the *SMNII* gene.

Table 9.25 The differential diagnosis of spinal muscular atrophy (SMA).

Limb girdle muscular dystrophy, dystrophinopathy (Duchenne and Becker)
Acid maltase deficiency
Hexosaminidase deficiency
Congenital myopathy – nemaline, central core
Myasthenia gravis, polymyositis
CIDP
CMT 2
Kennedy's disease
MND
Paraneoplastic syndromes

Clinical features

SMA Type I (infantile, Werdnig–Hoffmann)

This develops in infancy with failure to achieve a sitting posture and death by 2 years. There may be loss of fetal movements *in utero* and the baby is born floppy with a weak cry and failure to suck, swallow and achieve head control or sitting posture. Contractures develop after immobilization and death usually occurs by 2 years as a result of respiratory failure.

SMA Type II (intermediate)

In SMA Type II (intermediate SMA) muscle weakness develops after 6 months and manifests as motor development delay. Independent sitting is achieved but not walking. Kyphoscoliosis, severe contractures, skeletal deformity and respiratory muscle weakness may lead to death in early adulthood but prolonged survival is possible if respiratory involvement is limited or with appropriate ventilatory support.

SMA Type III (juvenile, Kugelberg–Welander)

SMA Type III (juvenile SMA) becomes symptomatic in early childhood (>18 months) and patients achieve mobility. Fasciculation, cramps and a fine tremor are common and there is proximal limb weakness and wasting more prominent in the lower limbs. SMA III is highly variable and often stabilizes. Prognosis can often be predicted by the age of onset and severity. SMA III may be compatible with normal life expectancy.

SMA Type IV (adult onset)

Adult SMA represents a heterogeneous group. An autosomal dominant pattern of inheritance accounts for up to 30% of cases and is not associated with chromosome 5 abnormalities or known dHMN mutations. The clinical pattern is variable with onset between the third and sixth decades. There may be slowly progressive limb girdle or scapulo-peroneal weakness with difficulty climbing stairs, arising from chairs or walking that resembles limb girdle dystrophy. Respiratory muscle involvement and scoliosis are rare but there may be vocal cord impairment.

Other forms of SMA

Severe forms of SMA associated with death in infancy include X-linked arthrogryphosis multiplex (X-linked infantile SMA) characterized by hypotonia, areflexia and multiple congenital

contractures and diaphragmatic SMA (SMARD-1) in which there is gynaecomastia, congenital fractures and sensory neuropathy (see below). Fazio–Londe is a form of MND limited to the lower cranial nerves starting in the second decade of life and progressing to death over 1–5 years. Brown–Vialetto Van Laere presents largely in females in the second decade with bulbar palsy and deafness.

Distal SMA is a misnomer and is covered under distal hereditary motor neuropathies. Differential diagnosis: see Table 9.25

Kennedy's disease (X-linked bulbo-spinal neuronopathy)
Kennedy's disease is of particular importance because the clinical pattern resembles MND. With a frequency of 1/50,000 it is not uncommon. Kennedy's affects males with onset in the third decade or later. It is caused by a CAG trinucleotide repeat expansion in the androgen receptor gene. The condition is characterized by prominent oral and perioral fasciculation, muscle cramps, progressive dysarthria and dysphagia and progressive lower motor neurone bulbar, shoulder girdle, axial and limb weakness. UMN signs are not seen. Sensory involvement occurs. Associations include gynaecomastia, diabetes mellitus, testicular atrophy and infertility. Kennedy disease progresses more slowly than conventional MND and respiratory muscle involvement is less common. Serum CK may be elevated and nerve conduction studies may show reduced amplitude of both motor and sensory action potentials with diffuse, predominantly chronic denervation changes on EMG. The diagnosis is confirmed by genotyping.

Hexosaminidase-A deficiency
The most severe form of hexosaminidase-A deficiency is Tay–Sachs syndrome (Chapter 18). However, a milder form may develop in children or adults characterized by a form of SMA associated with prominent muscle cramps, tremor, dementia, cerebellar atrophy and sensory involvement.

Investigation
Serum CK is often normal in SMA I–IV but elevated in Kennedy, SMARD-1 and other rare forms of SMA.

Neurophysiological studies show reduced CMAPs but normal conduction velocities and SAPs, except in Kennedy's where sensory involvement is identified in 80% of cases. EMG shows acute denervation and chronic reinnervation. Muscle biopsy is not especially helpful and shows features of acute denervation and secondary myopathic change.

Genetic confirmation of mutations in the *SMN1* or androgen receptor genes is diagnostic. Mutations may not be found in some rare forms of childhood SMA and in many patients with adult onset SMA.

Management
There is no specific treatment available for SMA. The management largely involves the treatment of musculoskeletal complications which vary with age of onset and severity. However, trials of treatment are ongoing with sodium valproate, one of several agents which increases transcription from the *SMN2* gene, which may slow progress of the condition.

Ventilatory support may be necessary in SMA II. Invasive respiratory support leads to improved survival in some patients. Non-invasive ventilation may be necessary if nocturnal hypoventilation develops. Scoliosis develops if there has been paraspinal weakness prior to the growth spurt and spinal correction may be necessary to preserve mobility and ventilatory function. The provision of walking aids including braces and callipers may allow younger patients to remain ambulant for many years.

Disorders of the neuromuscular junction

Functional or structural abnormalities of the neuromuscular junction (NMJ) interfere with the transmission of neural impulses from motor nerves to muscles. In myasthenia gravis, antibodies mediate damage to the post-synaptic acetylcholine receptor. In Lambert–Eaton myasthenic syndrome, antibody-mediated block of the pre-synaptic calcium channels results in a deficit of quantal release. Congenital myasthenia is caused by defects affecting pre-synaptic, synaptic and post-synaptic mechanisms leading to NMJ impairment.

Myasthenia gravis

Myasthenia gravis (MG) is an autoimmune disorder caused by antibodies directed against the acetylcholine receptor (AChR) in the muscle membrane (Figure 9.13). The serum antibody to the AChR and its interaction with the target antigen are well characterized.

The nicotinic AChR is a transmembrane glycoprotein with five subunits arranged around a central ion channel. These subunits are designated α, β, δ, γ and ε, each of the two α units has an extracellular acetylcholine binding site. The fetal AChR has a γ subunit in place of the ε. The AChR ion channel is closed in the resting state and when the binding sites of both α-subunits are occupied the channel opens transiently. There is a continuous process of turnover and renewal of AChR at the NMJ; impaired transmission induces increased transcription of AChR genes, which eventually allows full recovery of the NMJ.

IgG anti-acetylcholine receptor antibodies (AChRAb) are detectable in 75% of patients with MG. These antibodies bind to the receptor leading to blockade and cross-link muscle surface AChR increasing their rate of internalization or bind complement leading to destruction of the muscle end-plate. Loss of voltage gated Na^+ channels at the end-plate leads to reduced muscle membrane depolarization and an increase in the threshold necessary to initiate a muscle action potential.

'Antibody negative' myasthenia gravis
20–25% of patients with MG are AChRAb negative, known as seronegative MG (SNMG). IgG auto-antibodies to muscle-specific kinase (MuSK) can be found in >50% of ocular/generalized SNMG. MuSK is a receptor tyrosine kinase expressed

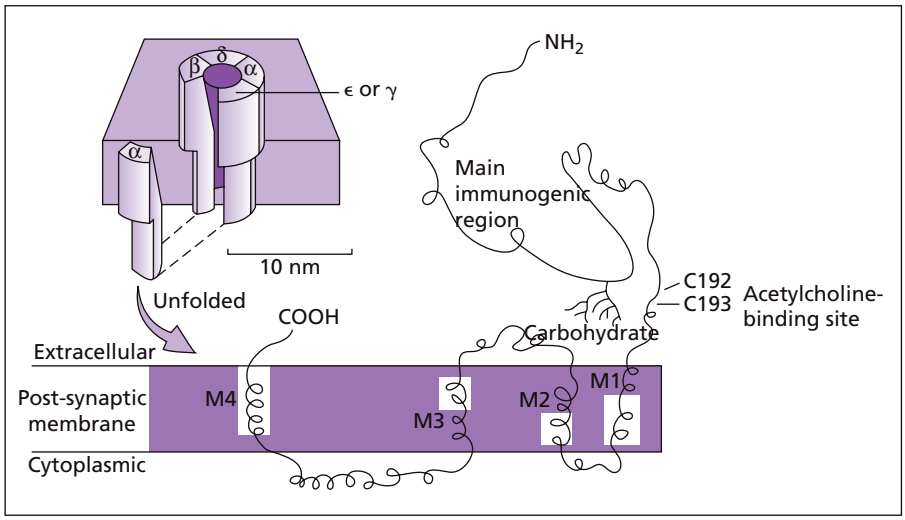

Figure 9.13 The acetylcholine receptor. The subunits of the acetylcholine receptor – α, β, γ, δ or ε are arranged like barrel staves around the central ion pore. Each subunit winds through the junctional membrane four times (sites M1, M2, M3 and M4). In the unfolded view of the subunit, the amino-terminal end of the subunit is extracellular, where it is accessible to acetylcholine, which binds at the site shown (amino acids 192 and 193). In myasthenia gravis, autoantibodies may bind to various epitopes of all subunits, but a high proportion of antibodies bind to the main immunogenic region of the subunit. (From Drachmann DB. *N Engl J Med* 1994; 330: 1797 with permission.)

Table 9.26 Drugs that impair neuromuscular transmission.

Antibiotics	Aminoglycosides (gentamicin, neomycin, streptomycin)
Antiarrhythmics	Quinine, quinidine, lidocaine and β-blockers
Antiepileptics	Phenytoin
Antirheumatoid drugs	D-penicillamine
	Chloroquine
Competitive neuromuscular junction blocking agents used during anaesthesia	D-tubocuarine
	Pancuronium
	Depolarizing agents (e.g. succinylcholine)

selectively in skeletal muscles. It helps cluster post-synaptic proteins, including AChR at the NMJ. Anti-MuSK antibodies may activate complement inducing lysis of the post-synaptic membrane.

Clinical features

MG has a bimodal pattern of onset; it occurs most commonly in women in the second and third decade but there is a second peak of incidence in the sixth and seventh decades with men being predominantly affected. Presentation is characterized by fatigable weakness in the ocular, cranial nerve, limb or truncal musculature.

A number of drugs may impair neuromuscular transmission and therefore precipitate or exacerbate myasthenic weakness; these are summarized in Table 9.26. D-penicillamine MG is usually mild and may remit when the drug is withdrawn; however, in others it may precipitate severe MG which proves difficult to control.

The initial manifestation is often fatigable visual blurring, diplopia and/or unilateral or asymmetrical ptosis which worsens towards the end of the day. Weakness remains localized to the ocular muscles in 15% of patients. The jaw, facial muscles, speech and/or swallow, neck, respiratory muscles and proximal limbs are all commonly affected. Selective diaphragm weakness is rare.

On examination, fatigable weakness can be demonstrated in any affected muscle by repetitive or sustained activity. Cogan's lid twitch sign is pathognomic. Cooling of the eye with an ice pack may lead to improvement in ptosis but its sensitivity and specificity in myasthenia remain uncertain. The ophthalmoplegia is fatigable and often does not fit the pattern of a single cranial nerve weakness. The medial and inferior rectus and superior oblique are most commonly affected but severe and occasionally total ophthalmoplegia may occur.

Respiratory muscle weakness is demonstrated by limited chest wall movement and excessive use of accessory muscles of respiration. Weakness of the truncal musculature leads to difficulty sitting from supine while limb weakness is characterized by fatigability in a limb girdle pattern. However, it may be markedly asymmetrical and occasionally distal musculature may be preferentially affected.

The anti-MuSK phenotype has a predominantly facial, bulbar and respiratory muscle weakness, often occurring in young female patients.

A differential diagnosis is summarized in Table 9.27. Myasthenia can coexist with other autoimmune diseases such as rheumatoid arthritis, pernicious anaemia, SLE, vitiligo and thyroiditis.

Diagnostic tests

The diagnosis of MG can be supported by clinical, laboratory and electrophysiological investigations.

An intravenous bolus of edrophonium may transiently improve the symptoms and signs of myasthenia and is the basis of the Tensilon test. However, false negatives are common, false positives occur with many other neuromuscular diseases, and it is contraindicated in the elderly or patients with cardiac disease.

Table 9.27 Differential diagnosis of myasthenia.

Ophthalmoplegia	Isolated cranial nerve palsies
	Thyroid eye disease
	Guillain–Barré syndrome
	Mitochondrial disease
	Oculopharyngeal muscular dystrophy
	Central causes (e.g. aneurysms, MS)
Bulbar and respiratory weakness	Acid maltase deficiency
	Motor neurone disease, Kennedy's disease
	Central causes (e.g. tumour, stroke and MS)
Proximal limb weakness	Myopathy including 'limb girdle', congenital myasthenia; inflammatory causes (e.g. polymyositis), LEMS

LEMS, Lambert–Eaton myasthenic syndrome.

Because neuroimmunological and electrical tests are now available the Tensilon test is often unnecessary.

Electrophysiological studies looking at repetitive stimulation and single fibre EMG (SFEMG) are abnormal in MG. Repetitive stimuli at a rate of 3 Hz lead to a decrement in the CMAP amplitude of >15% which should be reproducible. SFEMG is the most sensitive neurophysiological investigation of neuromuscular transmission. An increase in jitter may be restricted to the ocular or facial muscles. However, SFEMG is not specific and jitter may be seen in other disorders of the NMJ, nerve or muscle.

AChRAb are detected in approximately 75% of patients with generalized myasthenia and 50% with pure ocular myasthenia. AChRAb are the most specific marker for MG but they may be found in association with thymoma, SLE, autoimmune liver disease, inflammatory neuropathies and rheumatoid arthritis (especially when taking penicillamine) without any clinical evidence of myasthenia. Levels of AChRAb fluctuate with disease severity in an individual patient.

Anti-striated muscle antibodies are present in approximately 25% of patients with MG but up to 90% with concurrent thymoma. Anti-MuSK antibodies occur in >50% of SNMG cases and are not found in AChRAb positive MG cases. Other autoantibodies that may be present in myasthenia include anti-smooth muscle, antinuclear, antithyroid antibodies as well as rheumatoid factor and antibodies to gastric parietal cells and red blood cells.

Management

There are few randomized controlled trials in MG but treatment is based on clear principles which are determined by the age, sex, disease pattern and severity, the risk of side-effects and the availability of close clinical and investigational monitoring. Treatment may be symptomatic (anticholinesterases), disease modifying (immunosuppression with steroids, immunosuppressant drugs, immunoglobulins or plasma exchange) and/or surgical (thymectomy).

Anticholinesterases are the first line of treatment. They are of value in the early symptomatic treatment of MG as a single therapy or later as an adjunct to immunotherapy. Pyridostigmine is the most widely used. Side effects of anticholinesterases include muscle fasciculations and weakness occurring as a result of excessive stimulation of the nicotinic acetylcholine receptors. The abdominal cramps, diarrhoea, increased bronchial and oral secretions can be mitigated by antimuscarinic medication. Persistence of myasthenic weakness despite increasing doses of pyridostigmine is an indication for immunosuppressant treatment.

Corticosteroids can be extremely effective in improving myasthenic weakness and establishing remission. There is considerable variability in dosage, duration of treatment and clinical response to steroids. They should be commenced in hospital because of the significant risk of deterioration in proximal strength during the first 2 weeks of treatment. The risk is reduced if an incremental dosage is used. Marked improvement will occur in more than 50% of patients and remission in 25% with the time to maximum benefit approximately 6 months. Only 5% will show no significant improvement. While steroids are effective and inexpensive, their use is limited by considerable toxicity and they should be weaned to the lowest dosage possible to prevent glucocorticoid side effects. All patients likely to receive more than 7.5 mg/day steroid for more than 6 months should be treated to prevent iatrogenic osteoporosis, preferably with a bisphosphonate.

Azathioprine has been shown to reduce the dosage of prednisolone required to maintain remission and to reduce the number of treatment failures. The effects of azathioprine (<2.5 mg/kg) are extremely slow to develop and a therapeutic dosage may take up to 2 years for the full clinical effect to be seen. The risk of azathioprine toxicity may be reduced by screening for the activity of the enzyme thiopurine methyltransferase (TPMT) which metabolizes azathioprine. The risk of myelosuppression is increased in those with low activity.

Ciclosporin has also been shown to be effective in a randomized controlled trial. Ciclosporin has similar efficacy to azathioprine but works more rapidly. Its use is limited by significant side effects including nephrotoxicity and hypertension which contraindicate its use in pre-existing renal disease and necessitate the need for regular blood monitoring. Cyclophosphamide is now rarely used in MG because of its toxicity. Mycophenolate has recently been used as an alternative second line immunosuppressant agent if azathioprine has been ineffective or not been tolerated. It is well tolerated with relatively few side-effects.

Plasma exchange reduces AChRAb titres significantly but is often ineffective in SNMG. It is valuable in producing short-term improvement of severe myasthenic weakness but difficulties and complications of venous access, biochemical derangements and high overhead costs limit its use. IVIG is similar in efficacy to plasma exchange and is valuable in producing short-term improvement in myasthenic crisis and also occasionally as a long-term maintenance therapy.

Thymectomy has been used in the treatment of MG for 50 years. Approximately 15% of patients with MG have a thymoma (Figure 9.14) while up to 50% of patients with thymoma will develop myasthenia which may occur even after thymectomy. CT or MR imaging of the mediastinum should be undertaken

Figure 9.14 Large anterior mediastinal thymoma in an 80-year-old patient with mild generalized MG (MRI T2W).

in all patients with MG to exclude thymoma. Most are benign and encapsulated; however, 10% show malignant features with invasion of the capsule, local spread, seeding or even distant metastasis. Postoperative radiotherapy is generally recommended for invasive thymoma in which the tumour capsule has been penetrated. If metastatic spread has occurred, chemotherapy may be highly effective with varying regimes including cyclophosphamide, vincristine, cisplatin and doxorubicin proving effective, not just in reducing the thymoma, but also in controlling the myasthenia.

Objective evidence of the efficacy and role of thymectomy remains elusive. Evidence from open studies indicates thymectomy for non-thymomatous autoimmune MG increases the probability of remission or improvement. Up to 46% of patients with thymic hyperplasia may achieve full remission within 2–5 years of surgery and significant improvement and reduced treatment will be seen in up to 40%. Thymectomy is indicated for patients with seropositive MG from late childhood up to the age of 60 years. In those over 60 years, those with seronegative or ocular MG the role of thymectomy is less clear.

Ocular myasthenia gravis

In about 15% of MG the disease remains localized to the orbicularis oculi and extraocular muscles although EMG may show generalized NMJ abnormalities. Remission may occur in up to 20%. Response to anticholinesterases is often disappointing. Immunosuppression with steroids and azathioprine may be necessary if ptosis or diplopia are symptomatic.

Pregnancy and myasthenia

The effects of pregnancy on the patient and fetus should be considered separately. Myasthenia may worsen, improve or remain stable during pregnancy but there is a significant risk of deterioration in the puerperium. Pregnancy should ideally be planned when the patient is strong, steroids should be maintained at the lowest therapeutic dosage and, if possible, other immunosuppressants should be avoided. If pre-eclampsia occurs, magnesium sulphate should not be used because of the risk of further impairment of NMJ transmission.

The newborn is at risk of transient neonatal myasthenia which occurs in about 10% of myasthenic pregnancies. This condition is caused by transmission of anti-acetylcholine receptor antibody across the placenta.

Myasthenic crisis

Myasthenic crisis indicates the development of ventilatory failure. Approximately 20% of patients with MG will develop myasthenic crisis and, in up to 10%, there may be more than one episode. Respiratory failure in MG may be precipitated by bronchopneumonia, systemic sepsis, medication, surgery or inadequate treatment often related to a rapid tapering of the steroid dosage. Rarely, cholinergic crisis or the commencement of high-dose corticosteroids is to blame. In acute respiratory failure urgent elective tracheal intubation and ventilation should be considered when the vital capacity falls below 15 mL/kg. The rate of progression, the presence of bulbar weakness and the state of the patient are also crucial to the decision (see Chapter 19).

Cholinergic crisis

Cholinergic crisis is rare but should be suspected in patients taking high doses of anticholinesterase medication who have extensive cholinergic side effects. It may be necessary to admit the patient to ITU, intubate and ventilate and withdraw all anticholinergic medication.

Anaesthesia and peri-operative care

Because myasthenic crisis may be precipitated by anaesthesia, the stress of surgery or non-depolarizing neuromuscular blocking agents, elective surgery should be undertaken with experienced anaesthetic support following pre-operative plasma exchange or IVIG if necessary.

Other causes of abnormal neuromuscular transmission

Snake venoms, tick paralysis and toxic agents including organophosphates may affect neuromuscular transmission. Organophosphates (OPs) are used as nerve agents (Chapter 18) but are also widely employed as pesticides. Exposure may be occupational, food-borne or as a consequence of suicide attempts. Acute exposure results in cholinergic crisis. Respiratory muscle weakness is resistant to atropine and intubation is required. Longer term OP exposure may lead to a myasthenic syndrome or an axonal sensory motor neuropathy. Rarely, OP toxicity may cause late onset of neuropsychiatric and cognitive impairment or a parkinsonian syndrome.

Table 9.28 Causes of congenital myasthenia.

Pre-synaptic defect	
Reduced synaptic vesicles	Autosomal recessive
Failure of ACh resynthesis or packaging (choline acetyltransferase deficiency)

Acetylcholine receptor kinetic abnormality	Autosomal dominant > autosomal recessive
Channelopathies	
Slow channel	
Fast channel	
Sodium channel	

ACh, acetylcholine; AChR, acetylcholine receptor; CMS, congenital myasthenia syndrome.

Congenital myasthenia

Congenital myasthenic syndromes (CMS) are caused by inherited abnormalities of the NMJ that interfere with normal synaptic transmission. The conditions are rare but important to distinguish from SNMG because of the implications for management and genetic advice. In most patients there is a malformation in the structure or function of the pre- or post-synaptic NMJ although congenital acetylcholine deficiency may occur. The classification of CMS is summarized in Table 9.28. Abnormalities of post-synaptic function are most common.

Clinical features

CMS may present in infancy with hypotonia, failure to thrive, delayed motor milestones and unexplained apnoeic episodes. In children and adults the conditions are manifest as fatigable or fluctuating, ocular, facial and bulbar weakness although limb and truncal wasting and weakness may also be prominent. The weakness tends to progress during adolescence but then often stabilizes. There may be episodic worsening of the weakness, possibly triggered by intercurrent events such as pyrexia. On examination there is fatigable muscle weakness on exertion but a prominent myopathy and scoliosis may be present. Distal weakness, ocular and pupillary abnormalities are also occasionally present. There may be a positive family history. In infancy CMS may mimic muscular dystrophy, congenital and metabolic myopathy, spinal muscular atrophy or structural brainstem anomalies. In children and adults it is necessary to distinguish CMS from SNMG, forms of MND, LGMD and neuropathies.

Investigation

Standard MG investigations document an abnormality at the NMJ. Confirmatory diagnostic evidence comes from morphological and genetic NMJ studies. These include microelectrode recordings of miniature end-plate potentials to nerve stimulation, EM studies of intercostal muscle AChR density studies using iodine-123 labelled bungarotoxin, patch clamp studies of individual channels at the NMJ and genetic studies of target genes in the AChR and post-synaptic structure. There is no definitive treatment.

Lambert–Eaton myasthenic syndrome

Lambert–Eaton myasthenic syndrome (LEMS) is a rare disorder caused by impaired release of ACh by the presynaptic terminal of the NMJ. It is associated with underlying malignancy or autoimmune disease. LEMS is characterized by weakness and fatigue.

Clinical features

The onset is often insidious with the gradual development of progressive weakness and fatigue. The condition may occur at any age but is more common after 40 years. Underlying malignancy may be present in up to 50% of patients although this may not become apparent until more than 4 years after the onset of LEMS.

Fatigue is prominent at presentation. Weakness may affect the proximal muscles, particularly the legs and is often associated with aching and stiffness. Autonomic features including dry mouth, constipation and impotence are also common. Ophthalmoplegia, ptosis, bulbar and respiratory muscle weakness can occur but are less common than in seropositive autoimmune MG. Examination findings are characterized by proximal weakness with a fatigable component. Reflexes are reduced or absent but after a short period of sustained effort they become brisker showing the phenomenon of post-tetanic potentiation.

The most common underlying tumour is small cell lung cancer (>80%) but LEMS has also been reported in association with lymphoproliferative disorders, malignant thymoma and rarely with carcinoma of the breast, stomach, colon, prostate, kidney and bladder.

Aetiology

LEMS is an autoimmune disorder driven by antibodies to the voltage gated calcium channel (anti-VGCC Ab) of the presynaptic terminal. Serum from up to 90% of patients with paraneoplastic and autoimmune LEMS contain anti-VGCC Ab. In patients with small cell lung cancer it is likely that cancer cells contain antigen which mimics VGCC and induces the production of antibodies while the mechanism of production in the autoimmune condition is unclear.

Investigations

The diagnosis of LEMS is established by the presence of anti-VGCC antibodies and by characteristic electrophysiological findings. A small CMAP, a decremental response to repetitive

stimulation at low frequency (1–5 Hz) and an increment following sustained maximum voluntary contraction or 20–50 Hz repetitive stimulation are typical. SFEMG shows increased jitter and block.

A search for underlying malignancy and in particular small cell lung cancer must be conducted including FDG-PET if necessary. Malignancy negative LEMS patients should be closely followed up as an underlying tumour may become apparent after a long latent period.

Treatment

Any underlying carcinoma must be appropriately treated. Successful treatment often leads to improvement in LEMS.

Specific treatment is directed towards facilitation of neuromuscular transmission, removal of the antibody or suppression of its production. Pyridostigmine has a mild effect in enhancing neuromuscular transmission but most patients require 3,4 diaminopyridine which blocks presynaptic K^+ channels, lengthens depolarization of the nerve terminals and increases quantal ACh release. It is associated with paraesthesiae, anxiety and insomnia and an increased risk of seizures. If severe weakness persists despite these treatments immunomodulation treatment is indicated. The response to plasma exchange and IVIG is less reliable than in MG. Prednisolone, azathioprine and ciclosporin are all effective in LEMS.

Muscle diseases

The understanding of muscle disease has undergone a revolution in the last 20 years as a result of advances in immunohistochemistry and genetics which now allow accurate diagnosis of most of the inflammatory, genetic and metabolic muscle diseases. Many muscle diagnoses are now being revised as new knowledge becomes available.

Basic muscle biology

Muscle is a complex assembly of interacting proteins. Its principal function is to respond to a stimulus from a motor neurone by physically shortening its contractile apparatus with the conversion of electrical and chemical to mechanical energy.

The basic unit of a striated muscle is the myofibril. The myofibril is made up from many repeating functional multiprotein complexes of actin, myosin and titin called sarcomeres, the smallest functional unit of muscle. Thousands of sarcomeres are arranged end-to-end, giving muscle its striated microscopic appearance. Together these form the contractile apparatus. 'Thin' filaments of actin and 'thick' myosin filaments are arranged such that they may slide over each other, retaining their own length but shortening the sarcomere as the thin filaments are pulled towards the centre. The sarcomeres and myofibrils are enveloped in the mesh-like structure of the sarcoplasmic reticulum, which is central to excitation–contraction coupling.

In its simplest terms, electrical stimulation of the muscle cell causes a release of calcium ions from the intracellular sarcoplasmic reticulum. This in turn activates the contractile apparatus (Figure 9.15a) and an energy-dependent interaction occurs between the actin and myosin filaments of the sarcomere. As calcium levels fall, the interaction between actin and myosin ends, the sarcomere extends again and so the muscle relaxes.

Together with the sarcomere is an array of other structures. First, a series of structural proteins anchor the contractile apparatus within the sarcomere (Figure 9.15a). A number of further proteins then link the sarcomere to the cell membrane (the sarcolemma) and extracellular matrix (Figure 9.15b). Dystrophin is attached at one end to actin and at the other to a complex of glycoproteins (including, amongst others, the dystroglycans, sarcoglycans and laminin) that are closely associated with the sarcolemma. In addition, various ion channels span the cell membrane, and their role in moderating the influx and efflux of potassium, sodium, calcium and chloride is crucial to proper muscle function.

Muscle is a complex structural and functional unit. Genetic or acquired abnormalities of any of the proteins or processes above may result in disease. However, muscle is also highly metabolically active tissue and so is vulnerable to any derangement of energy release. Disorders of metabolism (carbohydrate, lipid, oxidative phosphorylation) therefore form the other fundamental basis of muscle disease.

Clinical assessment of the patient with muscle disease

Some muscle diseases such as Duchenne muscular dystrophy, myotonic dystrophy or inclusion body myositis can often be confidently diagnosed at the bedside. For the remainder, the clinical assessment of patients remains paramount. Although diagnostic investigations for suspected muscle disease have never been so powerful, notably with the ability of DNA testing to confirm the presence (or absence) of a disease-causing genetic defect, further evaluation must be guided appropriately by the differential diagnosis generated from the findings of the history and examination.

History

The primary focus of any history is on the particular complaint of the patient. The most fundamental symptoms of muscle disease are given in Table 9.29. It is crucial to ensure that what the patient reports is, in fact, what he or she means. This is not always an easy task. 'Weakness' may refer to stiffness, tiredness or pain. Persevere.

As with all disease where the differentiation of genetic from acquired disease is important, the date of symptom onset is very useful. Open questioning may reveal the perceived onset. Subsequent specific questions should be asked about the patient's antenatal history, birth, developmental milestones, sporting ability and achievements and general health in youth. The onset may regress by a decade or two.

Pigmenturia (try 'coca-cola urine') should be specifically asked for, together with any provocation and whether it was associated

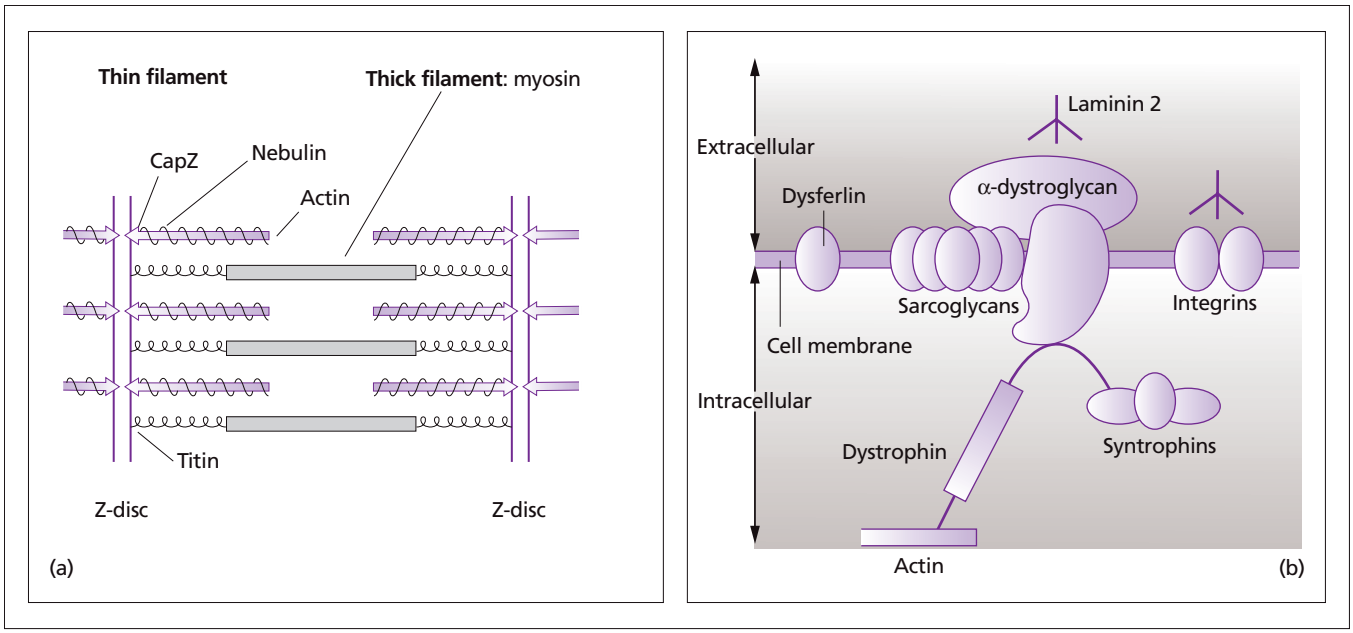

Figure 9.15 (a) Simplified schematic representation of muscle contractile apparatus. Thin filaments are comprised of actin molecules as the core, wrapped in the template protein, nebulin, plus troponin and tropomyosin (latter two not shown). They are capped at the Z-disc with CapZ and at the other end with tropomodulin (not shown). Thick filaments of myosin are bound by titin to the Z-disc. One element of titin is elastic. Contraction involves interaction of thick and thin filaments so latter move towards centre. (b) Simplified schematic representation of muscle cell membrane and associated non-neuromuscular junction proteins. (Some components omitted for clarity.)

Table 9.29 Issues important in history-taking in muscle disease.

Symptom	Details
Weakness	Confirmation of reduced strength and function
	Onset, duration and progression
	Assessment of degree of weakness and subsequent disability, e.g. date of first use of walking aids
	Pattern of muscle involvement – proximal limb (reaching objects from shelves, standing from sitting) versus distal limb (opening jars or bottles, tripping over) versus selective focal
	Variability and, if present, exacerbating or relieving factors (always consider the possibility of fatigability)
Pain	Confirmation of myalgia, rather than, for example, impaired sensation
	Localized versus generalized
	Severity
	Precipitating, exacerbating or relieving factors
	Association with any other symptom
Cramps	Localised versus generalised
	Precipitating, exacerbating or relieving factors
	Association with any other symptom
Stiffness	Identification of specific failure of relaxation (myotonia), e.g. difficulty releasing grip or opening eyes
	Localized versus generalized
	Exacerbating or relieving factors
Fatigue	Distinction from other symptoms
	Precipitating, exacerbating or relieving factors
Pigmenturia	Precipitating factors
	Association with any other symptom

with other symptoms. Some patients may have had solitary or only infrequent episodes.

Paroxysmal or variable symptoms (e.g. cramps, spasms, stiffness – and more specifically myotonia) require further questions, seeking to identify provoking, exacerbating or relieving factors. Such influences may be crucial in refining the clinical features of a channelopathy.

Other relevant systems need to be enquired about, with particular attention paid to cardiac symptoms (palpitations, exertional dyspnoea, ankle swelling and paroxysmal nocturnal dyspnoea) and respiratory complaints (especially any suggestion of neuromuscular compromise, often first manifest as unrefreshing sleep, orthopnoea, morning headache or daytime tiredness). A suspected multi-system condition requires attention be paid to other possible involvement (e.g. the rash of dermatomyositis or deafness in mitochondrial disease).

The history should also document the current function of the patient (working from head to toe). This semi-quantification is useful to assess any change over time, and also in answering specific questions later (as typically generated by welfare benefit assessments, driving licence reviews and other bureaucratic agencies).

Assessment of the past medical history is directed at identifying other conditions that may either cause muscle symptoms (e.g. rheumatological or endocrine disease), mimic them or make their assessment or treatment more difficult (e.g. orthopaedic conditions or a peripheral neuropathy). Specific questions should be asked about any difficulties with anaesthesia. Myotonic dystrophy may first be revealed by peri-operative cardiac arrhythmia or difficulty weaning from a ventilator, while certain myopathies, notably central core disease but also the dystrophinopathies, can lead to malignant hyperthermia reactions. A thorough medication history is also required, including over-the-counter preparations, alternative remedies and recreational drugs, and any temporal association with symptoms explored.

Examination

As part of a complete neurological examination, this should follow the classic procedure of inspection, palpation and assessment of power and function, with certain particular measures in addition, such as testing for myotonia. Inspection should be focused on assessment of muscle bulk (palpation can identify subtle wasting, and also note textural differences in muscle), any involuntary movements (fasciculation, myokymia, myotonia) and any skeletal abnormalities (e.g. scapular winging, kyphoscoliosis).

Power assessment may well require additional examination techniques to those routinely employed. Subtle facial weakness can be revealed by formally testing eyelid and lip closure. Speech gives a good indication of lingual and palatal function and specific requests for buccal, palatal and lingual consonant production in addition to a demonstration of a cough (see below) and a sustained note can indicate more specific impairments. Neck extension and flexion should be tested with the patient both lying and upright. Neck power patterns can be very revealing.

Table 9.30 Simple bedside functional motor tests.

Lifting head from lying down
Straight leg rising from lying down
Standing from lying down and/or squatting and/or sitting
Ability to walk on heels or on tiptoes
Ability to hop on one foot
Ability to run
Time to walk a specified distance
Time to climb a flight of stairs
Raising arms above head

Experienced clinicians learn that muscle strength testing needs appreciation of the confounding actions of suboptimal effort ('give-way' weakness) or when pain is a limitation. Accordingly, bedside tests of disability rather than impairment can give a more useful guide, particularly on serial examinations, to assess disease progression or treatment effect when impairment testing is not so reliable (Table 9.30).

Myotonia should be tested by sustained grip or eyelid closure, and/or by percussion of appropriate muscles (e.g. thenar eminence, forearm or even the tongue). Respiratory function can be assessed by looking for abdominal paradox on deep inspiration and expiration (the abdomen normally distends on inspiration), plus specific assessment of sniff and cough strength. Spirometry allows quantification of respiratory function, with the caveat that poor effort and air leak resulting from facial weakness must be taken into consideration.

Investigation of muscle diseases

Creatine kinase

This enzyme is continuously released at low level in to the circulation, a process increased by any injury to muscle or by excessive activity. In addition, there is considerable variation in CK levels across a normal population. CK is proportional to the muscle bulk of an individual, and routine exercise and alcohol will increase the levels. Furthermore, values in Afro-Caribbean and Asian populations are higher. Thus, the CK result should be interpreted in the light of an appropriate normal range. Quantification of different isozymes (e.g. myocardial CK-MB) is not of use, although it should be noted that other enzymes may be released from muscle (such as AST). Finally, some muscle disorders (notably myotonic dystrophy) do not usually cause CK to be elevated.

Neurophysiology

Needle EMG can be helpful in distinguishing myopathy from an otherwise indistinct lower motor neurone pattern of weakness. The classic findings in myopathy are spontaneous activity with fibrillations, positive sharp waves and complex repetitive discharges plus polyphasic, low amplitude, short duration units on voluntary contraction. This pattern is common to several underlying processes and neurophysiological examination is less useful

in refining the diagnosis of muscle disease than when used to investigate neuropathy. Other electrophysiological phenomena may be seen, such as myotonia – sustained activation, while specialized serial examination after cooling a limb, or after exercise of varying duration, forms a crucial element in assessing possible channelopathies.

Muscle biopsy

Muscle biopsy is often the keystone of diagnosis. It should be considered and, if possible, performed in all cases before any treatment is initiated. Close liaison with the pathologist and technician is essential because experience in both the preparation of biopsy material and its microscopic evaluation is critical. Practically this may necessitate sending the patient or the biopsy specimen material to a specialist centre. The muscle selected should ideally be moderately involved. Pathologists often have particular experience with certain muscles and this should influence the choice.

Initial histological diagnosis is based on the presence or absence of inflammatory change, necrosis, fibre atrophy or other structural change (vacuoles or inclusion bodies). Enzyme stains may identify certain conditions (e.g. absent acid phosphorylase in McArdle's disease, or reduced cytochrome oxidase staining in mitochondrial disorders). Immunostaining for various structural proteins (e.g. dysferlin, desmin and the sarcoglycans) have greatly improved the diagnosis of the dystrophies, as patterns of reduced or altered expression have been identified. If required, EM may detect more subtle abnormalities (glycogen molecules, or features of mitochondrial disease not otherwise apparent).

Metabolic testing

Exercise testing (most safely performed non-ischaemically), with serial collection of blood samples for lactate and ammonia levels in normal subjects generates a three- to fivefold increase in both. However, in glycolytic or glycogenolytic disorders, the lactate rise is reduced (or absent) with excessive elevation of ammonia. Myoadenylate deaminase deficiency, by contrast, causes a normal rise in lactate but no change in ammonia. Specialized centres can perform analysis of other enzyme function in biopsied muscle, such as the mitochondrial respiratory chain or carnitine metabolism.

Genetic testing

Specific DNA analysis has revolutionized diagnosis of muscle disease. In some conditions of distinctive clinical appearance (e.g. myotonic dystrophy or facioscapulohumeral muscular dystrophy [FSHD]), it can form the first step in investigation, possibly sparing the patient more invasive tests. In other situations, such as the limb girdle dystrophies, genetic testing should be appropriately guided by other findings, notably the muscle biopsy.

Genetic muscle diseases

The clinical practice and understanding of genetic muscle disease is changing rapidly as a direct result of the wealth of recent molecular genetic discoveries. Approximately 1/6000–7000 of the UK population has one of many diverse genetically determined muscle diseases. Duchenne muscular dystrophy, caused by mutations in the dystrophin gene, is a young onset severe progressive muscle wasting disease which can be lethal in late teens without appropriate respiratory and cardiac support. In contrast, some myopathies caused by mutations in mitochondrial DNA can develop in late adult life manifesting as external ophthalmoplegia or mild proximal myopathy with a relatively indolent course. The mortality in genetic muscles diseases is often determined by the degree of cardiac and/or respiratory muscle involvement and therefore cardiorespiratory screening is essential in the assessment of patients presenting with suspected genetic muscle disease. Careful clinical evaluation and attention to the family history will reduce the differential diagnosis sufficiently to rely on direct genetic testing alone. Sometimes EMG and muscle biopsy may not be required. Where the distinction between inflammatory and genetic myopathy is difficult, genetic testing may now be helpful in resolving it. In a specialist muscle service one sees many cases where prominent inflammatory infiltrates on biopsy have led to the erroneous diagnosis of polymyositis in patients subsequently shown genetically to have dysferlinopathy or FSHD.

Where a precise DNA-based diagnosis is possible patients and families can be provided with accurate prognostic and genetic counselling information and entered into a rational screening programme for recognized complications. As national networks for DNA-based diagnosis become available more patients will have access to this diagnostic precision.

Genetic testing is now often the first investigation in myotonic dystrophy and FSHD and, if positive, muscle biopsy is often not required. In other more heterogeneous genetic muscle diseases, such as limb girdle muscular dystrophy (LGMD), muscle biopsy with careful immunohistochemical analysis is usually required to direct gene testing. However, as gene sequencing technologies become increasingly available even LGMD gene analysis may be selected at an earlier stage in the diagnostic process.

In this section we mention the more common genetic muscle diseases (Table 9.31) encountered by adult neurologists. The aim is to describe clinical features and to suggest an efficient diagnostic strategies (Table 9.32). DNA-based diagnosis may accelerate and simplify the diagnostic process, thereby providing the most accurate information for patients with these diseases.

Muscular dystrophies

Many genes causing different muscular dystrophies have been discovered in recent years. The causative proteins have various functions; dystrophic muscle may be the relatively non-specific end result of a number of different pathogenic pathways. The proteins identified to date include sarcolemmal structural proteins (e.g. dystrophin, sarcoglycans and dysferlin), nuclear envelope proteins (emerin, lamin a/c), enzymes (calpain, fukutin-related protein), sarcomeric proteins (myotilin) and extracellular matrix proteins (laminin, collagen type 6; Figure 9.15b). For some disorders, such as myotonic dystrophy, a single gene accounts for

most cases and a simple gene test is available. In contrast, for other disorders, such as LGMD, the situation regarding testing is more complex because of genetic heterogeneity.

Xp21 dystrophies: the dystrophinopathies

Dystrophin is a major muscle cell structural protein that lies just below the sarcolemma and helps to stabilize the sarcolemma during muscle contraction. It links intracellular actin to a complex set of transmembrane proteins which in turn link to elements of the extracellular matrix (particularly to an extracellular protein called laminin). Genetic defects in the dystrophin protein are associated with two major phenotypes: Duchenne and Becker muscular dystrophy.

Duchenne is an aggressive and lethal dystrophy affecting boys in which there is a severe reduction in the amount of the dystrophin protein in muscle. To date there is no curative treatment, but improved ventilatory support has recently been shown to increase the quality of life and life expectancy.

Becker muscular dystrophy is more likely to be encountered in adult muscle practice. Severity correlates with the amount of dystrophin protein present. Becker patients present as a limb girdle pattern of muscle weakness with pseudohypertrophy of calf muscles. Cardiomyopathy is an important complication; occasionally, severe dilated cardiomyopathy may be the presenting feature.

Diagnosis can be achieved by genetic testing. However, most testing protocols only screen a proportion of the gene as it is so large. Therefore a 'negative' genetic test does not exclude the diagnosis. A muscle biopsy with dystrophin immunohistochemical studies may therefore be required.

Genetic counselling in families as for an X-linked recessive disease is important but one-third of dystrophinopathy cases represent new mutations without family history. Female carrier status may be ascertained by dosage-sensitive polymerase

Table 9.32 Diagnostic strategies for inherited myopathies.

Condition	DNA based diagnosis available?	Muscle biopsy needed?
Xp21 dystrophies (dystrophinopathies)	Yes, but negative gene test does not exclude diagnosis	Yes, if genetic test negative
Emery–Dreifuss muscular dystrophy	Yes, but usually only after immunohistochemistry for lamin a/c and emerin	Yes, muscle biopsy remains important
Limb girdle muscular dystrophies	Yes, check *FKRP* gene first. If negative muscle immunohistochemistry will reduce number of candidate proteins	Yes, muscle biopsy required in most cases
Facioscapulohumeral dystrophy	Yes, indirect genetic test available through regional genetics laboratory	Not usually unless genetic test for *FSHD* negative. Inflammatory muscle biopsy may cause difficulty distinguishing from polymyositis
Oculopharyngeal muscular dystrophy	Yes	Not usually
Myotonic dystrophy and PROMM	Yes	Not usually, unless gene tests for MD/PROMM negative
Bethlem myopathy	Not widely available. Consider skin and muscle biopsy. Exclude lamin a/c, emerin and SEPN1	May be helpful for exclusion. May not be definitive
Mitochondrial respiratory chain diseases	Yes (?age associated decline in MtDNA mutation load in blood). *POLG* gene analysis in CPEO	Yes (a) If blood MtDNA analysis negative (b) Muscle needed for mitochondrial enzyme analysis (c) Muscle MtDNA better for MtDNA analysis
Metabolic muscle disorders (glycogenoses, lipidoses)	Yes, but not usually first line	Yes. Also consider specialist metabolic testing, often first line, e.g. non-ischaemic lactate test (glycogenoses) or blood acylcarnitine/urinary organic acids (lipid disorders)

CPEO, chronic progressive external ophthalmoplegia; FKRP, fukutin-related protein; FSHD, facioscapulohumeral dystrophy; MD, mytonic dystrophy; POLG, polymerase gamma; PROMM, proximal myotonic myopathy; SEPN1, selenoprotein 1.

chain reaction (PCR). The importance of the need for an effective treatment has provoked great interest in gene therapy approaches and trials are in progress.

Emery–Dreifuss muscular dystrophy

Emery–Dreifuss muscular dystrophy (EDMD) is a readily recognizable muscular dystrophy which should be considered if contractures are a prominent early clinical feature. Patients present with a scapulohumeroperoneal pattern of muscular weakness and often have strikingly thin muscles. Contractures of the cervical extensor muscles as well as the biceps and long finger flexor tendons are common. Cardiac conduction defects are also frequent and cardiac screening is important.

EDMD is now known to be caused by mutations in genes coding for nuclear envelope proteins emerin and lamin A/C which are located in the membrane surrounding the muscle cell nucleus. Their exact function is uncertain. Emerin causes the X-linked form of EDMD and lamin A/C causes the less common dominant and recessive forms. Accurate genetic diagnosis is critical to provide accurate genetic counselling. Mutations in the lamin A/C gene have also been described in a form of LGMD (LGMD1B; Table 9.33), an autosomal recessive axonal neuropathy and partial lipodystrophy.

Congenital muscular dystrophy

The congenital muscular dystrophies are a genetically heterogeneous group of disorders which present at birth often as floppy infants, who subsequently experience impaired motor and sometimes cognitive development. Kyphoscoliosis is common and varying degrees of brain developmental abnormalities may occur. The degree of CNS involvement tends to determine the overall clinical severity. Patients at the mildest end of the spectrum may present in late teens to the adult neurology muscle clinic with an indolent myopathy, sometimes with contractures.

Nine genes causing CMD have been identified and a classification into five clinical subtypes has been proposed based partly on the underlying molecular defects. In all but one group there is a major defect in the basal lamina or the extracellular matrix of the skeletal muscle fibre. Group 1 patients have a defect in laminin α2. Group 2 patients have defects in glycosylation of α-dystroglycan and some are therefore allelic with LGMD2I caused by *FKRP* mutations (see LGMD section). Group 3 exhibit severe contractures and have defects in extracellular matrix, e.g. collagen type-6, and selenoprotein N (SEPN1). Group 4 have a reduction in integrin α-7 and Group 5 remain uncharacterized.

Table 9.33 Genes/proteins causing limb girdle muscular dystrophies (LGMD).

Type	Chromosome	Protein	Clinical
Autosomal dominant			
LGMD 1A	5q22–q34	Myotilin	Rare, distal legs affected first; slow progression, late CMP in 50%; CK 2–10 × normal
LGMD 1B	1q	Lamin a/c	Rare; proximal legs affected first; slow progression; CMP in 60%; CK 1–2 × normal
LGMD 1C	3p25	Caveolin	Uncommon; variable phenotype: raised CK to progressive proximal weakness, no CMP, CK 3–40 × normal
LGMD 1D	7q	Unknown	Two families; proximal weakness, no CMP, CK 1–3 × normal
LGMD 1E	6q23	Unknown	Single family, proximal weakness, frequent sudden death from CMP; CK 2–4 × normal
LGMD 1F	7q32	Unknown	Single family, proximal weakness, no CMP CK often normal
Autosomal recessive			
LGMD 2A	15q15	Calpain	Uncommon but many different mutations found, very varied phenotype; no CMP, CK 3–80 × normal
LGMD 2B	2p13	Dysferlin	Uncommon with many different muations and variable phenotype (including within family); typically distal weakness; no CMP, CK 10–80 × normal
LGMD 2C	13q	γ-sarcoglycan	Rare, often early onset and loss of walking; respiratory weakness in some, CMP unusual, CK 5–20 × normal
LGMD 2D	17q21	α-sarcoglycan	Rare, variable phenotype but can be early onset, CMP unusual; CK 5–20 × normal
LGMD 2E	4q12	β-sarcoglycan	Rare; typically early onset with severe disability; CMP occasionally; CK 5–20 × normal
LGMD 2F	5q33	δ-sarcoglycan	Rare; early onset with severe disability; proximal weakness; CMP unusual; CK 10–50 × normal
LGMD 2G	17q11	Telethonin	Rare; teenage onset with proximal and distal leg weakness; CMP in 50%; CK 10–30 × normal
LGMD 2H	9q31	TRIM32	Very rare, slow progression; no CMP; CK 2–20 × normal
LGMD 2I	19q13	FKRP	Most common in UK; variable phenotype but respiratory involvement not uncommon and CMP in 30%; CK 4–30 × normal
LGMD 2J	2q31	Titin	Very rare; alleic to Finnish distal myopathy: causes proximal weakness but often relatives with distal weakness
LGMD 2K	9q34	POMT1	Rare; progressive proximal weakness with learning disability and ankle contractures; CK 8–40 × normal
LGMD 2L	11p13	None known	Very rare; CK very raised, no CMP. French–Canadian families, quadriceps and biceps weakness
LGMD 2M	9q31	Fukutin	Very rare; CK very high, infantile onset, proximal and distal weakness legs >arms. May improve with steroids

CK: creatine kinase; CMP: cardiomoyopathy; FKRP, fukutin-related protein; POMT, protein O-mannosyltransferase.

Limb girdle muscular dystrophies

There have been many recent gene discoveries in LGMD. An array of proteins with surprisingly different functions has been shown to cause the LGMD phenotype (Table 9.33). Although patients have the common feature of a limb girdle pattern of muscular weakness without facial involvement, clinical differences exist. For example, the propensity to develop cardiomyopathy or respiratory muscle failure varies considerably between different forms. DNA-based diagnosis will allow logical monitoring programmes of cardiac and respiratory function to be developed.

The recessive LGMDs are far more common than the dominant forms. Three of the most common recessive forms for which gene testing is increasingly available are considered in detail.

Calpainopathy – LGMD2A

LGMD caused by calpain mutations typically develops around the age of 15 years with a range of onset between 2 and 40 years. Early milestones are usually normal and pelvic girdle muscle weakness precedes later development of shoulder girdle weakness. On examination, there is typically a scapulohumeralpelvic distribution of weakness. The involvement of periscapular muscles is reminiscent of FSHD but facial involvement is absent or minimal. Muscle atrophy is usually a prominent feature, as opposed to hypertrophy in many other dystrophies (e.g. Becker dystrophy and LGMD21). Particular atrophy of the posterior compartment of the thigh may be a distinguishing clinical feature compared to other LGMDs. Loss of ambulation usually occurs 12–30 years after the onset. Cardiac involvement is not a feature and reduced vital capacity seems to occur only in severe very advanced cases. CK is elevated initially in the course of the disease but not as high as in LGMD2I, dystrophinopathies or LGMD2B.

Dysferlinopathy – LGMD2B

There is a broad phenotypic range associated with mutations in the dysferlin gene. Most simply, there is a proximal LGMD type presentation and a distal presentation (also known as Miyoshi myopathy; see below). In the LGMD presentation, weakness usually begins between 18 and 20 years in a pelvifemoral distribution, often with marked quadriceps involvement. The onset may be relatively abrupt with a very high CK leading to polymyositis as a differential diagnosis. Later, weakness in the arms develops with particular involvement of the biceps. Weakness usually spares the deltoids and also the periscapular muscles so scapula winging is not usual. A degree of lower limb distal involvement affecting gastrocnemius and soleus is not uncommon. Imaging of gastrocnemius may show early changes and may be diagnostically helpful in an otherwise LGMD presentation. Facial and extraocular muscles are spared. Cardiac involvement is not reported.

The other main presentation of dysferlinopathy is with marked lower limb posterior calf compartment weakness, known as Miyoshi myopathy. Patients complain of difficult standing on their tip-toes and over time the weakness spreads to include the limb girdle muscles. A very high CK and sometimes marked infiltrates in the muscle biopsy can cause confusion with myositis but immunohistochemistry using dysferlin antibodies in combination with genetic analysis of the dysferlin gene is usually diagnostic.

Fukutin-related protein dystrophy (LGMD2I)

LGMD2I usually presents between the ages of 11 and 40 years with a mild phenotype but can present with a severe Duchenne-like pattern and degree of weakness. The distribution of muscle involvement is similar, irrespective of the severity with a predilection for axial, neck flexor and the proximal pelvic and shoulder girdle muscles. Facial muscles are usually spared. Scapula winging is common. There may be striking hypertrophy of the tongue, brachioradialis, calves and sometimes the quadriceps. In contrast, there may be atrophy of pectoralis major and deltoid muscles. Prominent lumbar lordosis is common and exercise induced cramping is a frequent complaint. Importantly, one-third of cases develop a dilated cardiomyopathy. Respiratory muscle involvement is also common, manifesting as nocturnal hypoventilation. In contrast to dystrophinopathies, respiratory failure may occur even while the patient remains ambulatory. LGMD2I is caused by mutations in the gene known as the fukutin-related protein (FKRP) which codes for a glycosylation enzyme. Recent data suggest it may be the most common cause of adult onset LGMD identified to date and a single mutation may account for many cases.

Facioscapulohumeral muscular dystrophy

FSHD is an important autosomal dominant disorder frequently encountered in adult specialist muscle practice. Patients commonly have facial muscle weakness as the initial symptom, which may be followed by periscapular and humeral muscle involvement. Later in the disease course lower limb weakness, particularly anterior tibial and abdominal wall weakness may occur. It is notable that the distribution of weakness is often asymmetric, with the right side often being more involved. Isolated periscapular weakness without facial involvement may occur. The severity is variable ranging from isolated asymmetrical scapular winging through to pronounced early onset weakness rendering the patient wheelchair-bound. Scoliosis, deafness and retinal vasculopathy are uncommon additional features.

FSHD is almost fully penetrant by the age of 30 years. It has been known for over 10 years that the gene for FSHD is located on chromosome 4, but identification of the exact gene has remained elusive. Surprisingly, a search of the mapped region did not reveal any genes but did reveal contraction (truncation) of a normally occurring non-coding repeated DNA sequence. The presence of this truncated region of DNA has been shown to associate strongly with chromosome 4 linked FSHD and this is the basis of the available genetic test. It is important to note that this is an indirect genetic test and unlike all the other gene tests described here it is not the gene itself that is being analysed.

Nevertheless, this truncation detection genetic test is a useful aid in the precise diagnosis of FSHD. It is believed that truncation of this region may have a detrimental effect on the true FSHD gene which is suspected to be located elsewhere on chromosome 4, known as the positional variegation effect.

Oculopharyngeal muscular dystrophy

Oculopharyngeal muscular dystrophy (OPMD) is an uncommon disorder characterized by late onset pharyngeal muscle weakness and ophthalmoplegia. It is usually autosomal dominant and highly penetrant although recessive inheritance may occur. OPMD may enter into the differential diagnosis in patients with late onset ophthalmoplegia. The most common genetic defect is an expansion of a short (GCG)7–13 triplet in the poly-A binding protein 2 (*PAB2*) gene on chromosome 14q. Genetic testing for the expanded repeat sequence is available and usually obviates the need for muscle biopsy (Plate 9.10).

Myotonic dystrophy and proximal myotonic myopathy

Myotonic dystrophy (dystrophia myotonica) is an autosomal dominant multi-system disorder ranging in severity from a severe congenital myopathy, which may be fatal, to late onset isolated cataracts. Neuromuscular symptoms in a typical case include facial weakness, mild distal myopathy and myotonia. Variable additional symptoms include cataracts, endocrine disturbance such as diabetes mellitus, cardiomyopathy, hair loss, cognitive slowing, daytime somnolence, bowel dysmotility and respiratory muscle weakness. It is the presence of one or more of these additional features in combination with typical muscle symptoms that usually leads to the correct diagnosis on clinical grounds. However, diagnostic difficulty may arise if the muscular symptoms are not evident or are subtle. For example, we have seen cases presenting initially to diabetic, cardiac, gastrointestinal or memory clinics before full diagnosis.

Genetic anticipation is a prominent feature in myotonic dystrophy. The molecular correlate of anticipation has been shown to be an unstable trinucleotide repeat (CTG) in the 3′ untranslated region of a gene on chromosome 19 called myotonin kinase. Recent evidence suggests that the expanded repeat may exert its toxic effect at the RNA level. There is evidence that the expanded untranslated repeated sequence in RNA forms abnormal degradation resistant nuclear deposits (aggregates). Such nuclear deposits probably impair nuclear matrix function resulting in altered expression of other genes. This effect on other genes may explain the diverse multi-system clinical involvement. For example, there is evidence that expression of the skeletal muscle voltage gated chloride channel is altered in patients with myotonic dystrophy. The resulting chloride channel dysfunction is the probable basis of the myotonia. Mutations in this chloride channel are also the basis of the pure myotonic disorder myotonia congenita.

The diagnosis of myotonic dystrophy is usually straightforward on clinical grounds. DNA-based diagnosis is the initial investigation of choice. A detailed family history will usually reveal other affected members. Genetic counselling should be as for an autosomal dominant disorder with full penetrance but variable expression. It is particularly important to identify females at risk of inheriting the gene in pedigrees. This is because the severe, often lethal, congenital form is confined to the offspring of affected females. Such females can then be offered appropriate genetic counselling and also prenatal diagnosis if they wish.

Patients with myotonic dystrophy should be followed up in a muscle clinic where they can be monitored for systemic complications. There is currently no curative treatment, but the potential now exists to develop drugs which may reduce the abnormal RNA deposition. In most patients myotonia is not symptomatic and does not need treatment. In those cases with symptomatic myotonia we suggest mexiletene is the drug of choice provided the cardiac QT interval is normal.

If the genetic test for MD is negative, consideration should be given to a disorder known as PROMM (proximal myotonic myopathy). This less common disorder is characterized by proximal rather than distal myopathy, but in other respects may exhibit similar features to myotonic dystrophy. Muscle pain may be a prominent feature that may suggest the diagnosis on clinical grounds. The γ-GT concentration may be raised. The genetic defect underlying this autosomal dominant disorder has recently been identified as a CCTG repeat sequence in intron 1 of a zinc finger protein gene on chromosome 3. As in myotonic dystrophy there is evidence that this untranslated defect operates at the RNA level, resulting in nuclear aggregates. Mild anticipation is reported in PROMM families but a severe congenital form has not been described to date (Plate 9.7).

Bethlem myopathy

Bethlem myopathy is an autosomal dominant myopathy caused by mutations in one of three different genes for collagen type 6: COL6A1 and COLA6A2 on chromosome 21q22.3 and COL6A3 on chromosome 2q37. Onset of this so-called 'contractural phenotype' is typically in the first or second decade although occasionally a congenital onset is observed with reduced fetal movements, dislocated hips and arthrogryposis. In childhood there are delayed motor milestones, waddling gait and tripping with falls. There is slow progression in the first decade although there may be stabilization and even transient improvement of muscle strength in the second decade. There is then subsequently slow progression. Life expectancy is usually normal and there is no evidence for cardiorespiratory involvement. Two-thirds of patients require a wheelchair by the age of 50 years. Physical examination shows generalized symmetrical muscle atrophy particularly in the shoulder girdle, upper arms and below the knees. There is general mild weakness with a proximal emphasis. Later there is forearm and neck flexor weakness and also anterior tibial weakness. There is no ophthalmoplegia and facial weakness is rare. Prominent flexion contractures at the interphalangeal joints of the fingers, elbows and ankles are present in most patients and contractures at the metacarpophalangeal joints, shoulders (pectoralis major), tibialis anterior, hamstrings, quadriceps and erector spinae and jaw muscles frequently occur with

no relationship between the severity of the weakness and the severity of the contractures. Treatment is supportive.

Muscle biopsy is non-specific. Immunofluorescence of patient fibroblast cultures sometimes shows a reduced expression of collagen type 6 but can be normal. Genetic testing is not widely available. The differential diagnosis includes other myopathies with prominent early contractures including EDMD, autosomal dominant LGMD and rigid spine syndrome with mutations in the selenoprotein N (*SEPN1*) gene and these can be excluded.

Distal myopathies

Distal myopathy is a term that encompasses a variety of genetic and acquired muscle disorders characterized by progressive muscle weakness and wasting beginning in the feet and hands. It is therefore a relatively non-specific category. Most genetic and acquired muscle diseases have a proximal presentation and distal myopathies are uncommon. The clinical classification of a patient into a distal myopathy is helpful because it potentially narrows the differential diagnosis. There are at least 17 primary genetic distal myopathies described in the literature, most of which are very rare. Six of the best characterized entities are outlined in Table 9.34 along with some information about age at onset, muscle biopsy findings and genetics.

When a patient presents with a predominant distal myopathy, in addition to the disorders outlined in Table 9.34, other diagnostic possibilities to consider include FSHD, inclusion body myositis (IBM), myotonic dystrophy, distal hereditary motor neuropathy, central core disease, nemaline myopathy and lipid storage myopathy. Usually in each of these conditions there are associated clinical features (see above and below) which aid the diagnostic process. Although some of the genes for the disorders in Table 9.34 have been identified gene testing is not yet easily available. Exclusion of other conditions by careful clinical evaluation, genetic testing and often muscle biopsy is usually required. Often biopsy of a distal lower limb muscle is more likely to reveal diagnostic pathology. Increasingly, MRI may be used to identify muscle involvement and aid muscle selection for biopsy.

Congenital myopathies

The congenital myopathies are a group of uncommon muscle disorders that were defined on the basis of distinctive morphological muscle biopsy features. Many different disorders are described in the literature. Generally, patients present as floppy infants, sometimes with congenitally dislocated hips, and then usually have delayed motor milestones. The muscle weakness generally follows a fairly indolent course with a benign prognosis. These patients sometimes only first come to attention in the adult muscle clinic. Central core myopathy and nemaline myopathy are of particular note and are described here.

Table 9.34 Summary of the six well-characterized distal myopathies.

Disease	Onset	Weakness	Biopsy	Genes
Welander	>40	Hands	Dystrophic, rimmed vacuoles	AD, 2p13
Miyoshi	>15	Posterior calf	Dystrophic	AR, Dysferlin
Nonaka	>15	Anterior calf	Myopathic, rimmed vacuoles	AR, GNE
Tibial MD	>35	Anterior calf	Dystrophic, rimmed vacuoles	AD, Titin
LODM	>40	Anterior calf	Vacuoles	AD, 2q31
EODM	3–25	Anterior calf	Myopathic	AD, 14q

AD, autosomal dominant; AR, autosomal recessive; EODM, early onset distal myopathy; GNE, glucosamine (UDP-N-acetyl)-2-epimerase/N-acetylmannosamine kinase; LODM, late onset distal myopathy; MD, muscular dystrophy.

Central core disease

Central core disease (CCD) is an autosomal dominant disorder that presents with neonatal hypotonia. There may be a breech presentation, sometimes with dislocated hips or arthrogryposis. Motor milestones are delayed. There is mild proximal symmetrical muscle weakness and ambulation is usually achieved. Disability is usually mild. Significant cardiorespiratory problems are rare. CCD is associated with an increased risk of malignant hyperthermia (MH). However, the relationship between CCD and MH is complex and only around 30% of CCD patients have MH susceptibility. Most patients with pure MH have histologically normal muscle. Muscle biopsy in CCD typically shows central cores that are devoid of oxidative enzyme and phosphorylase activity. Both MH and CCD are caused by mutations in the ryanodine receptor gene *RYR1*. MH susceptibility testing should be offered to all patients with CCD.

Nemaline myopathy

Nemaline myopathy (NM) is characterized by the presence of rod-shaped structures (nemaline rods) in the muscle fibres. Inheritance can be autosomal dominant or recessive and to date six genetic loci have been described. Three clinical severities are seen: a severe congenital form, the typical congenital form and an adult onset form.

The severe congenital form presents with severe neonatal hypotonia and respiratory insufficiency. Reduced fetal movements are reported *in utero*. Occasionally there may be severe arthrogryposis and dilated cardiomyopathy. Early mortality because of respiratory complications is common. Occasional long-term survival with respiratory support has been described accompanied by major motor weakness and inability to ambulate. The typical congenital form presents with neonatal hypotonia with less respiratory difficulty. Weakness is milder and although motor milestones are delayed independent ambulation is achieved and most patients have an independent life.

The adult onset form presents between the ages of 20 and 50 years. Myalgia may be predominant with moderate proximal weakness which is usually slowly progressive. Facial muscle weakness and neck flexion weakness are common in all forms. The face is often elongated with a tent-shaped mouth and a high arch palate. The degree of the facial abnormality correlates with the overall severity of the condition. Some adult cases have been described with more rapidly progressive weakness. Respiratory involvement is rare but can occur; nemaline myopathy should always be considered in the adult presenting with unexplained

respiratory muscle weakness. All the known NM genes identified encode components of the sarcomeric thin filaments. In AD NM mutations in α and β tropomyosin are found and in recessive NM nebulin, NEM1, NEM2 and troponin-1 mutations are described. Mutations in α-actin and ACTA1 may cause either dominant or recessive disease.

Skeletal muscle channelopathies

Periodic paralyses and myotonias

Periodic paralysis and inherited myotonia were the first human disorders in which genetic dysfunction of ion channel genes was identified. They are conditions in which there is a disturbance in skeletal muscle fibre membrane excitability. The periodic paralyses are autosomal dominant disorders in which patients experience focal or generalized episodes of muscle weakness of variable duration. They have been characterized on the basis of the change in serum potassium during an attack. In hyperkalaemic periodic paralysis potassium triggers an attack which will be ameliorated by glucose ingestion. In contrast, patients with hypokalaemic paralysis will notice improvement with potassium ingestion but worsening with glucose. The classification based upon potassium is useful clinically although a genetic classification has now emerged (Table 9.35). Mutations in one of three skeletal muscle ion channels genes associate with human periodic paralysis. These are the voltage gated sodium and calcium channel genes *SCN4A* and *CACNA1S* and the voltage-independent potassium channel gene *KCNJ2*. All forms of periodic paralysis share the common feature that during an attack the muscle fibre membrane becomes electrically inexcitable but the mechanisms leading to this state vary and are described below.

Myotonia is a clinical disorder in which patients experience muscle stiffness because of a failure of normal electrical inactivation of activated muscle. Myotonia may result from genetic mutations in either the muscle voltage gated chloride channel *CLCN1* (dominant or recessive myotonia congenita) or the voltage gated sodium channel *SCN4A* (dominant paramyotonia congenita).

Hyperkalaemic periodic paralysis and myotonias caused by skeletal muscle sodium channel dysfunction

In hyperkalaemic periodic paralysis (hyperPP) patients typically experience recurrent attacks of muscle weakness starting in the first decade of life. Precipitants include rest following exercise, cold, potassium ingestion or stress. Attacks may vary in severity from mild weakness to total paralysis. The duration of attacks is usually less than 2 hours. Typically, the attack frequency declines with age but patients often develop a fixed myopathy of variable severity. Muscle biopsy in such cases often reveals tubular aggregates and or a vacuolar change. In humans, unlike equine forms, death is extremely rare in hyperPP or hypoPP. Cardiac arrhythmias are also uncommon except in Andersen's syndrome (see below).

HyperPP is caused by 'gain of function' point mutations in the muscle sodium channel *SCN4A*. Sodium channel α-subunit mutations (*SCN4A*) lead to defective fast inactivation of the skeletal muscle Na^+ channel. The resulting persisting inward sodium current (a gain of function) impairs repolarization and increases membrane excitability. Depending on the degree of increased membrane excitability, a patient may experience myotonia or paralysis. It is notable that similar gain of function mutations in a neuronal sodium channel gene *SCN1A* result in increased neuronal excitability and associate with a form of epilepsy (see

Table 9.35 Skeletal muscle channelopathies: a genetic classification.

Gene	Channel	Disease	Inheritance
*CACNA1S**	Calcium channel	HypoPP1	AD
	L-type calcium α-subunit	MH	AD
*SCN4A**	Sodium channel	HyperPP	AD
	Nav1.4 α-subunit	PMC	AD
		PAM	AD
		HypoPP2	AD
*KCNJ2**	Potassium channel, $K_{ir}2.1$	Andersen's syndrome	AD
*CLCN1**	Chloride channel, ClC1	Myotonia congenita	AD/AR
		MD1, MD2†	AD
RYR1	Ryanodine receptor	MH	AD
	Calcium release channel	Central core disease	AD¶
			AR

AD, autosomal dominant; AR, autosomal recessive; ClC1, chloride channel 1 gene/channel; Hyper PP, hyperkalaemic periodic paralysis; HypoPP, hypokalaemic periodic paralysis; $K_{ir}2.1$, potassium inward rectifier; MH, malignant hyperthermia; PAM, potassium aggravated myotonia; PMC, paramyotonia congenita.

* DNA-based diagnosis available in UK.

† Altered splicing of *CLCN1* has been shown in both forms of myotonic dystrophy (MD) as the basis of the myotonia.

¶ Gain of function.

below), thus representing a direct pathophysiological parallel between muscle and brain sodium channel diseases.

Many attacks are brief and do not require treatment. If necessary, acute attacks can be terminated by ingestion of carbohydrate or inhaled salbutamol. Preventative treatment with acetazolamide or a thiazide diuretic may be required. It remains unproven if reducing attack frequency with such agents reduces the likelihood of the subsequent development of myopathy.

Paramyotonia congenita (PMC) is a form of myotonia that appears during exercise and worsens with continued activity. EMG at rest often shows some myotonia. Low temperature often precipitates symptoms in these patients and cooling produces repetitive spontaneous motor unit discharges with a decrement in the muscle action potential amplitude. PMC is also caused by mutations in the voltage gated skeletal muscle sodium channel α-subunit (*SCN4A*) and PMC is therefore allelic with hyperPP. PMC is inherited as a highly penetrant autosomal dominant trait. Mutations have been found throughout the gene, although exon 24 appears to be a hotspot for mutations. PMC associated point mutations confer a gain of function. However, the resulting impairment of fast inactivation is less than that associated with mutations associated with hyperPP. Mexiletene is an effective symptomatic treatment for PMC. Milder forms of myotonia without cold sensitivity are also described in association with different sodium channel point mutations, known as potassium aggravated myotonia.

Hypokalaemic periodic paralysis – a muscle calcium or sodium channel disorder

Hypokalaemic periodic paralysis (hypoPP) is autosomal dominant with de novo dominant mutations accounting for one-third of cases. Attacks are precipitated by a period of exercise followed by rest or by carbohydrate loading. Attacks typically develop in the early hours of the morning and may last hours to days. Serum potassium is typically low at the onset but may normalize quickly. Attack frequency tends to decline with age but a fixed myopathy may develop. Myotonia does not occur in hypoPP.

Point mutations in two separate muscle channel genes may cause hypoPP. The majority of cases harbour one of three point mutations in the L-type calcium channel, *CACNA1S* – also known as hypoPP type 1. Far less frequent mutations have been described in the muscle sodium channel *SCN4A* (known as hypoPP-type 2).

Mutations in the L-type calcium channel α_1-subunit (dihydropyridine receptor; *CACNA1S*) account for about 70% of cases of hypoPP. All mutations are arginine substitutions in the voltage sensor (S4) of the channel protein. It remains unclear how mutations in *CACNA1S*, which does not have a major role in determining muscle membrane excitability, result in paralysis but experimental studies indicate that loss of the normal function of the channel is necessary for the attacks.

HypoPP associated with *CACNA1S* mutations exhibits reduced penetrance in females (50%) compared to complete penetrance in males. Specific mutations appear to have discrete clinical features, e.g. R528H is common, with later onset and associated myalgias.

HypoPP can also be caused by missense loss of function mutations in the voltage sensor of domain 2 of *SCN4A* but these are uncommon in the UK. There is some evidence that such hypoPP cases may experience worsening of attacks with prominent myalgia when exposed to acetazolamide. In this setting an alternative carbonic anhydrase inhibitor dichlorfenamide seems to be effective.

In summary, current evidence indicates that hyperPP is a gain of function disorder caused by *SCN4A* point mutations. In contrast, hypoPP associates with loss of function mutations in either *CACNA1S* or in *SCN4A*. It remains unclear how loss of function mutations result in the partially depolarized inexcitable state that occurs in hypoPP.

Periodic paralysis and cardiac arrhythmias – a skeletal muscle potassium channel disorder

Most cases of periodic paralysis do not associate with cardiac arrhythmias because the responsible channel (*CACNA1S*, *SCN4A*) is not expressed in cardiac muscle. Andersen–Tawil syndrome is a form of dyskalaemic periodic paralysis in which cardiac involvement is frequent (the resting ECG commonly shows bigeminy). In addition to periodic paralysis, patients may have atrial and/or ventricular arrhythmias and may also have characteristic facial and skeletal features (Plate 9.8). From a practical point of view, this disorder should be considered in any case of periodic paralysis with arrhythmia.

Andersen's syndrome is caused by mutations in a potassium channel termed Kir2.1. This inward rectifying potassium channel Kir2.1 is encoded by *KCNJ2* on chromosome 17q23. The functional channel is a homotetramer important for cardiac and skeletal muscle membrane hyperpolarization and also has a role in skeletal bone precursor cell migration and fusion during development. There is intrafamilial variability and partial manifestation of the phenotype is common. During an attack, serum potassium is most commonly low but may be normal or high. In patients with hypokalaemia, oral potassium supplements may improve the weakness. In some families, increasing plasma potassium concentration with acetazolamide improves arrhythmias at the expense of exacerbating weakness. Once the diagnosis is made detailed cardiac assessment is needed. However, the optimum management to prevent malignant arrhythmias is not certain.

Myotonia congenita – a skeletal muscle chloride channel disorder

Dominant (Thomsen's disease) and recessive (Becker's disease) forms of myotonia congenita are recognized. Patients experience differing degrees of muscle stiffness and muscle hypertrophy. The dominant form is less common and generally milder. Patients present with muscle stiffness because of impaired voluntary muscle relaxation. Patients describe marked muscle stiffness at the onset of activity, but the more they continue the less stiff the muscles become – the so-called 'warm-up phenomenon'. While

90% show myotonia on EMG, only 50% have percussion myotonia on examination. There is usually normal power at rest, although a minority have proximal weakness. Muscle hypertrophy and myalgia may occur in both forms but are more prominent in the more common recessive form of the disease. Electrophysiologically, *in vivo* myotonia (and paramyotonia) is characterized by uncontrolled repetitive action potentials at the sarcolemma initiated by a voluntary activation. This persistent involuntary activation prevents the patient from relaxing the muscle, hence the complaint of muscle stiffness and limitation of free flowing movements.

Both forms of myotonia congenita are caused by mutations in a muscle voltage gated chloride channel (*CLCN1*) located on chromosome 7q35.10. There is evidence that, unlike all other voltage gated ion channels, this channel has two separate ion pores through which chloride ion passage may occur. The resting membrane potential in skeletal muscle is mainly dependent upon the chloride channel conductance; *CLCN1* mutations result in impaired chloride conductance and so produce partial depolarization of the membrane. This creates the electrophysiological condition of increased excitability and repetitive firing after muscle activation, necessary for myotonia to occur.

Metabolic muscle disease

Mitochondrial respiratory chain diseases

A bewildering array of clinical phenotypes may associate with dysfunction of the mitochondrial respiratory chain. The respiratory chain is critical for aerobic ATP production and it is therefore perhaps unsurprising that virtually any body tissue can be affected. Tissues such as skeletal muscle and brain, with a high dependence on ATP, are commonly affected. The clinical manifestations of skeletal myopathy varies and can include: progressive external ophthalmopleagia, isolated proximal myopathy or, less commonly, distal myopathy (Plate 9.9). Exercise intolerance is a frequent accompaniment to limb myopathy and rhabdomyolosis is an infrequent but recognized complication. Myopathy may occur in isolation or in combination with a more complex phenotype which may involve the CNS. Examples of classic CNS mitochondrial disease include mitochondrial encephaolomyopathy with lactic acidosis and strokes (MELAS) and mitochondrial encepahlomyopathy with ragged red fibres (MERRF; Plate 9.9). Although the typical mitochondrial syndromes in their fully developed form can usually be recognized by the experienced neurologist, there is a wide variety of clinical presentations and mitochondrial disease may frequently enter the differential diagnosis in patients with complex CNS disorders, especially if limb weakness is present.

A combination of genetic and muscle histochemical and biochemical investigations can usually result in an accurate diagnosis. Muscle biopsy remains an extremely important investigation in patients suspected to have mitochondrial disease. The hallmark muscle biopsy finding of the ragged red fibres on the Gomori trichrome stain is diagnostic in many, but not all, patients with mitochondrial respiratory chain disease.

Mitochondrial respiratory chain disease may be more common than previously considered. One study indicated possibly 10/100,000 in the UK population. Although most adult patients with mitochondrial disease harbour mutations in mitochondrial DNA, mutations in nuclear encoded genes can cause respiratory chain dysfunction resulting in neurological illness. To date, most of the nuclear genes identified cause mitochondrial respiratory chain disease with a neonatal or early childhood onset. However, recently mutations in the nuclear gene for mitochondrial polymerase gamma (*POLG*) have been found in adults presenting with one of a number of phenotypes that the adult neurologist is more likely to encounter.

It is evident that all forms of inheritance (autosomal dominant, autosomal recessive, X-linked, maternal and sporadic) are possible in mitochondrial respiratory chain disease depending on the genetic basis. The majority of adult mitochondrial phenotypes associate with primary mutations in mitochondrial DNA (MtDNA) (Table 9.36). These include large-scale rearrangements

Table 9.36 Classification of mitochondrial respiratory chain diseases.

Defects in MtDNA	
Mutations in protein coding genes	**Phenotype**
e.g. Mitochondrial ND genes	LHON
	MELAS
Mutations in ATPase genes	NARP
	Leigh's disease
Mutations in protein synthesis genes	
tRNA genes	CPEO
	Myopathy
	MELAS
	MERRF
rRNA genes	Deafness
Defects in nuclear genes	
Defects in intergenomic signalling	
POLG	AD CPEO
	AR CPEO
	MERRF/MELAS
Defects in MT resp. chain assembly	
SURF-1	Leigh's disease
Defects in resp. chain subunit genes	
Complex I, II, III or IV	Encephalomyopathies
Defects in mitochondrial motility	AD optic atrophy

AD, autosomal dominant; AR, autosomal recessive; CPEO, chronic progressive external ophthalmoplegia; LHON, Leber's hereditary optic neuropathy; MERFF, myoclonic epilepsy with ragged red fibres; MELAS, mitochondrial encephaolomyopathy, lactic acidosis, strokes; MT, mitochondria; NARP, neuropathy, ataxia, retinitis pigmentosa; ND, northern dot; POLG, polymerase gamma.

Table 9.37 Common mitochondrial phenotypes in adults.

Phenotype	Genetics	Inheritance
CPEO	Deletion in mtDNA	Sporadic
	Multiple deletions	AR/AD
	MtDNA point mutations	Maternal
Myopathy	Deletion mtDNA	Sporadic
	MtDNA point mutations	Sporadic or maternal
MELAS	MtDNA point mutation (A3243G)	Maternal
MERRF	MtDNA point mutation (A8344G)	Maternal
LHON	MtDNA point mutation (11778)	Maternal

AD, autosomal dominant; AR, autosomal recessive; CPEO, chronic progressive external ophthalmoplegia; LHON, Leber's hereditary optic neuropathy; MELAS, myoclonic epilepsy with lactic acidosis, strokes; MERRF, mitochondrial encephalopathy with ragged red fibres.

(such as deletions) which are only infrequently passed on to the succeeding generation. In contrast, the other common mutations in MtDNA, point mutations, are usually passed down the maternal line. Unfortunately, the factors that determine the amount of a particular point mutation that may be passed down cannot be predicted with accuracy. Thus, it is extremely difficult to offer women who harbour disease-causing point mutations accurate recurrence risks. Until current research efforts identify the factors that influence the recurrence risks for such women, the only definite way to avoid maternal transmission is to consider ovum donation.

A mitochondrial respiratory chain disease may be suspected in a number of clinical settings and it is generally helpful to consider splitting up defined phenotypes (Table 9.37), although in practice there is considerable clinical overlap.

Typical phenotypes that predominantly involve skeletal muscle include isolated myopathy, chronic progressive ophthalmoplegia and the Kearns–Sayre syndrome. Typical phenotypes that include a combination of myopathy with prominent CNS involvement include MELAS and MERRF.

Isolated mitochondrial myopathy

Isolated chronic progressive external ophthalmoplegia (CPEO) and Kearns–Sayre syndrome are common manifestations of mitochondrial disease. Onset may be before 20 or after 50 years in most cases. There is a slow evolution of symmetrical extraocular muscle weakness and diplopia is uncommon. Ptosis progresses over time and measures to raise the eyelids may be required such as eyelid props or sometimes eyelid surgery. A single clonal deletion of mtDNA is the most common genetic defect in patients with CPEO, although point mutations in tRNA genes and multiple deletions of mtDNA may be the cause.

Kearns–Sayre syndrome is defined by the triad of progressive external ophthalmoplegia (PEO), pigmentary retinopathy and onset before the age of 20 years, with at least one of the following: high CSF protein >100 mg/dL, cerebellar ataxia or cardiac conduction block. It is most commonly caused by single large deletions in mtDNA but has a far more serious prognosis compared to isolated CPEO. Patients often have a progressive limb myopathy and frequently require a pacemaker for AV block. Patients with later onset nearer to 20 years may have a milder prognosis.

Autosomal dominant/recessive progressive external ophthalmoplegia (PEO) with multiple deletions

AD/AR progressive external ophthalmoplegia is an adult onset condition caused by nuclear genes that affect mtDNA maintenance resulting in multiple deletions of mtDNA. In addition to PEO there may be a variety of clinical features including peripheral neuropathy, ataxia, tremor, parkinsonism, depression, cataracts, pigmentary retinopathy, deafness, rhabdomyolysis and hypogonadism. A particular variant of multiple deletion PEO is the syndrome of mitochondrial neurogastrointestinal encephalomyopathy (MNGIE) is characterized by PEO and marked gastrointestinal malfunction and cachexia. There is also a multiple deletion PEO variant in which there is dramatic sensory ataxic neuropathy termed SANDO (sensory ataxic neuropathy dysarthria and ophthalmoplegia). A number of different nuclear genes have been implicated in these different multiple deletions disorders and one of the most common is the gene encoding the mitochondrial DNA polymerase gamma (*POLG1*).

MELAS

MELAS is a serious stroke syndrome that most commonly associates with point mutations in mtDNA transfer RNA genes. The most common is the A3243G mutation in the tRNA gene for leucine (*UUR*) accounting for around 80% of MELAS cases. The stroke-like episodes are often dramatic and are different from typical ischaemic strokes in that the patients are encephalopathic. Typically, episodes begin with severe 'migraine-like' headache with nausea and vomiting. There may be focal or generalized seizures in an episode followed by hemipareis, hemianopia or cortical blindness. The strokes are often parieto-occiptial and do not conform to vascular territories. Patients often experience multiple stroke-like episodes. Dementia, ataxia, deafness, muscle weakness, cardiomyopathy and diabetes are frequent accompaniments. Treatment of acute episodes is supportive.

MERRF

MERRF patients experience myoclonus, epileptic seizures, ataxia and muscle weakness. Onset is usually in childhood but adult onset is described. Myoclonus is stimulus sensitive and the seizures may be tonic–clonic and there is often photosensitivity. There is a common lysine tRNA gene mutation associated with MERRF. In addition to myopathy, approximately one-third of MERRF cases have significant cardiomyopathy.

In practice, the mitochondrial disease needs to be considered when there may only be fragments of full clinical syndromes or the patients have elements of a number of different syndromes. Useful pointers to consider in patients with CNS syndromes that

might suggest a mitochondrial aetiology are the presence of myopathy, neuropathy or deafness in the context of a complex CNS phenotype.

Treatment and support for patients with mitochondrial disease
Patients with confirmed mitochondrial disease require support in a multidisciplinary clinical team setting. Often this is lead by a neurologist and a therapist with close links to a range of different disciplines as required such as physiotherapy, occupational therapy, cardiology, endocrinology/diabetes, audiology and speech therapy. Although a number of medications/vitamins have been suggested there is little in the way of convincing trial data to support their use. However, some data exist in support of coenzyme Q10 which we offer to all patients with mitchondrial respiratory chain diseases.

Diagnostic strategy in suspected mitochondrial disease
In practice, if a mitochondrial respiratory chain disease is suspected it is sensible to select the available mtDNA point mutations (3243, 8344 and 8993) to be analysed in a blood sample. The hit rate from this limited analysis of blood mtDNA is likely to be low. However, if positive, a secure diagnosis of mitochondrial disease is achieved without the need for further investigations. In CPEO patients *POLG* gene mutation analysis is possible. In patients with Leber's hereditary optic neuropathy (LHON) the majority of cases will have a mutation at 11778, 14484 or 3460 and the hit rate for leucocyte DNA testing much better. In a non-LHON patient if no mutation is detected in blood the gold standard investigations include muscle biopsy and respiratory chain enzymology. The majority of patients with a mitochondrial DNA mutation will have ragged red fibres and/or cytochrome C oxidase negative fibres and/or a measurable defect on mitochondrial respiratory chain enzymology. Furthermore, muscle tissue is a much better tissue to analyse for mtDNA mutations, in particular mtDNA deletions are more reliably detectable. If the above assessments do not produce a positive result and an mtDNA mitochondrial disease is suspected, total sequence analysis on muscle mtDNA can be undertaken and is increasingly available in specialist centres.

Glycogenoses and lipid storage disorders
In addition to mitochondrial respiratory chain disorders the other metabolic disorders in muscle include defects in glucose metabolism (glycogen storage disorders) and defects in fat metabolism (lipid storage disorders). Patients with these autosomal recessive disorders generally develop muscle pain on exertion. Myoglobinuria and sometimes fulminant rhabdomyolysis may occur. Patients with McArdle's disease (the most common glycogenosis caused by myophosphorylase deficiency) present with muscle pain soon after commencing exercise. The pain can be severe and cramping, often causing the patient to stop. A second wind phenomenon is common. The forearm non-ischaemic lactate test will show a blunting of the expected rise in muscle lactate induced by repeated isometric exercise because of a failure to breakdown glycogen. Muscle biopsy will allow histioenzymatic staining for myophosphorylase, absent in McArdle's disease. Genetic testing is available but is usually performed after the metabolic defect has been confirmed.

Of the many disorders of lipid metabolism, the most common lipid storage disorder is carnitine palmitoyl transferase-II (CPT-II) deficiency. Adults with CPT-II deficiency usually present with muscle pain induced by prolonged exercise, and often the pain may not develop until some time after exercise. Post-exercise myoglobinuria is frequent. Rhabdomyolysis is more likely to occur after fasting or if there is intercurrent infection or dehydration. Hypoketotic hypoglycaemia may occur. Occasionally, patients with CPT-II deficiency present with a painless proximal myopathy. Muscle biopsy light microscopy may reveal abnormal accumulations of lipid. Muscle tissue can be used for specific enzyme assays. The pattern of acylcarnitines in blood is particularly useful whenever a lipid storage disorder is being considered. Molecular genetic diagnosis is available.

Conclusions
The diagnosis of patients with genetic muscle disorders has truly entered the molecular genetic era. DNA-based diagnosis is now available for many of these disorders and often removes the need for invasive tests such as muscle or nerve biopsy. Efficient selection of genetic tests is important and neurophysiology has a particularly important role in this regard for genetic muscle channelopathies. Muscle biopsy remains essential in certain situations, e.g. in the comprehensive investigation of patients with LGMD and in some metabolic myopathies. It is worth noting that while a blood sample is all that is required for testing in nuclear gene disorders, muscle tissue remains most useful for mitochondrial DNA analysis. In our view, all clinical neurologists need to be aware that a wealth of genetic diagnostic possibilities exists for these patients, and that achieving such diagnostic precision on a routine basis is important. Often, this will involve referral to a specialist muscle service.

Acquired muscle diseases

Inflammatory myopathies
The inflammatory myopathies are diseases whose primary pathology is of inflammation within muscle. This definition thus excludes those genetic muscle disorders discussed above in which inflammatory change may occur (e.g. dystrophinopathy, FSHD or dysferlinopathy), and also diseases in which inflammation affects associated structures rather than muscle itself, as in polymyalgia rheumatica. The inflammatory myopathies can be divided into four principal classes on the basis of their aetiology (Table 9.38). Their diagnosis can be further refined by distinctive clinical and pathological features that reflect differing fundamental causes and processes, although at present the latter are incompletely understood.

Idiopathic inflammatory myopathies
These are the most commonly encountered acquired muscle diseases and their discussion forms the framework for the remaining conditions. Three subtypes exist:

Table 9.38 The inflammatory myopathies.

Idiopathic
Dermatomyositis, polymyositis, inclusion body myositis
Associated with connective tissue disease
SLE, rheumatoid arthritis, mixed connective tissue disease, Sjögren's disease
Infective/post-infective
Viral (HIV, EBV, CMV, HTLV-1), bacterial (staphylococcal, Lyme, tuberculosis), parasitic (nematodes, cestodes, protozoa)
Miscellaneous
Vasculitic, non-infective granulomatous (e.g. sarcoid), eosinophilic syndromes

CMV, cytomegalovirus; EBV, Epstein–Barr virus; HTLV, human T-lymphocyte virus; SLE, systemic lupus erythematosus.

1 *Dermatomyositis* (DM) in which the inflammatory process also, but not necessarily, involves the skin.
2 *Polymyositis* (PM): isolated inflammation of the muscles (but similar findings may occur in association with several rheumatological diseases; see below).
3 *Inclusion body myositis* (IBM) which has a distinctive clinical pattern with less, if any, inflammatory change on biopsy.
All three share the key features of proximal lower limb wasting and weakness as the main clinical findings. However, they may be distinguished by specific features of their clinical presentation and the findings on investigation. All are caused by separate pathological mechanisms. However, distinguishing one from another, or indeed from other conditions, can be difficult. There remains both incomplete understanding of their aetiology and a dearth of evidence on which to base decisions about their treatment.

Dermatomyositis
Dermatomyositis is the inflammation of muscle and skin. Epidemiological data are imprecise, but DM is uncommon, with an incidence of approximately 1/100,000. Unlike the other idiopathic inflammatory myopathies, children can be affected and it is by far the most common such condition in that age group. DM is more common in non-Caucasians and in women.

DM is a humorally mediated autoimmune disorder, in which the pathology is that of a microvasculopathy (Plate 9.10a). Activated complement is found deposited in muscle capillaries and other tissues, which directs subsequent cellular inflammation. The trigger to this is unknown but postulated mechanisms include deposition of circulating immune complexes or a response to an as yet unknown endothelial antigen.

Clinically, DM typically produces a subacute, progressive, proximal and symmetrical weakness, affecting the lower limbs more than the arms. Rarely does the condition lead to pronounced distal weakness. CK is usually raised (see below). There is often some myalgia, but not severe pain. The extraocular and facial muscles are typically spared, but dysphagia may be a problem in severe or advanced cases, while neuromuscular respiratory compromise is also well recognized. A more explosive presentation can occur, even leading to overt myoglobinuria.

The skin manifestations of DM usually precede the myopathy, but they may be difficult to detect if they are not specifically looked for, particularly in people with dark skin. The classic dermatological presentations are the 'heliotrope' erythematous rash of the face (especially the eyelids) and upper trunk. This rash is photosensitive, and often occurs with some oedema and telangiectasia. The hands can typically demonstrate Gottron papules, thickening over the surfaces of the knuckles, but may also show either a more subtle general coarseness of the skin ('mechanic's hands') or nail bed capillary change.

Some patients have the skin changes only without clinical weakness or any elevation of CK, leading to the diagnostic term 'dermatomyositis sine myositis'. Muscle biopsy in these cases usually demonstrates the abnormalities seen in DM. In such amyopathic patients, the condition may resolve without need for immunosuppressive treatment, although recent work identified a high incidence of interstitial lung complications. Finally, typical DM over time may lead to calcinosis within affected tissues. Calcinosis can be quite marked and produces striking changes on imaging. Early treatment is thought beneficial in minimizing this last complication.

Other systems may also be involved, notably the lungs and the heart. Approximately 20% of patients demonstrate evidence of an interstitial lung disease which can rarely be the first symptom. The most common symptoms are of cough and dyspnoea, typically with bibasal crepitations on auscultation of the chest. Lung complications are most commonly slowly progressive but symptoms can develop acutely. Twenty five per cent of those patients with abnormal pulmonary investigations remain asymptomatic. Pulmonary complications are associated with Jo-1 (anti-tRNA synthetase) IgG antibodies. These are present in 20% of DM cases of whom 70% have evidence of interstitial lung disease. The lung pathology is variable, but only bronchiolitis obliterans is likely to respond to immunosuppression. Early treatment, aiming to prevent permanent pathological muscle change, also prevents severe long-term pulmonary disease.

The exact incidence of cardiac involvement in idiopathic myositis is uncertain but several studies found congestive heart failure and ischaemia to be more common than in controls. Up to 50% of cases in some series have ECG evidence of dysrhythmias, conduction block or ischaemic change pointing to a high incidence of subclinical cardiac involvement. Case reports have identified similar inflammatory change in both the myocardium and conducting system to that found in skeletal muscle.

Large series of cases of DM find an approximate 20% association with malignancy, most commonly with adenocarcinoma and gynaecological tumours. Those most at risk are older, female and non-Caucasian patients. A thorough clinically directed approach to detecting an underlying malignancy is therefore indicated, with careful history-taking and examination for undisclosed

symptoms or signs (e.g. weight loss, post-menopausal bleeding, breast lump or rectal mass). Appropriate further examination with imaging and/or specialist review may be necessary.

The prognosis of DM is worse in those with pulmonary or cardiac complications, underlying malignancy, arthritis, hypergammaglobulinaemia or in acute or febrile presentations.

Polymyositis

Polymyositis is characterized by a progressive, proximal and symmetrical weakness without the skin lesions seen in DM. It is probably of similar or slightly lower incidence and prevalence to DM. It is very rare in those under 20, and is typically a disease of middle or later life. The course of PM is variable but is somewhat slower to evolve than DM. Although it can be rapidly progressive, the most frequent presentation is with progressive weakness, in which the exact onset is difficult to pinpoint and symptoms progress over months. Myalgia is typical but rarely severe. As with DM, distal and facial weakness is rare but respiratory muscle involvement can occur and can be life-threatening; it is most often seen when the disease is rapidly worsening.

Polymyositis differs fundamentally from DM in being a cell-mediated disease. CD8-positive T lymphocytes respond to an unknown muscle antigen by invading and destroying non-necrotic muscle fibres that express major histocompatibility complex protein (MHC-1; Plate 9.10b). Unlike DM, blood vessels are spared. Respiratory and cardiac complications can develop at similar rates as occur in DM. Polymyositis also shares with DM the particular association of interstitial lung disease with antisynthetase antibodies.

Because PM presents with an absence of helpful associated clinical signs such as the skin involvement of DM or the particular pattern of weakness of typical IBM, 'pure' PM can be diagnosed in error. At the clinically milder end of the spectrum, care must be taken not to over-interpret pain or submaximal effort on examination. At the other, PM must be distinguished from other conditions that can provoke a raised CK and inflammatory changes on biopsy. All the clinical and investigation findings must be considered together and an open mind kept to the need to review or revise a diagnosis over time. In particular, 'failure' to respond to immunosuppressants should raise the possibility that a dystrophic process is, in fact, the cause.

Inclusion body myositis

Sporadic inclusion body myositis occurs somewhat more frequently than DM or PM and is probably the most prevalent acquired myopathy. Unlike either PM or DM it appears to be most commonly a disease of Caucasian men. Other racial groups seem less frequently affected and the male to female ratio is 3 : 2. Typically, IBM occurs late in life and onset before age 30 years is highly unusual. Rare hereditary forms of IBM exist with either autosomal recessive or dominant patterns of inheritance.

The onset of IBM is insidious and usually slower than seen with PM or DM. Classically, IBM causes a distinctive pattern of wasting and weakness involving the quadriceps and deep finger flexors (Plate 9.11). This compromises the most crucial functions of the upper and lower limbs, hand grip and maintaining upright posture; falls may occur relatively early, because of buckling of the knees. Dysphagia occurs in 10–30%. Ankle dorsiflexion weakness can also occur, and these distal signs, plus occasional mild facial involvement and a frequently asymmetrical pattern of weakness allow clinical distinction to be made from other conditions.

The aetiology of IBM is uncertain. Whether it is a degenerative process and whether any endomysial inflammatory component (which may be substantial) is merely a secondary process is still debated. Support for it being degenerative comes from both the finding of amyloid material in the almost pathognomic cellular inclusions and rimmed vacuoles seen on biopsy (Plate 9.10c), and the failure of IBM to respond to all immunosuppressant medications in controlled trials.

There appears to be no link to malignancy. Antisynthetase antibodies are less frequently associated than with DM or PM, and pulmonary or cardiac complications are unusual.

Investigation of inflammatory myopathy

Serum creatine kinase levels

The level of serum CK is raised in all three conditions and offers some guide to the degree of inflammation. It may be raised up to 50 times normal in severe PM and DM; the typical rise in IBM is typically less than 10-fold. It is very important to note that definite deterioration can occur without an accompanying rise in CK, especially of DM. It should also be borne in mind that quoted 'normal' values of CK can be misleadingly low as there is considerable variation in CK levels across a normal population. As such, diagnosis of 'pure PM' should not be made solely on a borderline elevation in CK levels.

Neurophysiology

Typical myopathic features are common in myositis, while frequent fibrillation and spontaneous repetitive discharges can be indicative of active inflammation. A useful rule of thumb from highly experienced practitioners is that when EMG is performed to confirm myopathy, seemingly normal findings frequently turn out to be IBM.

Muscle biopsy

Muscle biopsy is the keystone of diagnosis. It should be considered and if at all possible performed in every case before treatment is initiated. The idiopathic inflammatory myopathies share some pathological features but aspects of the pathology of each may be diagnostic (Table 9.39; Plate 9.10). Typical changes are not always present, however, and thus interpretation can be difficult. The clinical and pathological findings need to be interpreted in conjunction to make the correct diagnosis.

Table 9.39 Characteristic pathological findings of the idiopathic inflammatory myopathies.

Condition	Muscle fibres	Blood vessels
DM	Focal infarctions; perifascicular atrophy	Capillary necrosis and undulating tubules or other endothelial abnormalities; deposition of immunoglobulin and activated complement membrane attack complex
PM	Partial invasion of non-necrotic fibres by activated CD8 lymphocytes and macrophages (seen less in IBM and not in DM). Uniform expression of class I MHC products on surface of all fibres	Rarely involved: possible secondary capillary necrosis
IBM	Rimmed vacuoles; inclusions staining for ubiquitin and amyloid; 15–18 nm tubular filaments in nucleus or cytoplasm (may require extensive EM)	Can be normal; possible increased capillarity

DM, dermatomyositis; EM: electron microscopy; IBM, inclusion body myositis; MHC: major histocompatibility complex; PM, polymyositis.

Extended investigation of inflammatory neuropathies

• *Lung:* a chest radiograph may identify bibasal shadowing. Chest radiography is insensitive, being normal in 10% of those with proven lung involvement. High-resolution CT scanning is more sensitive, characteristically revealing linear opacities and a 'ground glass' appearance of the lung bases. Pulmonary function tests are also indicated; a restrictive pattern with reduced lung volumes and decreased diffusing capacity for carbon monoxide is typical.

• *Heart:* an ECG is indicated in all patients. Clinical evidence of cardiac involvement necessitates further assessment with 24-hour Holter recording, echocardiography and review by a cardiologist.

Treatment of idiopathic inflammatory myopathies

The treatment of idiopathic inflammatory neuropathies is based largely on expert opinion rather than any evidence. Indeed, the Cochrane collaboration's systematic review on the treatment of DM and PM concluded that, 'the small number of randomized trials of immunosuppressants and immunomodulatory therapies are inadequate to decide whether these agents are beneficial'. Guidelines for management are open to the influences of personal practice, but one suggested approach is given in Table 9.40.

For IBM no beneficial effect has been demonstrated for any agent tested. Despite this, individual cases may show a response to medication, essentially when a significant degree of inflammatory change is shown on biopsy. Under such circumstances, a trial of steroid (oral prednisolone 30–40 mg/day for 3–4 months) should be considered, and if successful, the dose slowly reduced, introducing steroid-sparing drugs if appropriate.

In all cases, non-pharmacological measures to support the patient are also crucial. Multi-disciplinary assessment from physiotherapists, occupational therapists and, if indicated, speech therapists, dietitians and colleagues from other medical disciplines, is recommended. Regular follow-up to assess progress and identify and treat potential complications is essential.

Table 9.40 Treatment of the idiopathic inflammatory myopathies, in the absence of evidence.

Steroids, aiming for rapid stabilization

Prednisolone 1 mg/kg/day by mouth until CK normal, then reduce (e.g. 5–10 mg monthly, with slower reduction for the last 20–30 mg)

If very acute resolution required: IV methylprednisolone 500 mg/5 days to initiate steroid course

Osteoporosis and gastric ulcer prophylaxis

Steroid-sparing agents (aiming to reduce side effects and maintain disease control)

First line

1 Azathioprine, starting at 1 mg/kg or below, and increasing by 25 mg every 1–2 months to a maximum of 2.5 mg/kg, as tolerated and guided by the degree of lymphocyte suppression and clinical response
Thiopurine methyltransferase checked beforehand
Blood monitoring of FBC and LFT necessary.

2 Methotrexate, increasing to 20–25 mg/day maximum *once weekly* with folic acid on other days, blood monitoring required; watch for pulmonary fibrosis and cirrhosis. NPSA guidelines available in UK

Second line

1 Ciclosporin: of use if first line drugs ineffective; blood monitoring required

2 IVIG: for refractory cases, particularly if deteriorating and rapid response sought

3 Cyclophosphamide, consider if poor response to other drugs (may be given as cycles of IV preparation in combination with other drugs; see peripheral nerve vasculitis)

CK, creatine kinase; FBC, full blood count; IV, intravenous; IVIG, intravenous immunoglobulin; LFT, liver function test; NPSA, National Patient Safety Agency,

Inflammatory myopathies associated with connective tissue disease

Although rheumatological diseases can lead to weakness through musculoskeletal deformity, neuropathy, muscle ischaemia or medication side effects, certain patterns of inflammatory myopathy are recognized, albeit infrequently. Systemic sclerosis occurs in conjunction with a DM-like picture in approximately 10% of

cases, and 5–10% of people with SLE have a condition similar to PM. Sjögren's syndrome can rarely be seen with features similar to either DM or IBM. Myositis is very rare with either rheumatoid arthritis or polyarteritis nodosa. Muscle biopsy should be considered in any patient with a confirmed rheumatological illness, in particular if the CK is raised and EMG identifies myopathic features.

Inflammatory and other myopathies associated with infection

A number of viruses cause myositis. Common infections (Coxsackie, EBV, CMV, influenza) have all been associated with acute and chronic muscle inflammation, although such complications are rare and the underlying mechanism is unclear. A definite causative link has been established for the retroviruses HIV and human T-lymphocyte virus (HTLV-1) and myositis.

At seroconversion, HIV can lead to a polymyositis that can be explosive enough to provoke myoglobulinuria, and which is steroid-responsive. A nemaline rod myopathy may also develop at this stage of infection, with a raised CK and specific findings on biopsy. With the onset of AIDS, a necrotizing myopathy with proximal weakness, typically a normal CK and necrotic fibres on biopsy occurs. HIV wasting disease or 'slim' is frequently encountered in sub-Saharan Africa, but rarely in industrialized populations. 'Slim' is defined as more than 10% weight loss and weakness and fever or diarrhoea for at least 1 month, without any other causative condition. It appears to be caused by a combination of increased metabolic demand, anorexia and possible endocrine derangement and altered lipid metabolism. It leads to muscle wasting without myalgia, and when biopsied most typically shows type II fibre atrophy. Treatment is by improved nutrition and antiretrovirals. People with HIV are also at greater risk of infectious pyomyositis, which is typically multifocal and slower to evolve than the non-HIV-associated form. The range of causative organisms also differs with cryptococcus, toxoplasma, CMV and atypical mycobacteria implicated.

HTLV-1 is endemic in the Caribbean and Japan and most commonly leads to a slowly evolving myelopathy. It can alternatively provoke a polymyositis, which seems to follow expression of HTLV-1's tax-1 protein in muscle cells, rather than any sustained viral replication. HTLV-1 induced PM may respond to immunosuppression.

Non-viral infective myopathies occur with bacteria or parasites. Suppurative pyomyositis is typically a tropically acquired illness in which a staphylococcal abscess forms at the site of injury. In industrialized populations, immunosuppression from medication or conditions such as diabetes, liver disease or malignancy are more commonly associated than HIV. Staphylococci account for the great majority of infections but others including TB and fungi also occur. The diagnosis is largely clinical and treatment includes aspiration (which aids identification of the infective organism) and drainage if required and appropriate antibiotics.

Lyme disease, in addition to its more frequent CNS and nerve involvement, can unusually lead to myositis; this may be either a localized painful swelling or a rarer generalized dermatomyositis-like picture. Treatment is of the underlying spirochaete with appropriate antibiotics.

Some parasites cause focal or multi-focal muscle inflammation. Cestodes (cysticerci), nematodes (trichinella) and protozoa (toxoplasma, trypanosomes), all typically ingested in undercooked meat, can infect muscle. Muscle symptoms are often mild and self-limiting and it is involvement of the CNS that prompts identification and medication.

Other inflammatory myopathies

Granulomatous myopathies

Granulomatous myopathies present as a slowly evolving proximal weakness, possibly with dysphagia. Over time, flexion contractures may develop in the forearms and muscle hypertrophy may become evident. The serum CK is typically elevated and muscle biopsy demonstrates focal non-caseating granulomas. The differential is wide, including sarcoidosis, autoimmune conditions (rheumatoid arthritis, mixed connective tissue disease, Wegener's granulomatosis or in association with myasthenia gravis and thymoma) plus some infections (fungal, mycobacterial, protozoal). Many, but not all, respond to treatment with steroids.

Eosinophilic myopathic syndromes

Three forms of inflammatory myopathy are associated with eosinophilic infiltration of muscle, a systemic eosinophilia, or both. Eosinophilic polymyositis is similar to the classic PM described above, but occurs in conjunction with eosinophils, which are elevated in the circulation and prominently present on muscle biopsy. In eosinophilic fasciitis, pathological inflammation is limited to the fascia, and the fascia lata is the best site for confirmatory biopsy. Finally, dietary L-tryptophan, apparently contaminated by an acetaldehyde ditryptophan derivative, led to the eosinophilia myalgia syndrome. A marked eosinophilia developed with muscle pain and weakness with a scleroderma-like skin reaction and a peripheral neuropathy. Symptoms resolved after the medication was ended, although steroids were required to speed improvement in some cases.

Macrophagic myofasciitis

This is a rare but pathologically distinctive focal reaction at the site of vaccination, possibly directed against the aluminium hydroxide adjuvant of the vaccines. Originally described in France, after the adoption of hepatitis B vaccination, cases have now been reported from other countries. Many patients report systemic systems of fatigue, and CK can be significantly raised. Several years may elapse between the vaccination and the onset of the syndrome. Periodic acid–Schiff (PAS) positive macrophage infiltration of connective tissue is seen on biopsy. Steroid treatment is beneficial.

Myopathies associated with malignancy

Weakness may simply accompany tumour-induced cachexia, but cancers can cause a number of other muscle disorders.

Dermatomyositis and (less so) polymyositis can be associated with a range of malignancies (ovary, lung, gastrointestinal, non-Hodgkin's lymphoma) and, if so, have a worse prognosis.

An aggressive necrotizing myopathy is rarely seen in older patients with cancer (lung, gastrointestinal adenocarcinoma and breast). A rapidly progressive proximal weakness is typically accompanied by an elevated CK, while muscle biopsy demonstrates foci of necrosis. Steroids and treatment of the underlying tumour may help arrest symptoms.

Rare paraneoplastic antibody-driven myopathies have been reported. Waldenström's macroglobulinaemia can generate IgM against the muscle proteoglycan decorin. Myasthenia gravis, with or without underlying thymoma, can generate antibodies against skeletal muscle that cause rippling muscle disease: painful cramps with visible ripples of the muscle that often worsen with pyridostigmine but improve with immunosuppression.

Endocrine myopathies

Thyroid

Hypothyroidism frequently causes non-specific fatigue, myalgia and cramps and a raised CK. Untreated and over time a proximal symmetrical weakness can develop. The CK is not related to the level of weakness. Typically, the EMG shows myopathic changes and the histopathological findings are non-specific. Less commonly, myokymia may be seen and rarely severe muscle oedema may develop with subsequent rhabdomyolysis. The myopathy responds to thyroid replacement but is slow to do so.

Hyperthyroidism when severe is often associated with muscle weakness. Unlike hypothyroidism, distal muscles can be affected, sometimes in isolation. CK is not elevated. Symptoms are worse with severe and acute hyperthyroidism ('thyroid storm'). There is a rare inflammatory myopathy associated with hyperthyroidism, clinically similar to the idiopathic condition, and also causing a raised CK.

Adrenal

Cushing's syndrome leads to steroid myopathy as described below, while Addison's disease (whether primary or iatrogenic) typically causes myalgia, cramps and fatigue. Inadequate circulating levels of corticosteroids may lead to proximal weakness, which can lead to respiratory difficulty. Adequate steroid replacement is curative.

Parathyroid

Both inadequate and excessive levels of parathyroid hormone may lead to a mild progressive proximal myopathy. CK is more frequently raised in the former case, but normal in the latter.

Acromegaly

Untreated, excess growth hormone will cause a proximal weakness, sometimes with muscle hypertrophy and with an elevated CK. Some 50% of acromegalics show myopathic changes on EMG. Correction of the underlying condition leads to resolution of the myopathy.

Table 9.41 Drugs associated with myopathy.

Lipid-lowering: statins, fibrates, nicotinic acid, ezetimibe
Steroids
Abuse: alcohol, heroin, cocaine
Cardiac: amiodarone, perhexiline
Rheumatological treatments: colchicines, chloroquine, hydroxychloroquine
Other: ipecac (anorexics), streptokinase, zidovudine, α-interferon, d-penicillamine

Drugs and myopathy

A variety of drugs have been identified as causing a myopathy (Table 9.41). Some, such as steroids, will eventually cause a deleterious effect on all those who receive them. Others, such as statins, will do so to only some. The spectrum of drug-induced myopathy varies from an asymptomatic raised CK to profound weakness with rhabdomyolysis. Drugs may also worsen an existing muscle disease or, alternatively, unmask one that was previously hidden.

Statin myopathy

Statins inhibit the enzyme HMG CoA reductase, reducing the formation of cholesterol and also ubiquinone (coenzyme Q10). Series identify an eightfold risk of myopathy in those taking statins, raised to 42-fold if a fibrate is taken concurrently. This equates to about 1–6/10,000 treated. Approximately two million people in the UK were taking a statin in 2006, so only several hundred were expected to develop such side effects. It appears that the risk of statin-induced myopathy is dose-dependent but higher in the elderly or those with diabetes, hypothyroidism or concurrent renal or liver disease. Also at greater risk are those taking fibrates, especially gemfibrozil, or inhibitors of the hepatic enzyme CYP3A4 (including ciclosporin, proton pump inhibitors, various antifungals, calcium-channel blockers, SSRIs, grapefruit juice). The most common problem is of an asymptomatic elevation of CK, and the most frequent symptoms are of myalgia and cramps.

The classic pathological finding is a necrotizing myopathy which betrays the associated risk of rhabdomyolysis. Alternatively, statins can induce inflammatory or mitochondrial change (the latter with normal CK), or unmask an underlying metabolic condition.

A suggested management strategy for statin myopathy is given in Table 9.42. Stopping the statin usually leads to improvement within a few weeks, but myalgia and raised CK may persist and severe myopathy can leave permanent sequelae.

Zidovudine and other antiretrovirals

A toxic mitochondrial myopathy may follow the use of zidovudine (AZT), because of its inhibition of mitochondrial DNA replication. Those affected develop myalgia, exercise intolerance, proximal or generalized weakness and raised CK, usually after some time on the drug. A muscle biopsy is indicated, looking for

cytochrome oxidase-negative fibres, not least to differentiate the diagnosis from that of HIV myositis. The myopathy usually resolves when zidovudine is stopped, although 3–4 months may be required. Zidovudine is also well recognized for its potential to expose a pre-existing carnitine deficiency.

Table 9.42 Management of statin myopathy (Mastaglia 2006).

Prevention	Start those at higher risk on lowest dose statin (e.g. pravastatin 10 mg/day)
CK raised without symptoms	Check CK again after 1 month; discontinue statin if CK rises further or symptoms develop
CK raised with symptoms	Stop statin. Consider co-enzyme Q10. Then: If symptoms resolve and the CK falls to normal, reinitiate statin at lowest dose If symptoms or elevated CK persist for 6 months off treatment, then perform muscle biopsy (to look for exposed inflammatory/mitochondrial myopathy) If the symptoms worsen or CK rises further, then proceed to urgent muscle biopsy

CK, creatine kinase.

Recently, the syndrome of nucleoside-associated lactic acidosis was been reported. Multiple symptoms including abdominal pain, vomiting, cough, shortness of breath, weight loss, together with myopathy and a painful axonal neuropathy develop subacutely in the first months of treatment. Cases have been reported up to 3 years after treatment began. Serum lactate is raised and muscle biopsy reveals necrosis plus mitochondrial abnormalities. Treatment is supportive, with fluids and bicarbonate to neutralize the acidosis, and the retroviral drug should be stopped. However, mortality is high at up to 50% and recovery is slow.

Steroid myopathy

Chronic administration of steroids reduces muscle protein synthesis, leading to insidious proximal weakness, especially of the quadriceps muscles. CK is not elevated and so any such rise necessitates separate investigation. Myopathy can occur at any dose but the incidence is highest with dexamethasone, betamethasone and triamcinolone, while for prednisolone daily doses in excess of 40 mg appear to confer the highest risk.

The pathological change is of selective type II (particularly IIB) fibre atrophy. The condition is usually reversible and so if

Table 9.43 Causes of rhabdomyolysis.

Acquired muscle disease	
Exertion	Extreme exertion, status epilepticus, status asthmaticus, prolonged involuntary movement
Crush	Multiple trauma, prolonged immobility (e.g. pre-operative, coma, torture)
Temperature	Pyrexia, exposure to extreme heat, burns
Ischaemia	Arterial occlusion, compartment syndrome, DIC, sickle cell disease
Metabolic	Hyper-/hyponatraemia, hypophosphotaemia, hyperosmolar state
Endocrine	Hypothyroidism, diabetic ketoacidosis, non-ketotic hyperosmolar coma
Alcohol	
Inflammatory	Polymyositis, dermatomyositis, vasculitis, paraneoplastic necrotizing myopathy
Drugs (see chapter 18)	Coma induced by alcohol, opioids or CNS depressants Agitation, e.g. following amphetamines. Possibly associated with serotonin syndrome or neuroleptic malignant syndrome Prolonged involuntary movements, e.g. drug-induced dystonic states Metabolic effects – statins, antidepressants, carbon monoxide, colchicines
Toxins	Snake bites
Infections	Viral – HSV, enterovirus, influenza A+B, CMV, EBV, adenovirus, HIV Bacterial – acute pyomyositis, staphylococcal/streptococcal Others – plasmodium, trichinella, toxoplasma
Inherited muscle disease	
Metabolic	Disorders of glycolytic – glycogenolytic pathway Disorders of fatty acid oxidation Disorders of purine cycle Mitochondrial respiratory chain Malignant hypothermia
Other hereditary muscle disease	e.g. congenital myopathy, dystrophinopathy, myotonic dystrophy

CMV, cytomegalovirus; DIC, disseminated intravascular coagulopathy; EBV, Epstein–Barr virus; HSV, herpes simplex virus.

possible steroids should be withdrawn. If withdrawal is not possible, the dosage should be reduced to the minimum and/or switched to an alternate-day regimen.

Rhabdomyolysis

Rhabdomyolysis is the breakdown of striated muscle fibres that leads to the release of muscle enzymes into the circulation. Myoglobinuria occurs when the haem-binding protein, myoglobulin, appears in the urine leading to a brownish discoloration with concentrations >250 μg/mL. The severity of rhabdomyolysis can vary from an asymptomatic elevation of muscle enzymes to severe electrolyte imbalance with acute renal failure. Rhabdomyolysis usually results from muscle injury because of trauma or other external causes (e.g. medication or intoxication) but may also develop if there is an underlying muscle disorder (Table 9.43). Therapeutic medication, substance abuse and toxins can cause rhabdomyolysis through a wide variety of mechanisms including prolonged coma, seizures, agitation, hypothermia, metabolic effects or direct myotoxicity.

Presentation depends on the cause of rhabdomyolysis but there is usually severe myalgia, muscle swelling and pigmenturia in association with greatly elevated CK (often >100,000). Compartment syndrome is characterized by severe muscle swelling in a limited anatomical space which may cause extreme pain and secondary vascular and neural compromise. The onset of renal failure may be manifest as oliguria and hypotension with haem pigmented casts. Electrolyte derangement arises from muscle lysis and renal failure and may include severe hyperkalaemia and hyperphosphotaemia with hypocalcaemia resulting from deposition of calcium salts within injured muscles. A secondary hypoalbuminaemia with hypotension, shock and cardiac arrhythmias may develop.

Management is treatment of the underlying disorder, correction of fluid and electrolyte abnormalities and prevention of renal failure. This usually involves plasma volume expansion with forced diuresis. The development of compartment syndrome may require fasciotomy.

10 Multiple Sclerosis and Demyelinating Diseases

Siobhan Leary, Gavin Giovannoni, Robin Howard, David Miller, Alan Thompson

Introduction

Multiple sclerosis is an inflammatory demyelinating disorder of the CNS. Although the characteristic pathological lesions were first described over 150 years ago, its aetiology and pathophysiology remain to be fully elucidated. However, advances in pathological, immunological and genetic techniques have provided a greater understanding of the disease mechanisms involved. The application of magnetic resonance imaging (MRI) over the last two decades has also provided important insights into the dynamics of the disease which have subsequently been used in diagnosis and monitoring. Multiple sclerosis is a complex disease with an unpredictable prognosis which may cause numerous and diverse symptoms and accumulating disability. Major advances in disease modification have been made in the last two decades and multiple sclerosis is no longer an 'untreatable' condition. However, current therapeutic agents have limited efficacy and do not prevent disease progression in the long term. Management requires a responsive and comprehensive approach involving multiple health disciplines. This chapter outlines the features of multiple sclerosis as we understand them today and reviews current practice in diagnosis and management. Other white matter diseases are also reviewed.

Epidemiology

It is estimated that there may be 85,000 people living with multiple sclerosis in the UK (population approximately 61 million). The prevalence is 100–150/100,000 population, with an annual incidence of new cases of 3.5–7/100,000. The incidence of multiple sclerosis worldwide tends to increase with increasing latitude, although there are clear exceptions. It is more common in temperate regions, such as northern Europe, North America and southern Australasia, but much rarer in the tropics. Geographical variations are seen over relatively small distances, e.g. it is more common in Scotland than in south-east England. Multiple sclerosis typically presents at 20–40 years of age. Females are more susceptible than males by a factor of approximately 2:1. There is evidence that the incidence of multiple sclerosis in females has been disproportionately increasing, and a steady increase in the sex ratio to over 3:1 has been reported in a Canadian population.

Migration studies

Some migration studies have demonstrated that people who migrate from one geographical area to another before adolescence are essentially subject to the same level of risk of the area to which they migrate; subjects who migrate after adolescence carry with them the incidence of the area from which they migrated. However, this age threshold is not evident in all studies, e.g. age at migration was not significantly associated with risk of multiple sclerosis in a migrant population in Australia. Although the risk of multiple sclerosis generally declines in migrants from high-risk to low-risk areas, the converse is not seen consistently in migrants from low-risk to high-risk areas. An increased risk is not seen in Caribbean and Asian immigrants to the UK initially, although the risk may increase over time, but the benefit is not passed on to the next generation. Migration may explain the higher incidence of multiple sclerosis than expected for latitude in countries such as Israel and South Africa.

Health economics

Multiple sclerosis is the most common cause of neurological disability in young adults and health care costs result in considerable financial burden to society. Many people are in education or employment at the time of diagnosis but, over time, reduced capacity to work and unemployment is common, which results in further indirect costs to society. In 2005, the cost of multiple sclerosis in the UK was estimated as over €40,000 per person with

Neurology: A Queen Square Textbook Edited by Charles Clarke, Robin Howard, Martin Rossor and Simon Shorvon
ISBN: 978-1-405-13443-9

multiple sclerosis per year, with a total annual cost of over €3 billion. The total annual cost across Europe was estimated as €12.5 billion, with just over half arising from direct costs and the remainder from informal care and indirect costs. If intangible costs were included, the total annual cost was estimated as €23 billion.

Aetiology

The aetiology of multiple sclerosis is complex and cannot be ascribed to a single genetic or environmental factor. There is wide acceptance that interactions between genes and environmental factors lead to tissue injury by autoimmune mechanisms, implicated by immunological and pathological observations in people with multiple sclerosis and by extensive studies in the animal model of experimental allergic encephalomyelitis (EAE). Multiple sclerosis is weakly associated with other putative autoimmune disorders, including Hashimoto thyroiditis, psoriasis, inflammatory bowel disease and possibly rheumatoid arthritis, which may suggest that people with multiple sclerosis are predisposed to autoimmunity in general.

Genetic susceptibility

It is well recognized that genetic factors contribute to the occurrence of multiple sclerosis. Twin studies have demonstrated much higher concordance rates in monozygotic twins (approximately 30%) than dizygotic twins (approximately 5%) and family studies have shown that relatives of people with multiple sclerosis have a greater risk for the disease than the general population, approximately 3–5% in first degree relatives. No increased risk is seen in adopted relatives, and an intermediate risk is seen in half siblings, indicating that the familial risk is related to genetic rather than micro-environmental factors.

Genes that contribute to multiple sclerosis susceptibility have been difficult to identify because individually they exert only a relatively modest effect on disease risk. The only consistent genetic association and linkages identified are with alleles of the human lymphocyte antigen (HLA) class II region, part of the major histocompatibility complex (MHC); particularly HLA-DRB1*15 and HLA-DQB1*06. The role of class I alleles is inconsistent; recent reports suggest that some class I alleles may increase the risk of multiple sclerosis independently of the DRB1*15 and DQB1*06 alleles, while other class I alleles decrease the overall risk of multiple sclerosis in DRB1*15 and DQB1*06 carriers. There are likely to be multiple epistatic interactions at the HLA class I and II loci, with susceptibility and resistance alleles interacting to determine overall multiple sclerosis risk. HLA antigens are involved in immunoregulation, and so the genetic effect may be exerted through immunopathogenic mechanisms. More recently, multiple sclerosis has been associated with a polymorphism in the interleukin-7 receptor alpha gene (*IL7RA*). This is likely to be a real association as it has been replicated by several groups in multiple cohorts.

Environmental factors

Geographical gradients, migration studies and high discordant rates in monozygotic twins indicate that environment has a significant influence on the development of multiple sclerosis. Migration studies suggest that exposure to environmental factor(s) in early adolescence is associated with the development of multiple sclerosis. As multiple sclerosis may be uncommon in areas where sanitation is poor and the prevalence of parasitic infections is high, and as there is an increased incidence of autoimmune diseases in developed counties, the 'hygiene hypothesis' has been evoked. This suggests that exposure to infections in early childhood may protect against multiple sclerosis. However, the hygiene hypothesis has been largely discredited by conjugal pair, adopted children and sibship studies, which show no attributable risk to the familial micro-environment. Family-based genetic epidemiological approaches have found no evidence of non-genetic transmissibility within the familial micro-environment, which implies that the environment appears to influence the risk of multiple sclerosis at a population level. Several environmental factors have been proposed as aetiologically significant in multiple sclerosis, including transmissible agents and non-infectious factors.

Transmissible agents

Numerous transmissible agents have been implicated as the possible cause of multiple sclerosis. Suggested candidates include Epstein–Barr virus (EBV), human herpes virus type 6 (HHV-6), multiple sclerosis associated human endogenous retrovirus and *Chlamydia pneumoniae*. The epidemiological data associating EBV infection with multiple sclerosis is the strongest. A consistent finding is that almost all subjects with multiple sclerosis, >99%, are infected with EBV compared to only about 90% of control subjects. People who have had infectious mononucleosis or who have high titres of anti-EBV antibodies have a higher risk of developing multiple sclerosis compared to subjects who have not had infectious mononucleosis or who have low titres of anti-EBV antibodies. The association of EBV infection with multiple sclerosis may simply be a ubiquitous epiphenomenon that is required at the onset of the disease. There are several theories to explain how infection may cause multiple sclerosis but definitive evidence to suggest causation has been lacking. A recent pathological study has found evidence of EBV infection in B cells and plasma cells in the brain, with viral reactivation in acute lesions and ectopic B cell follicles, in multiple sclerosis but not in other neuro-inflammatory diseases. This still does not establish causation, but suggests that EBV persistence and reactivation may have an important role in pathogenesis. However, this finding has not yet been replicated in other studies.

Vitamin D and sunlight exposure

Two associated factors that have been recognized as a potential explanation for the link between geography, in particular latitude, and the incidence of multiple sclerosis are sunlight exposure and vitamin D status. Experimental and epidemiological data suggest

that high levels of vitamin D decrease the risk of multiple sclerosis. Taking vitamin supplementation, which includes vitamin D, has been associated with a reduction in the risk of developing multiple sclerosis and small uncontrolled studies suggest vitamin D supplementation may decrease the incidence of relapses. A lower risk of multiple sclerosis is associated with high serum 25-hydroxy vitamin D levels in subjects of European extraction. In the northern hemisphere significantly fewer people with multiple sclerosis are born in November and significantly more are born in May, with a reversal of this ratio in the southern hemisphere. The fact that month of birth and risk of multiple sclerosis are associated implies an interaction with the environment that may act during gestation or shortly after birth. It has been proposed that this month of birth effect is linked to the vitamin D status of the mother but this has not been confirmed.

Smoking

Smoking prior to the onset of multiple sclerosis has emerged as a significant, albeit moderate, risk factor for the subsequent development of multiple sclerosis. It has been suggested that smoking may increase the risk of developing progressive disease, but a recent study found no effect of smoking on progression of disease. It has been hypothesized that smoking may explain the increase in incidence of multiple sclerosis in females, but this is unlikely as this increase predates the increase in incidence of female smokers.

Other environmental factors such as diet, alcohol consumption, recreational drug use, oral contraceptive pill exposure and vaccination have not been shown to increase the risk of multiple sclerosis.

Pathophysiology

The characteristic pathological feature of multiple sclerosis is the focal plaque or lesion. The lesions of multiple sclerosis were first depicted by Carswell in 1838 and the principal elements were described by Charcot in 1868 – demyelination, relative preservation of axons, gliosis and a variable amount of inflammation. This histological overview remains just as accurate today but the precise roles and inter-relationships of these elements in the pathogenesis of multiple sclerosis are still not fully elucidated. Furthermore, it is evident that the pathology of multiple sclerosis is not just confined to white matter lesions but involves the grey matter and macroscopically normal-appearing white matter (NAWM).

Pathology

Lesions occur throughout the CNS but particularly in the optic nerves, peri-ventricular white matter and corpus callosum, brainstem and cerebellar white matter, and cervical cord. Macroscopically, lesions are generally round or oval and, in broad terms, may be pink and soft, representing acute or active lesions, or grey and firm, representing chronic lesions (Plate 10.1). Brain atrophy and ventricular enlargement and atrophy of the spinal cord and optic nerves may be evident. Microscopically, acute lesions are characterized by active demyelination with marked inflammatory infiltrates, predominantly T lymphocytes and macrophages, associated with a variable degree of axonal damage and loss (Plate 10.1). In chronic lesions there is extensive loss of myelin, abundant astrocytic gliosis and axonal loss.

Table 10.1 Pathological classification of active multiple sclerosis lesions. (After Lucchinetti *et al.* 2000.)

I	T-cell/macrophage associated
II	Antibody/complement associated
III	Distal oligodendrogliopathy
IV	Oligodendrocyte degeneration in the peri-plaque white matter

Different patterns of demyelination in active lesions have been described. Lucchinetti and colleagues studied actively demyelinating lesions in a large sample of multiple sclerosis biopsy and postmortem samples and proposed four different patterns (Table 10.1). Inflammatory infiltrates, dominated by T lymphocytes and macrophages, were seen in all lesions. Patterns I and II were similar and lesions were typically sharply demarcated and centred on small veins and venules. High numbers of oligodendrocytes were seen. Pattern II was distinguished from Pattern I by prominent deposition of immunoglobulins and complement. Patterns III and IV were associated with signs of oligodendrocyte dystrophy. Pattern III lesions were diffuse with ill-defined borders. They were not centred on vessels and there was a preserved rim of myelin around vessels in some lesions. Unlike other patterns, where loss of myelin proteins was evenly distributed, there was a preferential loss of myelin-associated glycoprotein. There was pronounced loss of oligodendrocytes and oligodendrocyte apoptosis was seen. Pattern IV lesions were sharply demarcated. There was loss of oligodendrocytes and oligodendrocyte death was seen in a small rim of peri-lesional white matter. All active lesions within an individual patient exhibited the same pattern and there was no intra-individual heterogeneity. Patterns I and II were found in all clinical subtypes of multiple sclerosis. Pattern III was mainly found in people with disease duration of less than 2 months. Pattern IV lesions were only found in a variant of primary progressive disease. Therefore it was suggested that mechanisms of demyelination may be different in different subtypes and stages of the disease. However, this is not universally accepted. Different types of active lesions have been reported within individuals, and it has been suggested that the Pattern III lesions represent a very early stage in the development of acute lesions. Further study should be facilitated by the Multiple Sclerosis Lesion Project, an international collaboration, which has been designed to study the clinical, radiological and pathological correlates of multiple sclerosis lesions.

The role of inflammation in the pathogenesis of lesions also remains unclear. Axonal damage has been shown to occur not

only in the presence of active inflammation, but also in chronic demyelinated lesions. Lesions in people who have died shortly after a relapse have been shown to have zones of extensive oligodendrocyte apoptosis and microglial activation in myelinated tissue (Pattern III) containing few or no lymphocytes or myelin phagocytes suggesting that lesion formation may be related to a process other than inflammation.

Active lesions are predominantly seen in acute relapsing disease and are rare in secondary and primary progressive disease, in which chronic lesions predominate. However, slow expansion of chronic lesions may occur in progressive disease. These lesions are characterized by a rim of activated microglia, at the edge of the lesion, which are associated with active demyelination.

Remyelination is seen in a large proportion of lesions, often at the edges of lesions, although it may be present throughout the lesion. Remyelination may be extensive and result in remyelination of the complete lesion, described pathologically as a shadow plaque. Although historically remyelination has been felt to occur predominantly in early relapsing disease, it is now apparent that extensive remyelination may also occur in progressive disease. It is not known why remyelination occurs in some lesions and not others.

Pathological abnormalities are also seen in NAWM. In contrast to the extensive inflammation seen in focal lesions, there may be a mild but diffuse inflammatory reaction in NAWM. Perivascular cuffing and diffuse inflammatory infiltrates and microglia activation are seen. Diffuse axonal injury is also evident. This does not correlate with the extent of lesions and so is not explained by Wallerian degeneration arising from focal lesions alone. Therefore, there appears to be a mechanism of axonal injury that is independent of focal lesions. Pathological changes are also not just confined to the white matter, and striking cortical demyelination may be seen. Subcortical lesions may extend into the cortex or small focal lesions may be present within the cortex, but extensive subpial demyelination may also occur. These diffuse changes in the NAWM and cortex are present far more extensively in progressive than in relapsing disease.

It has been previously suggested that relapses and disease progression may be occurring through distinct mechanisms, with relapses resulting from inflammatory demyelination and progression resulting from neurodegeneration. The recent advances in the elucidation of the immunopathology of multiple sclerosis provide support for a more unifying hypothesis. Multiple sclerosis typically starts with acute inflammation, arising from specific immune mechanisms, which are discussed below, resulting in focal inflammatory demyelinating lesions. Over time, inflammation becomes sequestered within the CNS. This inflammation may be non-specific and low grade but it drives the slow expansion of chronic lesions and the diffuse injury in the NAWM and cortex.

Autoimmune pathogenesis

The first step in the autoimmune pathogenesis of multiple sclerosis is believed to be that an environmental agent(s) combined with a genetic predisposition resulting in the production of pathological autoreactive T cells. After a latent period of 10–20 years a breakdown in immunological tolerance, possibly by a systemic trigger such as a non-specific viral infection or exposure to a superantigen, activates these autoreactive T cells.

During the normal process of immunosurveillance, memory $CD4^+$ T-helper (Th) cells selectively cross the blood–brain barrier, through a process involving the interaction of their cell surface adhesion molecules with those expressed on CNS endothelium. Once within the peri-vascular space, these cells are presumably activated by professional antigen-presenting cells (probably macrophages or microglia) to proliferate and produce pro-inflammatory cytokines. Antigen recognition occurs via the tri-molecular complex, consisting of HLA, T-cell receptor and CD3 molecules. This requires additional co-stimulatory signals, e.g. interactions between HLA-MHC I and II molecules and their respective CD8 and CD4 molecules, and CD28/B7-2/1 pairs.

Humoral immunity appears to have an important role in multiple sclerosis, and intrathecal antibody synthesis is characteristic of the disease. The presence of B-cell clonal expansion in CSF and in lesions indicates an antigen-driven response within the CNS. Ectopic B-cell follicles have also been found in the meninges and are anatomically associated with subpial cortical lesions, providing further evidence that B cells are involved in immunopathogenesis.

Potential autoantigens implicated in the pathogenesis of multiple sclerosis include myelin basic protein, proteolipid protein, myelin-associated glycoprotein, myelin oligodendrocyte glycoprotein and alpha-B crystallin. The presence of specific cytokines, e.g. interleukin 12 (IL12) and IL23, govern the type of Th response. Th1-like cytokines (IL2, interferon γ and tumour necrosis factor α [TNF-α]) or Th23-like cytokines (IL17) initiate a cell-mediated inflammatory cascade which activates macrophages, microglia, astrocytes and endothelial cells. This results in further cytokine production and recruitment of inflammatory cells by the up-regulation of adhesion molecule expression on endothelial cells and by the production of chemo-attractants, such as chemokines. Astrocytes and macrophages produce mutually stimulating cytokines (IL1 and TNF-α). These and other pro-inflammatory T-cell cytokines up-regulate the production of numerous mediators of inflammation, which are toxic to oligodendrocytes, axons and neurones. These substances include TNF-α, free oxygen and nitrogen radicals, complement, proteases and eicosanoids.

Autoantibodies, particularly to surface myelin antigens, may be crucial to the development of demyelination. Autoantibodies to axonal elements, e.g. gangliosides and neurofilaments, may have functional consequences and may contribute to conduction abnormalities and axonal loss. In addition to myelin damage, programmed cell death or apoptosis of the oligodendrocyte may occur as a result of oxidative stress and death signalling induced by TNF-α. Antibodies and complement assist Fc-receptor mediated phagocytosis by opsonization. Phagocytosis also occurs via the macrophage scavenger and low-density lipoprotein receptors.

T-regulatory cells and immunomodulatory cytokines produced by these cells are important in down-regulating and controlling the focal inflammation. Elimination of autoreactive T cells by apoptosis may be important in controlling inflammation.

The combination of both cell and humorally-mediated inflammatory cascades causes oligodendrocyte, axonal and neuronal toxicity, which in turn is believed to release sequestered CNS antigens which are hypothesized to initiate further cycles of autoimmune-induced inflammation via intra- or intermolecular antigen determinant spreading.

Demyelination results in a reduction in the safety factor of conduction, with complete or intermittent conduction block, which produces clinical symptoms and signs, some of which may be intermittent. Resolution of inflammation and oedema initially may result in clinical improvement. Over a longer time, remyelination and/or axonal plasticity (synthesis of new sodium channels along demyelinated axonal segments) restores axonal conduction, albeit with a reduced safety factor of conduction, which results in remission. There is evidence that growth factors produced as part of the inflammatory response stimulate the process of remyelination. Transient neurological symptoms may occur secondary to the residual reversible conduction block, typically in relation to fatigue, changes in body temperature and systemic inflammation. Ephaptic transmission may cause paroxysmal positive neurological symptoms. Axonal loss and gliosis, as a consequence of acute or diffuse injury, cause permanent neurological impairment and disability.

Clinical course

Multiple sclerosis is characterized by lesions disseminated throughout the CNS, which may appear, disappear or gradually worsen over time, and this is reflected in its clinical presentation and course. Its presentation is variable and its course and prognosis are unpredictable, although broad clinical categories of the disease are well recognized.

Types of multiple sclerosis

Clinical disease activity in multiple sclerosis may manifest as relapses or insidious progression. According to the occurrence and timing of these features, four main categories of multiple sclerosis have been outlined in the widely accepted classification of Lublin and Reingold (Figure 10.1).

Relapsing remitting multiple sclerosis

Approximately 85% of individuals present with relapses and remissions. A relapse is defined as an episode of acute or subacute neurological dysfunction lasting a minimum of 24 hours. A relapse usually evolves over days or weeks, plateaus and then remits to a variable degree, from minimal resolution to complete recovery. Further relapses may then occur at irregular intervals. The average relapse frequency in the relapsing remitting phase of the disease is approximately one relapse per year.

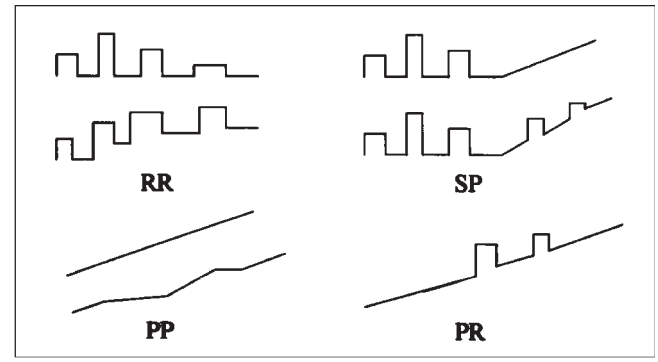

Figure 10.1 Clinical course of multiple sclerosis: illustration of the relationship between increasing disability and time in the different types of multiple sclerosis (PP, primary progressive; PR, progressive relapsing; RR, relapsing remitting; SP, secondary progressive). (After Lublin & Reingold 1996.)

Secondary progressive multiple sclerosis

Relapsing remitting multiple sclerosis may evolve into a gradually progressive course with accumulating irreversible neurological deficit and disability, classified as secondary progressive multiple sclerosis. The proportion of people developing secondary progressive disease increases with length of follow-up. In a large Canadian natural history study, 41% of people with relapsing remitting multiple sclerosis entered the secondary progressive phase within 6–10 years of disease onset increasing to 58% between 11 and 15 years after onset. After 20 years approximately 80% had developed secondary progressive multiple sclerosis. Superimposed relapses may continue to occur in the secondary progressive phase, although less frequently as the disease progresses.

Primary progressive multiple sclerosis

In primary progressive multiple sclerosis there is insidious disease progression from onset, resulting in gradual accumulation of neurological deficit or disability, without relapse or remission. It accounts for approximately 10–15% of multiple sclerosis. Males and females are affected with equal frequency. The average age of onset is older in primary progressive multiple sclerosis, approximately 40 years compared to 30 years in relapsing remitting multiple sclerosis.

Progressive relapsing multiple sclerosis

Progressive relapsing multiple sclerosis refers to the small number of people who have progressive disease from onset with superimposed relapses, but the term is now rarely used. Insidious progression is the predominant feature and relapses are usually mild. Progressive relapsing multiple sclerosis is considered to be largely similar to primary progressive multiple sclerosis. Approximately one-quarter of people initially diagnosed with primary progressive multiple sclerosis will later have relapses, and a relapse may occur decades after disease onset.

Natural history and prognosis

The natural history of multiple sclerosis is extremely variable. The spectrum of disease activity ranges from clinically asymptomatic demyelinating lesions, detected incidentally on imaging or at postmortem, to an aggressive course with rapidly accumulating disability. It is not possible to predict prognosis in an individual, but natural history studies have provided data on disease progression in different multiple sclerosis populations.

Clinically isolated syndromes

A clinically isolated syndrome refers to a first acute episode suggestive of CNS demyelination, and it may be the first presentation of multiple sclerosis. The average risk of developing multiple sclerosis following a clinically isolated syndrome has been reported as between 30% and 70%, although the risk increases with the length of follow-up. People presenting with unilateral optic neuritis may have a lower risk of converting to multiple sclerosis than other clinical presentations. Abnormal MRI at first presentation has been consistently shown to confer a higher risk of conversion to multiple sclerosis than if MRI is normal. Long-term follow-up studies, ranging from 7 to 20 years, have reported the development of multiple sclerosis to occur in 56–88% of people with lesions on MRI and in 8–22% of those with a normal scan. The lesion number and load at first presentation may also have prognostic relevance, with higher lesions loads modestly predictive of the likelihood of developing disability in the long term.

Established multiple sclerosis

Natural history studies have conventionally assessed disease progression in multiple sclerosis by measuring the time taken to reach disability milestones. Such studies have shown that the median time to reach a level of disability requiring assistance for walking is between 15 and 30 years.

There has been debate as to the effect of the disease type on long-term prognosis. Relapsing remitting multiple sclerosis has been felt to carry a better prognosis, but a French natural history study from a single large centre reported that disease progression in the long term is largely independent of disease type. However, this requires replication in other studies. Although accumulation of irreversible disability is slower in the relapsing and remitting phase, once the secondary progressive phase is entered the initial course does not seem to significantly influence long-term prognosis.

The influence of residual disability from relapses on long-term accumulation of disability has been similarly debated. Residual neurological deficit following a relapse is common. For example, an increase in disability was demonstrated in one study in up to 42% of people at 2 months following a relapse. However, further recovery may take place over a longer time. Analysis of the placebo arms of treatment trials in relapsing remitting multiple sclerosis has suggested that relapses, although resulting in confirmed disability over 6 months, do not seem to have a consistent effect on the development of sustained disability over the course of a typical study (mean 2.66 years). Further study is required to understand the effect of relapses on long-term disability.

The age of onset does not seem to significantly influence long-term prognosis. Younger age of onset has previously been considered a good prognostic marker but this is not really the case as, although the time to develop permanent disability may take longer, disability still occurs at a younger age. The older age of onset associated with primary progressive multiple sclerosis has also previously been felt to be a poorer prognostic marker. However, the average age of onset in primary progressive multiple sclerosis is similar to that of the progressive phase in secondary progressive multiple sclerosis. The rate of progression is also similar in the primary and secondary progressive groups, with disability milestones being reached at similar ages.

Male sex has been suggested to be associated with a poorer prognosis, but recent studies suggest that this may not be clear-cut. Factors reported to be associated with a more favourable prognosis include monosymptomatic onset, afferent symptoms (sensory, optic neuritis) at onset, complete recovery from first attack, a long interval between first and second relapses and a low relapse frequency in early disease. However, such associations are weak and it is not possible to reliably predict individual prognosis.

Benign multiple sclerosis

Benign multiple sclerosis refers to a disease course with accumulation of minimal or no disability. There is no consensus definition, but it is often taken as an Expanded Disability Status Scale (EDSS) score ≤3 (Table 10.2) at 10–15 years after disease onset. A systematic review of published studies has reported the frequency of benign multiple sclerosis as 26.7%, but the proportion of people with benign disease decreases with length of follow-up. In a large British Columbian cohort only half of those with benign disease at 10 years still fulfilled the criteria at 20 years, with the remainder having developed secondary progression. There are no reliable indicators of a benign course, although follow-up over 20 years in a US cohort found that the longer the disease duration and the lesser the disability, the more likely an individual was to remain stable. It is well recognized that even long-standing benign disease may progress with the development of severe disability.

Aggressive multiple sclerosis

An aggressive or malignant disease course may result from severe or frequent relapses with little or no neurological recovery or from rapid disease progression. However, aggressive disease is uncommon and early death in multiple sclerosis is rare.

The Marburg variant of multiple sclerosis refers to an acute fulminant disease course, usually monophasic, which may result in death within a few months. Its clinical presentation relates to its site, which may be cerebral, brainstem or spinal cord. In cerebral presentations, confusion and seizures may occur. MRI shows large lesions, correlating to destructive hypercellular demyelinating lesions on neuropathological examination, which typically enhance and may have associated oedema and mass

Table 10.2 Expanded Disability Status Scale (EDSS). Functional systems (FS) are pyramidal, cerebellar, brainstem, sensory, bowel and bladder, visual and cerebral. (Kurtzke JF. Rating neurologic impairment in multiple sclerosis: an Expanded Disability Status Scale (EDSS). *Neurology* 1983: 33: 1444–1452.)

0.0	Normal neurological examination
1.0	No disability, minimal signs in one FS
1.5	No disability, minimal signs in more than one FS
2.0	Minimal disability in one FS
2.5	Minimal disability in two FS
3.0	Moderate disability in one FS or mild disability in three or four FS, although fully ambulatory
3.5	Fully ambulatory but with moderate disability in one FS and mild disability in one or two FS; or moderate disability in two FS; or mild disability in five FS
4.0	Fully ambulatory without aid, self-sufficient up and about some 12 hours a day despite relatively severe disability in one FS or combinations exceeding limits of previous steps; able to walk without aid or rest some 500 m
4.5	Fully ambulatory without aid, up and about much of the day, able to work a full day, may otherwise have some limitation of full activity or require minimal assistance; able to walk without aid or rest some 300 m
5.0	Ambulatory without aid or rest for about 200 m; disability severe enough to impair full daily activities (e.g. to work a full day without special provisions)
5.5	Ambulatory without aid or rest for about 100 m, disability severe enough to preclude full daily activities
6.0	Intermittent or unilateral constant assistance (cane, crutch, brace) required to walk about 100 m with or without resting
6.5	Constant bilateral assistance (canes, crutches, braces) required to walk about 20 m with or without resting
7.0	Unable to walk beyond approximately 5 m even with aid, essentially restricted to wheelchair; wheels self in standard wheelchair and transfers alone, up and about in wheelchair some 12 hours a day
7.5	Unable to take more than a few steps; restricted to wheelchair; may need aid in transfer, wheels self but cannot carry on in standard wheelchair a full day; may require motorized wheelchair
8.0	Essentially restricted to bed or chair or perambulated in wheelchair, but may be out of bed itself much of the day; retains many self-care functions; generally has effective use of arms
8.5	Essentially restricted to bed much of day; has some effective use of arm(s); retains some self-care functions
9.0	Helpless bed patient; can communicate and eat
9.5	Totally helpless bed patient; unable to communicate effectively or eat/swallow
10.0	Death due to MS

MS, multiple sclerosis.

effect (Figure 10.2). The condition must also be distinguished from acute disseminated encephalomyelitis, acute haemorrhagic leucoencephalitis and vasculitis.

Baló concentric sclerosis refers to a particular neuropathological lesion variant, which may also be evident on MRI, characterized by alternating concentric layers of myelin loss and relative preservation of myelin. It may be seen in association with a fulminant course, although it may also occur in more benign disease.

Mortality

Mortality rates are increased compared to the general population. The average life expectancy in multiple sclerosis in a Canadian study was reported as 6–7 years less than a control population. The cause of death in approximately half was directly attributed to complications of multiple sclerosis. A significantly increased incidence of suicide was seen in the multiple sclerosis population of 7.5 times that of the general poulation. A more recent Danish study reported survival in multiple sclerosis to be approximately 10 years shorter than the general population. The suicide rate was more than twice the rate of the general population.

Early onset multiple sclerosis

Although rare, the onset of multiple sclerosis may be in childhood. Early onset, before the age of 16 years, occurs in approximately 2–5% of individuals. A relapsing remitting disease onset is typical, and a primary progressive course is much rarer than in adult onset disease. Prognosis may be considered better in that the time to develop disability is longer than in adult onset multiple sclerosis, but overall individuals develop disability at a younger age. Over half are likely to develop secondary progressive multiple sclerosis by the age of 30 years. The paediatric multiple sclerosis population may be an ideal group in which to study aetiological factors, and there has been a recent upsurge of interest in this group. A large international collaboration has recently reported that paediatric multiple sclerosis may be associated with exposure to EBV, but not with other common childhood viral infections.

Factors affecting relapse activity

Various health and lifestyle factors have been proposed to affect relapse activity in multiple sclerosis. It is important that people with multiple sclerosis are aware of these factors to facilitate informed decisions regarding their lifestyle.

Infections

Systemic infections may trigger a relapse or exacerbate existing symptoms of multiple sclerosis. An association between common viral and bacterial infections and risk of relapse has been documented, but such infections are difficult to avoid. Infections may

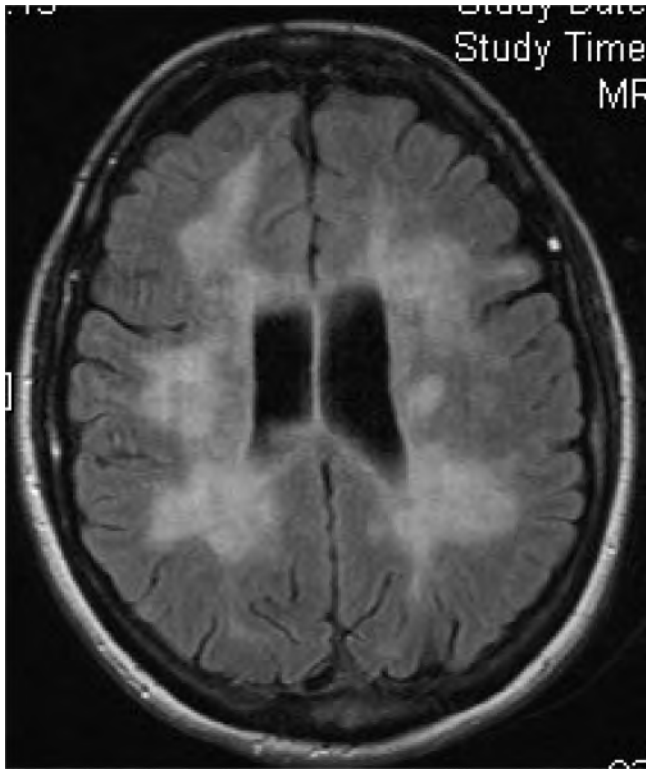

Figure 10.2 Marburg variant of multiple sclerosis (MRI T1W axial).

occur as a complication of multiple sclerosis, e.g. urinary tract infections resulting from retention and chest infections resulting from aspiration. Therefore, addressing the underlying cause of infections may be preventative and, where possible, infections should be anticipated and treated early. Cigarette smoking, aside from its well-known health risks, may increase the occurrence of respiratory tract infections and should be discouraged.

Pregnancy

The effect of pregnancy on disease activity is an important concern among women of childbearing age. A large prospective study of pregnancy in multiple sclerosis confirmed that relapse rate declines during pregnancy, especially in the third trimester, increases during the first 3 months postpartum and then returns to pre-pregnancy rate. The incidence of postpartum relapse was 28%. An increased relapse rate in the pre-pregnancy year and during pregnancy, and higher disability at pregnancy onset, were associated with a higher risk of postpartum relapse. Epidural analgesia and breastfeeding were not found to increase the risk of relapse.

Stress

Prospective studies have reported stressful life events to be associated with an increased risk of relapse. A meta-analysis also supported an association between stressful life events and subsequent relapses although did not link relapse to specific stressors. Physical trauma has been proposed to trigger relapses but a systematic review of the evidence has not supported this link.

Diet

Despite popular interest in the effect of diet on multiple sclerosis there is little evidence to support an association between dietary factors and disease activity. A systematic review concluded that no dietary intervention has been shown to significantly affect disease progression. Linoleic acid, an omega-6 fatty acid, was associated with slight decreases in relapse rate and severity, but the studies were small and of limited design.

Vaccines

The question of whether vaccination may immunologically trigger a relapse has been investigated and there is no clear evidence to support this hypothesis. Most vaccines have not been investigated prospectively, but a double blind, placebo controlled study of influenza vaccine showed no effect on relapse rate or disease progression. There has been particular concern regarding hepatitis B vaccination but a large case cross-over study found no increased risk of relapse following hepatitis B or any vaccination. Current expert opinion is that vaccinations are not contraindicated in multiple sclerosis, and national guidelines recommend that people with multiple sclerosis should be offered vaccination against influenza. However, it must not be forgotten that live vaccines may be contraindicated in individuals on immunosuppressant therapy.

Clinical features

Multiple sclerosis can cause a wide variety of symptoms mirroring involvement of any part of the CNS. The spinal cord, optic nerves and brainstem are commonly involved sites. In a European database of clinically isolated syndromes, 46% of individuals presented with a spinal cord syndrome, 21% with optic neuritis and 10% with a brainstem syndrome. The presentation was polysymptomatic in 23% of cases. Differences in presenting symptoms are seen between disease types. In relapsing remitting multiple sclerosis, the most common symptoms are sensory and visual, whereas in primary progressive disease the most usual presentation is locomotor. During the course of the disease a multitude of symptoms may occur. These include weakness, spasticity, numbness, paraesthesia, pain, visual loss, diplopia, ataxia, tremor, vertigo, sphincter and sexual dysfunction, dysphagia, dysarthria, repiratory dysfunction, temperature sensitivity, fatigue, cognitive and psychiatric disturbance.

There are no symptoms or signs that are pathognomonic for multiple sclerosis, although characteristic clinical features are seen. Optic neuritis is a common manifestation. It presents with eye pain, which is exacerbated by eye movement, and blurring of vision. The visual impairment may progress over a few days, but not usually longer than 1–2 weeks. Continued progressive visual

failure or loss of perception to light should alert to the possibility of alternative diagnoses. On examination, colour vision and visual acuity are impaired and a scotoma, classically central, may be detected. The optic disc may be normal but swelling may be present, and pallor of the optic disc may develop later. A relative afferent pupillary defect is usually present.

Diplopia may be a presenting symptom and usually is symptomatic of a VIth nerve palsy or an internuclear ophthalmoplegia. As the disease advances, unilateral or bilateral internuclear ophthalmoplegia, identified on conjugate lateral gaze as impaired adduction on the side of the lesion and nystagmus of the abducting eye, is commonly seen but may often be asymptomatic.

A partial spinal cord syndrome is a frequent presentation. Typically, altered sensation starts in one foot and spreads to involve both legs and, to a varying extent, ascends to the trunk and arms. Variable degrees of numbness and tingling may occur but complete loss of sensation is unusual. On examination, all sensory modalities may be impaired and a sensory level may be discerned although, as the relapse recovers, a persistent bilateral sensory level is uncommon. Oppenheim hand, a functionally useless hand caused by loss of position sense, may be a characteristic presentation of a lesion in the posterior columns of the cervical cord.

Motor involvement becomes more common as the disease advances and weakness is a prominent symptom. Weakness is usually greater in the legs than the arms, and paraparesis is frequently asymmetrical. Spasticity may manifest as stiffness, clonus or spasms. On examination, signs usually reflect upper motor neurone involvement with hypertonia, hyper-reflexia and positive Babinski responses. However, focal wasting, flaccidity and loss of tendon reflexes may be seen, and may result from denervation in the spinal cord.

Spinal cord involvement also commonly results in bladder and bowel disturbance. Bladder disturbance may result from a combination of detrusor hyper-reflexia, manifesting as urgency, frequency and incontinence, and incomplete emptying because of sphincter dyssynergia and poorly sustained detrusor contractions, resulting in hesitancy and incomplete emptying. Constipation is the most common bowel symptom, although urgency and incontinence is not infrequent. Sexual function in males and females is frequently affected, because of central neurological dysfunction, although psychological and other factors may also contribute.

An initial cerebellar presentation is uncommon but cerebellar involvement is frequent during the course of the disease, evidenced by nystagmus, dysarthria, limb ataxia and intention tremor and truncal ataxia. Gait ataxia may contribute to the classic spastic ataxic gait, but it may also cause disabling gait disturbance in the absence of significant weakness and spasticity.

Fatigue may be one of the most disabling symptoms in multiple sclerosis, and may impact on all activities. An exercise-induced motor fatigue and an unprovoked but severe generalized exhaustion may be reported. Fatigue appears to be related to electrophysiological and immunological effects of multiple sclerosis, and is often worse during relapses, but disturbed sleep, medication and depression may also be contributory factors. Heat sensitivity is a common symptom, caused by the increased temperature inducing slowing of nerve conduction. Uhthoff phenomenon refers to the transient blurring of vision on exercise or in hot environments brought about by underlying optic nerve disease.

Cognitive impairment is well documented to occur in multiple sclerosis and mild deficits may be apparent in early disease. Attention, information processing, memory and executive functions are predominantly affected. Severe dementia may occur but, particularly in early disease, may suggest an alternate diagnosis. Depression occurs more frequently than in the general population but is usually mild and is often reactive to the diagnosis and ensuing neurological deficits. Emotional lability, with pathological crying or laughing, may occur. Psychosis is an uncommon manifestation of multiple sclerosis, but may rarely be the presenting episode.

Pain is common in multiple sclerosis and is usually chronic. It is often myelopathic in origin, typically resulting in a burning pain in the legs and hands. Paroxysmal pain may occur, most notably trigeminal neuralgia. Pain may also result indirectly from other related problems such as spasms and musculoskeletal complications.

A characteristic feature of multiple sclerosis is the occurrence of paroxysmal symptoms, resulting from electrical instability within lesions. A typical episode is of acute onset with symptoms of short duration, less than 2 minutes, occurring up to 30 or more times a day. The whole episode usually resolves spontaneously within a few weeks to months. The nature of the symptoms reflects the underlying site of the lesion. Infratentorial lesions may result in trigeminal neuralgia and paroxysmal dysarthria and ataxia. Tonic spasms, painful tonic contractions usually involving one or two limbs unilaterally, may arise from sites in the corticospinal tract. Other paroxysmal sensory disturbances may occur and paroxysmal itching is described.

Other positive symptoms include Lhermitte's symptom, a brief electrical sensation radiating down the back into the legs or arms precipitated by neck flexion, caused by a lesion in the cervical cord, and phosphenes resulting from optic nerve demyelination. Lesions involving the facial nucleus or nerve may cause hemifacial spasm or facial myokymia. Epilepsy, originating from juxtacortical or cortical lesions, is seen 2–3 times more commonly than in the general population, and rarely may be the presenting symptom.

Diagnosis

Multiple sclerosis is a clinical diagnosis that requires appropriate expertise to confirm evidence of CNS lesions disseminated in time and space and to exclude other diseases. Investigations may be used to:

1 Exclude other diseases;
2 Provide evidence of dissemination in time and space; and
3 Provide evidence of immunological disturbance.

Diagnostic investigations

Magnetic resonance imaging

The plaques of white matter demyelination in multiple sclerosis are readily visualized on MRI by virtue of an increase in the amount and mobility of water protons in the lesions. The standard imaging sequence is a T2-weighted spin echo or fast spin echo, with an additional fast FLAIR (fluid attenuated inversion recovery) sequence that suppresses signal from cerebrospinal fluid (CSF) and increases the conspicuity of cerebral hemisphere lesions.

The value of MRI in diagnosis comes through its high sensitivity for detecting clinically silent lesions, and showing them in characteristic locations; the detection of blood–brain barrier breakdown in acute lesions using gadolinium-enhanced T1-weighted MRI is also a useful finding. MRI may be normal in clinically definite multiple sclerosis, but this is unusual: lesions are seen in the brain in approximately 95% and spinal cord lesions in approximately 70% with a clinically definite diagnosis. The characteristic locations for foci of demyelination are: periventricular, corpus callosum, juxtacortical, brainstem, cerebellar white matter and spinal cord (Figure 10.3). Lesions are usually small (3–10 mm diameter), may have an oval or rounded shape, and usually extend to the parenchymal surface in the brainstem and spinal cord. Cord lesions are most often seen in a posterior or lateral location, involve white and grey matter, and affect only part of the cord in cross-section (Figure 10.4). Gadolinium enhancement is invariable in new lesions in relapsing multiple sclerosis, can be homogeneous or ring-shaped, and lasts an average of 2–6 weeks (Figure 10.5).

In people with a clinically isolated syndrome (CIS), clinically silent cerebral white matter lesions are seen in 50–70%. The presence of MRI lesions confers a relatively high risk for future development of clinically definite multiple sclerosis as already discussed. Development of new T2 or gadolinium-enhancing lesions on follow-up MRI increases the likelihood of early clinical relapses and, accordingly, the development of clinically definite multiple sclerosis.

The major limitation of MRI is specificity: there are many other causes of cerebral white matter lesions (Table 10.3). Small vessel disease is an especially common cause of areas of T2 hyperintensity on white matter and over one-third of the general population aged over 50 years will exhibit areas of high signal. These are small, and mainly subcortical rather than peri-ventricular. Basal ganglia involvement is not uncommon and central pontine abnormalities are also seen (unlike multiple sclerosis, not extending to the surface). Cord lesions do not occur with ageing per se and their detection in older patients is a particularly useful pointer to demyelination.

Mitochondrial disease
Susac's syndrome

CADASIL, cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy; SLE, systemic lupus erythematosus.

Other multifocal and inflammatory disorders may at times be difficult to distinguish from multiple sclerosis on clinical and imaging grounds: sarcoidosis, systemic lupus erythematosus (SLE), Sjögren's syndrome, Behçet's disease, CNS vasculitis, acute disseminated encephalomyelitis (ADEM) and neuromyelitis optica (NMO). There are some distinctive imaging findings, e.g.

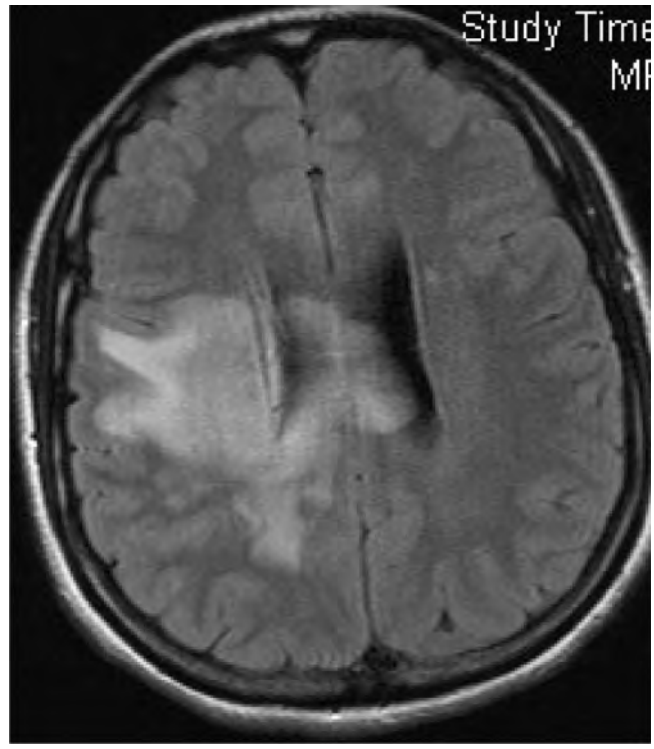

Figure 10.6 Large right temporo-parietal lesion with extension into the splenium of the corpus callosum (MRI T1W axial).

meningeal enhancement in sarcoidosis; multifocal, punctate and peri-vascular enhancement in CNS vasculitis; extensive brainstem lesions in Behçet's disease; monophasic disease activity in ADEM, with partial and sometimes marked resolution at follow-up; extensive longitudinal cord lesions in ADEM and NMO. Numerous other non-inflammatory white matter disorders may also enter the differential diagnosis, e.g. progressive multi-focal leucoencephalopathy, cerebral autosomal dominant arteriopathy with subcortical infarcts and leucoencephalopathy (CADASIL). In leucodystrophies (e.g. Krabbe's disease, adrenomyeloneuropathy) or metabolic disorders such as phenylketonuria, the white matter abnormalities are typically symmetrical. Rarely, demyelinating lesions may manifest as a single, large or tumefactive lesion within a cerebral hemisphere mimicking a cerebral tumour (Figure 10.6). These lesions tend to be extensive but circumscribed with little mass effect or vasogenic oedema and there may be pathological ring enhancement; however, these lesions appear to resolve rapidly with corticosteroid therapy.

Conventional MRI is relatively insensitive to cortical grey matter lesions and abnormalities in NAWM that are nevertheless abundant in multiple sclerosis. These pathological changes can be detected using more sophisticated imaging techniques. Quantitative MRI abnormalities have been demonstrated in NAWM and include decreased magnetization transfer ratio, increased T1 relaxation time, increased mean diffusivity and decreased

N-acetylaspartate on spectroscopy. While the development of techniques to better detect and quantify these more extensive abnormalities may have some diagnostic role in future, the greater importance seems likely to be in understanding pathogenic mechanisms and assigning prognosis.

Cerebrospinal fluid

When both clinical and imaging features are characteristic for multiple sclerosis, many neurologists will not feel that a lumbar puncture is required, although there are some geographical variations in practice. In those regions where Lyme disease is common, exclusion of this treatable condition warrants a lumbar puncture in almost all suspected multiple sclerosis cases (however, it should be noted that the usual clinical features of neuroborreliosis – facial palsy and meningoradiculitis – are not a common presentation for multiple sclerosis). In clinically definite multiple sclerosis, intrathecally synthesized oligoclonal immunoglobulin G (IgG) bands are found in approximately 90% of patients. A parallel blood sample is required to demonstrate the intrathecal origin of bands as the passive transfer of bands from the systemic circulation has no diagnostic value. Isoelectric focusing and immunodetection of oligoclonal bands is the gold standard technique to provide evidence of intrathecal antibody synthesis (Plate 10.2). A raised IgG index may be informative but is not as sensitive or specific. About two-fifths of patients have a mildly raised CSF white cell count (5–50 mononuclear cells/mm^3) and protein.

Oligoclonal bands occur in other CNS inflammatory disorders including infections (e.g. neurosyphilis, subacute sclerosing panencephalitis [SSPE], neuroborreliosis, human T-lymphocyte virus type 1 [HTLV-1] associated myelopathy and CNS varicella zoster), vasculitis, collagen-vascular disorders and paraneoplastic disease but they are less common in neurosarcoidosis, Behçet's disease and NMO. Whereas in multiple sclerosis the antigenic specificity of the bands is largely unknown, in SSPE and varicella zoster they are largely directed against measles and herpes zoster antigens, respectively.

Laboratory procedures for optimal CSF examination in suspected multiple sclerosis have been defined recently by an expert international panel. Some new laboratory methods for detecting oligoclonal bands, including IgM bands, have been investigated and suggested as being more sensitive and specific in diagnosing and predicting the course of multiple sclerosis. More extensive studies are required to determine their clinical utility.

Evoked potentials

For 10–20 years prior to the widespread introduction of MRI, evoked potentials were important and frequently used diagnostic investigations. Their role was similar to MRI: detection of clinically silent CNS white matter lesions. Because they are less sensitive in this respect than MRI, they are not often requested as part of contemporary diagnostic work-up. The most useful of these investigations is the visual evoked potential; the demonstration of a markedly delayed P100 wave of normal amplitude provides strong evidence for optic nerve demyelination (Figure 10.7). It may still be useful in supporting the diagnosis, especially when the clinical syndrome is in the spinal cord or brainstem and MRI is normal or shows only minor non-specific abnormalities or is obtained in an older age group where the specificity of white matter abnormalities is less. Brainstem auditory evoked potentials and somato-sensory evoked potentials are generally less useful, although may sometimes have a role in establishing the nature of a lesion.

Autoantibodies

No autoantibody has been confirmed to be diagnostic for multiple sclerosis to date. A recent study of CIS patients – who also
