DEDICATED TO

My father, who dedicated his life to medicine and represents the so many who have provided opportunities and examples for each of us in our careers.

Thomas M. Habermann, MD

FOREWORD

Mayo Clinic Internal Medicine: Concise Textbook reflects the continued commitment by the faculty of the Department of Internal Medicine to its mission of scholarship. One of the key traditions in medicine is the passing of knowledge from physician to physician. In 1928, William J. Mayo, MD, wrote, "The glory of medicine is that it is constantly moving forward, that there is always more to learn. The ills of today do not cloud the horizon of tomorrow, but act as a spur to greater effort."* This book is a response to these themes. My hope is that it will aid in the care of patients.

Nicholas F. LaRusso, MD
Chair, Department of Internal Medicine
Mayo Clinic, Rochester, Minnesota

*Mayo WJ. The aims and ideals of the American Medical Association. Proceedings of the 66th Annual Meeting of the National Education Association of the United States, 1928. p. 158-63.

PREFACE

Scientific observations and clinical advances are moving at a remarkable pace. These changes require physicians to remain abreast of the latest developments not only in their areas of expertise but also in areas beyond their sphere of expertise. To assist physicians in this endeavor, the Department of Medicine at Mayo Clinic remains committed to providing information to physicians in a timely manner. *Mayo Clinic Internal Medicine: Concise Textbook* is designed to meet the needs of medical students, nurse practitioners, physician assistants, physicians-in-training, and practicing clinicians by updating their knowledge of internal medicine and providing a concise review of internal medicine.

The overall approach to learning medicine can be summed up in two questions: What is it? What do you do for it? The goal is to have a concise review that is readable and easy to follow with algorithms, diagrams, radiographs, and pathologic findings. This book is divided into subspecialty topics, each chapter written by an author(s) with clinical expertise in the designated topic. Images and tables are provided. Each chapter has bulleted items that highlight key points. These may be summary points from previous paragraphs or new points. Bulleted items also address typical clinical scenarios. These scenarios emphasize classic clinical presentations. Pharmacy tables are included with many of the chapters. The scenarios and pharmacy tables highlight two key points. First, general internists, subspecialists, nurse practitioners, physician assistants, and family physicians diagnose diseases in internal medicine. Second, the predominant type of patient management is pharmacologic. Knowledge of the indications, toxic effects, and drug interactions is of paramount importance.

We thank everyone who contributed to the development of this book. We are indebted to all authors for their contributions. We thank the staffs of the Section of Scientific Publications, Department of Medicine, and Division of Media Support Services at Mayo Clinic for their contributions to this book. The support and cooperation of the publisher, Informa Healthcare, are gratefully acknowledged.

We trust that this book will serve as an update and advance the reader's knowledge of internal medicine.

We hope that you enjoy this review as much as we have.

TABLE OF CONTENTS

1

Preparing for the U.S. Medical Licensing Examination Step 2

Amit K. Ghosh, MD
Christopher M. Wittich, PharmD, MD

The National Board of Medical Examiners (NBME) is responsible for administering the U.S. Medical Licensing Examination (USMLE). In its current form, the examination has four parts: step 1, step 2 CK (clinical knowledge), step 2 CS (clinical skills), and step 3. The step 1, step 2 CK, and step 3 examinations all include multiple-choice questions of different degrees of complexity.

The USMLE step 1 includes questions that measure the ability of candidates to apply basic science to clinical problems and is set at the level expected of a U.S. student finishing the second year of medical school. The USMLE step 2 CK focuses on principles of clinical science that are important for the student to apply while practicing medicine under supervision during postgraduate training. The USMLE step 2 CS is typically taken during the third or fourth year of medical school. Many students choose to take and pass the examination before applying for a residency position. A student or graduate of a school accredited by the Liaison Committee on Medical Education or the American Osteopathic Association can take the examinations in any order. Graduates of a foreign medical school can take the USMLE step 2 CK before step 1, although they have to pass the USMLE step 1 before registering for the USMLE step 2 CS. The USMLE step 3 assesses the ability of a physician to care for patients in an unsupervised setting and has a greater emphasis toward management of disorders. Candidates have to pass both steps 1 and 2 before registering for step 3. The step 3 examination is usually taken at the end of the first year of residency, although a few states do permit graduates to take this examination before joining a residency.

Part I of this chapter is aimed at candidates preparing for the USMLE step 2 CK. However, candidates preparing for any examinations that have multiple-choice questions also may benefit from the information, which covers various aspects of preparation for an examination, strategies to answer the questions effectively, and avoidance of pitfalls. Part II of this chapter is aimed at candidates preparing for the USMLE step 2 CS. However, candidates preparing for any examination dealing with standardized patients (such as Objective Structured Clinical Examinations, administered by many medical schools) also may benefit from the information.

Part I
Clinical Knowledge Examination

Amit K. Ghosh, MD

Aim of the USMLE Step 2 CK Examination

The NBME has stated that the USMLE step 2 CK tests the breadth and depth of a candidate's knowledge in clinical sciences to ensure that the candidate has attained the necessary proficiency required for the practice of medicine under supervision during postgraduate training.

Examination Format

Details regarding the examination, training requirements, eligibility requirements, application forms, and other related information can be obtained from the USMLE Web site: http://www.usmle.org. This site also includes information on test material and software tutorials. Candidates can save time on the day of the examination

by familiarizing themselves with the tutorial session well beforehand, and they can then use the 15 minutes assigned for this activity on examination day as additional break time.

The USMLE step 2 CK examination is a computerized examination of 9 hours in duration. It includes eight 60-minute examination blocks, an optional 15-minute tutorial session, and 45 minutes of self-scheduled free time. The average number of questions in each examination block varies from 46 to 50. Within the 60-minute examination blocks, candidates can review and change their responses (although this tendency needs to be kept to a minimum). After 60 minutes or if a candidate has declared that a block is finished, there is no returning to that portion of the examination. The candidate then decides whether to take a brief break or start working on the next 60-minute examination block.

Almost all of the questions are clinical and based on correct diagnosis and management. Because there is no penalty for guessing the answers, candidates should answer every question. Most questions are based on the presentations of patients. The ability to answer these questions requires integration of information provided from several sources (such as history, physical examination, laboratory test results, and consultations), prioritization of alternatives, or use of clinical judgment. The overall ability to manage a patient in a cost-effective, evidence-based approach is stressed. Questions that require simple recall of medical facts are usually kept to a minimum. The examination is reviewed by committee members from academic settings, community practices, and licensing communities across the United States and Canada to ensure the questions are relevant to a general practice.

- Candidates should answer every question; there is no penalty for guessing.
- Most questions are based on presentations of patients.
- Questions that require simple recall of medical facts are in the minority.

A list of normal laboratory values and illustrative materials (such as electrocardiograms, blood smears, Gram stains, urine sediments, chest radiographs, and photomicrographs) necessary to answer questions are provided. Candidates should interpret the abnormal values on the basis of the normal values provided and not on the basis of the normal values to which they are accustomed in their practice or training. Although much of the information contained in this chapter is obtained from the previous information booklets, candidates for USMLE step 2 CK examination should read the material from the USMLE Web site because the NBME may change various components of the format of the examination.

- A list of normal laboratory values and illustrative materials necessary to answer questions are provided.
- The materials in the USMLE Web site should be read by candidates.

Scoring

The final score is dependent on the total number of correct answers. There is no negative marking for incorrect answers; hence, candidates are advised to answer all questions.

Each candidate receives a 3-digit score that is calculated from a formula that includes the percentage score and percentile compared with those of other examinees. The minimum passing score is 182. This corresponds to answering 60% to 70% of the questions correctly.

The Examination Content

The content of USMLE step 2 CK examinations is developed from material along two dimensions (dimensions 1 and 2).

Dimension 1 includes topics on normal growth and development, basic concepts, and general principles. Questions address normal growth and development during infancy and childhood, adolescence and senescence, medical ethics, jurisprudence, applied biostatistics, and clinical epidemiology.

Dimension 2 includes questions on individual disorders, subdivided according to physician task. The first set of tasks addresses promoting preventive medicine and health maintenance and includes assessment of risk factors, understanding epidemiologic data, and application of primary and secondary preventive measures. The second set of tasks addresses understanding mechanisms of disease, including etiology, pathophysiology, and effects of treatments. The third set of tasks addresses establishing a diagnosis, determining the next best step from the history and results of physical examination, or interpreting laboratory and radiologic test results. The fourth set of tasks addresses applying principles of management, including questions on best-care practices for ambulatory and inpatient settings.

The full content of topics for both dimensions of the USMLE step 2 CK examination is available on the USMLE Web site (http://www.usmle.org), which all candidates should review critically and with which they should be completely familiar.

Question Format

Each examination block contains 46 to 50 questions, 75% to 80% of which are multiple-choice, single-best–answer questions. The question may include a case history, a brief statement, a radiograph, a graph, or a picture (such as a blood smear or Gram stain). Each question has five possible answers (lettered A to E), and the candidates should identify the single-best answer. More than one answer may seem to be correct or partially correct for a question. Also, the traditionally correct answer may not be listed as an option. In that situation, the one answer that is better than the others should be selected. If unsure of an answer, candidates should make a calculated guess. Remember, unanswered questions are counted as wrong answers.

The remaining questions are of the matching-set variety, and they are usually at the end of the examination. They are related to a common topic. There could be as many as 26 lettered options, followed by two or more relatively brief vignettes. Candidates are asked to choose the best single option that answers a question. One should start by reading and becoming familiar with the option list. The question should be read carefully. Within a set, a given option might be used once or more than once or never used. When faced with answering matching-set questions with several options, one should

try to answer the question *before* looking at the list of choices in the option list as a means of being efficient with time. As noted above, most questions are based on the presentations of patients. The examples in this chapter and the examples included in the USMLE step 2 CK information booklet (138 questions) should help candidates become familiar with the question format. Several books and computer programs are available that can be used to practice answering these types of questions.

- Questions are mostly of the single-best–answer type (75%), and the remaining are of the matching-set type (25%).
- Various study guides should be used to become familiar with the question format.

Examples of Questions

Single-Best Answer
Select the single best answer for each of the following questions.

1. A 56-year-old woman is referred to you for evaluation of dyspnea and chest pain of 6 weeks in duration. The chest pain is nonpleuritic, nonexertional, and located along the lower right lateral chest cage. She has no fever, cough, or chills. During the past few weeks, she has been experiencing constant low back pain. The patient underwent right mastectomy 4 years ago because of carcinoma of the breast with metastatic involvement of the right axillary lymph nodes. She received radiotherapy followed by chemotherapy for 24 months. Examination now shows diminished breath sounds in the right lower lung field. Results of the remainder of the examination are unremarkable. A chest radiograph suggests a moderate right pleural effusion. Which one of the following tests is most likely to be helpful in confirming the suspected diagnosis?

   A. Bone scanning with technetium Tc 99m diphosphonate
   B. Bone marrow aspirate and biopsy
   C. Scalene fat pad biopsy
   D. Thoracentesis
   E. Mammography

2. A 20-year-old male military recruit returns home from several weeks of summer training in boot camp. He appears in your office the following day with a 12-day history of fever (38°C), coryza, pharyngitis, and cough. Physical examination discloses a bullous lesion over the right tympanic membrane and scattered crackles in both lung fields. Blood cell count shows mild thrombocytopenia. A chest radiograph shows patchy alveolar-interstitial infiltrates in both lungs. Which one of the following is the best treatment for this patient?

   A. Erythromycin
   B. Penicillin
   C. Trimethoprim
   D. Clindamycin
   E. Ceftazidime

3. A 49-year-old male executive comes to your office with a 6-month history of cough, shortness of breath, and chest tightness soon after substantial exertion. He notices these symptoms soon after he finishes a game of racquetball. He is a nonsmoker and has no risk factors for coronary artery disease. Results of physical examination in your office are normal. His weight is normal for his height. The chest radiograph is normal. A treadmill test for ischemic heart disease is negative. Which one of the following diagnostic tests is indicated?

   A. CT of the chest
   B. Arterial blood gas studies at rest and after exercise
   C. Spirometry before and after exercise
   D. Ventilation-perfusion lung scanning
   E. Cardiopulmonary exercise testing

4. A 43-year-old asymptomatic man has chronic hepatitis C. Therapy for 12 months with a combination of interferon and ribavirin failed to clear the virus. Laboratory results are notable for an alanine aminotransferase value of 65 U/L and normal values for bilirubin, albumin, and prothrombin time. A liver biopsy shows a mild lymphocytic portal infiltrate but no fibrosis. Which one of the following statements about this patient is true?

   A. He should be given lamivudine.
   B. He should have screening for hepatocellular carcinoma and undergo ultrasonography and α-fetoprotein testing every 6 months.
   C. He should have endoscopy to look for esophageal varices.
   D. He should be referred for liver transplantation.
   E. He should receive the hepatitis A and B vaccines if he is not already immune.

5. A patient who is positive for human immunodeficiency virus (HIV) and has low CD4 counts is receiving multidrug treatment. He complains of colicky flank pain, and many crystals are subsequently noted on urinalysis. Which one of the following drugs is most likely causative?

   A. Ribavirin
   B. Trimethoprim-sulfamethoxazole
   C. Indinavir
   D. Acyclovir
   E. Ganciclovir

6. A 34-year-old woman comes to your office with a 4-week history of hemoptysis, intermittent wheeze, and generalized weakness. On examination her blood pressure is 186/112 mm Hg. She appears cushingoid and has noted these changes taking place during the past 12 weeks. Auscultation discloses localized wheezing in the left mid-lung area. The chest radiograph indicates partial atelectasis of the left upper lobe. She is referred to you for further evaluations. Which one of the following is least likely to provide useful information for diagnosis and treatment?

A. Serum adrenocorticotropic hormone level
B. 24-Hour urine test for 5-hydroxyindoleacetic acid level
C. Bronchoscopy
D. CT of the chest
E. Serum potassium level

7. A 62-year-old woman presents with the onset of eye discomfort and diplopia. She has not noted any other new neurologic symptoms. Neurologic examination shows a normal mental status and neurovascular findings. Reflexes are slightly decreased in the lower extremities. Gait and coordination are normal. Cranial nerves show an inability to adduct, elevate, and depress the eye. Pupillary reaction is normal. Motor strength testing is negative. Sensation is normal, except there is decreased vibratory and joint position sensation in the feet. What abnormality would be expected?

A. Saccular aneurysm of the cavernous sinus on CT
B. Brain stem neoplasm on MRI
C. Left temporal sharp waves on electroencephalography
D. Increased fasting blood sugar
E. Increased erythrocyte sedimentation rate

8. A 42-year-old man who is an office worker presents to the emergency department with acute dyspnea. He has smoked 1 1/2 packs per day for 25 years and had been relatively asymptomatic except for a smoker's cough and mild dyspnea on exertion. Physical examination findings are not remarkable except for slightly diminished intensity of breath sounds over the right lung and some prolonged expiratory slowing, consistent with obstructive lung disease. The chest radiograph shows extensive infiltrates in the upper two-thirds of the lung fields. Which one of the following conditions is most likely responsible for this patient's symptoms?

A. Pulmonary alveolar proteinosis
B. Silicosis
C. Pulmonary eosinophilic granuloma (histiocytosis X)
D. Idiopathic pulmonary fibrosis
E. Sarcoidosis

9. In a 34-year-old man with acute myelomonocytic leukemia, fever and progressive respiratory distress develop, and the chest radiograph shows diffuse alveolar infiltrates. The patient completed intensive chemotherapy 6 weeks earlier. The total leukocyte count has remained less than 0.5×10^9/L for more than 3 weeks. He is currently (for at least 10 days) receiving a cephalosporin (ceftazidime). Which one of the following is the most appropriate therapy for this patient?

A. Clindamycin
B. Blood transfusion to increase the number of circulating leukocytes
C. Antituberculous (triple-drug) therapy
D. Amphotericin intravenously
E. Pentamidine aerosol

The answers to the questions are as follows: 1, D (metastatic pleural effusion); 2, A (*Mycoplasma* infection); 3, C (exercise-induced asthma); 4, E; 5, C (side effect of HIV medications); 6, B (bronchial carcinoid); 7, D (complications of diabetes mellitus, paralysis of cranial nerve III); 8, C (histiocytosis X, or pulmonary eosinophilic granuloma, with spontaneous pneumothorax); 9, D (disseminated aspergillosis in a leukopenic patient).

Questions 1 through 3 are examples of questions that are aimed at evaluating knowledge and judgment about problems that are encountered frequently in practice and for which physician intervention makes a considerable difference. These questions judge the candidate's minimal level of clinical competence. These questions include descriptions of typical clinical features of metastatic breast carcinoma, *Mycoplasma* pneumonia, and exercise-induced asthma, respectively. Therefore, the decision making is relatively easy and straightforward. Questions 4 through 9 are more difficult to answer because they are structured to reflect excellence in clinical competence rather than just minimal competence. In other words, they require more extensive knowledge (i.e., knowledge beyond that required for minimal competence) in internal medicine and its subspecialties. Although most of the questions on the examination are based on the presentations of patients, some require recall of well-known medical facts.

Matching-Set Questions

Questions 10-14

Match the characteristics of each of the genitourinary disorders described below with its associated organism.

A. *Trichomonas vaginalis*
B. *Gardnerella vaginalis*
C. Human papillomavirus
D. *Candida albicans*
E. *Neisseria gonorrhoeae*

10. Greenish, frothy, vaginal discharge, motile flagellate seen microscopically on wet mount preparation

11. Cheesy-white vaginal discharge

12. Associated with carcinoma of the cervix

13. Right iliac fossa pain, Gram stain of cervical smear might show gram-negative diplococci

14. Vaginal discharge with fishy odor, "clue" cells on microscopy

The answers to the questions are as follows: 10, A; 11, D; 12, C; 13, E; 14, D.

Preparation for the Test

Training during medical school forms the foundation on which advanced clinical knowledge is accumulated. Most candidates will require a minimum of 6 to 8 months of intense preparation for the examination. Cramming just before the examination is counter-

productive and is unlikely to be successful. It must be remembered that this is a 9-hour grueling computerized examination for which adequate preparation is mandatory. Candidates should start by becoming familiar with the scope of and kinds of questions in the examination. All orientation materials are available on a CD or by download from the Web site. The tutorial on how to take the test should be reviewed several times in order to become completely familiar with the steps required to move from screen to screen, mark questions for later review, look up the table of normal laboratory values, and open figures in the questions. One should get into the habit of spending around 60 seconds with each question.

Preparation for the USMLE Step 2 CK examination should start at the beginning of the third year of medical school. Some of the methods of preparation for the USMLE examination are described below. Additionally, each candidate may develop her or his own system.

Each candidate should study a standard textbook of internal medicine to obtain a thorough knowledge base in all areas of internal medicine. Ideally, the candidate should use one textbook and not jump from one to another, except for reading certain chapters that are outstanding in a particular textbook. The most effective way to use the textbook is with patient-centered reading; this should occur throughout medical school and the residency program. This book and similar board review syllabi are excellent tools for brushing up on important board-relevant information several weeks to months before the examination. This book is designed as a study guide rather than a comprehensive textbook of medicine. Therefore, it should not be used as the sole source of medical information for the examination.

- Candidates should thoroughly study a standard textbook of internal medicine.
- This book is designed as a study guide and should not be used as the sole source of information for preparation for the examination.

The *Review for USMLE Step 2 CK*, part of the National Medical Series for Independent Study, is extremely valuable for obtaining practice in answering multiple-choice questions. The questions and answers are useful for learning the type of questions asked and the depth of knowledge expected for various subjects.

Some candidates find it helpful to prepare for the examination in study groups. Formation of two to five candidates per group permits study of different textbooks and review articles in journals. The group should meet regularly as each candidate is assigned reading materials. Selected review articles on common and important topics in internal medicine should be included in the study materials. Indiscriminate reading of articles from many journals should be avoided. In any case, most candidates who begin preparation 6 to 8 months before the examination will not find time for extensive study of journal materials. Information in recent (within 6-9 months of the examination) medical journals is unlikely to be included in the examination. Notes and other materials the candidates have gathered during medical school are also good sources of information. These clinical "pearls" gathered from mentors will be of help in remembering certain important points.

- Study groups may help cover large amounts of information.
- Indiscriminate reading of articles from many journals should be avoided.
- Information in recent (within 6-9 months of the examination) medical journals is unlikely to be included in the examination.

Candidates should try to remember some of the uncommon manifestations of the most common diseases (such as polycythemia in common obstructive pulmonary disease) and common manifestations of uncommon diseases (such as pneumothorax in eosinophilic granuloma). The majority of the questions on the examination involve conditions most commonly encountered in clinical practice. Several formulas and points should be memorized (such as the anion gap, calculated serum osmolality, and osmolar gap equations). The clinical training obtained and the regular study habits formed during medical school are the most important aspects of preparation for the examination.

In general, the examination rarely has questions about specific drug dosages or specific chemotherapy regimens used in oncology. Rather, questions are geared toward concepts regarding the treatment of patients. Questions regarding adverse effects of medications are common on the examination, especially when the adverse effect occurs frequently or is potentially serious. The candidate is also expected to recognize when a clinical condition is a drug-related event.

- Study as much as possible about board-eligible topics.
- Learn about the uncommon manifestations of common diseases and the common manifestations of uncommon diseases.

Day of the Examination

Adequate time is allowed to read and answer all the questions; therefore, there is no need to rush or become anxious. The time is given in the right lower corner of the computer screen, and this should be checked to ensure that you are at least halfway through the examination when half the time has elapsed. Start by answering the first question and continue sequentially. Almost all of the questions follow a case presentation format. Do not be alarmed by lengthy questions; look for the question's salient points. When faced with a confusing question, do not become distracted by that question. Mark it so you can find it later, then go to the next question and come back to the unanswered ones at the end. However, as mentioned before, this tendency to leave questions unanswered should be limited because experience has shown that the initial intuitive response to questions is often accurate and efforts to change the answer at a later time could prove counterproductive. Extremely lengthy stem statements or case presentations are apparently intended to test the candidate's ability to separate the essential from the unnecessary or unimportant information. You may want to highlight important information presented in the question in order to review this information after reading the entire question and the answer options. This habit, too, should be kept to a minimum. Remember that each additional activity that you do (e.g., highlight sections of the question and hesitation) uses precious time.

- Look for the salient points in each question.
- If a question is confusing, mark it to find it later and come back to the unanswered questions at the end.

Some candidates may fail the examination despite the possession of an immense amount of knowledge and the clinical competence necessary to pass the examination. Their failure to pass the examination may be caused by the lack of ability to understand or interpret the questions properly. The ability to understand the nuances of the question format is sometimes referred to as "boardsmanship." Intelligent interpretation of the questions is very important for candidates who are not well versed in the format of multiple-choice questions. Tips on "boardsmanship" include the following:

- All questions whose answers are known should be answered first.
- Spend adequate time on questions for which you are certain of the answers to ensure that they are answered correctly. It is easy to become overconfident with such questions, and thus you may fail to read the questions or the answer options carefully. Make sure you never make mistakes on easy questions.
- Read the final sentence (that appears just before the multiple answers) several times to understand how an answer should be selected. Recheck the question format before selecting the correct answer. Read each answer option thoroughly through to the end. Occasionally a response may be only partially correct. At times, the traditionally correct answer is not listed. In these situations, select the best alternative listed. Watch for qualifiers such as "next," "immediately," or "initially."
- Avoid answers that contain absolute or very restrictive words such as "always," "never," or "must." Answer options that contain absolutes are likely incorrect.
- Try to think of the correct answer to the question before looking at the list of potential answers. Assume you have been given all the necessary information to answer the question. If the answer you had formulated is not among the list of answers provided, you may have interpreted the question incorrectly. When a patient's case is presented, think of the diagnosis before looking at the list of answers. It will be reassuring to realize (particularly if your diagnosis is supported by the answers) that you are on the "right track."
- Abnormalities on, for example, the photographs, radiographs, and electrocardiograms will be obvious. Remember that pictures and figures are expensive. Hence, truly normal figures, radiographs, and electrocardiograms are not used on the examination.
- If you do not know the answer to a question, very often you are able to rule out one or several answer options and improve your odds at guessing.
- Occasionally, you can use information presented in one question to help you answer other difficult questions.

Candidates are well advised to use the basic fund of knowledge accumulated from clinical experience and reading to solve the questions. Approaching the questions as "real-life" encounters with patients is far better than trying to second-guess the examiners or trying to analyze whether the question is "tricky." As indicated above, the questions are never "tricky," and there is no reason for the NBME to trick the candidates into choosing wrong answers.

It is better not to discuss the questions or answers (after the examination) with other candidates. Such discussions usually cause more consternation, although some candidates may derive a false sense of having performed well on the examination. In any case, the candidates are bound by their oath to the NBME not to discuss or disseminate the questions. Do not study between examination sessions; also, cramming the night before the examination might produce anxiety or fatigue and might be counterproductive.

- Approach questions as "real-life" encounters with a patient.
- There are no "trick" questions.

Connections

Associations, causes, complications, and other relationships between a phenomenon or disease and clinical features are important to remember and recognize. For example, Table 1-1 lists some of the "connections" between infectious and occupational factors and pulmonary diseases. Each subspecialty has many similar connections, and candidates for the USMLE and other examinations may want to prepare lists like this for different areas.

Computer-Based Testing

Candidates can take the computer-based test for the certification test examination. Computer-based testing provides a more flexible, quieter, and professional environment for examination.

Candidates are encouraged to access the online tutorial at http://www.usmle.org. This tutorial allows the candidate to become familiar with answering questions, changing answers, making notes electronically, accessing the table of normal laboratory values, and marking questions for review.

Table 1-1 Examples of Connections Between Etiologic Factors and Diseases

Etiologic factor	Agent, disease
Cattle, swine, horses, wool, hide	Anthrax
Abattoir worker, veterinarian	Crucellosis
Travel to Southeast Asia, South America	Melioidosis
Squirrels, chipmunks, rabbits, rats	Plague
Rabbits, squirrels, infected flies, or ticks	Tularemia
Birds	Psittacosis, histoplasmosis
Rats, dogs, cats, cattle, swine	Leptospirosis
Goats, cattle, swine	Q fever
Soil, water-cooling tower	Legionellosis
Military camps	Mycoplasmosis
Chicken coops, starling roosts, caves	Histoplasmosis
Soil	Blastomycosis
Travel in southwestern United States	Coccidioidomycosis
Ohio and Mississippi river valleys	Histoplasmosis
Decaying wood	Histoplasmosis
Gardeners, florists, straw, plants	Sporotrichosis
Progressive, massive fibrosis	Silicosis, coal, hematite, kaolin, graphite, asbestosis
Autoimmune mechanism	Silicosis, asbestosis, berylliosis
Monday morning sickess	Byssinosis, bagassosis, metal fume fever
Metals and fumes producing asthma	Baker's asthma, meat wrapper's asthma, printer's asthma, nickel, platinum, toluene diisocyanate (TDI), cigarette cutter's asthma
Increased incidence of tyberculosis	Silicosis, hematite lung
Increased incidence of carcinoma	Asbestos, hematite, arsenic, nickel, uranium, chromate
Welding	Siderosis, pulmonary edema, bronchitis, emphysema
Centrilobar emphysema	Coal, hematite
Generalized emphysema	Cadmium, bauxite
Silo filler's lung	Nitrogen dioxide
Farmer's lung	*Thermoactinomyces*, *Micopolyspora*
Asbestos exposure	Mesothelioma, bronchogenic carcinoma, gastrointestinal cancer
Eggshell calcification	Silicosis, sarcoid
Sarcoid-like disease	Berylliosis
Diaphragmatic calcification	Asbestosis (also ankylosing spondylitis)
Nonfibrogenic neumoconioses	Tin, emery, antimony, titanium, barium
Minimal pathology in lungs	Siderosis, baritosis, stannosis
Bullous emphysema	Bauxite lung

Part II
Clinical Skills Examination

Christopher M. Wittich, PharmD, MD

The USMLE step 2 CS examination is unique because, instead of the ubiquitous multiple-choice format, it uses standardized patients to test the examinee. Unlike the other steps of the USMLE, which are computer-based and offered at many testing locations around the United States, it is offered only in Atlanta, Chicago, Houston, Los Angeles, and Philadelphia.

Aim of the USMLE Step 2 CS Examination

The NBME has stated that the USMLE step 2 CS assesses the breadth and depth of a candidate's knowledge in clinical science to ensure that the candidate has attained the necessary proficiency required for the practice of medicine under supervision during postgraduate training. There is special focus on determining whether the candidate has the foundation for the safe and effective practice of medicine. According to the NMBE, the USMLE step 2 CS tests the ability to gather information from patients, perform a physical examination, and communicate the results verbally and in a written format.

The patient encounters are designed to test the applicant's ability to practice medicine in a safe manner while under supervision. The cases included are aimed to include diseases commonly seen in practice in the United States.

Examination Format

The USMLE step 2 CS examination is 8 hours in duration. During this time, 12 patient encounters occur. There are two breaks during the examination; the first is 30 minutes long, and the second is 15 minutes long. Candidates are given 15 minutes for each patient encounter and then 10 minutes to write the note. The proctors notify you when 5 minutes remain and when time is up. Do not write or continue to work after time has been called. If you finish the patient encounter in less than 15 minutes, you may leave the examination room and begin writing your note. However, you will not be allowed to reenter the examination room.

A stethoscope and white laboratory coat should be taken to the examination. If you forget to bring these items, they will be supplied by the testing center. However, you could benefit from using your own stethoscope because it would allow you to become familiar with its use before the examination. Professional but comfortable attire should be worn on the test day. No other equipment, including telephones, digital watches, or personal digital assistants, should be taken to the examination. The examination rooms are equipped with the tools needed for the physical examination: an examination table, sink with paper towels, examination gloves, blood pressure cuffs, otoscopes, and ophthalmoscopes. A clipboard, paper, and a pen also are provided.

The testing center is a series of examination rooms. Testing coordinators direct the candidates through the test. You will be directed to a patient room. At the door will be an instruction sheet. It is vital to read this sheet at the start of the patient encounter. The instruction sheet contains pertinent information needed for the patient encounter, including the patient's name, age, reason for the visit, and vital signs.

After reading the instruction sheet, you will be told to enter the examination room. Typically, you will encounter a standardized patient. Treat this person as you would any patient you would see as a medical student. It is important to be polite, empathetic, and professional. Greet the patient, and then proceed with the patient encounter. The goal of the patient encounter is to obtain a focused history and examination, based on the information given on the instruction sheet, that are sufficient to develop an initial differential diagnosis and plan. If the patient asks a question, it should be answered to the best of your ability. Patients can have either acute or chronic problems. Your patient encounter should focus only on the reason the patient is visiting the physician. You should not do a complete physical examination. The USMLE does not allow rectal, pelvic, genitourinary, female breast, or corneal reflex examinations to be performed. If you believe that these would provide useful information, they can be included in the diagnostic plan. It is important to remember that the patients are trained to simulate physical findings. If you encounter a positive physical finding, assume it really is positive and document it in the patient note. You also will be evaluated on hygiene (washing your hands before and after the physical examination) and patient modesty (proper draping of the patient during the physical examination).

- Before entering the examination room, read the instruction sheet to obtain vital information about the patient and the setting.
- On the basis of the instruction sheet, complete a focused history and physical on the standardized patient.

After the patient encounter is finished, you will be required to document the findings in a patient note. You could be expected to either handwrite your note or type it on a computer. If you are asked to handwrite your note, it is imperative that your handwriting be legible. A standard form will be supplied on which to write the note. The sections of the note include History, Physical Examination, Differential Diagnosis (possibilities listed as #1 to #5), and Diagnostic Work-up (possibilities listed as #1 to #5).

The NBME allows two styles of notes to be submitted for scoring. The first style is a narrative note. In this type of note, complete or nearly complete sentences are used to relay the details of the pertinent positive and negative findings from the history or present illness, past medical history, review of systems, social history, and family

history. The second style is a bulleted note. In this type of note, short statements using key words and phrases are listed with bullets or dashes. In both types of notes, common medical abbreviations are allowed. The USMLE gives a list of common and allowed abbreviations on its Web site (http://www.usmle.org).

- After the patient encounter, you will be required to document the history, physical, differential diagnosis, and diagnostic work-up.

In the differential diagnosis section of the note, five possibilities can be listed. List them in descending order of likelihood (the most likely diagnosis as #1 and the least likely as #5). In the work-up section of the note, five possible evaluations can be listed. Remember that if a prohibited physical examination finding would be useful, list it in the work-up section. In both the differential diagnosis and work-up sections of the patient note, although five possibilities can be listed, a fewer number might be correcct. List only those that are most appropriate. Do not list consultations or treatment plans in the work-up section. This section should only include evaluations that would aid in diagnosis. If no diagnostic studies are warranted, do not leave the section blank. Instead, write "No studies warranted."

In addition to a simulated patient encounter, other types of encounters are possible. Instead of a chief complaint, laboratory values could be supplied. If this is the case, the focus should be on counseling and educating the patient. If no physical examination is warranted, write "no examination warranted" in the physical examination section of the patient note. Also, in certain cases, mannequins or simulators could be used for the physical examination (these will be for genital or rectal examinations).

Another case format is a telephone call. In this type of case, the patient information sheet will tell you specific information about the patient. After entering the room, you will speak by telephone with the simulated patient. Once the telephone is hung up, you are not allowed to make a second call to the simulated patient.

Further details regarding the examination, training requirements, eligibility requirements, application forms, and other pertinent information can be obtained from the USMLE Web site (http://www.usmle.org). This site also includes copies of the patient note template, examples of patient notes, and software to practice typing the note. It is recommended that these materials be reviewed before the examination to become familiar with their use.

Scoring

The USMLE step 2 CS is a pass or fail examination. There are three domains that all must be passed on a single test administration for a passing score to be awarded for the entire test: Integrated Clinical Encounter, Communication and Interpersonal Skills, and Spoken English Proficiency. Communication, interpersonal skills, and spoken English proficiency are evaluated by the trained standardized patients using rating scales. The ability to document the findings from the patient encounter, the differential diagnosis, and the diagnostic assessment plan are scored by physician raters. According to the NBME, these ratings are monitored to ensure consistency and fairness in rating.

The Integrated Clinical Encounter domain assesses data gathering and documentation. Data gathering is assessed from checklists of history and physical examination findings pertinent to the case. Documentation is assessed from the patient note generated by the candidate; physician raters score these notes.

The Communication and Interpersonal Skills domain assesses questioning skills, information-sharing skills, and professional manner and rapport. These are scored by the trained standardized patients using rating scales.

Spoken English Proficiency is assessed by the trained standardized patient using rating scales. This section is designed to test the clarity of spoken English during the patient encounter. Word pronunciation, word choice, and the effort required to understand the candidate are rated.

Preparation for the Test

Training during medical school forms the foundation on which advanced clinical knowledge is accumulated. Preparation for the USMLE step 2 CS examination should start at the beginning of the third year of medical school. Most candidates require 6 to 8 months of preparation for the examination. Cramming just prior to the examination is unlikely to be successful. Remember that the test is 8 hours of patient interaction and documentation of the findings. One should start by becoming familiar with the scope of the test and the patient simulation format before the testing day. The candidate should review the note template, acceptable abbreviations, and the styles of acceptable notes on the USMLE Web site (http://www.usmle.org). It is also important to review the time allotted for the patient interaction and for documentation of the findings.

Some methods of preparation for the USMLE step 2 CS examination are described below. Additionally, each candidate can develop his or her own system.

- Preparation for the USMLE step 2 CS examination should start at the beginning of the third year of medical school.

Each candidate should use a standard textbook of physical diagnosis. The elements of a history and physical examination should become second nature to the candidate. The most effective use of the textbook is patient-centered reading. As the candidate encounters patients during the third year of medical school, the salient features of disease presentation and physical findings should be explored.

An important step in preparation for the USMLE step 2 CS is demonstrating your physical diagnosis abilities to an expert and requesting feedback to improve. While on rotations during the third year of medical school, ask attending physicians or senior residents to watch you do a physical examination and give you suggestions on how to improve. Develop a system when doing a physical examination. Know the important components of the examination of all the organ systems. Become systematic, on the basis of recommendations of physical diagnosis textbooks, when approaching each organ system. Additionally, the more physical findings you determine, the more likely you are to recognize an abnormality when you

come across it again in the future. One technique to obtain increased exposure to auscultatory findings is to review tapes of, for example, heart sounds and lung sounds (available in most medical school libraries).

To prepare for the differential diagnosis section of the examination, it is helpful to review handbooks for symptom-driven differential diagnosis. These handbooks provide common differential diagnoses based on symptoms in the patient history. For example, the differential diagnosis of leg edema could include cellulitis, edema, venous thrombosis, or lymphedema.

Candidates for whom English is a second language should be sure that their spoken English is easily understood by a patient. Practice avoiding medical jargon. Practice correct pronunciation of medical terms. Ask attending physicians or classmates to give you feedback as to whether your spoken English is easy to understand. If it is not, extra time should be devoted to improvement.

Writing a succinct note after a patient encounter is a skill that takes refinement. Practice writing patient notes after every patient encounter during the third year of medical school. Ask your attending physicians to give you feedback about the content and style of your notes. When writing notes, practice getting to the point without leaving out important details. Develop a system to document physical examination findings in a logical order and use the system for every patient encounter.

- Candidates should thoroughly study a standard textbook of physical diagnosis.
- Handbooks on symptom-specific differential diagnosis are helpful to review.
- Practice written documentation of patient encounters.
- Ask for feedback from attending physicians on whether your spoken English is easily understood.

Day of the Examination

Confirm the date and directions to the testing center before your examination day, and arrive at the testing center early. It is imperative to bring a government-issued identification that includes a picture of yourself, the scheduling permit supplied by USMLE, and your stethoscope and white laboratory coat. Follow the directions of testing officials as you move from one patient encounter to the next. Once time is called, stop working immediately. Remember to relax and treat the standardized patient as you would any patient you would see as a medical student.

2

Allergy

Gerald W. Volcheck, MD

Allergy Testing

Standard allergy testing relies on identifying the IgE antibody specific for the allergen in question. Two classic methods of doing this are the immediate wheal-and-flare skin test (a small amount of antigen is introduced into the skin and evaluated at 15 minutes for the presence of an immediate wheal-and-flare reaction) and in vitro testing.

Allergy testing that does not have a clear scientific basis includes cytotoxic testing, provocation-neutralization testing or treatment, and "yeast allergy" testing.

Patch Tests and Prick (Cutaneous) Tests

Many seem confused about the concept of patch testing of skin as opposed to immediate wheal-and-flare skin testing. Patch testing is used only to investigate contact dermatitis, a type IV hypersensitivity reaction. Patch tests require about 96 hours for complete evaluation (similar to tuberculin skin reactivity that requires 72 hours). Most substances that cause contact dermatitis are small organic molecules that can penetrate various barriers inherent in the skin surface. The mechanisms of hypersensitivity postulated to explain these reactions usually involve the formation of haptens of endogenous dermal proteins.

Inhalant allergens, in comparison, generally are sizable intact proteins in which each molecule can be multivalent with respect to IgE binding. These molecules penetrate the skin poorly and are seldom involved in cutaneous type IV hypersensitivity reactions. They cause respiratory symptoms and are identified by prick skin testing.

- Patch testing is used to investigate contact dermatitis.
- Prick (immediate) skin testing is used to investigate respiratory allergy to pollens and molds.

Prick, scratch, and intradermal testing involve introducing allergen to the skin layers below the external keratin layer. Each of these techniques becomes increasingly sensitive (but less specific) because with the deeper, intradermal tests, allergen is introduced more closely to responding cells and at higher doses. Allergen skin tests performed by the prick technique adequately identify patients who have important clinical sensitivities without identifying a large number of those who have minimal levels of IgE antibody and no clinical sensitivity. Intradermal testing is used in selected cases, including evaluating allergy to stinging insect venoms and to penicillin. Drugs with antihistamine properties, such as H_1 receptor antagonists, and many anticholinergic and tricyclic antidepressant drugs can suppress immediate allergy skin test responses. The H_2 receptor antagonists have a small suppressive effect. Corticosteroids can suppress the delayed-type hypersensitivity response but not the immediate response.

- Intradermal skin tests are more sensitive but less specific than prick skin tests.
- Intradermal skin testing is used to investigate allergy to insect venoms and penicillin.

In Vitro Allergy Testing

In vitro allergy testing initially involves chemically coupling allergen protein molecules to a solid-phase substance. The test is then conducted by incubating serum (from the patient) that may contain IgE antibody specific for the allergen that has been immobilized to the membrane for a standard time. The solid phase is then washed free of nonbinding materials from the serum and incubated in a second solution containing a reagent (e.g., radiolabeled anti-IgE antibody). The various wells are counted, and the radioactivity is correlated directly with the preparation of a standard curve in which known amounts of allergen-specific IgE antibody were incubated with a set of standard preparations of a solid phase. In vitro allergy testing uses the principles of radioimmunoassay or chromogen activation.

It is important to understand that this test only identifies the presence of allergen-specific IgE antibody in the same way that the allergen skin test does. Generally, in vitro allergy testing is not as sensitive as any form of skin testing and has some limitations because of the potential for chemical modification of the allergen protein while it is being coupled to the solid phase by means of covalent reaction. Generally, it is more expensive than allergen skin tests and has no advantage in routine clinical work. In vitro allergy testing may be useful clinically for patients who have been taking antihistamines

and in whom no positive histamine responsiveness can be induced in the skin or for patients who have primary cutaneous diseases that make allergen skin testing impractical or inaccurate (e.g., severe atopic eczema with most of the skin involved in a flare).

- Skin testing is more sensitive and less expensive than in vitro allergy testing.

Asthma

Pathology

The pathologic features of asthma have been studied chiefly in fatal cases; some bronchoscopic data are available about mild and moderate asthma. The histologic hallmarks of asthma are listed in Table 2-1.

- The histologic hallmarks of asthma include mucous gland hypertrophy, mucus hypersecretion, epithelial desquamation, widening of the basement membrane, and infiltration by eosinophils.

Pathophysiology

Bronchial hyperresponsiveness is common to all forms of asthma. It is measured by assessing pulmonary function before and after exposure to methacholine, histamine, cold air, or exercise. Prolonged aerosol corticosteroid therapy reduces bronchial hyperresponsiveness. Prolonged therapy with certain other anti-inflammatory drugs, for example, cromolyn sodium or nedocromil, also reduces bronchial hyperresponsiveness. Note that although both cromolyn and nedocromil were originally touted as "antiallergic" (they inhibit mast cell activation), they affect most cells involved in inflammation; also, the effects on these cells occur at lower doses than those that inhibit mast cell activation.

- Bronchial hyperresponsiveness generally is present in all forms of asthma.
- Prolonged aerosol corticosteroid therapy reduces bronchial hyperresponsiveness.

Table 2-1 **Histologic Hallmarks of Asthma**

Mucous gland hypertrophy
Mucus hypersecretion
Alteration of tinctorial and viscoelastic properties of mucus
Widening of basement membrane zone of bronchial epithelial membrane
Increased number of intraepithelial leukocytes and mast cells
Round cell infiltration of bronchial submucosa
Intense eosinophilic infiltration of submucosa
Widespread damage to bronchial epithelium
Large areas of complete desquamation of epithelium into airway lumen
Mucous plugs filled with eosinophils and their products

Persons who have allergic asthma generate mast cell and basophil mediators that have important roles in the development of endobronchial inflammation and smooth muscle changes that occur after acute exposure to allergen. Mast cells and basophils are prominent during the immediate-phase reaction.

- In the immediate-phase reaction, mast cells and basophils are important.

In the so-called late-phase reaction to allergen exposure, the bronchi display histologic features of chronic inflammation and eosinophils become prominent in the reaction.

- In the late-phase reaction, eosinophils become prominent.

Patients who have chronic asthma and negative results on allergy skin tests seem to have an inflammatory infiltrate in the bronchi and histologic findings dominated by eosinophils when asthma is active. Patients with sudden asphyxic asthma may have a neutrophilic rather than an eosinophilic infiltration of the airway.

Various hypotheses explain the development of nonallergic asthma. One proposal is that the initial inflammation represents an autoimmune reaction arising from a viral or other microbial infection in the lung and, for reasons unknown, inflammation becomes chronic and characterized by a lymphocyte cytokine profile in which interleukin (IL)-5 is prominent. The intense eosinophilic inflammation is thought to come from the IL-5 influence of T cells in the chronic inflammatory infiltrate. Airway macrophages and platelets have low-affinity IgE receptors on their membranes and are activated by cross-linking of these receptors by allergen, suggesting that some phases of lung inflammation in allergy may involve the macrophage as a primary responder cell.

- IL-5 stimulates eosinophils.
- Airway macrophages and platelets have low-affinity IgE receptors.

The two types of helper T cells are TH1 and TH2. In general, TH1 cells produce interferon-γ and IL-2, and TH2 cells produce IL-4 and IL-5. IL-4 stimulates IgE synthesis. Hence, many clinical scientists believe that atopic asthma is caused by a preferential activation of TH2 lymphocytes.

- IL-4 stimulates IgE synthesis.
- TH2 lymphocytes produce IL-4 and IL-5.

Important characteristics of cytokines are summarized in Table 2-2.

Genetics of Asthma

The genetics of asthma is complex and confounded by environmental factors. No "asthma gene" has been discovered.

The gene encoding the beta subunit of the high-affinity IgE receptor is located on chromosome 11q13 and is linked to total IgE, atopy, and bronchial hyperreactivity. Polymorphic variants of the β_2-adrenergic receptor are linked to bronchial hyperreactivity. The gene for IL-4 is located on chromosome 5q31 and is linked to total IgE.

Table 2-2 Characteristics of Cytokines

Cytokine	Major actions	Primary sources
IL-1	Lymphocyte activation Fibroblast activation Fever	Macrophages Endothelial cells Lymphocytes
IL-2	T- and B-cell activation	T cells (TH1)
IL-3	Mast cell proliferation Neutrophil, macrophage maturation	T cells Mast cells
IL-4	IgE synthesis	T cells (TH2)
IL-5	Eosinophil proliferation and differentiation	T cells (TH2)
IL-6	IgG synthesis Lymphocyte activation	Fibroblasts T cells
IL-8	Neutrophil chemotaxis	Fibroblasts Endothelial cells Monocytes
IL-10	Inhibits IFN-γ, IL-1 production	T cells Macrophages
IL-13	Promotes IgE synthesis	T cells
IFN-α	Antiviral activity	Leukocytes
IFN-γ	Activates macrophages Stimulates MHC expression Inhibits TH2 activity	T cells (TH1)
TNF-γ	Antitumor cell activity	Lymphocytes Macrophages
TNF-β	Antitumor cell activity	T cells
GM-CSF	Stimulates mast cells, granulocytes, macrophages	Lymphocytes Mast cells Macrophages

GM-CSF, granulocyte-macrophage colony-stimulating factor; IFN, interferon; IL, interleukin; MHC, major histocompatibility complex; TH, helper T cell; TNF, tumor necrosis factor.

Occupational Asthma

Every patient interviewed about a history of allergy or asthma must be asked to provide a detailed occupational history. A large fraction of occupational asthma escapes diagnosis because physicians obtain an inadequate occupational history. An enormous range of possible industrial circumstances may lead to exposure and resultant disease. The most widely recognized types of occupational asthma are listed in Table 2-3.

- Inquiry into a possible occupational cause of asthma is important for all patients with asthma.

As new industrial processes and products evolve, occupational asthma may become more common. An example of this is latex-induced asthma among medical workers, associated with the widespread use of latex gloves. The incidence of occupational asthma is estimated to be 6% to 15% of all cases of adult-onset asthma.

- Allergy to latex is an important cause of occupational asthma.

Gastroesophageal Reflux and Asthma

The role of gastroesophageal reflux in asthma is not known. Two mechanistic hypotheses are 1) reflex bronchospasm from acid in the distal esophagus and 2) recurrent aspiration of gastric contents. Although a well-documented reflex in dogs links acid in the distal esophagus to vagally mediated bronchospasm, this reflex has not been demonstrated consistently in humans. The other hypothesis is that gastric contents reach the tracheobronchial tree by ascending to the hypopharynx.

Asthma-Provoking Drugs

It is important to recognize the potentially severe adverse response that patients with asthma may show to β-blocking drugs, β_1 and β_2 blockers, including β_1 selective β-blocking agents. Patients with asthma who have glaucoma treated with ophthalmic preparations of timolol and betaxolol (betaxolol is less likely to cause problems) may experience bronchospasm.

- β-Blocking drugs, including eyedrops, can cause severe adverse responses.

Table 2-3 Industrial Agents That Can Cause Asthma

Metals
Salts of platinum, nickel, chrome
Wood dusts
Mahogany
Oak
Redwood
Western red cedar (plicatic acid)
Vegetable dusts
Castor bean
Cotton
Cottonseed
Flour
Grain (mite, weevil antigens)
Green coffee
Gums
Industrial chemicals and plastics
Ethylenediamine
Phthalic and trimellitic anhydrides
Polyvinyl chloride
Toluene diisocyanate
Pharmaceutical agents
Phenylglycine acid chloride
Penicillins
Spiramycin
Food industry agents
Egg protein
Polyvinyl chloride
Biologic enzymes
Bacillus subtilis (laundry detergent workers)
Pancreatic enzymes
Animal emanations
Canine or feline saliva
Horse dander (racing workers)
Rodent urine (laboratory animal workers)

- So-called β_1 selective β-blocking agents such as atenolol may also provoke asthma.

Persons taking angiotensin-converting enzyme inhibitor drugs may develop a chronic cough that can mimic asthma. This cough may not be accompanied by additional bronchospasm.

- Angiotensin-converting enzyme inhibitors can cause coughing.

Aspirin ingestion can cause acute, severe, and fatal asthma in a small subset of patients with asthma. The cause of the reaction is unknown but probably involves the generation of leukotrienes. Most of the patients affected have nasal polyposis and hyperplastic pansinus mucosal disease and are steroid-dependent for control of asthma. However, not all asthma patients with this reaction to aspirin fit the profile. Many nonsteroidal anti-inflammatory drugs can trigger the reaction to aspirin; the likelihood of a drug causing the reaction correlates with its potency for inhibiting cyclooxygenase enzyme. Structural aspects of the drug seem unrelated to its tendency to provoke the reaction. Only nonacetylated salicylates such as choline salicylate (a weak cyclooxygenase inhibitor) seem not to provoke the reaction. Leukotriene-modifying drugs may be particularly helpful in aspirin-sensitive asthma.

- Aspirin and other nonsteroidal anti-inflammatory drugs can cause acute, severe asthma.
- Asthma, nasal polyposis, and aspirin sensitivity form the "aspirin allergy triad."
- Leukotriene modifiers may be helpful in aspirin-sensitive asthma.

Traditionally, asthma patients have been warned not to take antihistamines because the anticholinergic activity of some antihistamines was thought to cause drying of lower respiratory tract secretions, further worsening the asthma. However, antihistamines do not worsen asthma, and, in fact, some studies have shown a beneficial effect. Thus, occasionally an antihistamine is specifically prescribed for asthma because it may have some beneficial effect on asthmatic inflammation.

- Antihistamines are not contraindicated in asthma.

Cigarette Smoking and Asthma

A combination of asthma and cigarette smoking leads to accelerated chronic obstructive pulmonary disease. Because of accelerated decline in irreversible obstruction, all asthma patients who smoke should be told to stop smoking.

Environmental tobacco smoke is an important asthma trigger. In particular, children with asthma who are exposed to environmental smoke have more respiratory infections and asthma attacks.

Medical History

A medical history for asthma includes careful inquiry about symptoms, provoking factors, alleviating factors, and severity. Patients with marked respiratory allergy have symptoms when exposed to aeroallergens and often have seasonal variation of symptoms. If allergy skin test results are negative, one can be reasonably certain that the patient does not have allergic asthma.

- In allergic asthma, symptoms are either sporadic and consistently related to exposure or are seasonal.

Respiratory infections (particularly viral), cold dry air, exercise, and respiratory irritants can trigger allergic and nonallergic asthma.

- Patients with allergic asthma are likely to respond to many nonimmunologic triggers.
- Cold dry air and exercise can trigger asthma.

Assessment of Severity

Asthma is mild intermittent if 1) the symptoms are intermittent (two times a week or less), 2) continuous treatment is not needed,

and 3) the flow-volume curve during formal pulmonary function testing is normal between episodes of symptoms. Even for patients who meet these criteria, inflammation (albeit patchy) is present in the airways and corticosteroid inhaled on a regular basis diminishes bronchial hyperresponsiveness.

- Corticosteroid inhaled regularly diminishes bronchial hyperresponsiveness.

Asthma is mild, persistent, or moderate when 1) the symptoms occur with some regularity (more than two times a week) or daily, 2) there is some nocturnal occurrence of symptoms, or 3) asthma exacerbations are troublesome. For many of these patients, the flow-volume curve is rarely normal and complete pulmonary function testing may show evidence of hyperinflation, as indicated by increased residual volume or an increase above expected levels for the diffusing capacity of the lung for carbon dioxide. Patients with mild, moderate, or severe persistent asthma should receive treatment daily with anti-inflammatory medications, usually inhaled corticosteroids.

Asthma is severe when symptoms are present almost continuously and the usual medications must be given in doses at the upper end of the dose range to control the disease. Most patients with severe asthma require either large doses of inhaled corticosteroid or oral prednisone daily for adequate control. Most of them have been hospitalized more than once for asthma. The severity of asthma can change over time, and one of the first signs that asthma is not well controlled is the emergence of nocturnal symptoms.

- Nocturnal symptoms suggest that asthma is worsening.

Methacholine Bronchial Challenge

If a patient has a history suggestive of episodic asthma but has normal results on pulmonary function tests on the day of the examination, the patient is a reasonable candidate for a methacholine bronchial challenge. The methacholine bronchial challenge is also useful in evaluating patients for cough in whom baseline pulmonary function appears normal. Positive results indicate that bronchial hyperresponsiveness is present (Table 2-4). Some consider isocapneic hyperventilation with subfreezing dry air (by either exercise or breathing a carbon dioxide/air mixture) or exercise testing as alternatives to a methacholine challenge.

Do not perform a methacholine challenge in patients who have severe airway obstruction or a clear diagnosis of asthma. Usually, a 20% decrease in forced expiratory volume in 1 second (FEV_1) is considered a positive result.

- Patients with suspected asthma and normal results on pulmonary function tests are candidates for methacholine testing.

Differential Diagnosis

The differential diagnosis of wheezing is given in Table 2-5.

Medications for Asthma

Medications for asthma are listed in Table 2-6. Currently, the only anticholinergic drug available in the United States for treating asthma is ipratropium bromide, although it is approved only for treating chronic obstructive pulmonary disease. Several short-acting β-adrenergic compounds are available, but albuterol or pirbuterol is probably prescribed most. More side effects occur when these medications are given orally rather than by inhalation. Nebulized β-agonists are rarely used long-term in adult asthma, although they may be life-saving in acute attacks. For home use, the metered-dose inhaler or dry powdered inhalation is the preferred delivery system. Salmeterol and formoterol are two long-acting inhaled β-agonists. Both should be used in combination with inhaled corticosteroids. Theophylline is effective for asthma but has a narrow therapeutic index. Note that drug interactions (cimetidine, erythromycin, and quinolone antibiotics) can increase the serum level of theophylline.

- Theophylline has a narrow therapeutic index.
- β-Agonists are best delivered by the inhaler route.

Cromolyn and nedocromil are inhaled anti-inflammatory medications that are appropriate for treatment of mild or moderate asthma. The

Table 2-4 Medical Conditions Associated With Positive Findings on Methacholine Challenge

Current asthma
Past history of asthma
Chronic obstructive pulmonary disease
Smoking
Recent respiratory infection
Chronic cough
Allergic rhinitis

Table 2-5 Differential Diagnosis of Wheezing

Bronchiolitis (including bronchiolitis obliterans), croup
Cystic fibrosis

Table 2-6 Medications for Asthma

Bronchodilator compounds
Anticholinergic drugs (ipratropium bromide)
β_2-Agonist drugs
Short-acting (albuterol, pirbuterol)
Long-acting (salmeterol, formoterol)
Methylxanthines (theophylline)
"Anti-allergic" compounds
Cromolyn
Nedocromil
Glucocorticoids
Systemic
Prednisone
Methylprednisolone
Topical
Triamcinolone acetonide
Beclomethasone
Flunisolide, budesonide
Antileukotrienes
Leukotriene receptor antagonists (zafirlukast, montelukast)
Lipoxygenase inhibitors (zileuton)

5-lipoxygenase inhibitor zileuton and the leukotriene receptor antagonists zafirlukast and montelukast are approved for treatment in mild persistent asthma. These agents work by decreasing the inflammatory effects of leukotrienes. Zileuton can cause increased liver function test results. Cases of Churg-Strauss vasculitis have also been linked to zafirlukast, although a clear cause-and-effect relationship has not been established.

Corticosteroid Therapy

Many experts recommend inhaled glucocorticoids for mild persistent asthma because of the potential long-term benefits of reduced bronchial hyperresponsiveness and reduced airway remodeling (fibrosis). Long-term use of β-agonist bronchodilators may adversely affect asthma; this also argues for earlier use of inhaled glucocorticoids. Asthma mortality has been linked to the heavy use of β-agonist inhalers. This association may simply reflect that patients with more severe asthma (who are more likely to die of an asthma attack) use more β-agonist inhalers. However, prolonged and heavy use of inhaled β-agonists may have a direct, deleterious effect on asthma, although this has not been proved. Certainly, asthma patients with regularly recurring symptoms should have inhaled corticosteroids (or cromolyn or nedocromil) as part of the treatment.

- Prescribe inhaled glucocorticoids for mild, moderate, and severe persistent asthma.
- Long-term use of β-agonist bronchodilators may worsen asthma.

The inflammatory infiltrate in the bronchial submucosa of asthma patients likely depends on lymphokine secretory patterns. Corticosteroids may interfere at several levels in the lymphokine cascade.

Bronchoalveolar lavage and biopsy studies show that corticosteroids inhibit IL-4, IL-5, and granulocyte-macrophage colony-stimulating factor in asthma.

Monocytes or platelets may be important in the asthmatic process. Corticosteroids modify activation pathways for monocytes and platelets. Furthermore, corticosteroids have vasoconstrictive properties, which reduce vascular congestive changes in the mucosa, and they tend to decrease mucous gland secretion.

- Corticosteroids reduce airway inflammation by modulating cytokines.
- Corticosteroids can inhibit the inflammatory properties of monocytes and platelets.
- Corticosteroids have vasoconstrictive properties.
- Corticosteroids decrease mucous gland secretion.

The most common adverse effects of inhaled corticosteroids are dysphonia and thrush. These unwanted effects occur in about 10% of patients and can be reduced by using a spacer device and rinsing the mouth after administration. Usually, oral thrush can be treated successfully with oral antifungal agents. Dysphonia, when persistent, may be treated by decreasing or discontinuing the use of inhaled corticosteroids.

Detailed study of the systemic effects of inhaled corticosteroids shows that these agents are much safer than oral corticosteroids. Nevertheless, there is evidence that high-dose inhaled corticosteroids can affect the hypothalamic-pituitary-adrenal axis and bone metabolism. Also, high-dose inhaled corticosteroids may increase the risk of future development of glaucoma, cataracts, and osteoporosis. Inhaled corticosteroids can decrease growth velocity in children and adolescents. The effect of inhaled corticosteroids on adult height is not known, but it appears to be minimal.

Poor inhaler technique and poor compliance can result in poor control of asthma. Therefore, all patients using a metered-dose inhaler or dry powder inhaler should be taught the proper technique of using these devices. Most patients using metered-dose inhaled corticosteroids should use a spacer device with the inhaler.

- The most common cause of poor results is poor inhaler technique.
- Patients should use a spacer device with metered-dose inhaled corticosteroids.

Anti-IgE Treatment With Omalizumab

Omalizumab is the first recombinant humanized anti-IgE monoclonal antibody approved for use in asthma. It blocks IgE binding to mast cells and is indicated for refractory moderate to severe persistent allergic asthma. It is approved for use in patients 12 years and older with positive skin or in vitro allergy testing. Dosing is based on the patient's IgE level and body weight. The dosage is typically 150 to 375 mg subcutaneously every 2 to 4 weeks.

- Omalizumab is approved for use in refractory moderate to severe persistent asthma.

Goals of Asthma Management

The goals of asthma management are listed in Table 2-7.

Management of Chronic Asthma

Baseline spirometry is recommended for all patients with asthma, and home peak flow monitoring is recommended for those with moderate or severe asthma (Fig. 2-1).

- Spirometry is recommended for all asthma patients.
- Home peak flow monitoring is recommended for those with moderate or severe asthma.

Environmental triggers should be discussed with all asthma patients, and allergy testing should be offered to those with suspected allergic asthma or with asthma that is not well controlled. Although allergy immunotherapy is effective, it is recommended only for patients with allergic asthma who have had a complete evaluation by an allergist.

Management of Acute Asthma

Inhaled β-agonists, measurements of lung function at presentation and during therapy, and systemic corticosteroids (for most patients) are the cornerstones of managing acute asthma. The Institute for Clinical Symptoms Improvement provides an algorithm for management (Fig. 2-2). Generally, nebulized albuterol, administered repeatedly if necessary, is the first line of treatment. Delivery of β-agonist by metered-dose inhaler can be substituted in less severe asthma attacks. Inhaled β-agonist delivered by continuous nebulization may be appropriate for more severe disease.

- Inhaled β-agonist can be delivered by intermittent nebulization, continuous nebulization, or metered-dose inhaler.

It is important to measure lung function (usually peak expiratory flow rate but also FEV_1 whenever possible) at presentation and after administration of bronchodilators. These measurements provide invaluable information that allows the physician to assess the severity of the asthma attack and the response (if any) to treatment.

Patients who do not have a prompt and full response to inhaled β-agonists should receive a course of systemic corticosteroids. Patients with the most severe and poorly responsive disease (FEV_1, <50%; oxygen saturation, <90%; moderate to severe symptoms) should be treated on a hospital ward or in an intensive care unit.

- Measure pulmonary function at presentation and after giving bronchodilators.

Table 2-7 Goals of Asthma Management

No asthma symptoms
No asthma attacks
Normal activity level
Normal lung function
Use of safest and least amount of medication necessary
Establish therapeutic relationship between patient and provider

- Most patients with acute asthma need a course of systemic corticosteroids.

Allergic Bronchopulmonary Aspergillosis

Allergic bronchopulmonary aspergillosis is an obstructive lung disease caused by an allergic reaction to *Aspergillus* in the lower airway. The typical patient presents with severe steroid-dependent asthma. Most patients with this condition have coexisting asthma or cystic fibrosis.

- Allergic bronchopulmonary aspergillosis develops in patients with asthma or cystic fibrosis.

The diagnostic features of allergic bronchopulmonary aspergillosis are summarized in Table 2-8. Fungi other than *Aspergillus fumigatus* can cause an allergic bronchopulmonary mycosis similar to allergic bronchopulmonary aspergillosis.

Chest radiography can show transient or permanent infiltrates and central bronchiectasis, usually affecting the upper lobes (Fig. 2-3). Advanced cases show extensive pulmonary fibrosis.

Allergic bronchopulmonary aspergillosis is treated with systemic corticosteroids. Total serum IgE may be helpful in following the course of the disease. Antifungal therapy has not been effective.

Chronic Rhinitis

Medical History

Vasomotor rhinitis is defined as nasal symptoms occurring in response to nonspecific, nonallergic irritants. Common triggers of vasomotor rhinitis are strong odors, respiratory irritants such as dust or smoke, changes in temperature, changes in body position, and ingestants such as spicy food or alcohol. This is considered a nonallergic rhinitis.

- Vasomotor rhinitis is defined as nasal symptoms in response to nonspecific stimuli.

Historical factors favoring a diagnosis of *allergic* rhinitis include a history of nasal symptoms that have a recurrent seasonal pattern (e.g., every August and September) or symptoms provoked by being near animals. Factors favoring *vasomotor* rhinitis include symptoms provoked by strong odors and changes in humidity and temperature.

Table 2-8 Diagnostic Features of Allergic Bronchopulmonary Aspergillosis

Clinical asthma
Bronchiectasis (usually proximal)
Increased total serum IgE
IgE antibody to *Aspergillus* (by skin test or in vitro assay)
Precipitins or IgG antibody to *Aspergillus*
Radiographic infiltrates (often upper lobes)
Peripheral blood eosinophilia

Fig. 2-3. Chest radiograph in allergic bronchopulmonary aspergillosis shows cylindrical infiltrates involving the upper lobes.

- Allergic rhinitis has a recurrent seasonal pattern and may be provoked by being near animals.
- Triggers of vasomotor rhinitis include strong odors and changes in humidity and temperature.

Factors common to allergic rhinitis and vasomotor rhinitis (thus, without differential diagnostic value) include perennial symptoms, intolerance of cigarette smoke, and history of "dust" sensitivity. Factors that suggest fixed nasal obstruction (which should prompt physicians to consider other diagnoses) include unilateral nasal obstruction, unilateral facial pain, unilateral nasal purulence, nasal voice but no nasal symptoms, disturbances of olfaction without any nasal symptoms, and unilateral nasal bleeding (Table 2-9).

- Perennial symptoms, intolerance of cigarette smoke, and history of "dust" sensitivity are common to allergic and vasomotor rhinitis.
- House dust mite sensitivity is a common cause of perennial allergic rhinitis.

Allergy Skin Tests in Allergic Rhinitis

The interpretation of allergy skin test results must be tailored to the unique features of each patient.

1. For patients with perennial symptoms and negative results on allergy skin tests, the diagnosis is vasomotor rhinitis.
2. For patients with seasonal symptoms and appropriately positive allergy skin tests, the diagnosis is seasonal allergic rhinitis.
3. For patients with perennial symptoms, allergy skin tests positive for house dust mite suggest house dust mite allergic rhinitis. In this case, dust mite allergen avoidance should be recommended. Patients should encase their bedding with allergy-proof encasements, remove carpeting from the bedroom, and keep the relative humidity in the house at 40% to 50% or less.

Corticosteroid Therapy for Rhinitis

The need for systemic corticosteroid treatment for rhinitis is limited. Occasionally, patients with severe symptoms of hay fever may benefit greatly from a short course of prednisone (10 mg four times daily by mouth for 5 days). This may induce sufficient improvement so that topical corticosteroids can penetrate the nose and satisfactory levels of antihistamine can be established in the blood. Severe nasal polyposis may warrant a longer course of oral corticosteroids. Sometimes, recurrence of nasal polyps can be prevented by continued use of topical corticosteroids. Polypectomy may be required if nasal polyps do not respond to treatment with systemic and intranasal corticosteroids.

- Treatment of nasal polyposis can include oral prednisone, followed by topical corticosteroids.

In contrast to systemic corticosteroid therapy, topical corticosteroid agents for the nose are easy to use and have few adverse systemic effects. Intranasal corticosteroids may decrease growth velocity in children.

- Intranasal corticosteroids may decrease growth velocity in children.

Long-term treatment with decongestant nasal sprays may have "addictive" potential (a vicious cycle of rebound congestion called "rhinitis medicamentosa" caused by topical vasoconstrictors). In contrast, inhaled corticosteroid does not induce dependence.

- Unlike decongestant nasal sprays, intranasal corticosteroid does not induce tachyphylaxis and rebound congestion.

A substantial number of patients with vasomotor rhinitis also have a good response to intranasal (topical aerosol) corticosteroid therapy, especially if they have the nasal eosinophilia or nasal polyposis form of vasomotor rhinitis.

Table 2-9 Differential Diagnosis of Chronic Rhinitis

Allergic rhinitis
Vasomotor rhinitis
Rhinitis medicamentosa
Sinusitis
Nasal polyposis
Nasal septal deviation
Foreign body
Tumor

- Many patients with vasomotor rhinitis have a good response to topical aerosol corticosteroid therapy.

If a patient with hay fever does not receive adequate relief with topical corticosteroid plus antihistamine therapy, it may indicate the need for systemic corticosteroid treatment and the initiation of immunotherapy.

- If pharmacologic management fails, allergy immunotherapy should be considered for patients with allergic rhinitis.

An unusual side effect of intranasal corticosteroids is nasal septal perforation. Dry powder spray cannisters deliver a powerful jet of particulates, and a few patients have misdirected the jet to the nasal septum.

- Rarely, topical corticosteroid nasal sprays cause perforation of the nasal septum.

Antihistamines and Decongestants

Antihistamines antagonize the interaction of histamine with its receptors. Histamine may be more causative than other mast cell mediators of nasal itch and sneezing. These are symptoms most often responsive to antihistamine therapy.

Pseudoephedrine is the most common agent in nonprescription drugs for treating cold symptoms and rhinitis and usually is the active agent in widely used proprietary prescription agents. Phenylpropanolamine has been removed from the market because of its association with hemorrhagic stroke in women. Several prescription and nonprescription combination agents combine an antihistamine and decongestant. Decongestant preparations are often the only therapeutic option for patients with vasomotor rhinitis unresponsive to topical glucocorticoids.

- Pseudoephedrine is the most common decongestant in nonprescription preparations.

Middle-aged and older men may have urinary retention caused by antihistamines (principally the older drugs that have anticholinergic effects) and decongestants. Although there has been concern for years that decongestants may exacerbate hypertension because they are α-adrenergic agonists, no clinically significant hypertensive response has been seen in patients with hypertension that is controlled medically.

- Antihistamines and decongestants may cause urinary retention in men.
- The elderly are more sensitive to the anticholinergic effects of antihistamines.

Immunotherapy for Allergic Rhinitis

Until topical nasal glucocorticoid sprays were introduced, allergen immunotherapy was considered first-line therapy for allergic rhinitis when the relevant allergen was seasonal pollen of grass, trees, or weeds. Immunotherapy became second-line therapy after topical corticosteroids were introduced because immunotherapy 1) requires more time commitment during the build-up phase and 2) carries a small risk of anaphylaxis to the immunotherapy injection itself. However, immunotherapy for allergic rhinitis can be appropriate first-line therapy in selected patients and is highly effective.

Immunotherapy is usually reserved for patients who have no satisfactory relief from intranasal corticosteroids or who cannot tolerate antihistamines. Controlled trials have shown a benefit for pollen, dust mite, and cat allergies and a variable benefit for mold allergy. Immunotherapy is not used for food allergy or nonallergic rhinitis. The practice is less uniform with respect to mold allergens, with endorsement divided in the subspecialty.

- Immunotherapy usually is reserved for patients who receive no relief from intranasal glucocorticoids or who cannot tolerate antihistamines.
- Controlled trials have shown that immunotherapy is effective for allergic rhinitis.
- Anaphylaxis is a risk of immunotherapy.
- Immunotherapy for allergic rhinitis can be first-line therapy in selected patients.

Environmental Modification

House Dust Mites

House dust mites are so small that they cannot maintain their own internal water unless the ambient humidity is high. They eat all kinds of organic matter but seem to favor mold and epidermal scale shed by humans. They occur in all human habitations, although the population size varies with local conditions. The only geographic areas free of house dust mites are at high elevations with extreme dryness.

- House dust mites require high humidity to survive.
- They are found in nearly all human habitations.

Areas in the home harboring the most substantial mite populations are bedding and fabric-upholstered furniture (heavily used) and any area where carpeting is on concrete (when concrete is in contact with grade). Although carpeting is often cited as an important mite-related problem, carpet on wooden floors in a dry, well-ventilated house usually harbors only a small number of dust mites. Aerosol dispersion of allergen from this source is not great compared with that from bedding and furniture. To prevent egress of allergen when the mattress and pillows are compressed by occupancy of the bed, encase the bedding (and sometimes, when practical, furniture cushions) in plastic dust-proof encasements. To some degree, this also prevents infusion of water vapor into the bedding matrix. These two factors combine to markedly decrease the amount of airborne allergen. In contrast, recently marketed acaricides that kill mites or denature their protein allergens have not proved useful in the home. Measures for controlling dust mites are listed in Table 2-10.

- Dust mite is an important respiratory allergen.
- The most substantial mite populations are in bedding and fabric-upholstered furniture.
- Plastic encasements prevent egress of allergen.

Table 2-10 Dust Mite Control

Encase bedding and pillows in airtight encasements
Remove carpeting in bedroom
Remove upholstered furniture from bedroom
Remove all carpeting laid on concrete
Discontinue use of humidifier
Wash bedding in hot water
Run dehumidifier

- Chemical sprays (acaricides) capable of either killing mites or denaturing the protein allergens are not substantially helpful when applied in the home.

Pollen

Air conditioning, which enables the warm-season home to remain tightly closed, is the principal defense against pollinosis. Most masks purchased at local pharmacies cannot exclude pollen particles and are not worth the expense. Some masks can protect the wearer from allergen exposure. These include industrial-quality respirators designed specifically to pass rigorous testing by the Occupational Safety and Health Administration (OSHA) and the National Institute for Occupational Safety and Health (NIOSH) and be certified as capable of excluding a wide spectrum of particulates, including pollen and mold. These masks allow persons to mow the lawn and do yard work, which would be intolerable otherwise because of exposure to pollen allergen.

- Only industrial-quality masks are capable of excluding pollen particles.

Animal Dander

No measure can compare with getting the animal completely out of the house. No air filtration scheme that is feasible for average homeowners to install can eliminate allergen from an actively elaborating animal. If complete removal is not tenable, some partial measure must be considered.

If the house is heated or cooled by a forced-air system with ductwork, confining the pet to a single room in the house is only partially effective in reducing overall exposure, because air from every room is collected through the air-return ductwork and redistributed through a central plenum. If air-return ducts are sealed in the room where the animal is kept and air can escape from the room only by infiltration, exposure may be reduced. The room selected for this measure should be as far as possible from the bedroom of the person with the allergy. Naturally, the person should avoid close contact with the animal and should consider using a mask if handling the animal or entering the room where the animal is kept is necessary. Most animal danders have little or nothing to do with animal hair, so shedding status is irrelevant. Bathing cats about once every other week may reduce the allergen load in the environment.

- Complete avoidance is the only entirely effective way to manage allergy to household pets.

Sinusitis

Sinusitis is closely associated with edematous obstruction of the sinus ostia (the osteomeatal complex). Poor drainage of the sinus cavities predisposes to infection, particularly by microorganisms that thrive in low oxygen environments (e.g., anaerobes). In adults, *Streptococcus pneumoniae*, *Haemophilus influenzae*, anaerobes, and viruses are common pathogens. In addition, *Branhamella catarrhalis* is an important pathogen in children.

Important clinical features of acute sinusitis are purulent nasal discharge, tooth pain, cough, and poor response to decongestants. Findings on paranasal sinus transillumination may be abnormal.

- Purulent nasal discharge, tooth pain, and abnormal findings on transillumination are important clinical features of sinusitis.

Physicians should be aware of the complications of sinusitis, which can be life-threatening (Table 2-11). Mucormycosis can cause recurrent or persistent sinusitis refractory to antibiotics. Allergic fungal sinusitis is characterized by persistent sinusitis, eosinophilia, increased total IgE, antifungal (usually *Aspergillus*) IgE antibodies, and fungal colonization of the sinuses. Wegener granulomatosis, ciliary dyskinesia, and hypogammaglobulinemia are medical conditions that can cause refractory sinusitis (Table 2-12).

Untreated sinusitis may lead to osteomyelitis, orbital and periorbital cellulitis, meningitis, and brain abscess. Cavernous sinus thrombosis, an especially serious complication, can lead to retrobulbar pain, extraocular muscle paralysis, and blindness.

Persistent, refractory, and complicated sinusitis should be evaluated by a specialist. Sinus computed tomography (CT) is the preferred imaging study for these patients (Fig. 2-4).

Amoxicillin, 500 mg three times daily, or trimethoprim-sulfamethoxazole (one double-strength capsule twice daily) for 10 to 14 days is the treatment of choice for uncomplicated maxillary sinusitis.

The sensitivity of plain radiography of the sinuses is not as good as that of CT (using the coronal sectioning technique). Good-quality coronal CT scans show greater detail about sinus mucosal surfaces, but CT usually is not necessary in acute uncomplicated sinusitis. CT is indicated, though, for patients being considered for a sinus operation and for those in whom standard treatment for sinusitis fails. However, patients with extensive dental restorations

Table 2-11 Complications of Sinusitis

Hypogammaglobulinemia
Tumor

that contain metal may generate too much artifact for CT to be useful. For these patients, magnetic resonance imaging techniques are indicated.

- Sinus imaging is indicated for recurrent sinusitis.
- Sinus CT is preferred to sinus radiography for complicated sinusitis.

Urticaria and Angioedema

The distinction between acute and chronic urticaria is arbitrary and based on the duration of the urticaria. If it has been present for 6 weeks or longer, it is called chronic urticaria.

Secondary Urticaria

Most patients simply have urticaria as a skin disease (chronic idiopathic urticaria), but occasionally it is the presenting sign of more serious internal disease. It can be a sign of lupus erythematosus and other connective tissue diseases, particularly the "overlap" syndromes that are more difficult to categorize. Malignancy, mainly of the gastrointestinal tract, and lymphoproliferative diseases are associated with urticaria, as occult infection may be, particularly of the gallbladder and dentition. Immune-complex disease has been associated with urticaria, usually with urticarial vasculitis, and hepatitis B virus has been identified as an antigen in cases of urticaria and immune-complex disease.

- Urticaria can be associated with lupus erythematosus and other connective tissue diseases, malignancy, infection, and immune-complex disease.

A common cause of acute urticaria and angioedema (other than the idiopathic variety) is drug or food allergy. However, drug or food allergy usually does not cause chronic urticaria.

- Chronic urticaria and angioedema are often idiopathic.
- A common secondary cause of acute urticaria and angioedema is drug or food allergy.

Relation Between Urticaria and Angioedema

In common idiopathic urticaria, which lasts 2 to 18 hours, the lesions itch intensely because histamine is one of the causes of wheal formation.

- Typical urticarial lesions last 2-18 hours and are pruritic.

The pathophysiologic mechanism is similar for urticaria and angioedema. The critical factor is the type of tissue in which the capillary leak and mediator release occur. Urticaria occurs when the capillary events are in the tightly welded tissue wall of the skin—the epidermis. Angioedema occurs when capillary events affect vessels in loose connective tissue of the deeper layers—the dermis. Virtually all patients with the common idiopathic type of urticaria also have angioedema from time to time. When urticaria is caused by allergic reactions, angioedema may also occur. The only exception is hereditary angioneurotic edema (HANE), which is not related to mast cell mediator release but is a complement disorder. Patients with this form of angioedema rarely have urticaria.

C1 Esterase Inhibitor Deficiency

If HANE is strongly suspected, the diagnosis can be proved by the appropriate measurement of complement factors (decreased levels of C1 esterase inhibitor [quantitative and functional] and C4 [also C2, during an episode of swelling]).

- Levels of C1 esterase inhibitor and C4 are decreased in HANE.

The duration of individual swellings varies. Many patients with HANE have had at least one hospitalization for what appeared to be intestinal obstruction. If they avoid laparotomy on these occasions, the obstruction usually resolves in 3 to 5 days. Cramps and diarrhea may occur.

Lesions in HANE do not itch. The response to epinephrine is a useful differential point: HANE lesions do not respond well to

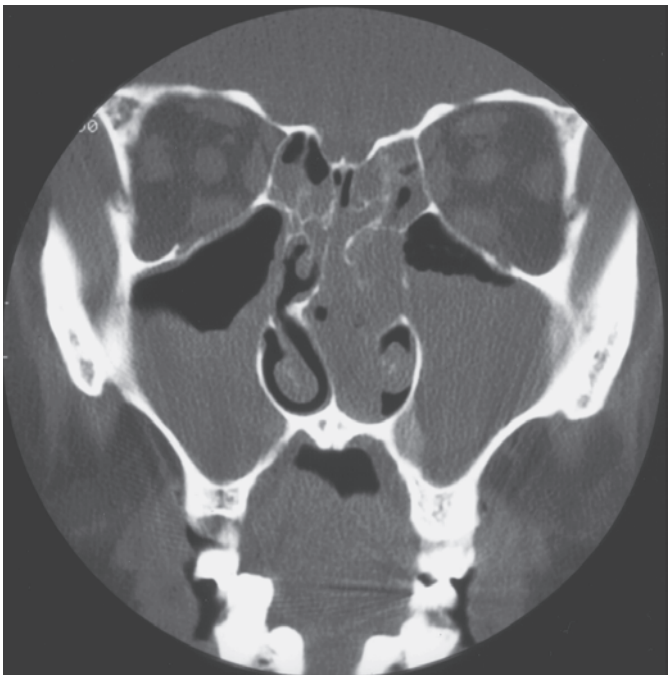

Fig. 2-4. Sinus computed tomogram showing opacification of the osteomeatal complex on the left, subtotal opacification of the right maxillary sinus, and an air-fluid level in the left maxillary antrum.

epinephrine, but common angioedema usually resolves in 15 minutes or less. Laryngeal edema almost never occurs in the common idiopathic type of disease (although it may occur in allergic reactions, most often in insect-sting anaphylaxis cases); however, it is relatively common in HANE (earlier articles cited a 30% mortality rate in HANE, with all deaths due to laryngeal edema). HANE episodes may be related to local tissue trauma in a high percentage of cases, with dental work often regarded as the classic precipitating factor.

- Most patients with HANE have been hospitalized for "intestinal obstruction."
- HANE lesions do not respond well to epinephrine.
- In HANE, laryngeal edema is relatively common.
- Dental work is the classic precipitating factor for HANE.

The common idiopathic form of urticaria and angioedema is usually unrelated to antecedent trauma except in special cases of delayed-pressure urticaria, in which hives and angioedema follow minor trauma or pressure to soft tissues (e.g., to the hands while playing golf). The response to pressure distinguishes this special form of physical urticaria from HANE.

It is reasonable to perform C4 and C1 esterase inhibitor assays (functional and quantitative) for all patients with unexplained recurrent angioedema, especially if urticaria is not present.

The three major types of HANE-like disorders are as follows:

1. Classic HANE is a genetic dysregulation of gene function for C1 inhibitor that is inherited in an autosomal dominant pattern. Therapy with androgens (testosterone, stanozolol, and danazol) reverses the dysregulation and allows expression of the otherwise normal gene, resulting in half-normal plasma levels of C1, which are sufficient to eliminate the clinical manifestations of the disease.

- Classic HANE is a genetic dysregulation (autosomal dominant).
- Testosterone, stanozolol, and danazol reverse the dysregulation.

2. In some cases of HANE, the gene for the C1 inhibitor mutates, rendering the molecule functionally ineffective but quantifiable in the blood. Thus, plasma levels of the C1 inhibitor molecule may be normal in these patients. This is the basis for requesting immunochemical and functional measures of serum C1 inhibitor (with immunochemical measures only, the diagnosis is missed in cases of normal levels of an inactive molecule). Both classic HANE (low levels of C1 esterase inhibitor) and classic HANE with the mutated gene for C1 inhibitor (nonfunctional C1 esterase inhibitor) are inherited forms of the disease. However, the proband may start the mutational line in both forms of HANE, so the family history is not positive in all cases.

- HANE with normal levels of C1 esterase inhibitor but nonfunctional (by esterase assay) indicates a gene mutation.

3. C1 esterase inhibitor deficiency may be an acquired disorder with malignancy or lymphoproliferative disease. Plasma levels for C1, C4, and C1 esterase inhibitor are low in acquired C1 esterase inhibitor deficiency. The hypothesis for the pathogenesis of this form of angioedema is that the tumor has or releases determinants that fix complement, and with constant consumption of complement components, a point is reached at which the biosynthesis of C1 inhibitor cannot keep up with the consumption rate, and the relative deficiency of C1 inhibitor allows episodes of swelling.

- C1 esterase inhibitor deficiency can be an acquired disorder in malignancy or lymphoproliferative disease.
- C1 levels are low in acquired C1 esterase inhibitor deficiency.

Physical Urticaria

Heat, light, cold, vibration, and trauma or pressure have been reported to cause hives in susceptible persons. Obtaining the history is the only way to suspect the diagnosis, which can be confirmed by applying each of the stimuli to the patient's skin in the laboratory. Heat can be applied by placing coins (soaked in hot water for a few minutes) on the patient's forearm. Cold can be applied with coins kept in a freezer or with ice cubes. For vibration, a laboratory vortex mixer or any common vibrator can be used. A pair of sandbags connected by a strap can be draped over the patient to create enough pressure to cause symptoms in those with delayed pressure urticaria. Unlike most cases of common idiopathic urticaria, in which the lesions affect essentially all skin surfaces, many cases of physical urticaria seem to involve only certain areas of skin. Thus, challenges will be positive only in the areas usually involved and negative in other areas. Directing challenges to the appropriate area depends on the history.

- For physical urticaria, the history is the only way to suspect the diagnosis, which can be confirmed by applying stimuli to the patient's skin.

Food Allergy in Chronic Urticaria

Food allergy almost never causes chronic urticaria. However, urticaria (or angioedema or anaphylaxis) can be an acute manifestation of true food allergy.

- Food allergy almost never causes chronic urticaria.
- Food allergy may cause acute urticaria, angioedema, or anaphylaxis.

Histopathology of Chronic Urticaria

Chronic urticaria is characterized by mononuclear cell perivascular cuffing around dermal capillaries, particularly involving the capillary loops that interdigitate with the rete pegs of the epidermis. This is the usual histologic location for most skin mast cells. It appears that there is about a tenfold increase in the number of mast cells in the cuff compared with the normal value. However, the number of mast cells is still small compared with that of other round cells in the cuff. This histologic picture is consistent throughout the skin, regardless of recent active urtication. Most pathologists consider "vasculitis" to indicate actual necrosis of the structural elements of blood vessels; thus, the typical features of chronic urticaria do not meet the criteria for vasculitis. Immunofluorescence studies on chronic urticaria biopsy samples are negative for fibrin, complement, and immunoglobulin deposition in blood vessels.

Urticarial vasculitis shows the usual histologic features of leukocytoclastic vasculitis.

- The characteristic histopathologic feature of chronic urticaria is a mononuclear cell perivascular cuff around capillaries.

Management of Urticaria

The history is of utmost importance if the 2% to 4% of cases of chronic urticaria actually due to allergic causes are to be discovered. A complete physical examination is needed, with particular attention to the skin (including some test for dermatographism) to evaluate for the vasculitic nature of the lesions and to the liver, lymph nodes, and mucous membranes. Laboratory testing need not be exhaustive: chest radiography, a complete blood count with differential count to discover eosinophilia, liver enzymes, erythrocyte sedimentation rate, serum protein electrophoresis, total hemolytic complement, antinuclear antibody, urinalysis, and stool examination for parasites. Only if the patient has strong allergic tendencies and some element in the history suggests an allergic cause is allergy skin testing indicated. However, patients with idiopathic urticaria often have fixed ideas about an allergy causing their problem, and skin testing often helps to dissuade them of this idea.

- The history is of utmost importance in diagnosing allergic urticaria.
- Laboratory testing may include chest radiography, eosinophil count, liver enzymes, erythrocyte sedimentation rate, serum protein electrophoresis, total hemolytic complement, and stool examination for parasites.

Management of urticaria and angioedema consists of blocking histamine, beginning usually with H_1 antagonists. The addition of H_2 antagonists may be helpful. Tricyclic antidepressants, such as doxepin, have potent antihistamine effects and are useful. Systemic corticosteroids can be administered for acute urticaria and angioedema or for very severe chronic idiopathic urticaria and angioedema.

- Urticaria and angioedema: management is usually with H_1 antagonists.
- Urticaria and angioedema: systemic corticosteroids are used for severe cases.

Food Allergy

Clinical History

The clinical syndrome of food allergy should prompt patients to provide a history containing some or all the following: For very sensitive persons, some tingling, itching, and a metallic taste in the mouth occur while the food is still in the mouth. Within 15 minutes after the food is swallowed, some epigastric distress may occur. There may be nausea and rarely vomiting. Abdominal cramping is felt chiefly in the periumbilical area (small-bowel phase), and lower abdominal cramping and watery diarrhea may occur. Urticaria or angioedema may occur in any distribution, or there may be only itching of the palms and soles. With increasing clinical sensitivity to the offending allergen, anaphylactic symptoms may emerge, including tachycardia, hypotension, generalized flushing, and alterations of consciousness.

In extremely sensitive persons, generalized flushing, hypotension, and tachycardia may occur before the other symptoms. Most patients with a food allergy can identify the offending foods. The diagnosis should be confirmed by skin testing or in vitro measurement of allergen-specific IgE antibody.

- Allergic reactions to food usually include pruritus, urticaria, or angioedema.

Common Causes of Food Allergy

Items considered the most common allergens are listed in Table 2-13.

Food-Related Anaphylaxis

Food-induced anaphylaxis is the same process involved in acute urticaria or angioedema to food allergens, except the severity of the reaction is greater in anaphylaxis. Relatively few foods are involved in food-induced anaphylaxis; the main ones are peanuts, shellfish, and nuts. Patients with latex allergy can develop food allergy to banana, avocado, kiwifruit, and other fruits.

- Anaphylaxis to food can be life-threatening.
- There is cross-sensitivity between latex and banana, avocado, and kiwifruit.

Allergy Skin Testing in Food Allergy

Patients presenting with food-related symptoms may have food allergy, food intolerance, irritable bowel syndrome, nonspecific dyspepsia, or one of many nonallergic conditions. A careful and detailed history on the nature of the "reaction," the reproducibility of the association of food and symptoms, and the timing of symptoms in relation to the ingestion of food can help the clinician form a clinical impression.

In many cases, allergy skin tests to foods can be helpful. If the allergy skin tests are negative (and the clinical suspicion for food allergy is low), the patient can be reassured that food allergy is not the cause of the symptoms. If the allergy skin tests are positive (and the clinical suspicion for food allergy is high), the patient should be counseled about the management of the food allergy. For highly sensitive persons, this includes strict and rigorous avoidance of the offending foods. These patients should also be given an epinephrine kit for self-administration in case of emergency.

If the diagnosis of food allergy is uncertain or if the symptoms are mild and nonspecific, sometimes oral food challenges are helpful.

Table 2-13 Common Causes of Food Allergy

Eggs	Shellfish
Milk	Soybean
Nuts	Wheat
Peanuts	

An open challenge is usually performed first. If negative, the diagnosis of food allergy is excluded. If positive, a blinded placebo-controlled challenge can be performed.

- Positive results on skin tests and double-blind food challenges can confirm the diagnosis of food allergy.
- If results of food skin tests are negative, food allergy is unlikely.
- Patients with anaphylaxis to food should strictly avoid the offending food and carry an epinephrine kit.

Stinging Insect Allergy

In patients clinically sensitive to Hymenoptera, reactions to a sting can be either large local reactions or systemic, anaphylactic reactions. With a large local sting reaction, swelling at the sting site may be dramatic, but there are no symptoms distant from that site. Stings of the head, neck, and dorsum of the hands are particularly prone to large local reactions.

Anaphylaxis caused by allergy to stinging insects is similar to all other forms of anaphylaxis. Thus, the onset of anaphylaxis may be very rapid, often within 1 or 2 minutes. Pruritus of the palms and soles is the most common initial manifestation and frequently is followed by generalized flushing, urticaria, angioedema, or hypotension (or a combination of these). The reason for attaching importance to whether a stinging insect reaction is a large local or a generalized one is that allergy skin testing and allergen immunotherapy are recommended only for generalized reactions. Patients who experience a large local reaction are not at increased risk of future anaphylaxis.

- Two varieties of reaction to sting: large local and anaphylactic.

Bee and Vespid Allergy

Yellow jackets, wasps, and hornets are vespids, and their venoms cross-react to a substantial degree. The venom of honeybees (family Apidae) does *not* cross-react with that of vespids. Unless the patient actually captures the insect delivering the sting, uncertainty will likely attend many cases of insect-stinging anaphylaxis. Thus, usually it is appropriate to conduct skin testing to honeybee and to each of the vespids. To interpret skin tests accurately, it is helpful to know which insect caused the sting producing the generalized reaction. Often, the circumstances of the sting can help determine the type of insect responsible. Multiple stings received while mowing the grass or doing other landscape jobs that may disturb yellow-jacket burrows in the ground are likely causes of yellow-jacket stings. A single sting received while near picnic tables or refuse containers at picnic areas is likely from a yellow jacket or possibly a hornet. Stings received while working around the house exterior (painting, cleaning eaves and gutters, or attic work) are most likely from wasps.

- Yellow jackets, wasps, and hornets are vespids, and their venoms cross-react.
- The venom of bees does not cross-react with that of vespids.
- It is helpful to know which insect caused the sting.

Allergy Testing

Patients who have had a generalized reaction warrant allergen skin testing. Patients who have had a large local reaction to one of the Hymenoptera stings do *not* warrant allergen skin testing because they are not at increased risk of future anaphylaxis.

- Generalized reaction warrants allergen skin testing.
- Large local reaction does not warrant allergen skin testing.

In many cases, skin testing should be delayed for at least 1 month after a sting-induced general reaction because tests conducted closer to the time of the sting have a substantial risk of being falsely negative. Positive results on skin testing that correlate with the clinical history are sufficient evidence for considering Hymenoptera venom immunotherapy.

- Skin testing should be delayed for at least 1 month after a sting-induced general reaction.
- Patients with clinical anaphylaxis and positive results on venom skin tests may benefit from venom immunotherapy.

Venom Immunotherapy

The decision to undertake venom immunotherapy can be reached only after a discussion between the patient and the physician. General indications for venom immunotherapy are listed in Table 2-14. Patients must understand that once initiated, the immunotherapy injection schedule must be maintained and that there is a small risk of immunotherapy-induced anaphylaxis. It is important that patients understand that despite receiving allergy immunotherapy, they must carry epinephrine when outdoors because of the 2% to 10% possibility that immunotherapy will not provide suitable protection. Most, but not all, patients can safely discontinue venom immunotherapy after 3 to 5 years of treatment.

- There is a small risk that venom immunotherapy will induce anaphylaxis.
- There is a 2%-10% chance that venom immunotherapy will not provide adequate protection.

Avoidance

The warnings that every patient with stinging-insect hypersensitivity should receive are listed in Table 2-15. The circumstances of each

Table 2-14 Indications for Venom Immunotherapy

History of anaphylaxis to a sting
Positive results on skin tests to venom implicated historically in the anaphylactic reaction
Patient's level of anxiety disrupts usual habits and activities in warm months
Occupational—risk of sting higher than usual
House painters
Outdoor construction workers
Forestry workers

Table 2-15 Dos and Don'ts for Patients With Hypersensitivity to Insect Stings

Avoid looking or smelling like a flower
Avoid flowered prints for clothes
Avoid cosmetics and fragrances, especially ones derived from flowering plants
Never drink from a soft-drink can outdoors during the warm months—a yellow jacket can land *on* or *in* the can while you are not watching, go inside the can, and sting the inside of your mouth (one of the most dangerous places for a sensitive patient to be stung) when you take a drink
Avoid doing outdoor maintenance and yard work
Never reach into a mailbox without first looking inside it
Never go barefoot
Always look at the underside of picnic table benches and park benches before sitting down
Never attempt physically to eject a stinging insect from the interior of a moving automobile, but pull over, get out, and let someone else remove the insect

patient may require additional entries to this list. Also, patients need to know how to use self-injectable epinephrine in its several forms. Many patients wear an anaphylaxis identification bracelet.

- All patients with stinging-insect sensitivity should carry an epinephrine kit.

Anaphylaxis

Anaphylaxis is a generalized reaction characterized by flushing, hypotension, and tachycardia. Urticaria and angioedema may occur in many cases, and in patients with moderate to severe asthma or rhinitis as a preexisting condition, the asthma and rhinitis can be made worse. This definition of *anaphylaxis* is based on clinical manifestations. A cellular and molecular definition of *anaphylaxis* is a generalized allergic reaction characterized by activated basophils and mast cells releasing many mediators (preformed and newly synthesized). The dominant mediators of acute anaphylaxis are histamine and prostaglandin D2. The serum levels of tryptase may be increased for a few hours after clinical anaphylaxis. Physiologically, the hypotension of anaphylaxis is caused by peripheral vasodilatation and not by impaired cardiac contractility. Anaphylaxis is characterized by a hyperdynamic state. For these reasons, anaphylaxis can be fatal in patients with preexisting fixed vascular obstructive disease in whom a decrease in perfusion pressure leads to a critical reduction in flow (stroke) or in patients in whom laryngeal edema develops and completely occludes the airway.

- The clinical hallmarks of anaphylaxis are flushing, hypotension, and tachycardia.
- Urticaria and angioedema may be present.
- Histamine and prostaglandin D2 are the dominant mediators of acute anaphylaxis.
- Peripheral vasodilatation causes hypotension of anaphylaxis.

Latex allergy is an important cause of intraoperative anaphylaxis. Patients with intraoperative anaphylaxis should be evaluated for possible latex allergy, usually by a skin test or in vitro assay. When persons with known latex allergy undergo invasive procedures, a latex-free environment is necessary. Patients with spina bifida or those with dermatitis, rhinitis, or asthma caused by latex allergy are at increased risk of anaphylaxis to latex.

- Latex allergy is an important cause of intraoperative anaphylaxis.

Drug Allergy

Classes of Drug Allergy Not Involving IgE or Immediate-Type Reactions

Stevens-Johnson Syndrome

Stevens-Johnson syndrome is a bullous skin and mucosal reaction; very large blisters appear over much of the skin surface, in the mouth, and along the gastrointestinal tract. Because of the propensity of the blisters to break down and become infected, the reaction often is life-threatening. Treatment consists of stopping the drug that causes the reaction, giving corticosteroids systemically, and providing supportive care. The patients are often treated in burn units. Penicillin, sulfonamides, barbiturates, diphenylhydantoin, warfarin, and phenothiazines are well-known causes. A drug-induced Stevens-Johnson reaction is an absolute contraindication to administering a causative drug to the patient.

- Stevens-Johnson syndrome is life-threatening and is an absolute contraindication for rechallenge with the drug.

Toxic Epidermal Necrolysis

Clinically, toxic epidermal necrolysis is almost indistinguishable from Stevens-Johnson syndrome. Histologically, the cleavage plane for the blisters is deeper than in Stevens-Johnson syndrome. The cleavage plane is at the basement membrane of the epidermis, so even the basal cell layer is lost. This makes toxic epidermal necrolysis even more devastating than Stevens-Johnson syndrome because healing occurs with much scarring. Often, healing cannot be accomplished without skin grafting, so the mortality rate is even higher than for Stevens-Johnson syndrome. Patients with toxic epidermal necrolysis should always be cared for in a burn unit because of full-thickness damage over 80% to 90% of the skin. The mortality rate is very high, as for burn patients with damage of this extent.

- Toxic epidermal necrolysis is a life-threatening exfoliative dermatitis.

Morbilliform Skin Reaction

Morbilliform skin reaction is the most common dermatologic manifestation of a drug reaction. It is an immune-mediated drug rash without IgE involvement, manifested by a macular-papular exanthem. The rash can be accompanied by pruritus but has no other systemic symptoms. It typically occurs more than 5 days after use

of a medication was begun. It is not associated with anaphylaxis or other serious sequalae.

- Morbilliform skin reaction is the most common dermatologic manifestation of a drug reaction and is not associated with anaphylaxis.

Ampicillin-Mononucleosis Rash

Ampicillin-mononucleosis rash is a unique drug rash that occurs when ampicillin is given to an acutely ill, febrile patient who has mononucleosis. The rash is papular, nonpruritic, rose-colored, and usually on the abdomen and has a granular feel when the fingers brush lightly over the surface of the involved skin. It is not known why the rash is specific for ampicillin and mononucleosis. This rash does not predispose to allergy to penicillin.

- Ampicillin-mononucleosis rash is papular, nonpruritic, rose-colored, and on the abdomen.
- This rash does not predispose to penicillin allergy.

Fixed Drug Eruptions

Fixed drug eruptions are red to red-brown macules that appear on a certain area of the patient's skin; any part of the body can be affected. The macules do not itch or have other signs of inflammation, although fever is associated with their appearance in a few patients. The unique aspect of this allergic phenomenon is that if a patient is given the same drug in the future, the rash develops in exactly the same skin areas. Resolution of the macules often includes postinflammatory hyperpigmentation. Except for cosmetic problems due to skin discolorations, the phenomenon does not seem serious. Antibiotics and sulfonamides are the most frequently recognized causes.

- In fixed drug eruptions, the same area of skin is always affected.

Erythema Nodosum

Erythema nodosum is a characteristic rash of red nodules about the size of a quarter, usually nonpruritic and appearing only over the anterior aspects of the lower legs. Histopathologically, the nodules are plaques of infiltrating mononuclear cells. Erythema nodosum is associated with several connective tissue diseases, viral infections, and drug allergy.

- Erythema nodosum rash is usually nonpruritic, appearing only over the anterior aspect of the lower legs.
- It is associated with several connective tissue diseases, viral infections, and drug allergy.

Contact Dermatitis

Contact dermatitis can occur with various drugs. Commonly, it is a form of drug allergy that is an occupational disease in medical or health care workers. In some patients receiving topical drugs, allergy develops to the drug or various elements in its pharmaceutical formulation, for example, fillers, stabilizers, antibacterials, and emulsifiers. Contact dermatitis is a manifestation of type IV hypersensitivity and clinically appears as an area of reddening on the skin which progresses to a granular weeping eczematous eruption of the skin, with some dermal thickening and a plaque-like quality of the surrounding skin. Histopathologically, the affected area is infiltrated by mononuclear cells. When patients are receiving treatment for a dermatitis, and contact hypersensitivity develops to corticosteroids or other drugs used in treatment, a particularly difficult diagnostic problem arises unless the physician is alert to this possibility. When contact hypersensitivity to a drug occurs, it does not increase the probability of acute type I hypersensitivity and is not associated with serious exfoliative syndromes. However, patients can develop exquisite cutaneous sensitivity of this type so that almost no avoidance technique in the workplace completely eliminates dermatitis; even protective gloves are only partly helpful. Thus, it can be occupationally disabling.

- Contact dermatitis is a form of drug allergy.
- It is a manifestation of type IV hypersensitivity.

Drug Allergy Involving IgE or Immediate-Type Reactions

Penicillin Allergy

Penicillin can cause anaphylaxis in sensitive persons. It is an IgE-mediated process that can be evaluated with skin testing to the major and minor determinants of penicillin. Patients with positive results on skin testing and a clinical history of penicillin allergy can be desensitized to penicillin, but the procedure may be hazardous.

- Penicillin can cause anaphylaxis.
- It is an IgE-mediated process diagnosed with penicillin skin testing.
- Patients can be desensitized, but the procedure may be hazardous.

Penicillin skin tests can be helpful in determining whether it is safe to administer penicillin to a patient with suspected penicillin allergy. About 85% of patients who give a history of penicillin allergy have negative skin tests to the major and minor determinants of penicillin. These patients generally are not at increased risk of anaphylaxis, and most can receive penicillin safely. If penicillin skin tests are positive, there is a 40% to 60% chance that an allergic reaction will develop if the patient is challenged with penicillin. Most of these patients should avoid penicillin and related drugs. However, if there is a strong indication for penicillin treatment, desensitization can be considered. The desensitization procedure involves the administration of progressively increasing doses of penicillin. Desensitization can be accomplished by the oral or intravenous route and is usually performed in a hospital setting.

Ampicillin, amoxicillin, nafcillin, and other β-lactam antibiotics cross-react strongly with penicillin. Early studies suggested that up to 20% to 30% of patients with penicillin allergy were also allergic to cephalosporins. More recent studies have suggested that the cross-sensitivity of penicillin with cephalosporins is much less, about 5%. Most studies have suggested that aztreonam does not cross-react with penicillin.

- About 5% of patients with penicillin allergy are also allergic to cephalosporins.
- Aztreonam does not cross-react with penicillin.

Radiographic Contrast Media Reactions

Radiographic contrast media can cause reactions that have the clinical appearance of anaphylaxis. Estimates of the frequency of these reactions are 2% to 6% of procedures involving intravenous contrast media. The incidence of intra-arterial contrast-induced reactions is lower. The anaphylactoid reactions *do not* involve IgE antibody (thus, the reason for the term "anaphylact*oid*" reactions). Radiocontrast media appear to induce mediator release on the basis of some other property intrinsic to the contrast agent. The tonicity or ionic strength of the media seems particularly related to anaphylactoid reactions. With the availability of low ionic strength media, the incidence of reactions has been lower.

- The frequency of contrast media reactions is 2%-6% of procedures.
- The reaction does not involve IgE antibody.
- Nonionic or low osmolar contrast media cause fewer anaphylactoid reactions than standard contrast media.

The frequency of radiocontrast media reactions can be decreased with the use of low ionic strength media in patients with a history of asthma or atopy. Patients with a history of reaction to radiocontrast media who subsequently need radiographic contrast media procedures can be pretreated with a protocol of 50 mg oral prednisone every 6 hours for three doses, with the last dose 1 hour before the procedure. At the last dose, 50 mg of diphenhydramine or an equivalent H_1 antagonist is recommended. Some studies show that the addition of oral ephedrine can be beneficial. However, most studies show that the addition of an H_2 antagonist is unnecessary.

- Patients with a history of systemic reactions to radiocontrast media should be pretreated with systemic corticosteroids and an H_1 antagonist and should be offered nonionic contrast agents.

Mastocytosis

Systemic mastocytosis is a disorder of abnormal proliferation of mast cells. The skin, bone marrow, liver, spleen, lymph nodes, and gastrointestinal tract can be affected. The clinical manifestations vary but can include flushing, pruritus, urticaria, unexplained syncope, fatigue, and dyspepsia. Bone marrow biopsies with stains for mast cells (toluidine blue, Giemsa, or chloral acetate esterase) and immunochemical stains for tryptase are the most direct diagnostic studies. Fluorescence in situ hybridization and polymerase chain reaction may detect a clonal disorder of systemic mastocytosis, Fip1-like-platelet-derived growth factor receptor α-1. Serum levels of tryptase and urinary concentrations of histamine and histamine metabolites may be increased.

Treatment initially consists of antihistamines. Cromolyn sodium given orally can be beneficial, especially in patients with gastrointestinal symptoms. Corticosteroids should be considered in severe cases, and interferon is a promising investigational treatment.

Eosinophilia

Eosinophilia is idiopathic, secondary (reactive), or primary. Idiopathic hypereosinophilic syndrome is a well-defined entity. Secondary causes include the following: infectious (tissue-invasive parasitosis); drugs; toxins; inflammation; atopy and allergies (asthma); malignancy (lymphoma, Hodgkin lymphoma, cutaneous T-cell lymphoma, and metastatic cancer); collagen vascular disease (eosinophilic vasculitis); pulmonary (hypereosinophilic pneumonitis, and Löffler syndrome); and eosinophilic myalgia syndrome. The primary clonal and monoclonal disorders include acute leukemia (myeloid and lymphoid); chronic myeloid leukemia; myelodysplastic syndrome and chronic myelomonocytic leukemia; classical and atypical myeloproliferative disorders (systemic mastocytosis); and unclassified (chronic eosinophilic leukemia). The clinical diagnostic approach is to exclude secondary eosinophilic disorders; to evaluate bone marrow aspirates and biopsy specimens with genetic and molecular studies; and to perform tests to assess eosinophilia-mediated tissue injury (chest radiography, pulmonary function tests, echocardiography, and serum trypsin levels). The differential diagnosis of eosinophilia is given in Table 2-16.

The clinical manifestations include weight loss, muscle weakness, and cutaneous induration. The laboratory hallmark is peripheral and tissue eosinophilia. Follow-up studies show that many affected patients continue to have marked disability months and years after the acute illness. Although corticosteroids are used in the treatment of this disorder, there is no evidence that corticosteroid therapy alters long-term disability or mortality.

Hypereosinophilia syndrome is an idiopathic eosinophilic disorder characterized by an absolute eosinophil count of more than 1,500/μL (1.5×10^9/L); chronic course of 6 months or longer; organ involvement as manifested by eosinophilia-mediated tissue injury (cardiomyopathy, dermatitis, pneumonitis, sinusitis, gastrointestinal

tract inflammation, left or right ventricular apical thrombus, and stroke); and no other causes of eosinophilia. The syndrome typically affects persons in the third through sixth decades of life; women are affected more often than men. Symptoms include fatigue, cough, shortness of breath, or rash. Cardiac involvement in hypereosinophilia syndrome is especially significant: endomyocardial fibrosis, mural thrombi, and mitral and tricuspid incompetence can occur. The clinical syndrome is one of a restrictive cardiomyopathy with congestive heart failure. Echocardiography and endomyocardial biopsy are important diagnostic tests.

Hypereosinophilia syndrome is treated with prednisone, 1 mg/kg per day, alone or in combination with hydroxyurea. Second-line therapy is recombinant interferon-alfa.

Common Variable Immunodeficiency

Common variable immunodeficiency can affect persons of all ages, both males and females. It is not a hereditary disorder. Patients have recurrent infections and hypogammaglobulinemia. Recurrent pyogenic infections include chronic otitis media, chronic or recurrent sinusitis, pneumonia, and bronchiectasis.

Patients with common variable immunodeficiency often have autoimmune or gastrointestinal tract disturbances. About one-half of patients have chronic diarrhea and malabsorption. There may be steatorrhea, protein-losing enteropathy, ulcerative colitis, or Crohn disease. Other gastrointestinal tract problems associated with the disease are atrophic gastritis, pernicious anemia, giardiasis, and chronic active hepatitis. Pathologic changes in the gastrointestinal tract mucosa include loss of villi, nodular lymphoid hyperplasia, and diffuse lymphoid infiltration.

Autoimmune anemia, thrombocytopenia, or neutropenia is present in 10% to 50% of patients. Inflammatory arthritis and lymphoid interstitial pneumonia are other associated conditions. Also, patients have an increased risk of a malignancy developing, particularly a lymphoid malignancy such as non-Hodgkin lymphoma.

The diagnosis of common variable immunodeficiency should be considered in patients with recurrent pyogenic infections and hypogammaglobulinemia. Associated gastrointestinal or autoimmune disease and the exclusion of hereditary primary immunodeficiencies support the diagnosis. Treatment is with intravenous gamma globulin.

Terminal Complement Component Deficiencies

Patients with deficiency of the terminal complement component C5, C6, C7, or C8 have increased susceptibility to meningococcal infections. The terminal complement components form the membrane attack complex that causes cell lysis; hence, deficiency of one of these components results in defective microbial killing. The terminal component C9 participates in membrane pore formation but is not essential for complement-mediated cell lysis. Thus, the rare patients with a C9 deficiency have limited increased susceptibility to infections.

Terminal complement component deficiency should be suspected in patients with recurrent meningococcal disease, a family history of meningococcal disease, or systemic meningococcal infection or in those infected with an unusual serotype of meningococcus. Diagnosis is confirmed with assay of total hemolytic complement and measurement of individual complement components.

Allergy Pharmacy Review

Sansana D. Bontaveekul, PharmD, Todd M. Johnson, PharmD

Drug (trade name)	Toxic/adverse effects	Drug interactions	Comments
Bronchodilators	Palpitations, tachycardia, hypertension, arrhythmia, tremor, nervousness, headache, insomnia, GERD or pharyngitis	β-Blockers may inhibit bronchodilator effect in patients with asthma Tricyclic antidepressants and sympathomimetics may cause hypertension MAO inhibitors may cause tachycardia or agitation	Bronchodilators must be used cautiously for those with DM, cardiovascular disorders, hyperthyroidism, or seizure β-Blockers may precipitate asthma in asthmatics
Albuterol (Proventil HFA, Ventolin HFA, Vospire ER)			
Epinephrine (Primatene Mist)			
Formeterol (Foradil)	Palpitations, headache, tremor, nervousness		
Ipratropium (Atrovent)	Ipratropium may cause blurred vision & dry mouth		
Ipratropium & albuterol (Combivent)			
Isoetharine (Bronkosol)	Isoetharine may cause hypertension, tachycardia, and palpitations	Isoproterenol or epinephrine may sensitize myocardium to effects of general anesthetics

Drug (trade name)	Toxic/adverse effects	Drug interactions	Comments
First-generation antihistamines[*†] (continued)			
Diphenhydramine HCl (Benadryl) Hydroxyzine HCl (Atarax) Hydroxyzine pamoate (Vistaril) Promethazine HCl (Phenergan)	Cardiovascular effects are uncommon & usually limited to overdosage Promethazine may lower seizure threshold Adverse anticholinergic effects: dryness of mouth, nose, throat; dysuria; urinary retention; blurred vision; thickening of bronchial secretions		Antihistamines exert various degrees of antihistaminic, anticholinergic, antimuscarinic activities & are useful as sedatives, antiemetics, anti–motion sickness, antitussive, & anti-parkinsonism agents Unlabeled use: increased appetite, weight gain (cyproheptadine) Caution for patients with angle-closure glaucoma, prostatic hypertrophy, stenosing peptic ulcer, pyloroduodenal obstruction, bladder neck obstruction
Second-generation antihistamines[*‡]			
Cetirizine HCl (Zyrtec)	Nausea, dyspepsia, dry mouth, headache, drowsiness	No clinically important drug interactions have been reported in patients taking cetirizine concomitantly with azithromycin, erythromycin, or ketoconazole	Cetirizine is a carboxylic acid metabolite of hydroxyzine The increase in polarity of cetirizine may decrease its distribution in CNS; thus, reduced potential for CNS adverse effects compared with 1st-generation antihistamines; incidence of certain adverse CNS effects (somnolence) is higher in patients taking cetirizine than in those taking other 2nd-generation antihistamines
Desloratadine (Clarinex)		Although AUC of desloratadine increases with concomitant use of erythromycin or ketoconazole, no clinically important changes measured by ECG, laboratory evaluations, vital signs, adverse events	Desloratadine, fexofenadine, & loratadine are selective for peripheral H_1 receptors & less sedating than 1st-generation antihistamines Desloratadine is a major metabolite of loratadine Dosage adjustment is recommended in patients with renal and/or hepatic impairment (cetirizine, desloratadine, loratadine, and fexofenadine—renal impairment only)

Allergy Pharmacy Review (continued)

Drug (trade name)	Toxic/adverse effects	Drug interactions	Comments
Second-generation antihistamines*‡ (continued)			
Fexofenadine HCl (Allegra)		Fexofenadine is active metabolite of terfenadine, but does not have cardiotoxic & drug interaction potentials of terfenadine; no clinically important adverse effects or changes in QT_c interval reported with concomitant use of erythromycin or ketoconazole despite increases in AUC and peak plasma concentration of fexofenadine	
Loratadine (Claritin, Claritin Reditabs, Tavist ND, Alavert)		Although AUC of loratadine increases with concomitant use of erythromycin or ketoconazole, no clinically important changes are indicated by ECG, laboratory evaluation, vital signs, adverse effects	
Nasal solution products	Bitter/bad taste, nasal burning/stinging/irritation, pharyngitis, sneezing	No clinically important drug interactions known	Histamine H_1 receptor antagonists
Azelastine HCl (Astelin)	Somnolence & headache can occur		Mast cell stabilizer; begin therapy before & continue at regular intervals during allergenic exposure
Cromolyn sodium (Nasalcrom)			
Histamine H_1 receptor antagonist ophthalmic products§			
Emedastine difumarate (Emadine) 0.05% ophthalmic solution	Transient eye burning/stinging, blurred vision, dry eyes, foreign body sensation, headache, bitter taste	Benzalkonium (preservative) may be absorbed by soft contact lens; wait at least 10 min after applying drug before inserting contact lenses	
Mast-cell stabilizer ophthalmic products§			
Amlexanox (Aphthasol)	Same as above		
Cromolyn sodium (Crolom) 4% ophthalmic solution	Same as above	Same as above	
Lodoxamide tromethamine (Alomide) 0.1% ophthalmic solution			
Pemirolast potassium (Alamast) 0.1% ophthalmic solution	Preservative in pemirolast is lauralkonium Cl; wait at least 10 min after applying drug before inserting contact lenses		
Nedocromil sodium (Alocril) 2% ophthalmic solution	Same as above	Same as above	

Allergy Pharmacy Review (continued)

Drug (trade name)	Toxic/adverse effects	Drug interactions	Comments
Histamine H_1 receptor antagonists and mast-cell stabilizer ophthalmic products§			
Azelastine HCl (Optivar) 0.5 mg/mL ophthalmic solution			
Ketotifen fumarate (Zaditor) 0.025% ophthalmic solution			
Olopatadine HCl (Patanol) 0.1% ophthalmic solution			

AUC, area under curve; CNS, central nervous system; DM, diabetes mellitus; ECG, electrocardiography; GERD, gastroesophageal reflux disease; MAO, monoamine oxidase.
*Histamine H_1 receptor antagonists.
†Oral or parenteral products.
‡Available in oral products only.
§To prevent contamination of products, care should be taken not to touch eyelids or surrounding areas with dropper tip of bottle.

Physical Examination

Even given all the recent technological advances in medical testing and imaging, it is imperative that physicians be able to accurately assess patients at the bedside. This chapter outlines the salient features of a thorough physical examination.

Jugular Venous Pressure

Jugular venous pressure indicates the pressure of the right atrium (Fig. 3-1). Changes in amplitude of waves may indicate structural disease and rhythm changes. The jugular venous pressure is normally 6 to 8 cm H_2O and is best evaluated with the patient supine at an angle of 45° or more. The right atrium lies about 5±1 cm below the sternal angle, and thus the estimated jugular venous pressure is equal to the height of the jugular venous pressure above the sternal angle + 5 cm. The normal waves profile contains an *a* deflection, which reflects atrial contraction; *c* deflection, closure of tricuspid valve; followed by the *x* descent, downward motion of right ventricle; and *v* deflection, atrial filling deflection while the tricuspid valve is closed followed by the *y* descent, representing ventricular filling as the tricuspid valve opens.

- Normal jugular venous pressure is 6-8 cm H_2O.
- Normal waves are *a*, atrial contraction; *c*, closure of tricuspid valve; and *v*, atrial filling.
- *x* descent, downward motion of right ventricle.
- *y* descent, early right ventricular filling phase.

The examiner should distinguish jugular venous pressure from carotid pulsations: jugular venous pressure varies with respiration, is nonpalpable with gentle pressure, and can be eliminated by obstructing pressure at the diastolic end. When the pressure is increased, consideration should be given to not only biventricular failure but also constrictive pericarditis, pericardial tamponade, cor pulmonale (especially pulmonary embolus), and superior vena cava syndrome.

Abnormalities of the waves indicate various conditions, as follows:

1. Increased jugular venous pressure, increased pressure indicating possible fluid overload. Common in congestive heart failure
2. Large *a* wave: tricuspid stenosis, right ventricular hypertrophy, pulmonary hypertension (i.e., increased right ventricular end-diastolic pressure)
3. Cannon *a* wave: atria contracting intermittently against a closed atrioventricular valve (atrioventricular dissociation)
4. Rapid *x* + *y* descent: constrictive pericarditis
5. Kussmaul sign: venous filling with inspiration, pericardial tamponade, or constriction. Paradoxical increase in venous pressure with inspiration occurs in pericardial tamponade, constriction, and right ventricular failure
6. Large, fused *cv* wave: tricuspid regurgitation

- Increased jugular venous pressure increases the likelihood of congestive heart failure fourfold.
- Increased jugular venous pressure can be associated with pulmonary embolus, superior vena cava syndrome, tamponade, and constriction.
- Abnormalities of waves:

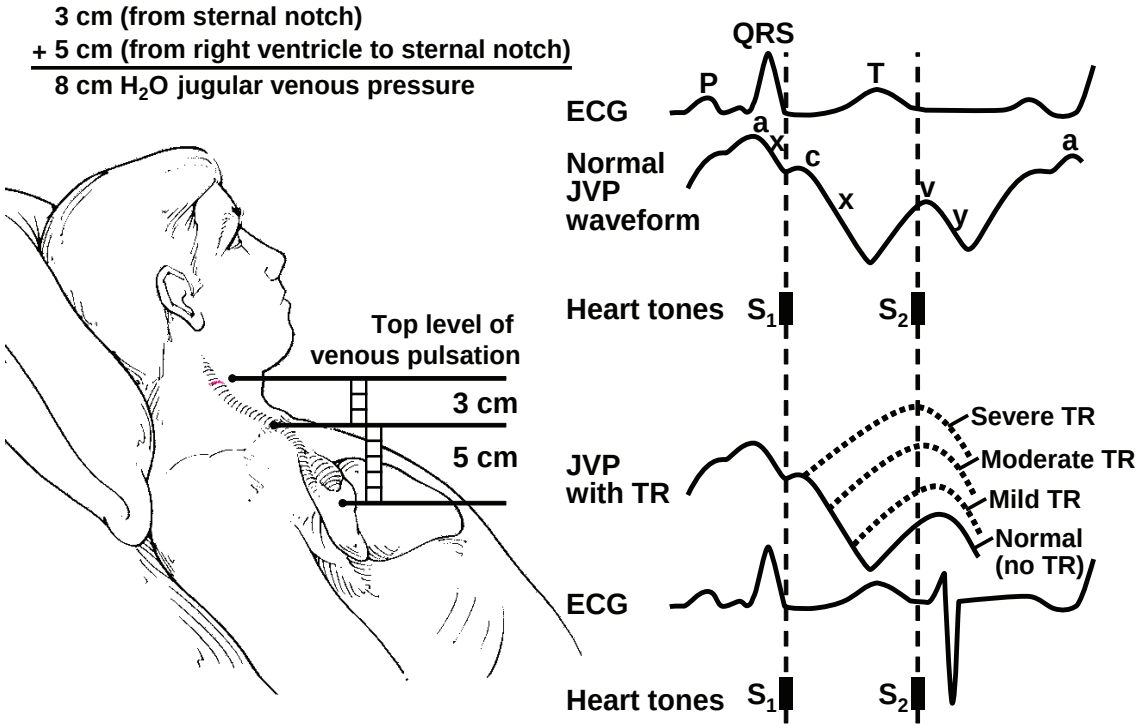

Fig. 3-1. Evaluation of jugular venous pressure (JVP). ECG, electrocardiogram; TR, tricuspid regurgitation.

large *a* wave: tricuspid stenosis, right ventricular hypertrophy, pulmonary hypertension
cannon *a* wave: atria contracting against a closed atrioventricular valve (atrioventricular dissociation)
rapid *x* + *y* descent: constrictive pericarditis

Arterial Pulse

Palpation of the radial pulse is useful for rate; the brachial or carotid pulse is checked for contour. Tardus is the timing and rate of rise of upstroke, and parvus is the volume. In hypertension, a radial-femoral delay (checking radial and femoral pulses simultaneously) may indicate accompanying aortic coarctation.

Abnormalities of the arterial pulse and their indicated conditions are as follows (Fig. 3-2):

1. Parvus and tardus: aortic stenosis
2. Parvus only: low output, cardiomyopathy
3. Bounding: aortic regurgitation or atrioventricular fistulas
4. Bifid (two systolic peaks): hypertrophic obstructive cardiomyopathy (from midsystolic obstruction)
5. Bisferiens (two systolic peaks, occurs when a large volume is ejected rapidly, and a distinct systolic dip): aortic regurgitation
6. Dicrotic (a systolic peak followed by diastolic pulse wave): left ventricular failure with hypotension, low output, and increased peripheral resistance
7. Pulsus paradoxus (exaggerated inspiratory decrease [>10 mm Hg] in pulse pressure): suggestive of tamponade
8. Pulsus alternans (alternating strong and weak pulse): severe depression of left ventricular function

Apical Impulse

This is normally a discrete area of localized contraction. It is usually maximal at the fifth intercostal space, midclavicular line.

Abnormalities of the apical impulse and their indicated conditions are as follows:

1. Apex displaced (laterally or downward or both), impulse poor and diffuse: cardiomyopathy
2. Sustained, but not necessarily displaced: left ventricular hypertrophy, aortic stenosis, often with large *a* wave
3. Trifid (or multifid): hypertrophic cardiomyopathy
4. Hyperdynamic, descended, and diffuse with rapid filling wave: mitral regurgitation, aortic regurgitation
5. Tapping quality, localized: mitral stenosis

- Abnormalities of apical impulse:
  Apex displaced, impulse poor and diffuse: cardiomyopathy
  Trifid: hypertrophic cardiomyopathy
  Tapping quality, localized: mitral stenosis

Additional Cardiac Palpation

A palpable aortic (A_2) component at the right upper sternum suggests a dilated aorta (aneurysm, dissection, severe aortic regurgitation, poststenotic dilatation in aortic stenosis, hypertension).

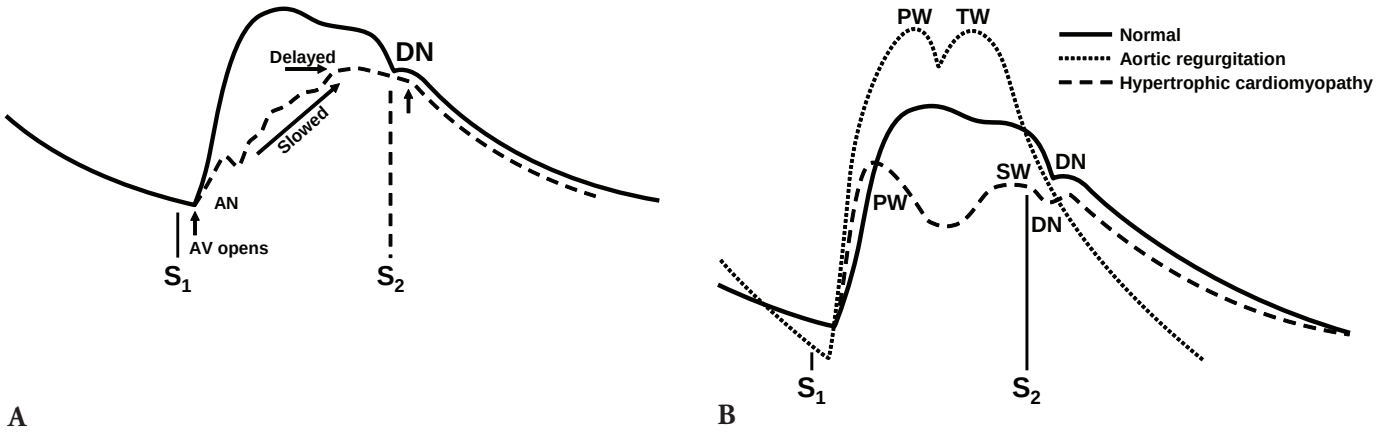

Fig. 3-2. Variations in arterial pulse. *A*, Solid line indicates normal contour. Dotted line indicates typical contour of calcific aortic stenosis (slowed and delayed). S_2 is delayed in aortic stenosis as ejection time prolongs. AN, anacrotic notch; AV, aortic valve; DN, dicrotic notch. *B*, Solid line indicates normal contour. Dotted line indicates aortic regurgitation (bisferiens pulse, rapid upstroke, percussion wave [PW], tidal wave [TW], rapid runoff). Dashed line indicates hypertrophic cardiomyopathy (bifid pulse, also known as "spike and dome," rapid PW, then often a secondary wave [SW]).

Severe tricuspid regurgitation may result in a pulsatile liver palpable in the right epigastrium. One should look for accompanying hepatojugular reflux, that is, distention of the external jugular vein 3 to 4 beats after compression of the liver. In patients with severe emphysema, the apical impulse rotates medially and may be appreciated in the epigastrium.

Right ventricular hypertrophy results in sustained lift, best appreciated in the fourth intercostal space 2 to 3 cm left parasternally. Diastolic overload (atrial septal defect, anomalous pulmonary venous return) results in a vigorous outward and upward motion but may not be sustained. In significant pulmonary hypertension, the pulmonic (P_2) component may be palpable (this may be physiologic in slender people with small anteroposterior diameter).

- Pressure overload usually results in sustained, lateralized impulses (left more than right ventricle).
- Volume overload (regurgitant lesions, atrial septal defect) usually is appreciated as dynamic and forceful but not sustained impulses.
- Palpable A_2 or P_2 components are pathologic in adults with average body habitus.

Thrills

These indicate turbulent flow (such as aortic stenosis, ventricular septal defect).

Heart Sounds

The art of cardiac auscultation is best understood by keeping in mind the relationship of the cardiac cycle (Fig. 3-3).

First Heart Sound

The first heart sound consists of audible mitral valve closure followed shortly by tricuspid valve closure and normally silent aortic and pulmonic opening. A loud first heart sound occurs with, for example, mitral stenosis and short PR intervals because the mitral valve is wide open when the left ventricle begins to contract and then slaps shut (assumes some preserved pliability of the mitral valve leaflets). The first heart sound also is augmented in hypercontractile states (fever, exercise, thyrotoxicosis, pheochromocytomas, anxiety, anemia). The intensity of the first sound is *decreased* if the mitral valve is heavily calcified and immobile (severe mitral stenosis) and with a long PR interval (occurs classically with acute rheumatic fever), poor left ventricular function, and rapid diastolic filling leading to premature mitral valve closure, as in aortic regurgitation.

- Loud first heart sound: short PR interval, mitral stenosis, hypercontractile states.
- Decreased intensity of first heart sound: mitral valve heavily calcified, long PR interval, aortic regurgitation.

Second Heart Sound

The second heart sound consists of aortic closure followed by pulmonary closure. Intensity of both is increased by hypertension (loud P_2 with pulmonary hypertension, P_2 then audible at apex). Intensity is decreased with heavily calcified valves (severe aortic stenosis). Normally, the second sound widens on inspiration and narrows on expiration as a result of the relative increase in blood return to the right heart during inspiration and greater capacitance of the lungs, such that A_2 moves closer to S_1 and P_2 moves farther away (Fig. 3-4). The sequence is reversed during expiration.

- The intensity of the second heart sound is increased by hypertension.
- The intensity is decreased with heavily calcified valves.

The interplay of multiple factors can affect the timing of the closure of semilunar values: electrical activation, duration of ventricular ejection, gradient across semilunar valves, and elastic recoil properties of the great vessels.

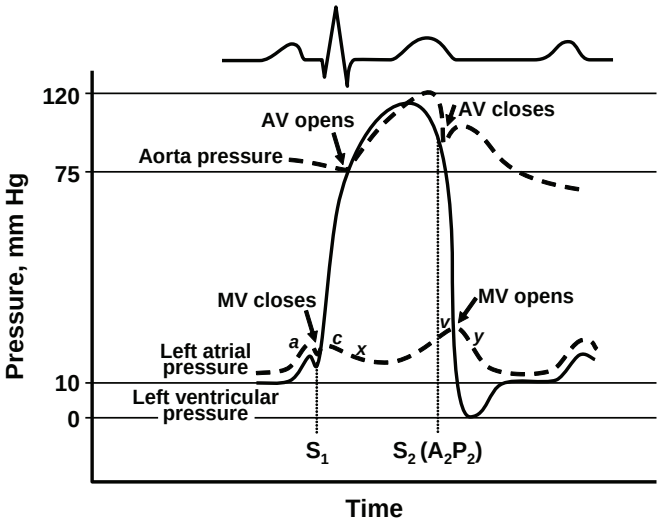

Fig. 3-3. The normal cardiac cycle. AV, aortic valve; MV, mitral valve.

Common conditions leading to abnormalities of splitting of the second heart sound and their indicated conditions are as follows:

1. Physiologic splitting: normal splitting due to respiratory variation of blood flow; on inspiration, A moves to the "left" closer to S_1, and P moves to the "right" away from S_1
2. Fixed split, particularly during expiration: atrial septal defect, widest split occurs with a combination of atrial septal defect and pulmonary stenosis
3. Paradoxic split (caused by delay in aortic closure so it closes after pulmonary valve): left bundle branch block
4. Persistent splitting: occurs during right bundle branch block. A_2 and P_2 are widely separated because of delayed electromechanical activation of the right ventricle; this effect is accentuated further by inspiration

- Abnormalities of splitting of second heart sound:
  Fixed split: atrial septal defect
  Paradoxic split: left bundle branch block
  Persistently split: right bundle branch block
- Mnemonic for S_1-S_2 (right ventricular-left ventricular sequence): "Many Things Are Possible" (MTAP; S_1 = mitral opens before tricuspid; S_2 = aortic closes before pulmonic).

Third Heart Sound

The third heart sound occurs in early diastole, coinciding with maximal early diastolic left ventricular filling. Its origin is debated, but it may be caused by tensing of the chordae as the blood distends the left ventricle during diastole. It is a low-pitched sound best heard with the bell of the stethoscope. It is normally heard in young people (younger than 30 years—a normal variant due to excellent ventricular distensibility) and pathologically in heart failure. In adults, it is associated with volume load on the left ventricle, such as aortic regurgitation, mitral regurgitation, and cardiomyopathy.

- Third heart sound is a normal variant in young adults.
- Third heart sound in older adults is associated with volume load on the left ventricle (aortic regurgitation, mitral regurgitation, cardiomyopathy).

Fourth Heart Sound

Like the third heart sound, this is a low-pitched sound best heard with the bell of the stethoscope, loudest at the apex. This occurs with the atrial kick as blood is forced into the left ventricle by atrial contraction when the left ventricle is stiff and noncompliant. Examples, such as in aortic stenosis, systemic hypertension, hypertrophic cardiomyopathy, and ischemia, often present with the generation of S_4. It cannot occur with loss of atrial contraction (i.e., atrial fibrillation).

- Fourth heart sound occurs in aortic stenosis, systemic hypertension, hypertrophic cardiomyopathy, and ischemia.
- It cannot occur with loss of atrial contraction (i.e., atrial fibrillation).

Opening Snap

Opening snap is an early diastolic sound caused by opening of the pathologic mitral valve. It is virtually always caused by mitral stenosis, and the interval from the second heart sound to the opening snap helps determine the severity. With severe mitral stenosis, the left atrial pressure is very high and thus the valve opens earlier, and the interval is less than 60 m/s.

- Opening snap is virtually always caused by mitral stenosis.

Murmurs

The specific murmurs are discussed with the individual valvular lesions described later in this chapter, but some broad guidelines follow here.

A systolic ejection murmur begins after the first heart sound and ends before the second sound. It may have a diamond-shaped quality with crescendo and decrescendo components, but, in general, the more severe the obstruction (the narrower the orifice), the louder the murmur and the later the peak of the murmur. It may be preceded by an ejection click, if the pliability of the valve is preserved. Echocardiography may be required if there is a diastolic murmur or

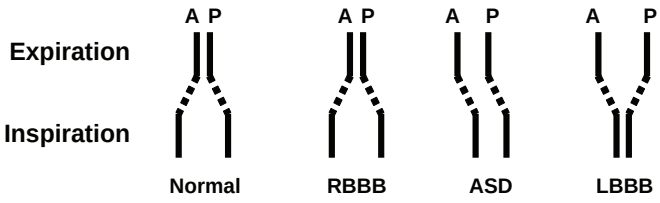

Fig. 3-4. Effects of respiration and conduction on the second heart sound. A, aortic closure; ASD, atrial septal defect; LBBB, left bundle branch block; P, pulmonary closure; RBBB, right bundle branch block.

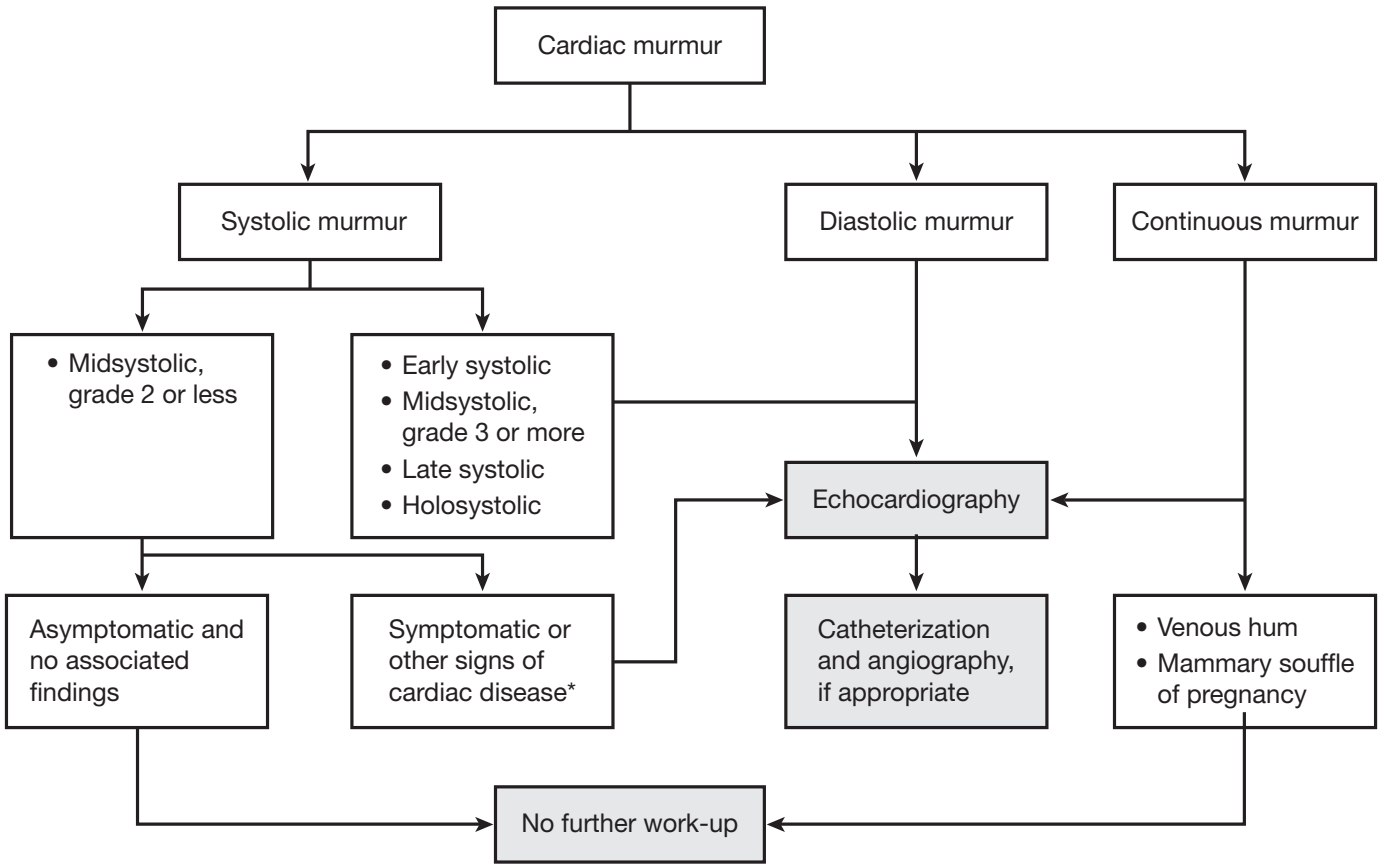

Fig. 3-5. Recommendations for evaluating heart murmurs. *If electrocardiography or chest radiography has been performed and the results are abnormal, echocardiography is recommended. (From Bonow RO, Carabello BA, Chatterjee K, de Leon AC Jr, Faxon DP, Freed MD, et al. ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Writing Committee to Revise the 1998 Guidelines for the Management of Patients With Valvular Heart Disease]. Circulation. 2006;114:84-231. Used with permission.)

a systolic murmur of grade 3 or higher or if there are other signs or symptoms of cardiac disease (Fig. 3-5).

- For systolic ejection murmur, in general, the more severe the obstruction, the louder the murmur and the later the peak.

A holosystolic murmur occurs when blood goes from a high-pressure to a low-pressure system (mitral regurgitation, ventricular septal defect). It engulfs the first and second heart sounds.

- A holosystolic murmur occurs with mitral regurgitation and ventricular septal defect.

Maneuvers That Alter Cardiac Murmurs

Inspiration increases venous return and thus increases right-sided sounds (S_3 and S_4) and murmur, tricuspid and pulmonary stenosis, and tricuspid and pulmonary regurgitation. *Valsalva* increases intrathoracic pressure, inhibiting venous return and thus decreasing preload. Most cardiac murmurs and sounds diminish in intensity during Valsalva maneuver because of decreased ventricular filling and decreased cardiac output (except hypertrophic obstructive cardiomyopathy, which increases because of dynamic left ventricular outflow obstruction accentuated by decreased preload). *Handgrip* increases cardiac output and systemic arterial pressure. A change in *posture* from supine to upright causes a decrease in venous return; therefore, stroke volume decreases, and this decrease causes a reflex increase in heart rate and peripheral resistance. *Squatting* and the *Valsalva maneuver* have opposite hemodynamic effects. Squatting increases peripheral resistance and increases venous return. The effects of maneuvers are shown in Table 3-1.

- Maneuvers that alter cardiac murmurs:
  - Inspiration
  - Valsalva
  - Handgrip
  - Change in posture
  - Squatting

Table 3-1 Effects of Physical Maneuvers and Other Factors on Valvular Diseases

Maneuver or factor	Result	Effect on murmur			
		Mitral regurgitation	MVP	Aortic stenosis	HOCM
Amyl nitrite	↓ afterload	↓	↑/0	↑	↑
Valsalva	↓ preload	↓	↑	↓	↑
Handgrip	↑ afterload	↑	↓/0	↓	↓
Post-PVC	↑ contractility ↓ afterload	=	↓	↑	↑*

HOCM, hypertrophic obstructive cardiomyopathy; MVP, mitral valve prolapse; PVC, premature ventricular complex.
*Although the murmur increases, the peripheral pulse decreases because of the increase in outflow obstruction.

Valvular Heart Disease

Aortic Stenosis

The pathophysiologic effect of aortic stenosis on the heart is that of a pressure load, leading to pressure hypertrophy of the left ventricle. Although cases of supravalvular and subvalvular aortic stenosis are appreciated, these are beyond the scope of this review. The vast majority of cases of aortic stenosis are due to valvular stenosis.

Types

The *congenital bicuspid* type of aortic stenosis occurs in 2% of the population. It may be associated with obstruction in infancy through early adulthood. It is the most common cause of aortic stenosis in adults younger than 55 years. Frequently, the valve is still pliable, and auscultation is thus different from that of degenerative aortic valve disease. An ejection click often precedes the systolic murmur. The earlier the click (i.e., the closer to the first sound), the more severe the stenosis. A_2 is delayed with progressive stenosis, and when severe there may be paradoxic splitting of the second sound. The lesion may be associated with coarctation of the aorta (10%). The diagnosis usually can be made successfully with two-dimensional and Doppler echocardiography without the need for cardiac catheterization in young people.

- Congenital bicuspid valvular aortic stenosis occurs in 2% of the population.
- It is the most common cause of aortic stenosis in adults younger than 55 years.
- An ejection click often precedes the systolic murmur.
- The earlier the click (closer to first heart sound), the more severe the stenosis.
- A_2 is delayed with progressive stenosis; when severe, there may be paradoxic splitting of the second sound.

Degenerative aortic valve disease is the most common cause of aortic stenosis in adults older than 55 years. The valve is tricuspid and calcified. When calcification is extensive, A_2 becomes inaudible.

- Degenerative aortic valve disease is the most common cause of aortic stenosis in adults older than 55 years.
- When calcification is extensive, A_2 becomes inaudible.

The *rheumatic* type of aortic valve disease is less common. It is associated with thickening and fusion of the aortic cusps at the commissures. It always occurs with a rheumatic mitral valve, although significant mitral stenosis or regurgitation may not always be evident. It usually occurs in adulthood (age 40-60 years), usually 15±5 years after acute rheumatic fever.

- The rheumatic type of aortic valve disease is a less common cause of valvular aortic stenosis.
- It usually occurs at 40-60 years of age.

Symptoms

The classic symptoms of the valvular type of aortic stenosis (regardless of type) include exertional dyspnea, syncope, angina, and sudden cardiac death. The onset of symptoms is an ominous sign. The presence of angina does not necessarily indicate coexisting coronary disease; rather, it is related to increased left ventricular filling pressure causing subendocardial ischemia.

- Symptoms of aortic stenosis: exertional dyspnea, syncope, angina, and sudden cardiac death.
- Angina does not necessarily indicate coexisting coronary disease.

Physical Examination

The pulse is parvus and tardus in hemodynamically significant aortic stenosis. The left ventricular impulse is localized, lateralized, and sustained. Arterial thrills may be palpable at the carotid, suprasternal notch, second intercostal space, or left and right sternal borders. A fourth heart sound may be present, both palpable and audible. A_2 is diminished and delayed and may even become absent with decreasing pliability of the aortic cusps. The ejection systolic murmur becomes louder and peaks later with increasing severity, radiating to the carotid arteries and the apex.

- The pulse is parvus (small) and tardus (delayed) in hemody-

namically significant aortic stenosis.
- The ejection systolic murmur becomes louder with increasing severity.
- A_2 is diminished, delayed, or absent with progressive aortic stenosis.

Diagnosis

Electrocardiography in aortic stenosis may show left ventricular hypertrophy (not a sensitive index; echocardiography is better), but the results often are normal in young patients. Left bundle branch block is common, and in later stages of the condition conduction abnormalities may develop (e.g., complete heart block) if the calcium impinges on the conducting system. On chest radiography, the heart size is normal, until left ventricular remodeling occurs in the late stages, even when the stenosis is severe. The aortic root may show poststenotic dilatation. In degenerative aortic valve disease, calcium in the valve leaflets may be seen, especially on a penetrated lateral view.

- Electrocardiography is often normal in young patients.
- Left bundle branch block is common on electrocardiography.
- The aortic root may show poststenotic dilatation on chest radiography.

Differential diagnoses include 1) hypertrophic cardiomyopathy (note different carotid upstroke and change in murmur with maneuvers) and 2) mitral regurgitation (murmur may radiate anteriorly and upward, particularly if there is rupture of a posterior mitral valve leaflet; there is no radiation to the carotid arteries).

Aortic stenosis can be diagnosed with bedside physical examination. The most important physical finding is the parvus and tardus pulse. However, the degree of aortic stenosis can be difficult to determine, particularly in older patients. Doppler echocardiography is useful for assessing gradients and correlates well with cardiac catheterization. Severe aortic stenosis is present when the mean Doppler gradient is more than 50 mm Hg and the valve area is less than 0.75 cm^2. Progression to symptoms can be insidious. Progression is about 0.12 cm^2 per year. With onset of symptoms, survival is 1 to 3 years (Fig. 3-6).

- Aortic stenosis can be diagnosed with bedside physical examination.
- The most important physical finding is the parvus and tardus pulse.
- Doppler echocardiography is useful for diagnosis.
- Severe aortic stenosis: gradient is >50 mm Hg and valve area is <0.75 cm^2.

Treatment

All patients with aortic stenosis should receive antibiotic prophylaxis for bacterial endocarditis. They should be educated about symptoms that may develop and should promptly report any evidence of symptoms: dyspnea, chest pain, angina, syncope, or congestive heart failure (Table 3-2). Aortic valve replacement is the only effective treatment for patients with severe obstruction.

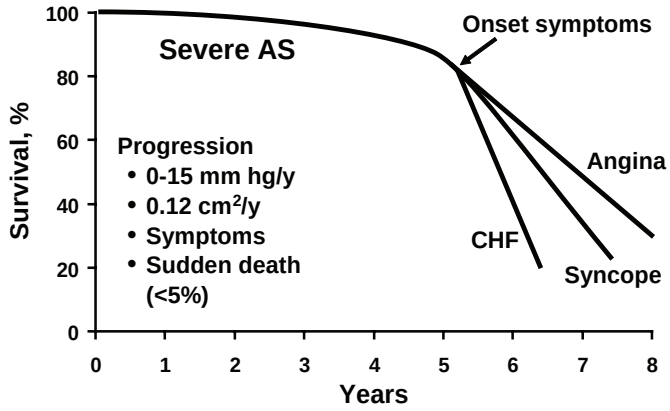

Fig. 3-6. Natural history of aortic stenosis (AS). CHF, congestive heart failure. (Modified from Ross J Jr, Braunwald E. Aortic stenosis. Circulation. 1968;37 Suppl 5:61-7. Used with permission.)

- Treatment for aortic stenosis is directed at prevention of subacute bacterial endocarditis and valve replacement with onset of symptoms.

Aortic Regurgitation

The pathophysiology of aortic regurgitation is that of volume and pressure overload on the left ventricle, leading to hypertrophy and dilatation. The cause can be related to either the aortic root or aortic valve and the condition can be acute or chronic (Table 3-3).

Valvular

Causes of valvular aortic regurgitation include 1) congenital bicuspid valve, 2) rheumatic fever, 3) endocarditis, 4) degenerative aortic valve disease, 5) seronegative arthritis, 6) ankylosing spondylitis, and 7) rheumatoid arthritis.

Aortic Root Dilatation

Various conditions have been associated with aortic root dilatation. Marfan syndrome can be associated with progressive dilatation of the aortic root and sinuses (so-called cystic medial necrosis). Prophylactic β-adrenergic blocker therapy is effective for slowing the rate of aortic dilatation and reducing the development of aortic complications in some patients with Marfan syndrome. When the aortic root reaches 5 to 5.5 cm or more in diameter, it should be replaced. Syphilis is an uncommon cause of aortic regurgitation and usually causes aortic root dilatation above the sinuses (syphilis spares the sinuses). It should be remembered that syphilis is associated with calcium in the aortic root on chest radiography. Age is also a related factor. With advancing age, the aorta dilates; hypertension also tends to accelerate this process. Acute aortic regurgitation may be associated with an aortic dissection.

- Marfan syndrome can be associated with aortic root dilatation.
- Hypertension is a common cause of (usually mild) aortic regurgitation.
- Syphilis is an uncommon cause of aortic regurgitation.

Table 3-2 Quantitation of the Severity of Aortic Stenosis and Treatment Guidelines

Severity	AVA, cm^2	AVA index, cm^2/m^2	Gradient, mm Hg	Follow-up or treatment
Normal	3.0-4.0		<10	
Mild	>1.5	>0.8	<25	SBE prophylaxis Echo every 5 y
Moderate	1.0-1.5	0.5-0.8	25-50	Monitor for symptoms Echo every 1-2 y
Severe	<1.0	<0.5	>50	Symptoms: operate No symptoms: echo every 6-12 mo

AVA, aortic valve area; echo, echocardiography; SBE, subacute bacterial endocarditis.

Data from Bonow RO, Carabello B, de Leon AC Jr, Edmunds LH Jr, Fedderly BJ, Freed MD, et al. ACC/AHA guidelines for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee on Management of Patients With Valvular Heart Disease]. J Am Coll Cardiol. 1998;32:1486-588.

Table 3-3 Aortic Regurgitation: Symptoms and Findings on Examination

	Acute	Chronic
Symptoms	Pulmonary edema Shock Arrhythmia Chest pain Dissection, RCA infarct	Dyspnea Fatigue Exercise intolerance Night sweats Palpitations
Examination	Faint, short murmur	Peripheral pulses Quincke and Duroziez signs, pistol-shot pulse Enlarged, diffuse, hyperdynamic LV Murmur LSB—valve etiology RSB—root etiology
Chest radiography	Wide mediastinum Pulmonary edema	Enlarged heart Enlarged aorta
Electrocardiography	Low voltage (if pericardial effusion) ST elevation II, III, F (if aortic dissection into RCA)	LVH

LSB, left sternal border; LV, left ventricle; LVH, left ventricular hypertrophy; RCA, right coronary artery; RSB, right sternal border.

Symptoms

The symptoms of acute aortic regurgitation are extreme: pulmonary edema, shock, and, often, chest pain (in the setting of aortic dissection). The symptoms of chronic aortic regurgitation include fatigue, dyspnea, palpitations, and exertional angina.

Physical Examination

With severe aortic regurgitation, several physical signs have been reported. A bounding, rapidly collapsing Corrigan pulse resulting from wide pulse pressure is found. A bisferiens pulse may be present. Other findings are de Musset head nodding, Duroziez sign (systolic and diastolic ["to-and-fro"] murmur of gentle compression with stethoscope) over the femoral artery, and Quincke sign (pulsatile capillary nail bed). Müller sign (systolic pulsations of the uvula) is often noted. The left ventricular impulse is diffuse and hyperdynamic, and the apex beat is often displaced downward. A diastolic decrescendo murmur is heard at either the left or the right sternal border, and the second heart sound may be paradoxically split because of increased left ventricular volume.

The duration of the murmur is related to the rate of pressure equilibration between the aorta and the left ventricle. Mild aortic regurgitation with physiologic diastolic pressures results in a holodiastolic murmur. The shorter the murmur, the faster the pressure equilibration, the more severe the aortic regurgitation, or the higher the left ventricular end-diastolic pressure. The loudness of the murmur does not correlate with the severity of aortic regurgitation, particularly in acute aortic regurgitation (such as with dissection). A systolic flow murmur is common, because of the increased ejection volume. It does not necessarily indicate coexistent structural aortic stenosis.

- Findings indicative of aortic regurgitation: bounding, rapidly collapsing Corrigan pulse, diastolic decrescendo murmur, and a second heart sound that may be paradoxically split.
- The duration, but not the loudness, of the murmur, is related to the severity of the aortic regurgitation (shorter is more severe).

Diagnosis

Although the diagnosis of aortic regurgitation can be made at bedside clinical examination, it can be missed if a patient with acute aortic regurgitation presents with little or no murmur. Electrocardiography often shows left ventricular hypertrophy. Echocardiography is best suited to gather the important functional and hemodynamic data needed to make management decisions in patients with aortic regurgitation.

Because aortic regurgitation has a long, silent, well-compensated natural history, key factors should be routinely followed with echocardiography: left ventricular size, aortic root size and morphology, valve morphology, left ventricular function (ejection fraction).

Chest radiography shows an enlarged cardiac shadow and prominence of the left ventricular enlargement in a leftward and

Table 3-4 Natural History of Severe Aortic Regurgitation

ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 1998 Guidelines for the Management of Patients With Valvular Heart Disease). Circulation. 2006;114:84-231. Used with permission.

inferior pattern. The aorta also may be enlarged, especially in Marfan syndrome.

Table 3-4 outlines the natural history of severe aortic regurgitation.

- Electrocardiography may show left ventricular hypertrophy.
- Echocardiography is useful to confirm diagnosis and guide therapy.

Treatment

Acute severe aortic regurgitation is a surgical emergency. As a bridge to operation, nitroprusside or inotropic agents may be considered to augment cardiac output. An intra-aortic balloon pump is contraindicated.

Chronic aortic regurgitation is a combined volume and pressure overload on the left ventricle. The left ventricle compensates by dilating and increasing compliance. Hence, patients with aortic regurgitation may remain asymptomatic for decades. The development of symptoms, however, usually reflects left ventricular dysfunction, and survival is limited unless surgical intervention is prompt. Medical management, such as an angiotensin-converting enzyme inhibitor or nifedipine, has been shown to slow ventricular dilatation in patients with severe aortic regurgitation and may help to delay operation. However, compensation cannot be maintained indefinitely and eventually left ventricular filling pressure increases, coronary flow reserve diminishes, and left ventricular dysfunction develops insidiously. Angina in the absence of epicardial coronary stenosis may be present. Asymptomatic dysfunction may develop in a subset of patients. In an attempt to operate before left ventricular dysfunction develops, several factors have been suggested: a systolic dimension more than 55 mm, a diastolic dimension more than 75 mm, or an ejection fraction less than 50%. Asymptomatic patients with dilated left ventricles need to be followed carefully; if there is evidence of resting left ventricular systolic dysfunction, progressive diastolic dysfunction, or rapidly progressive left ventricular dilatation, operation should be performed. The possibility for valve preservation (repair vs. replacement) may favor earlier operation before left ventricular dilatation has occurred.

- Acute aortic regurgitation is a surgical emergency.
- Patients with aortic regurgitation can be asymptomatic for several years.
- If symptoms develop, survival is limited unless surgical intervention is prompt.
- If ejection fraction decreases below normal, operation is needed.

Mitral Stenosis

Mitral stenosis is obstructive to the flow of blood from the left atrium to the left ventricle, preventing proper diastolic filling and leading to pulmonary congestion. Mitral stenosis is almost always due to rheumatic heart disease causing leaflet thickening with fusion of the commissures and later calcification.

Symptoms

Symptoms of mitral stenosis do not usually develop for decades after rheumatic fever. The murmur of mitral stenosis is apparent on physical examination about 10 years after rheumatic fever. Then, in another 10 years, symptoms develop, usually dyspnea and later orthopnea with paroxysmal nocturnal dyspnea, which can be insidious. Atrial fibrillation often causes considerable deterioration of clinical status. Hemoptysis and pulmonary hypertension with signs of right-sided failure (i.e., ascites and peripheral edema) are late manifestations. Systemic emboli also may result from atrial fibrillation (about 20% without anticoagulation).

- Mitral stenosis is almost always due to rheumatic heart disease.
- Symptoms do not develop for decades after mitral stenosis is found on physical examination.
- Symptoms: dyspnea, orthopnea with paroxysmal nocturnal dyspnea.
- Atrial fibrillation causes considerable deterioration of clinical status.

Physical Examination

The first heart sound in mitral stenosis is loud. The shorter the interval from the second heart sound (A_2) to the opening snap, the more severe the mitral stenosis. An opening snap occurs only with a pliable valve, and it disappears when the valve calcifies. The stenosis is mild if this interval is more than 90 ms, moderate if it is 80 ms, and severe if it is less than 60 ms. The diastolic murmur is a low-pitched, holodiastolic rumble, heard best at the apex with the bell of the stethoscope. The murmur may have presystolic accentuation if sinus rhythm is present. Right ventricular lift and increased P_2 are associated with pulmonary hypertension.

- Physical examination in mitral stenosis:
  Loud first heart sound
  The shorter the interval from A_2 to the opening snap, the more severe the stenosis

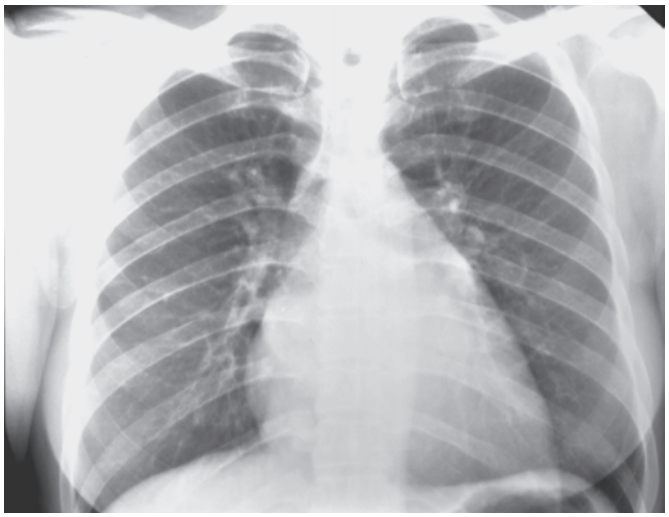

Fig. 3-7. Chest radiograph from a patient with severe mitral stenosis, showing a typical straight left heart border, prominent pulmonary artery, large left atrium, right ventricular contour, and pulmonary venous hypertension.

Diastolic murmur is a low-pitched holodiastolic rumble
The longer the murmur, the more severe the stenosis

Diagnosis

Electrocardiography shows P mitrale and later right ventricular hypertrophy. Chest radiography (Fig. 3-7) shows straightening of the left heart border with a large left atrial shadow and dilated upper lobe pulmonary veins. With pulmonary hypertension, the central pulmonary arteries become prominent. In severe stenosis, Kerley B lines may be present, indicating a pulmonary wedge pressure of more than 20 mm Hg.

- Electrocardiography shows P mitrale and later right ventricular hypertrophy.
- Chest radiography shows straightening of the left heart border, a large left atrial shadow, and dilated upper lobe pulmonary veins.
- In severe stenosis, Kerley B lines may be present.

Two-dimensional and Doppler echocardiography is the test of choice to diagnose mitral stenosis and determine its severity. Information is gained about valve gradient and valve area (Table 3-5), and pulmonary artery pressures can be noninvasively assessed. Cardiac catheterization is usually unnecessary unless the coronary arteries need to be studied or the echocardiographic findings do not concur with the clinical situation. Severe stenosis usually correlates with a mean gradient of 12 or more mm Hg.

- Two-dimensional and Doppler echocardiography is used to diagnose mitral stenosis and determine its severity.
- For diagnosis of mitral stenosis, cardiac catheterization is usually unnecessary.
- Severe stenosis correlates with a mean gradient ≥12 mm Hg.

Treatment

Rheumatic fever is the cause of mitral stenosis, and prophylaxis for rheumatic fever is warranted. Prophylaxis for endocarditis also is recommended.

Because mitral stenosis represents obstruction to diastolic filling, anything that shortens diastolic filling time will worsen the severity and symptoms of the disease (tachycardia, atrial fibrillation, exercise). Therefore, β-adrenergic blockers and calcium channel blockers are reasonable choices to help with better left ventricular filling. Salt restriction and diuretic therapy are useful for early symptoms.

The left ventricle is unaffected, protected from volume or pressure overload. It is small, vigorous, and possibly underfilled late in mitral stenosis. Intervention is not needed until there are symptoms of exertional dyspnea, pulmonary edema, or moderate pulmonary hypertension. Marked volume overload of the left atrium leads to increased stroke risk and intervention. Because atrial fibrillation is frequent and intermittent in the early stages, intermittent screening with Holter electrocardiography may be warranted, and anticoagulation should be considered early. With a pliable valve that is noncalcified and has no regurgitation, a mitral valve balloon valvuloplasty can be performed percutaneously, and this may preclude the need for valve replacement for at least 10 years.

- Intervention for mitral stenosis is indicated with exertional dyspnea, pulmonary edema, or moderate pulmonary hypertension (>50 mm Hg).
- Atrial fibrillation is a common consequence of left atrial volume overload.
- Anticoagulation should be considered for stroke prophylaxis.
- Percutaneous balloon valvuloplasty is probably the procedure of choice if the valve leaflets are pliable.

Mitral Regurgitation

Etiology

The mitral valve is a complex structure, and regurgitation can result from three general anatomical abnormalities: leaflet, tensor apparatus (chordal and papillary muscles), and alteration of myocardium. Common causes of mitral regurgitation include mitral valve prolapse syndrome and myxomatous degeneration, infective endocarditis, collagen vascular disease, ischemia, and rheumatic heart disease (Table 3-6). In the case of ischemic mitral regurgitation, the posterior medial papillary muscle with its single blood supply

Table 3-5 Severity of Mitral Stenosis, by Valve Area

Severity	Valve area, cm^2	Mean gradient, mm Hg	Systolic PAP, mm Hg
Mild	1.5-2	<6	Normal
Moderate	1-1.5	6-11	≤50
Severe	<1	≥12	>50

PAP, pulmonary artery pressure.

Table 3-6 Types of Mitral Regurgitation

Anatomical type	Clinical presentation	
	Chronic	Acute or subacute
Leaflets	Rheumatic Prolapse Annular calcification Connective tissue disease Congenital cleft Drug-related	Infective endocarditis
Tensor apparatus (chordal and papillary muscles)	Prolapse	Rupture of chordae Myocardial infarction Papillary muscle rupture
Myocardium	Regional ischemia or infarctions Dilated cardiomyopathy Hypertrophic cardiomyopathy	

Modified from McGoon MD, Schaff HV, Enriquez-Sarano M, Fuster V, Callahan MJ. Mitral regurgitation. In: Giuliani ER, Gersh BJ, McGoon MD, Hayes DL, Schaff HV, editors. Mayo Clinic practice of cardiology. 3rd ed. St Louis: Mosby; 1996. p. 1450-69. Used with permission of Mayo Foundation.

(compared with anterolateral, which has dual blood supply) is more susceptible.

- Most common causes of mitral regurgitation are mitral valve prolapse and myxomatous degeneration, ischemia, and infective endocarditis.

Symptoms

Chronic mitral regurgitation is a volume overload on the left ventricle with reduced afterload. Given time, the left ventricle can compensate by increasing stroke volume. Therefore, a long asymptomatic phase is possible. The most common symptoms of mitral regurgitation include fatigue, dyspnea (due to increased left atrial pressure), and pulmonary edema. Symptoms often worsen with atrial fibrillation.

Physical Examination

The findings of mitral regurgitation include a diffuse and hyperdynamic left ventricular impulse, which may be visible, and a palpable rapid filling wave. The first heart sound is usually obliterated, and there is a holosystolic murmur. The second heart sound is widely split (early A_2), and there is a third heart sound. A low-pitched early diastolic rumble indicates severe regurgitation; it represents a volume murmur and usually not coexisting mitral stenosis.

In acute mitral regurgitation, the murmur may be short because of increased left atrial pressure. In severe mitral regurgitation, the carotid upstroke may appear parvus, because of the low forward stroke volume, but not tardus. The left atrium may be palpable with systole, and the left ventricle, with diastole; there may be both third and fourth heart sounds. If the cause is ruptured chordae, an anterior leaflet murmur radiates to the axilla and back, and a posterior leaflet murmur radiates to the base and carotid arteries. Consider acute mitral regurgitation with a normal-sized heart, pulmonary edema, and acute onset of symptoms.

- Physical examination in mitral regurgitation:
  - First heart sound is usually obliterated
  - Holosystolic murmur is present
  - Second heart sound is widely split (early A_2)
  - Low-pitched early diastolic rumble indicates severe regurgitation

Diagnosis

Chest radiography may first show a dilated left atrium and then, as mitral regurgitation increases, dilatation of the left ventricle.

Pathophysiology

Mitral regurgitation is a volume overload with marked decrease in afterload which "offloads" the left ventricle. Filling volume must increase to maintain adequate forward output. This results in a hyperdynamic ventricle, and thus many patients with significant mitral regurgitation remain asymptomatic for many years. However, as with chronic aortic regurgitation, there may be development of asymptomatic left ventricular dysfunction. A low or low-normal ejection fraction therefore suggests significant ventricular dysfunction.

- Many patients with mitral regurgitation remain asymptomatic for many years.
- A low or low-normal ejection fraction suggests significant ventricular dysfunction.

All patients with mitral valve prolapse or any other cause of mitral regurgitation need endocarditis prophylaxis. There is no universally accepted medical treatment for mitral regurgitation. Symptoms indicate that intervention (mitral repair or replacement) is warranted. Most patients experience a decrease in ejection fraction after mitral valve repair or replacement.

Treatment

Asymptomatic patients with a normal or hyperdynamic ejection fraction can continue to undergo regular observation. Operation should be considered for symptomatic patients (note that ventricular function considerably influences the postoperative outcome), and, because afterload is increased when the mitral valve is replaced, left ventricular function may actually deteriorate. In mildly symptomatic patients, operation may be considered, particularly if serial examinations show progressive cardiac enlargement. Earlier operation may be indicated in patients who are suitable for mitral valve repair rather than replacement, especially when the ejection fraction is less than 60% or the left ventricular end-diastolic dimension is more than 45 mm.

- In symptomatic patients with mitral regurgitation, operation should be considered.
- In asymptomatic patients with an ejection fraction <60% or left ventricular end-systolic dimension >45 mm, operation may be considered, especially if mitral valve repair is possible.

Mitral Valve Prolapse

Pathophysiology and Natural History

Mitral valve prolapse is the most common valvular heart disease and is the most common cause of mitral regurgitation in the United States. Mitral valve prolapse refers to a systolic billowing of one or both mitral leaflets into the left atrium with or without mitral regurgitation. Estimates of prevalence in the general population range from 2% to 6%.

In patients with mitral valve prolapse, as with other causes of mitral regurgitation, the degree of left atrial and left ventricular dilatation depends on the severity of mitral regurgitation. In Marfan syndrome, the supporting apparatus is often involved with dilatation of the mitral annulus in addition to elongated chordae and redundant leaflets.

Other valves also may be involved with the same myxomatous degeneration, leading to tricuspid valve prolapse (occurring in approximately 40% of patients with mitral valve prolapse), pulmonic valve prolapse (~10%), and aortic valve prolapse (2%). Mitral valve prolapse is associated with secundum atrial septal defect and supraventricular arrhythmias (Curr Probl Cardiol. 1982;7:1-48).

The mitral valve prolapse syndrome is associated with a benign course in most patients. Patients with diagnostic auscultatory findings of click-murmur, thickened mitral leaflets on echocardiography, and left ventricular and atrial enlargement are at high risk for future complications, including atrial fibrillation, systemic embolism, and pulmonary hypertension. There is also a lifelong risk of ruptured mitral valve chordae, which may lead to acute decompensation. Infective endocarditis is a serious complication of mitral valve prolapse, although the overall incidence is low. There is also a small risk of sudden cardiac death (Fig. 3-8).

Physical Examination

Mitral valve prolapse is most commonly diagnosed with cardiac auscultation in asymptomatic patients or found incidentally on echocardiography performed for another reason. Yet, primary evaluation of the patient with mitral valve prolapse is a careful physical examination. The classic auscultatory finding is the midsystolic click, a high-pitched sound of short duration. There may be multiple clicks. Clicks result from sudden tensing of the mitral valve apparatus as the leaflets prolapse into the left atrium during systole. The midsystolic click(s) is frequently followed by a mid-late systolic murmur that is high-pitched, musical, or honking and often loudest at the cardiac apex. The character and intensity of the clicks and the murmur vary under loading conditions of the left ventricle. Dynamic auscultation is helpful for establishing the diagnosis of mitral valve prolapse syndrome. Changes in left ventricular end-diastolic volume result in changes in the timing of the midsystolic click(s) and murmur. When end-diastolic volume is decreased (such as with standing), the critical volume is achieved earlier in systole and the click-murmur complex occurs earlier after the first heart sound. By contrast, any maneuver that augments the volume of blood in the ventricle (e.g., squatting), reduces myocardial contractility, or increases left ventricular afterload lengthens the time from onset of systole to initiation of mitral valve prolapse, and the systolic click or murmur moves toward the second heart sound (Fig. 3-9) (Curr Probl Cardiol. 1976;1:1-60; J Am Coll Cardiol. 1998;32:1486-588).

Diagnosis

Results of electrocardiography most often are normal, although 24-hour ambulatory electrocardiographic recordings or event monitors may be useful for documenting arrhythmias. Chest radiography may show skeletal abnormalities such as pectus excavatum.

Echocardiography is the most useful noninvasive test for defining mitral valve prolapse. The definition includes more than 2 mm of posterior displacement of one or both leaflets into the left atrium. All patients with mitral valve prolapse should have an initial echocardiogram to determine the diagnosis, stratify risk, and define possible associated lesions (e.g., atrial septal defect). Serial echocardiograms are not usually necessary in asymptomatic patients with mitral valve prolapse unless there are clinical indications of worsening status.

Treatment

Reassurance is a major part of the management of patients with mitral valve prolapse because most are asymptomatic and lack a high-risk profile. A normal lifestyle and regular exercise are encouraged. Patients should be educated about when to seek medical advice (worsening symptoms) and about antibiotic prophylaxis for the prevention of infective endocarditis in patients with evidence of higher-risk profile (thickened leaflets, elongated chordae, mitral regurgitation, chamber enlargement).

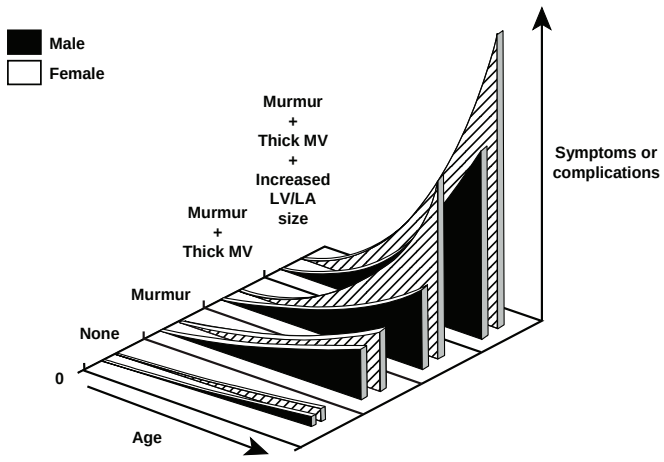

Fig. 3-8. Risk factors for complications in mitral valve prolapse. LA, left atrial; LV, left ventricular; MV, mitral valve. (From Boudoulas H, Kolibash AJ Jr, Wooley CF. Mitral valve prolapse: a heterogeneous disorder. Primary Cardiol. 1991;17:29-43. Used with permission.)

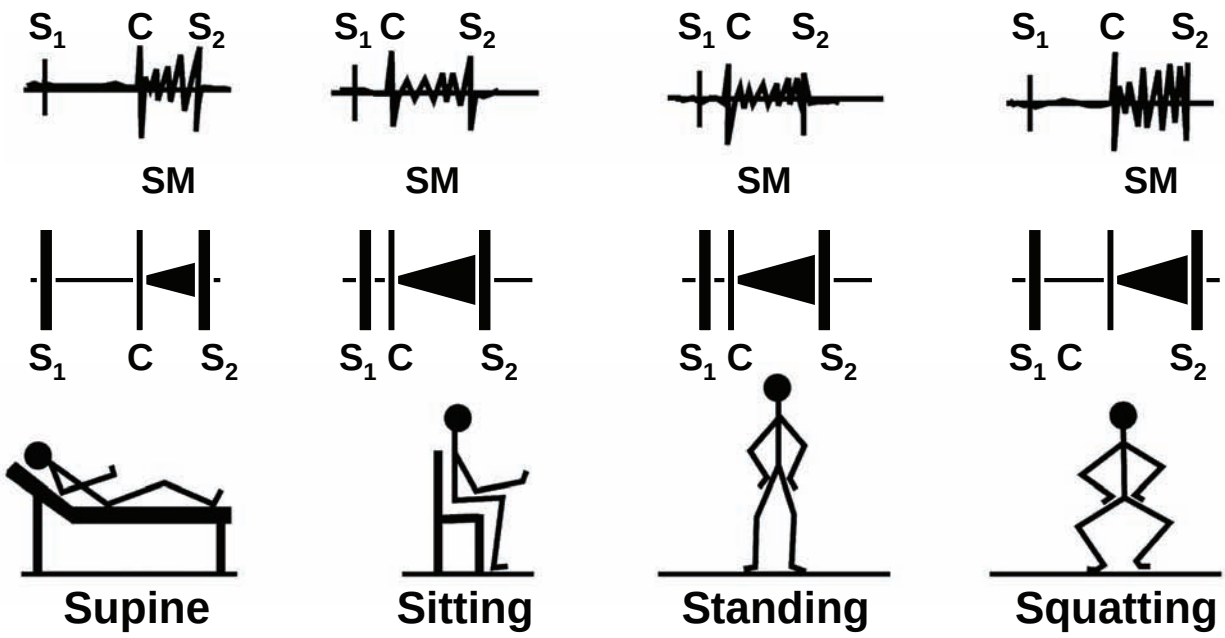

Fig. 3-9. Auscultation findings in mitral valve prolapse. C, click; SM, systolic murmur; ◀, murmur.

Common symptoms include palpitations, atypical chest pain that rarely resembles classic angina pectoris, dyspnea, and fatigue. Patients should be advised in cessation of the use of caffeine, alcohol, and cigarettes. Patients with recurrent palpitations often respond to therapy with β-adrenergic blockers or calcium channel blockers. Orthostatic symptoms due to postural hypotension and tachycardia are best treated with volume expansion, preferably by liberalizing fluid and salt intake. Transient cerebral ischemic episodes occur with increased incidence in patients with mitral valve prolapse, and some patients need long-term anticoagulation (Table 3-7).

Asymptomatic patients with mitral valve prolapse and no significant mitral regurgitation can be evaluated clinically every 3 to 5 years. Serial echocardiography is necessary only in patients who have high-risk features on the initial echocardiogram.

Surgery may be required for mitral valve prolapse. The thickened, redundant mitral valve often can be repaired rather than replaced, a procedure associated with a low operative mortality rate and excellent short- and long-term results, particularly in patients who have a flail mitral leaflet due to rupture of chordae tendineae or their marked elongation. Recommendations for surgery in patients with mitral valve prolapse and mitral regurgitation are the same as those for patients with other forms of severe mitral regurgitation.

Tricuspid Stenosis

The cause of tricuspid stenosis is almost always rheumatic, and it is never an isolated lesion. Carcinoid syndrome may cause tricuspid stenosis (usually causes tricuspid regurgitation), and in rare cases atrial tumors may be the cause.

- The cause of tricuspid stenosis is almost always rheumatic.

Tricuspid Regurgitation

This is usually caused by dilatation of the right ventricle. When there is right ventricular hypertension, tricuspid regurgitation is also common. It often accompanies mitral valve disease, but it may be related to 1) biventricular infarction, 2) primary pulmonary hypertension, 3) congenital heart disease (such as Ebstein anomaly), or 4) carcinoid syndrome—more commonly associated with tricuspid regurgitation than tricuspid stenosis.

- Tricuspid regurgitation is usually caused by dilatation of the right ventricle.
- It often accompanies mitral valve disease.

Tricuspid Valve Prolapse

This may occur as an isolated entity or in association with other connective tissue abnormalities. The tricuspid valve may prolapse or become flail as a result of trauma or endocarditis (commonly fungal or staphylococcal in drug addicts).

Physical Examination

Findings on physical examination include jugular venous distention with a prominent *v* wave, a prominent right ventricular impulse, a pansystolic murmur at the left sternal edge, possibly a right-sided third heart sound, and peripheral edema, ascites, and hepatomegaly.

Surgical Therapy

Tricuspid annuloplasty may be helpful if regurgitation is a result of right ventricular dilatation. However, if there is significant pulmonary hypertension, tricuspid valve replacement is usually required with either a biologic or a mechanical valve. Biologic prostheses in the

Table 3-7 Recommendations for Use of Aspirin and Oral Anticoagulants in Mitral Valve Prolapse

Indication	Class
1. Aspirin therapy for cerebral transient ischemic attacks	I
2. Warfarin therapy for patients aged ≥65 years, in atrial fibrillation with hypertension, mitral regurgitation murmur, or history of heart failure	I
3. Aspirin therapy for patients aged <65 years in atrial fibrillation with no history of mitral regurgitation, hypertension, or heart failure	I
4. Warfarin therapy after stroke	I
5. Warfarin therapy for transient ischemic attacks despite aspirin therapy	IIa
6. Aspirin therapy after stroke in patients with contraindications to anticoagulants	IIa
7. Aspirin therapy for patients in sinus rhythm with echocardiographic evidence of high-risk mitral valve prolapse	IIb

Data from Bonow RO, Carabello BA, Chatterjee K, de Leon AC Jr, Faxon DP, Freed MD, et al. ACC/AHA 2006 guidelines for the management of patients with valvular heart disease: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Writing Committee to Revise the 1998 Guidelines for the Management of Patients With Valvular Heart Disease). Circulation. 2006;114:84-231.

tricuspid position do not degenerate as quickly as prostheses in the left side of the heart. In patients with endocarditis, the tricuspid valve can be removed completely, and patients may tolerate this well for several years.

Congenital Heart Disease

Atrial Septal Defect

There are multiple types of atrial septal defects (Table 3-8).

Secundum Atrial Septal Defect

Patients with secundum atrial septal defect often survive to adulthood and may be asymptomatic. The condition is often detected on routine examination with the finding of a systolic flow murmur and "fixed" split second heart sound. If the defect has gone undetected, atrial fibrillation frequently develops by the fifth decade along with onset of symptoms, usually dyspnea with subsequent tricuspid regurgitation and right-sided heart failure. Stroke may occur as a result of paradoxical embolism.

- Patients with secundum atrial septal defect often survive to adulthood and may be asymptomatic.
- The condition is found on routine examination with the finding of a systolic flow murmur and "fixed" split second heart sound.
- Atrial fibrillation often develops in patients in their 50s with onset of symptoms.
- Stroke may occur as a result of paradoxical embolism.

Table 3-8 Types of Atrial Septal Defects

Type	%	Location	Associated findings	ECG findings
Ostium secundum	75	Fossa ovalis	None	Incomp RBBB, R axis
Sinus venosus	10	Vena cava	Anomalous PV	Incomp RBBB, ectopic P wave, R axis
Ostium primum	10-15	Lower septum	Cleft MV, Down syndrome	Incomp RBBB, L axis (LAHB)

ECG, electrocardiography; L axis, left axis deviation; LAHB, left anterior hemiblock; MV, mitral valve; P wave, atrial depolarization wave on ECG; PV, pulmonary veins; R axis, right axis deviation; RBBB, right bundle branch block.

Physical Examination

Findings include a normal or slightly prominent jugular venous pressure, a right ventricular heave or lift, an ejection systolic murmur in the pulmonary artery due to increased flow (usually less than grade 3/6), a fixed splitting of the second sound, and a tricuspid diastolic flow rumble if the shunt is large.

- Physical findings of secundum atrial septal defect:
  - Ejection systolic murmur in the pulmonary artery (never more than grade 3/6)
  - Fixed splitting of the second sound
  - Tricuspid diastolic flow rumble with large shunts

Diagnosis

Electrocardiography characteristically shows right bundle branch block and right axis deviation. Chest radiography shows pulmonary plethora, a prominent pulmonary artery, and right ventricular enlargement (Fig. 3-10). Young patients (younger than 40 years) with secundum atrial septal defect and sinus rhythm do not have left atrial enlargement. If the chest radiograph shows left atrial enlargement, consider another lesion, particularly primum atrial septal defect with mitral regurgitation.

- If the chest radiograph shows left atrial enlargement, consider primum atrial septal defect with mitral regurgitation.

Two-dimensional and color Doppler echocardiography usually can show the defect and right ventricular enlargement with volume overload. If visualization is poor, transesophageal echocardiography can be performed. Cardiac catheterization is usually unnecessary, unless coexisting coronary artery disease is suspected.

Sinus Venosus Atrial Septal Defect

An uncommon condition, this occurs in the superior portion of the atrial septum. It is often associated with anomalous pulmonary

Fig. 3-10. Chest radiograph from a patient with a large left-to-right shunt due to a secundum atrial septal defect. Note cardiac enlargement with right ventricular contour, very prominent pulmonary artery, and pulmonary plethora.

veins, usually the right upper. If echocardiography shows right ventricular volume overload and no secundum defect (because surface echocardiography can miss the sinus venosus area), consider sinus venosus atrial septal defect or anomalous pulmonary veins.

Primum Atrial Septal Defect (Partial Atrioventricular Canal)

This is a defect in the lower portion of the septum due to partial atrioventricular canal defect. The mitral valve is usually congenitally cleft and produces various degrees of regurgitation.

Diagnosis

On electrocardiography, findings are different from those of secundum type; left axis deviation and right bundle branch block are evident. More than 75% of patients have first-degree atrioventricular block. The chest radiographic findings are the same as those for secundum atrial septal defect, although there may be left atrial enlargement because of mitral regurgitation. Atrioventricular canal defects are the most common cardiac anomaly associated with Down syndrome.

- Electrocardiography shows left axis deviation with right bundle branch block and, commonly, first-degree atrioventricular block.
- Atrioventricular canal defects are the most common cardiac anomaly of Down syndrome.

Treatment of Atrial Septal Defects

Infective endocarditis is rare in patients with atrial septal defect, and antibiotic prophylaxis for endocarditis is not recommended (unless there is associated valvular heart disease). Patients with atrial septal defect have variable symptoms depending on the size of the shunt. Intervention should be considered once there is evidence of hemodynamic compromise: left-to-right shunting of more than 30% or evidence of right-sided chamber enlargement.

Surgical treatment has been successful for more than 30 years with very low complication rates. Recently, percutaneous closure with an occluder device was approved for use.

Ventricular Septal Defect

Ventricular septal defect occurs in different parts of the ventricular septum, most commonly classified as either in the membranous septum or in the muscular septum. Small defects produce a loud noise, and patients are often asymptomatic. The size of the hole determines the degree of left-to-right shunting. Small defects may have a long holosystolic murmur, often with a thrill at the left sternal edge, usually around the fourth interspace. Large defects may produce a mitral diastolic flow rumble at the apex, especially when the shunt is more than 2.5:1.

Typical clinical scenario: In adults, ventricular septal defect generally presents as a murmur in an asymptomatic patient. Large defects cause considerable symptoms early in life and are, in the United States, usually closed. In adults, a large ventricular septal defect generally has progressed to Eisenmenger syndrome (pulmonary hypertension) and cannot be closed (see Eisenmenger Syndrome below). It is critical to recommend prophylaxis for subacute bacterial endocarditis. Sometimes patients present with symptoms of this infection.

- Ventricular septal defects are most common in the membranous septum or the muscular septum.
- Small defects produce a loud noise.
- The size of the hole determines the degree of left-to-right shunting.

Patent Ductus Arteriosus

This condition is associated with maternal rubella. It produces essentially an "arteriovenous fistula." A small ductus is compatible with a normal lifespan. The ductus may calcify in adult life. A continuous "machinery" murmur envelops the second heart sound around the second interspace beneath the left clavicle. A large patent ductus arteriosus may produce ventricular failure. Surgical ligation is curative; subsequently, patients do not need prophylaxis for endocarditis.

All significant shunt lesions, when large, may produce increased pulmonary pressures and subsequently pulmonary vascular disease and pulmonary hypertension.

Typical clinical scenario: A patient in an ambulatory clinic is an asymptomatic adult with a loud continuous "machinery" murmur. It is crucial to recommend prophylaxis for subacute bacterial endocarditis.

- Patent ductus arteriosus is associated with maternal rubella.
- A small ductus is compatible with a normal lifespan.
- A continuous "machinery" murmur is present.
- Surgical ligation is curative; subsequently, prophylaxis for endocarditis is not needed.

- All of the above-described shunt lesions, when large, may produce increased pulmonary pressures and subsequently pulmonary vascular disease.

Eisenmenger Syndrome

Eisenmenger syndrome develops in the first few years of life when a large shunt (usually a ventricular septal defect or patent ductus arteriosus, less often atrial septal defect) produces pulmonary hypertension and irreversible pulmonary vascular disease. This condition causes the shunt to reverse so that blood flows from the right to the left, and subsequent cyanosis occurs. The condition is then inoperable. Death commonly occurs in the third or fourth decade of life as a result of exercise-induced syncope, arrhythmia, hemoptysis, and stroke. The cyanosis produces marked erythrocytosis, often with hemoglobin values in the teens or 20s. There is no need for phlebotomy in patients with a hemoglobin value less than 20 g/dL or a hematocrit value less than 65%. Also, repeated phlebotomies frequently lead to iron deficiency, and iron-deficient erythrocytes are more rigid than ordinary ones, and the risk of stroke is thereby increased. Phlebotomy may be necessary in symptomatic patients with a hemoglobin value more than 20 g/dL. Fluid should be replaced concomitantly in patients with Eisenmenger syndrome because hypotension and syncope may be fatal as a result of exacerbation of right-to-left shunting and hypoxia.

Typical clinical scenario: Patients have a long medical history because of the huge right-to-left shunts. A patient presents with syncope and erythrocytosis. Phlebotomy should not be used unless the patient has neurologic symptoms and a hemoglobin value more than 20 g/dL.

- Eisenmenger syndrome develops in the first few years of life.
- The syndrome produces pulmonary hypertension and irreversible pulmonary vascular disease.
- Death is common in the third or fourth decade of life.
- Associated conditions: exercise-induced syncope, arrhythmia, hemoptysis, and stroke.
- Cyanosis produces marked erythrocytosis.

Pulmonary Stenosis

This may occur as an isolated lesion or in association with a ventricular septal defect. Valvular pulmonary stenosis often causes few or no symptoms. The valve is frequently pliable, and it may be bicuspid. Thickened dysplastic valves, often stenotic, occur in association with the Noonan syndrome.

- Thickened dysplastic valves, often stenotic, occur with the Noonan syndrome.

Physical Examination

Findings include a prominent *a* wave in the jugular venous pulse; right ventricular heave; ejection systolic click—the earlier the click, the more severe the stenosis (the click indicates that the valve is pliable and noncalcified); ejection systolic murmur—the longer the murmur and the later peaking, the more severe the stenosis; and soft and late P_2 (with severe stenosis P_2 becomes inaudible). The pulmonary opening click is the only right-sided sound that gets softer with inspiration as the pulmonary valve partially opens with the inspiratory increase in venous return. Later in life, the valve may become so thick, calcified, and immobile that the ejection click disappears.

- Findings of pulmonary stenosis:
  Prominent *a* wave in the jugular venous pulse
  Ejection systolic click
  The pulmonary opening click is the only right-sided sound that gets softer with inspiration

Diagnosis

Electrocardiography shows right ventricular hypertrophy. On chest radiography, poststenotic pulmonary dilatation, especially of the left pulmonary artery (Fig. 3-11), is the hallmark.

The diagnosis can be reliably made with two-dimensional echocardiography, and Doppler reliably predicts the gradient and estimates right ventricular pressure. In asymptomatic patients, treatment is indicated when the right ventricular systolic pressure approaches two-thirds or more that of the systemic blood pressure. The treatment of choice for a pliable noncalcified valve is percutaneous balloon valvuloplasty, which has essentially replaced surgical valvotomy.

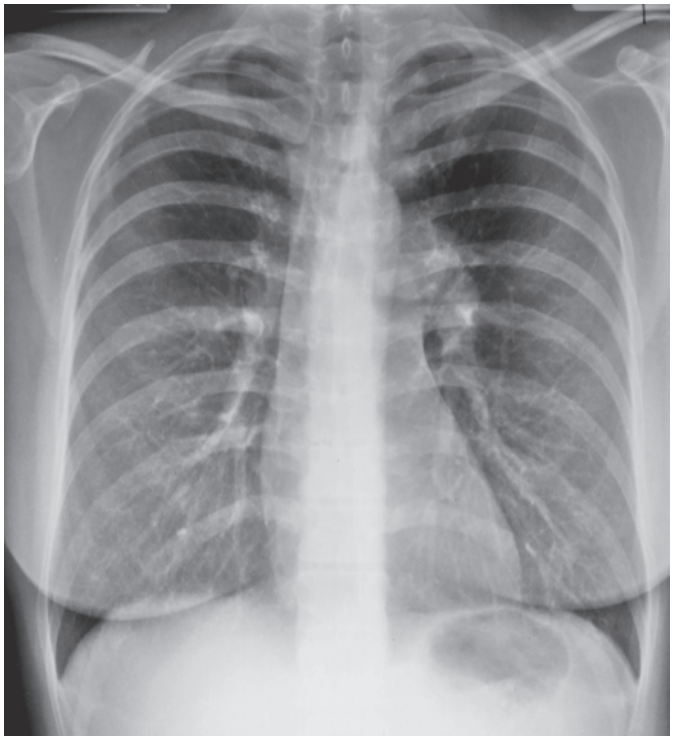

Fig. 3-11. Typical chest radiograph from a patient with valvular pulmonary stenosis, showing normal cardiac size and marked prominence of main and left pulmonary arteries, representing poststenotic dilatation. This does not occur with infundibular pulmonary stenosis. Lung fields appear mildly oligemic.

Typical clinical scenario: A young patient presents with dyspnea on exertion or exertional syncope. On examination, there is a murmur that is late-peaking and louder with inspiration. A systolic click is also heard, but it is softer with inspiration. A prominent *a* wave is seen on jugular venous profile. On echocardiography, the condition is diagnosed with a gradient more than 50 mm Hg across the pulmonary valve. If the valve is still pliable (usually to middle age), balloon valvuloplasty is the procedure of choice.

- The diagnosis of pulmonary stenosis is made with two-dimensional and Doppler echocardiography.
- The treatment for a pliable valve is percutaneous balloon valvuloplasty when the right ventricular systolic pressure is two-thirds or more that of the systemic pressure.

Coarctation of the Aorta

This is usually either a discrete or a long segment of narrowing adjacent to the left subclavian artery. It is more common in males and frequently is associated with a bicuspid aortic valve. Most cases of coarctation are diagnosed in childhood; only about 20% are diagnosed in adulthood. This is the most common cardiac anomaly associated with Turner syndrome. Other associations include aneurysms of the circle of Willis and aortic dissection or rupture. There is an increased incidence of aortic dissection or rupture in Turner syndrome, even in the absence of coarctation. As a result of the coarctation, systemic collateral vessels develop from the subclavian and axillary arteries through the internal mammary, scapular, and intercostal arteries.

- Coarctation of the aorta is more common in males.
- The condition is frequently associated with a bicuspid aortic valve.
- Only 20% of cases are diagnosed in adulthood.
- It is the most common cardiac anomaly associated with Turner syndrome.
- The incidence of aortic dissection or rupture is increased in Turner syndrome, even in the absence of coarctation.

There are five major complications of coarctation of the aorta: 1) cardiac failure, 2) aortic valve disease, 3) aortic rupture or dissection, 4) endarteritis, and 5) rupture of an aneurysm of the circle of Willis—this is exacerbated by the presence of hypertension, which occurs in the upper limbs. Systemic hypertension may be the presenting feature in adults. Some patients complain of pain and fatigue in the legs on exercise, reminiscent of claudication.

Symptoms

Typical clinical scenario: Coarctation should be considered in patients with hypertension who are younger than 50 years. There may be coexistent claudication of the lower extremities. Examination shows differentiated blood pressure; upper extremity hypertension and lower extremity hypotension. On simultaneous palpation of the radial and femoral pulses, there is a delay, smaller in the femoral arteries. Patients may present with symptoms of aortic rupture, dissection, congestive heart failure, or associated conditions of Turner syndrome, circle of Willis aneurysm, or bicuspid valve.

Physical Examination

Findings include an easily palpable brachial pulse; the femoral pulse is weak and delayed. There are differences in systolic pressure between the upper and the lower extremities. Exercise may exaggerate the systemic hypertension. An ejection click is present when there is an associated bicuspid valve. A_2 may be loud as a result of hypertension. A fourth heart sound may be present with associated left ventricular hypertrophy and hypertension. Murmurs may originate from 1) the coarctation, which can produce a systolic murmur over the left sternal edge and over the spine in the mid-thoracic region, and it sometimes extends into diastole in the form of a continuous murmur; 2) arterial collateral vessels, which are spread widely over the thorax; and 3) the bicuspid aortic valve, which may generate a systolic murmur.

- Physical findings of coarctation of the aorta: easily palpable brachial pulse, weak and delayed femoral pulse, differences in systolic pressure between the upper and the lower extremities.
- Coarctation can produce a systolic murmur over the left sternal edge and over the spine in the mid-thoracic region.
- Arterial collateral vessels are spread widely over the thorax.

Diagnosis

Results of electrocardiography may be normal. The more severe the coarctation stenosis and hypertension, the more likely is the finding of left ventricular hypertrophy with or without repolarization changes. Chest radiography may show rib notching from the dilated and pulsatile intercostal arteries and a "3" configuration of the aortic knob, which represents the coarctation site with proximal and distal dilatation.

- Chest radiographic findings in coarctation of the aorta are rib notching and a "3" configuration of the aortic knob.

The condition may be shown on echocardiography and Doppler, although imaging may be difficult in this area, and additional visualization may be necessary with digital subtraction angiography, magnetic resonance imaging, computed tomography, or angiography.

Treatment

Balloon angioplasty has been performed in some patients, although it has been associated with aneurysm formation and re-coarctation. Surgical treatment has been an accepted approach since 1945. However, there is a significant rate of hypertension after coarctation repair. As many as 75% of patients are hypertensive at 30-year follow-up. Surgically treated patients still often die prematurely of coronary artery disease, heart failure, stroke, or ruptured or dissected aorta. Age at operation is important. The 20-year survival rate is 91% in patients who have operation when they are younger than 14 years and 79% in patients who have operation when they are older than 14 years.

- Surgical repair is the accepted treatment of coarctation of the aorta.
- Even after successful operation, there is a high rate of cardiovascular complications.

- Surgically treated patients often die prematurely of coronary artery disease, heart failure, stroke, or ruptured or dissected aorta.

Ebstein Anomaly

This is a congenital lesion of the right heart that has a variable clinical spectrum. It involves an inferior displacement of the tricuspid valve ring into the right ventricular cavity, causing a sail-like elongated anterior cusp or tricuspid valve on echocardiography. The degree of displacement is variable, as is the degree of abnormality of the tricuspid valve. The inferior displacement of the tricuspid valve results in "atrialization" of the right ventricle. Maternal lithium ingestion during pregnancy has been associated with this anomaly.

- Ebstein anomaly is thought to be associated with maternal lithium ingestion during pregnancy.
- The anomaly involves inferior displacement of the tricuspid valve ring into the right ventricular cavity, causing a sail-like tricuspid valve on echocardiography.

Symptoms

Ebstein anomaly has a protracted natural history.

Typical clinical scenario: Although findings are highly variable, most patients present with cyanosis and dyspnea with or without atrial arrhythmias. The cyanosis is due to right-to-left shunting at the atrial level.

Physical Examination

The extremities are usually cool, often with peripheral cyanosis (a reflection of low cardiac output). A prominent *a* wave and, if tricuspid regurgitation is present, a *v* wave are present in the jugular venous pressure (although this is variable because the large right atrium may accommodate a large tricuspid regurgitant volume). A right ventricular lift is noted. The first heart sound has a loud tricuspid (T_1) component. A holosystolic murmur increases on inspiration at the left sternal edge from tricuspid regurgitation. One or more systolic clicks are noted (often may be multiple). Common associated conditions are secundum atrial septal defect, preexcitation syndrome, and bundle of Kent (atrioventricular accessory pathway in 13% of patients in a Mayo Clinic series). Patients with secundum atrial septal defects are often very cyanotic because of the increased right-to-left shunting, and they may present with neurologic events due to paradoxical embolism.

- Findings of Ebstein anomaly include cool extremities, often with peripheral cyanosis.
- A holosystolic murmur increases on inspiration.
- One or more systolic clicks are noted.
- Associated conditions: secundum atrial septal defect, preexcitation syndrome, and bundle of Kent.
- Patients with secundum atrial septal defects are often very cyanotic.

Diagnosis

Chest radiography shows a narrow pedicle with an enlarged globular silhouette and right atrial enlargement. The lung fields are normal or oligemic. On electrocardiography, a tall P wave ("Himalayan" P waves) and right bundle branch block are found.

Two-dimensional and Doppler echocardiography delineates the anatomy precisely, and cardiac catheterization is unnecessary. Electrophysiologic study may be necessary to delineate the bypass tract, if present.

Treatment

The long asymptomatic phase supports a policy of postponing surgical intervention until the patient has significant symptoms. Patients may require anticoagulation if an atrial septal defect is present and paradoxical emboli have occurred. In addition, there is high frequency of accessory atrioventricular pathways leading to tachycardia.

Pregnancy and Cardiac Disease

Physiologic Changes of Pregnancy

Plasma volume starts to increase in the first trimester and continues to increase through the third trimester to almost 50% more than normal. An increase in red cell mass also begins early and peaks in the second trimester, but not to the same degree as the plasma volume; thus, there is a relative anemia. The cardiac output increases by 30% to 50%, and peripheral resistance decreases. Heart rate also increases throughout pregnancy. Increased venous pressure in the lower extremities leads to pedal edema in 80% of healthy pregnant women.

- Physiologic changes of pregnancy include marked increased plasma volume and a moderate increase in red cell mass that causes a relative anemia.
- Peripheral resistance decreases.
- Cardiac output increases.

Because of these changes, the physical examination may suggest cardiac abnormalities to the unwary. Normal results of physical examination in a healthy pregnant woman include increased jugular venous pressure, bounding carotid pulses, and an ejection systolic murmur in the pulmonary area (should not be more than grade 3/6). The second heart sound is loud, and there is often a third heart sound or diastolic filling sound. A fourth heart sound occasionally may be heard.

- Ejection systolic murmur in the pulmonary area (not more than grade 3/6) is a normal finding in pregnancy.
- A third or fourth heart sound is common.

Although a third heart sound or diastolic filling sound is common, a long rumble should raise the possibility of mitral stenosis. Because of the decrease in peripheral resistance and increased output changes, stenotic lesions are less well tolerated than regurgitant ones; for example, a patient with aortic stenosis has exaggeration of the aortic valve gradient, whereas a patient with mitral regurgitation experiences "afterload reduction" with peripheral vasodilatation and so tolerates pregnancy better. Functional class of the patient is a consideration in terms of whether pregnancy is possible. Patients who are in New York Heart Association functional class III or IV have a maternal mortality rate approaching 7%.

- A third heart sound or diastolic filling sound is common in pregnancy, but a long rumble should raise the possibility of mitral stenosis.
- For patients in functional class III or IV, the maternal mortality rate approaches 7%.

Pregnancy is *absolutely contraindicated* in patients with the following conditions: 1) Marfan syndrome with a dilated aortic root—there is an increased risk of dissection and rupture because hormonal changes soften the connective tissue (there is unpredictable risk of dissection and rupture in Marfan syndrome and pregnancy even when the aortic root has normal size), 2) Eisenmenger syndrome (maternal mortality rate is 50%), 3) primary pulmonary hypertension, 4) symptomatic severe aortic stenosis, 5) symptomatic severe mitral stenosis, and 6) symptomatic dilated cardiomyopathy.

Although not absolute contraindications, the following conditions are also of concern in pregnancy: 1) atrial septal defect (deep venous thrombosis may lead to paradoxical embolus) and 2) coarctation (increased risk of dissection and rupture).

Patients at risk during pregnancy should minimize activity (decreases cardiac output), reduce sodium in the diet, and minimize anemia with iron and vitamin supplements.

If symptoms deteriorate and congestive heart failure supervenes, bed rest may need to be instituted. Arrhythmias such as atrial fibrillation need to be treated promptly in these situations. If necessary, cardioversion can be performed with apparently low risk to the fetus. Fetal cardiac monitoring should be performed at the same time. Occasionally patients need operative intervention. Operation during the first trimester is associated with a significantly increased rate of fetal loss. Percutaneous aortic, mitral, and pulmonary balloon valvuloplasty have been performed during pregnancy and may obviate cardiopulmonary bypass. Careful lead shielding of the fetus is needed during these procedures.

Drugs

Many cardiac drugs cross the placenta into the fetus but yet can be used safely when necessary and are not absolutely contraindicated in pregnancy. These include digoxin, quinidine, procainamide, β-adrenergic blockers, and verapamil. The β-adrenergic blockers can be associated with growth retardation of the fetus, neonatal bradycardia, and hypoglycemia. They may need to be used, however, in large doses in patients with hypertrophic cardiomyopathy, and fetal growth must be monitored.

Drugs that should be avoided are angiotensin-converting enzyme inhibitors (i.e., captopril), which cause fetal renal dysgenesis; phenytoin, which causes hydantoin syndrome and teratogenicity; and warfarin, which causes teratogenicity and abortion (should be especially avoided in the first and third trimesters). One noncardiac drug to avoid is tetracycline, which stains fetal teeth.

- Drugs to avoid in pregnancy: angiotensin-converting enzyme inhibitors (i.e., captopril), phenytoin, warfarin, and tetracycline.

Delivery

Delivery is a time of rapid hemodynamic swings. With each uterine contraction, about 500 mL of blood is released into the circulation. Cardiac output goes up with advancing labor. Oxygen consumption increases threefold. High-risk patients need careful monitoring with Swan-Ganz catheterization to maintain preload at an optimal level, maternal and fetal electrocardiographic monitoring, careful analgesia and anesthesia to avoid hypotension, delivery in the left lateral position so the fetus is not lying on the inferior vena cava (this position maintains venous return), and a short second stage of labor (delivery may need to be facilitated if labor progresses slowly).

Vaginal delivery is safer for most women because the average blood loss is less than 500 mL; with cesarean section it is 800 mL. Usually, cesarean section is performed only for obstetric indications. The new guidelines of the American Heart Association state that there is no need for antibiotic prophylaxis in an uncomplicated vaginal delivery.

- With each uterine contraction, 500 mL of blood is released into the circulation.
- There is no need for antibiotic prophylaxis in uncomplicated vaginal delivery.

Prosthetic Valves and Pregnancy

Most women of childbearing age who need a valve replacement will receive a biologic valve, and if they are in sinus rhythm they will usually not be receiving anticoagulants. Women with mechanical valves will be taking warfarin, and this poses a problem with teratogenicity (first trimester) and increased risk of spontaneous abortion. Anticoagulation in pregnancy is complex and controversial. In general, pregnancy should be diagnosed as soon as possible, therapy should be switched to unfractionated subcutaneous heparin (low-molecular-weight heparin has not yet been approved for this indication), and the activated partial thromboplastin time should be monitored. Many physicians now advocate that the patient be returned to warfarin therapy until delivery. Heparin also is associated with significant maternal complications (valve thrombosis and fetal loss). High-risk pregnancy teams adept at management are essential.

- In pregnant patients with mechanical valves, therapy should be switched from warfarin to unfractionated subcutaneous heparin, at least for the first trimester.
- Warfarin is associated with embryopathy.
- Heparin is associated with increased fetal loss.
- Warfarin is contraindicated in the first and third trimesters.

Hypertension and Pregnancy

High blood pressure during pregnancy is defined as an increment in systolic blood pressure of 30 mm Hg, an increment in diastolic blood pressure of 15 mm Hg or more, or an absolute diastolic blood pressure of 90 mm Hg or more. Hypertension during pregnancy may be 1) chronic hypertension (blood pressure ≥140/80 mm Hg before pregnant state), 2) transient hypertension (develops during pregnancy), 3) preeclampsia (starts ≥20 weeks of pregnancy), or 4) a combination of these.

For the medical management of hypertension, methyldopa is most extensively studied and is safe. β-Adrenergic blockers are safe

and efficacious but may lead to growth retardation and fetal bradycardia. Angiotensin-converting enzyme inhibitors are contraindicated because they cause fetal renal failure. Hydralazine is used when additional drug treatment is needed, but it may be associated with fetal thrombocytopenia. Calcium channel blockers are not extensively studied. Diuretics are effective because the hypertension of pregnancy is "salt-sensitive." Although there is not total agreement, the Working Group on Hypertension in Pregnancy allows continuation of the use of diuretics if they had been prescribed before gestation.

Pericardial Disease

The pericardium has an inner layer, the visceral pericardium, and an outer layer, the parietal pericardium. The space between the two layers contains 15 to 25 mL of clear fluid. The pericardium has three main functions: prevent cardiac distention, limit cardiac displacement because of its attachment to neighboring structures, and protect the heart from nearby inflammation.

Acute or Subacute Inflammatory Pericarditis

Symptoms

The chest pain of pericarditis is often aggravated by movement of the trunk, by inspiration, and by coughing. The pain is often relieved by sitting up. Low-grade fever and malaise are other findings.

Diagnosis

Pericardial friction rub may be variable. Chest radiography is usually normal. It may show globular enlargement if pericardial effusion is significant (at least 250 mL). Occasionally, pulmonary infiltrate or small pleural effusion is noted. Left pleural effusion predominates, and the cause is unknown. Electrocardiography shows acute concave ST elevation in all ventricular leads. The PR segment is also depressed in the early stages. Echocardiography allows easy diagnosis of pericardial effusion and determination of whether the pericardial effusion is hemodynamically significant.

- Chest pain is the presenting symptom of pericarditis.
- Electrocardiography shows concave ST elevation and a depressed PR segment.

Causes

The causes of pericarditis include viral pericarditis, idiopathic pericarditis, autoimmune and collagen diseases (systemic lupus erythematosus, rheumatoid arthritis, scleroderma), and postmyocardial infarction. The postcardiotomy syndrome follows open heart procedures. It presents with pyrexia, increased sedimentation rate, and pleural or pericardial chest pain. It occurs weeks to months after open heart operation. Its incidence decreases with age, and it usually responds to anti-inflammatory agents. Pericarditis also is associated with radiation and neoplasm, namely, Hodgkin disease, leukemia, and lymphoma. Breast, thyroid, and lung tumors can metastasize to the pericardium and cause pericarditis or pericardial effusion. Melanoma also metastasizes to the heart. Uremia and tuberculosis also can cause pericarditis. If no cause can be documented, idiopathic viral pericarditis is the most likely diagnosis, and treatment with nonsteroidal anti-inflammatory agents or high-dose aspirin usually resolves the condition.

- Causes of pericarditis: autoimmune and collagen diseases; postmyocardial infarction; radiation; neoplasm; breast, thyroid, and lung tumors; uremia; tuberculosis.

Pericardial Effusion

The response of the pericardium to inflammation is to exude fluid, fibrin, and blood cells, causing a pericardial effusion. The condition is not seen on chest radiography until the amount of effusion is 250 mL. If fluid accumulates slowly, the pericardial sac distends slowly with no cardiac compression. If fluid accumulates rapidly, such as with bleeding, tamponade can occur with relatively small amounts of fluid. Tamponade restricts the blood entering the ventricles and causes a decrease in ventricular volume. The increased intrapericardial pressure increases the ventricular end-diastolic pressure and mean atrial pressure, and the increased atrial pressure increases the venous pressure. The decreased ventricular volume and filling diminish cardiac output. Any of the previously listed causes of pericarditis can cause tamponade, but other acute causes of hemopericardium should be considered, such as ruptured myocardium after infarction, aortic dissection, ruptured aortic aneurysm, and sequelae of cardiac operation.

- Pericardial effusion is not seen on chest radiography until the amount is 250 mL.
- Tamponade can occur with small amounts of fluid.
- Tamponade restricts the blood entering the ventricles and decreases ventricular volume.

Clinical Features

Tamponade produces a continuum of features, depending on its severity. The blood pressure is low, the heart is small and quiet, tachycardia may be present, jugular venous pressure is increased, and pulsus paradoxus develops (increased flow of blood into the right heart during inspiration, decreased flow into the left heart). An increase in inspiratory distention of the neck veins (Kussmaul sign) may occur, as with constrictive pericarditis.

Treatment

Emergency pericardiocentesis is performed with echocardiography-directed guidance.

Constrictive Pericarditis

Diastolic filling of both ventricles is prevented by the pericardium. The smaller the ventricular volume, the higher the end-diastolic pressure. The most common causes are recurrent viral pericarditis, irradiation, previous open heart operation, tuberculosis, and neoplastic disease.

Symptoms

Dominantly right-sided failure, peripheral edema, ascites, and often dyspnea and fatigue are present.

- Symptoms of constrictive pericarditis: peripheral edema, ascites, dyspnea, and fatigue.

Physical Examination

The jugular venous pressure is increased (the patient should be observed when he or she is sitting or standing), and inspiratory distention of neck veins (Kussmaul sign) is present. The jugular venous pressure may show rapid descents, and pericardial knock is present in fewer than 50% of cases (sound is probably due to sudden cessation of ventricular filling). Ascites and peripheral edema are usually present. Chest radiography may show pericardial calcification, but no specific changes are found on electrocardiography.

- Signs of constrictive pericarditis: increased jugular venous pressure, inspiratory distention of neck veins, rapid descents of jugular venous pressure, and pericardial knock (fewer than 50% of cases).
- Chest radiography may show pericardial calcification.
- No specific changes are found on electrocardiography.

Diagnosis

Echocardiography and Doppler may be helpful, particularly Doppler, which shows hemodynamic effects of respiratory changes in mitral and tricuspid inflow velocities. Other methods such as computed tomography and magnetic resonance imaging help to delineate the thickness of the pericardium. The major confounding diagnosis is restrictive cardiomyopathy, and the distinction can be very difficult. Diastolic expansion of both ventricles is affected equally; therefore, diastolic pressure is increased and equal in all four chambers. Ventricular pressure curve shows characteristic "√" (square root sign) from rapid ventricular filling and equalization of pressures (also may be seen in restrictive cardiomyopathy). The *a* and *v* waves are usually equal, and *x* and *y* descents are rapid. If pulmonary artery systolic pressure is more than 50 mm Hg, myocardial disease is likely. If the end-diastolic pulmonary artery pressure is more than 30% of systolic pressure, myocardial disease is likely. Both of these findings are nonspecific, however.

Treatment

The treatment of choice for constrictive pericarditis is thoracotomy to remove the pericardium.

- Constrictive pericarditis is diagnosed from respiratory changes in mitral and tricuspid inflow velocities.
- The major confounding diagnosis is restrictive cardiomyopathy.
- Diastolic pressure is increased and equal in all four chambers.

The Heart and Systemic Disease

Many systemic diseases may have manifestations in the heart. This section describes those that are most likely to be included on the examination.

Hyperthyroidism

Effects

The cardiovascular manifestations of hyperthyroidism include an increase in heart rate, stroke volume, and cardiac output. Peripheral vascular resistance is decreased, and thus there is a widened pulse pressure. All of these lead to an increase in myocardial oxygen consumption and therefore may precipitate angina. Other potential symptoms include palpitations, tachycardia, presyncope or syncope, and shortness of breath on exertion.

- The effects of hyperthyroidism lead to increased myocardial work and oxygen consumption and therefore may precipitate angina and arrhythmias.

Symptoms

Typical clinical scenario: An elderly woman (hyperthyroidism is 4-8 times as common in women as in men) presents with weight loss, weakness, and tachycardia and may or may not have angina or atrial fibrillation (15%). Examination shows tremor of fingers and tongue; goiter may or may not be present.

Physical Examination

Common physical findings are tachycardia and a bounding pulse with a wide pulse present with forceful apical pulse and a systolic ejection murmur due to increased flows. Cardiac arrhythmias are common, particularly supraventricular tachycardia and atrial fibrillation. Atrial fibrillation occurs in 10% to 20% of patients with hyperthyroidism. Therefore, thyrotoxicosis should always be suspected in patients with atrial fibrillation and the thyroid function should be checked.

- Findings of hyperthyroidism: tachycardia, bounding pulse, forceful apical impulse, widened pulse pressure, and systolic ejection murmur.
- Cardiac arrhythmias are common, especially atrial fibrillation.
- Thyrotoxicosis in patients with atrial fibrillation.

Treatment

Treatment of underlying hyperthyroidism usually leads to reversal of cardiac symptoms. If atrial fibrillation is present, the risk of embolization is high and anticoagulation should be instituted. Cardioversion should not be attempted until a euthyroid state is achieved.

Hypothyroidism

Effects

Hypothyroidism leads to cardiac enlargement and decreased function due to infiltration of the myocardium with mucoproteins. This disorder decreases the metabolic rate and circulatory demand and causes bradycardia, decreased myocardial contractility and stroke volume, and an increase in peripheral resistance. In one-third of patients, a pericardial effusion is present. The cardiomyopathy of hypothyroidism is reversible if detected early. The hypothyroid state can increase cholesterol levels and accelerate atherosclerosis.

Symptoms

Typical clinical scenario: An elderly patient presents with depression, lethargy, and slowed mentation. Examination shows hair loss on the

scalp and eyebrows and macroglossia. Sinus bradycardia usually is present. Chest radiography shows increased cardiac size. Electrocardiography shows low voltage of QRS with prolonged intervals of QRS, PR, and QT.

- Hypothyroidism may lead to dilated cardiomyopathy.

Physical Examination

There may be cardiac enlargement due to the myocardial disease or to a commonly found pericardial effusion. The volume of pulses is decreased because of a decrease in myocardial contractility.

- Physical findings in hypothyroidism: cardiac enlargement, reduced myocardial contractility, and pericardial effusion (this occurs in a third of patients).
- Heart failure is less common, but it is reversible if found early.
- Atherosclerosis is accelerated.

Treatment

Treating the underlying cause likely leads to reversal of cardiac involvement.

Diabetes Mellitus

Effects

This condition frequently is associated with premature development of atherosclerosis. It is two times more prevalent in diabetic men and three times more prevalent in diabetic women than in a nondiabetic population. Patients with diabetes have an increased prevalence of hypertension and hyperlipidemia. Angina and myocardial infarction may often manifest as either atypical symptoms or silent ischemia. In fact, congestive heart failure may be the first manifestation of coronary artery disease among the diabetic population. There is also some evidence that cardiomyopathy unassociated with epicardial coronary atherosclerosis exists. This is speculated to be caused by small-vessel disease.

Treatment

The BARI (Bypass and Angioplasty Revascularization Investigation) trial found that coronary artery bypass grafting reduced the death rate more than percutaneous transluminal coronary angioplasty in patients with diabetes mellitus and multivessel coronary artery disease. However, stents and glycoprotein IIb/IIIa inhibitors were not routinely used in that trial. Patients with diabetes seem to have a higher complication rate than nondiabetics regardless of the interventional strategy chosen. If percutaneous intervention is chosen, glycoprotein IIb/IIIa inhibition and stent placement have better long-term control.

Preventive strategy is important. Trials have shown that aggressive management of traditional risk factors for coronary artery disease lowers mortality. Diabetic-specific risk factors for coronary artery disease include glycemic control and urinary protein excretion.

Randomized control trials have found that the use of antihypertensives for aggressive lowering of blood pressure (systolic pressure ≤120 mm Hg, diastolic pressure ≤80 mm Hg) reduces mortality. Statins and fibrates are effective for primary and secondary prevention of coronary artery disease in patients with both diabetes and hyperlipidemia. Aspirin also is effective for primary and secondary prevention. Angiotensin-converting enzyme inhibitors as a class reduce cardiovascular events and mortality in patients with diabetes who are older than 55 years and have additional risk factors (HOPE trial).

- Fatal myocardial infarction is more common in diabetics than in nondiabetics.
- Lipid lowering and glycemic control are important in the prevention of coronary artery disease.
- The prevalence of hypertension is increased in diabetes, but aggressive control lowers mortality.
- The incidence of silent myocardial ischemia is high.
- Angiotensin inhibition should be considered for primary and secondary prevention in diabetics with known vascular disease or with one or more traditional risk factors.
- Aspirin is beneficial for primary and secondary prevention in diabetes.

Amyloidosis

Effects

Amyloidosis is the result of multiple diseases leading to the extracellular deposition of insoluble proteins in organs. Organs involved typically are the liver, kidney, heart, gastrointestinal tract, and nervous tissue. In primary amyloidosis, nearly 90% of patients have clinical manifestations of cardiac dysfunction. The heart is enlarged, most often a result of thickened ventricular myocardium from the protein infiltration. Abnormalities of diastolic function, conduction, and ultimately systolic dysfunction can occur. Amyloid deposition in the cardiac valves leads to atrioventricular valvular regurgitation, which is usually not severe. Secondary amyloidosis occurs in association with chronic disease such as rheumatoid arthritis, tuberculosis, chronic infection, neoplasia (especially multiple myeloma), and chronic renal failure. Cardiac involvement occurs in secondary amyloidosis, but it is usually not a prominent feature. The entity of senile amyloidosis does exist, and the heart is the organ most commonly involved. The prevalence of this disorder increases after age 60 years. Familial amyloidosis is autosomal dominant. The characteristic amyloid protein is pre-albumin, and it can involve the heart.

Clinical Features

The following can occur in cardiac amyloid involvement: congestive heart failure, arrhythmias, sudden death, angina, chest pain, pericardial effusion (usually not hemodynamically significant), and murmurs. The natural history of the disease is usually intractable because of ventricular cardiac failure. Diastolic abnormalities are early common manifestations and are classic for "restrictive cardiomyopathy." The restrictive classification indicates a poor prognosis.

Symptoms

Typical clinical scenario: The diagnosis of amyloidosis should

be given particular consideration when a patient (usually 40-70 years) presents with dyspnea and progressive edema of the lower extremity. Ancillary conditions such as vocal hoarseness, carpal tunnel syndrome, or peripheral neuropathy may be present and point to the systemic nature of the disease. The patient often has received treatment with digoxin and a diuretic but has had little improvement. The key finding is a low-voltage QRS complex with or without other conduction abnormalities (such as increased PR interval or bundle branch block) coupled with echocardiographic findings of thick walls and usually preserved ventricular function.

Diagnosis

The diagnosis of cardiac involvement is made on the basis of electrocardiography, which shows a classic low-voltage QRS complex, which is nonspecific. In addition, echocardiography is particularly useful. Classically, echocardiography shows an increase in left ventricular wall thickness, in contradistinction to the small (or normal) voltage on electrocardiography (Fig. 3-12). Tissue characteristics on echocardiography are often described as granular. The atria generally are dilated. The cardiac valves may show some thickening and regurgitation. There may be a small pericardial effusion. Diastolic function generally is abnormal; in the early stages of the disease it shows a prolongation of the relaxation, and in the later stages it shows restrictive filling (consistent with high left ventricular filling pressures).

- In primary amyloidosis, 90% of patients have cardiac dysfunction.
- Echocardiographic features: thickened ventricular walls, granular myocardial appearance, dilated atria.
- Abnormal diastolic function: consistent with delay and relaxation in the early stages and with restrictive (increased ventricular filling pressure) patterns in the later stages.
- Hallmark: normal to reduced voltage on electrocardiography, in the face of "thick" walls on echocardiography.

Treatment

Treatment of the underlying cause may lead to a better prognosis. However, once cardiac amyloidosis is diagnosed, the prognosis generally is poor. Referral to a tertiary center with expertise in amyloidosis is warranted because experimental protocols have evolved into worthy treatments, such as stem cell transplantation in primary amyloidosis.

Hemochromatosis

Effects

Hemochromatosis is an iron-storage disease. There is a primary or a secondary form related to exogenous iron (usually from repeated blood transfusions) deposits within the cardiac cells. Cardiac hemochromatosis generally does not occur alone and is accompanied by involvement of other organ systems, primarily the tetrad of diabetes, liver disease, brown skin pigmentation, and congestive heart failure.

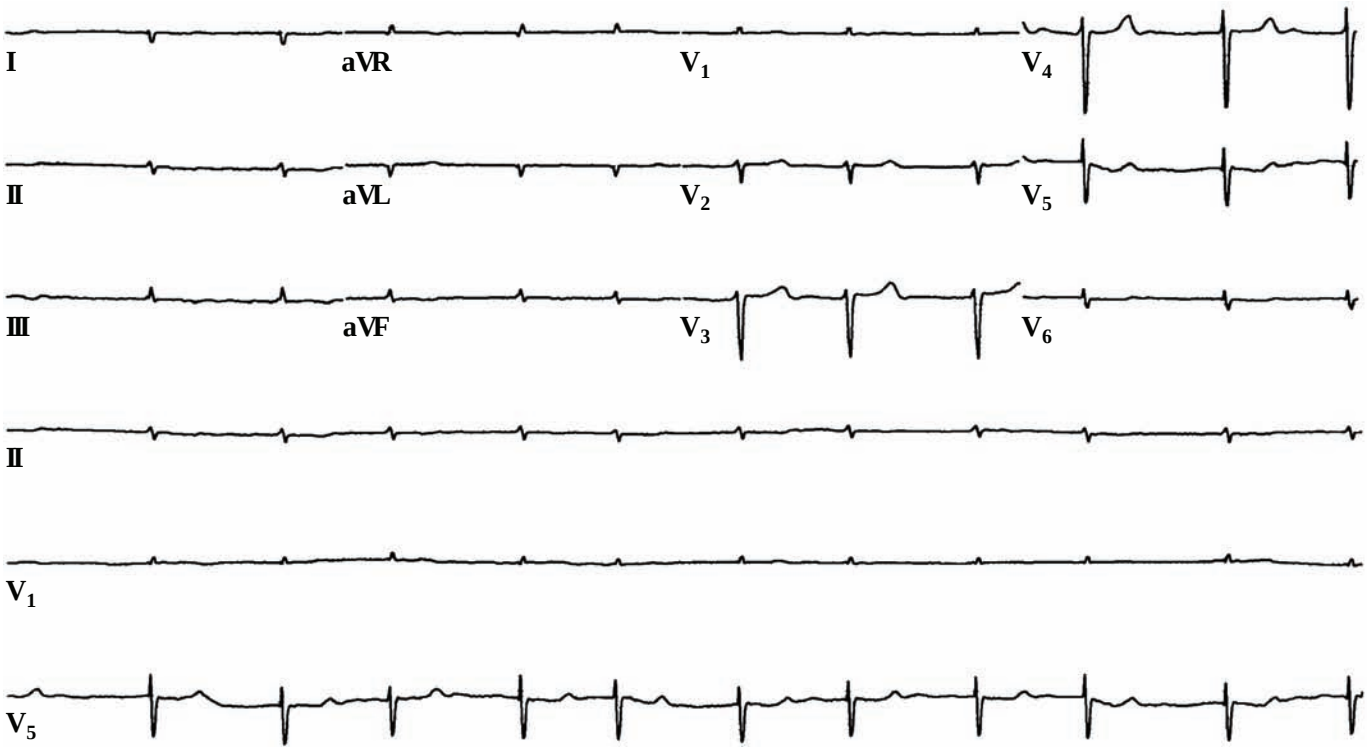

Fig. 3-12. Low-voltage complexes on electrocardiography in a patient with cardiac amyloidosis.

The condition may present with cardiomegaly, congestive heart failure, and arrhythmias. This disease has features of poor systolic and diastolic function. Once clinical cardiac symptoms appear, the prognosis is very poor unless treatment is initiated with a combination of phlebotomy and iron chelation.

Symptoms

Typical clinical scenario: Patients are middle-aged and present with symptoms and signs of heart failure. Clues to hemochromatosis are a well-tanned patient with diabetes or, at minimum, increased blood glucose value, arthralgias, and loss of libido. The diagnosis is made on the basis of increased transferrin saturation and increased serum ferritin value.

- Hemochromatosis is related to iron deposits within cardiac cells.
- Cardiac involvement in hemochromatosis does not occur alone; other organs are involved.
- The key to diagnosis is the tetrad of diabetes, liver disease, skin hyperpigmentation, and congestive heart failure.

Carcinoid Heart Disease

Effects

Carcinoid tumor is a malignant tumor. The primary site, usually gastrointestinal (terminal ileum), can produce a classic syndrome (in about 4% of patients) when metastatic to the liver or lungs. Malignant carcinoid tumors produce serotonin-like substances that cause cutaneous flushing, wheezing, and diarrhea, which is the carcinoid syndrome. These circulating substances are also toxic to valvular tissues. They are metabolized in the liver and lungs. Cardiac involvement occurs in approximately 50% of patients after hepatic or pulmonary metastasis. Therefore, toxic effects generally affect right-sided cardiac valves unless there is a shunt (generally a patent foramen ovale) that allows right-to-left movement of blood substances. Carcinoid lesions are fibrous plaques that form on valvular endocardium. The valve leaflets become thickened, relatively immobile, and retracted. The result is regurgitation with an element of stenosis of both the tricuspid and the pulmonary valves.

Symptoms

Typical clinical scenario: A 50- to 70-year-old patient presents with weight loss, fatigue, watery diarrhea (>10 stools daily), dyspnea on exertion, and audible wheezes. The patient has a red complexion and notes feeling hot flashes intermittently.

Physical Examination

Examination typically reveals a prominent *v* wave in an increased jugular venous pressure profile, a pulsatile liver that may be enlarged, ascites, and usually considerable peripheral edema.

Diagnosis

Electrocardiography typically shows right ventricular hypertrophy and right bundle branch block. Diagnosis is made by identification of a thickened tricuspid valve and pulmonary valve (left-sided valves only if a shunt is present) and the finding of liver metastasis on computed tomography, confirmed by a 24-hour urine study for 5-hydroxyindoleacetic acid. Acquired tricuspid and pulmonary stenosis with or without regurgitation is rare and should always raise the possibility of carcinoid heart disease.

- Carcinoid tumors produce serotonin-like substances that cause flushing, wheezing, and diarrhea.
- Changes occur in the tricuspid and pulmonary valves. Dominant lesions are tricuspid regurgitation, pulmonary regurgitation, and stenosis.
- Acquired tricuspid and pulmonary stenosis with or without regurgitation is rare and should always raise the possibility of carcinoid heart disease.

Treatment

Treatment of underlying carcinoid tumor is important for relief of symptoms. If there is evidence of right heart failure (intractable edema, ascites, dyspnea), then intervention may be warranted. Surgical therapies include tricuspid valve replacement and pulmonary valve resection.

Hypereosinophilic Syndrome

Effects

This syndrome affects young patients, generally male, who have a persistent eosinophil concentration of more than 1.5×10^9/L. The causes are several, including idiopathic hypereosinophilia, Löffler endocarditis, reactive or allergic eosinophilia, leukemic or neoplastic eosinophilia, or Churg-Strauss syndrome. All of these may have cardiac manifestations.

Clinical Features

Patients present with weight loss, fatigue, dyspnea, syncope, and systemic embolization. Cardiac manifestations include arrhythmias, myocarditis, conduction abnormalities, and thrombosis. Eosinophilic deposition occurs in the heart, where a clot forms in the apices of the ventricles and in the inflow portions under the mitral and tricuspid valves. This ultimately leads to matting down of the atrioventricular valve and causes considerable regurgitation. The clot ultimately scars, leading to endomyocardial fibrosis and restrictive cardiomyopathy.

- Hypereosinophilic syndrome may be present in patients with a persistent eosinophil value $>1.5 \times 10^9$/L.
- Hypereosinophilic syndrome presents with restrictive cardiomyopathy, atrioventricular valve regurgitation, and systemic embolization.
- Unexpected thromboembolism in the presence of normal left ventricular function should raise suspicion of this syndrome.
- Churg-Strauss syndrome should be considered if pulmonary involvement is present.
- Typical clinical scenario: A young patient has fatigue, weight loss, and dyspnea of relatively recent onset (months) and presents to the emergency department because of new right-sided weakness. Echocardiography shows a normal to small left ventricle, mitral valve abnormalities, and apical ventricular thrombus. The diag-

nosis is confirmed on the basis of a complete blood count with differential count.

Systemic Lupus Erythematosus

Systemic lupus erythematosus may involve any of the cardiac structures. Special features of involvement include the antiphospholipid syndrome, Libman-Sacks endocarditis, and congenital heart block in the offspring of mothers with lupus.

Offspring of mothers with anti-La and anti-Ro antibodies are at risk for development of neonatal lupus, characterized by myocarditis and inflammation and fibrosis of the conduction system, which may lead to congenital heart block.

Cardiac involvement in patients with systemic lupus erythematosus may include pericarditis, which is characterized by a positive antinuclear antibody in the pericardial fluid, myocarditis (more common in patients with anti-Ro antibody), a valvulopathy, coronary arteritis, and Libman-Sacks endocarditis.

Libman-Sacks endocarditis is a noninfective vegetation that may be present in up to 50% of patients with systemic lupus erythematosus. It does not generally embolize or interfere with valvular function.

- The offspring of mothers with anti-La and anti-Ro antibodies are at risk for congenital heart block.
- Approximately a third of patients with systemic lupus erythematosus may have clinical evidence of cardiac involvement, including pericarditis, endocarditis, myocarditis, and coronary arteritis.
- Typical clinical scenario: A mother with a history of multiple spontaneous abortions carries a baby to term, and the baby is born with complete heart block.

Scleroderma

Scleroderma affects the skin with sclerotic changes, the esophagus with dysphagia, and small vessels with manifestations such as Raynaud phenomenon. Cardiac involvement is manifested by intramural coronary involvement and immune-mediated endothelial injury, which is often associated with the Raynaud phenomenon clinically. Cardiac involvement is the third most common cause of mortality in patients with scleroderma. Conduction defects occur in up to 20% of patients, and a pericardial effusion is found in a third of patients, but it is often asymptomatic. Indirect cardiac involvement due to pulmonary hypertension and cor pulmonale is frequent.

- Cardiac involvement is the third most common cause of mortality in patients with scleroderma.
- Coronary vasculitis is associated with clinical Raynaud phenomenon.
- Conduction defects may occur in up to 20% of patients.

Rheumatoid Arthritis

Rheumatoid arthritis may be associated with involvement of nearly all cardiac components, including pericardium, myocardium, valves, coronary arteries, and aorta. Rheumatoid arthritis may cause both granulomatous and nongranulomatous inflammation of valve leaflets, which rarely leads to severe valvular incompetence. Pericarditis of rheumatoid arthritis usually is associated with a low glucose level and complement depletion in the pericardial fluid. Rheumatoid nodules may be deposited in the conduction system, leading to degrees of heart block. Aortitis and pulmonary hypertension due to pulmonary vasculitis are very rare complications of rheumatoid arthritis.

- Pericardial fluid accumulation in patients with rheumatoid pericarditis will be low in glucose and complement and is associated with nodular rheumatoid arthritis.
- Granulomatous involvement in the conduction system may lead to heart block.
- Nongranulomatous and granulomatous involvement of valvular tissue may lead to incompetence of cardiac valve structures.

Ankylosing Spondylitis

Aortic dilatation and aortic regurgitation may be present in approximately 10% of patients. Aortic valve cusps become distorted and retracted, leading to considerable aortic regurgitation. The conduction system may become involved as a result of both fibrosis and inflammation.

Marfan Syndrome

Marfan syndrome is an autosomal dominant condition associated with degenerative elastic tissues, leading to arachnodactyly, tall stature, pectus excavatum, kyphoscoliosis, and lenticular dislocation.

Common cardiac manifestations include mitral valve prolapse, aortic regurgitation due to aortic dilatation, and increased risk of aortic dissection. Long-term β-adrenergic blockade has been shown to decrease the rate of aortic dilatation and potential for dissection. Dissection occurs rarely in an aorta less than 55 mm in diameter. When dissection occurs, it tends to start in the ascending aorta and extend along the entire aorta.

Friedreich Ataxia

This is an autosomal recessive neurologic disorder that involves the heart in up to 90% of cases. It usually manifests as a symmetric hypertrophy and less commonly as a dilated cardiomyopathy.

Osteogenesis Imperfecta

Brittle bones, blue sclera, and deafness are the hallmarks of this condition, which leads to a lack of collagen-supporting matrix. Ultimately, there is a degeneration of elastic tissues, including aortic root dilatation, aortic regurgitation, annular dilatation, and chordal stretch leading to significant atrioventricular regurgitation.

Lyme Disease

Lyme disease is a spirochete infection by *Borrelia burgdorferi* organisms. Up to 10% of cases have clinical cardiac involvement. Cardiac manifestations include atrioventricular block and Lyme carditis. The diagnosis is generally made by biopsy of the right ventricular myocardium or gallium scanning.

Acquired Immunodeficiency Syndrome (AIDS)

Clinically apparent cardiac involvement may occur in up to 10% of patients with AIDS. Cardiac involvement has been reported as a

myocarditis in up to 50% of patients at autopsy. This may be associated with ventricular arrhythmias, dilated cardiomyopathy, pericarditis, or infectious or malignant invasion of the cardiac structures.

Cardiac Trauma

Contusion, in the acute stage, may lead to arrhythmia, increased cardiac enzyme values, transient regional wall motion abnormalities, and pericardial effusion or tamponade. It also has been reported to cause disruption of the aorta or valves (tricuspid valve most often) or right ventricular rupture.

Commotio cordis is sudden cardiac death due to trauma, characteristically mild trauma to the chest wall, which is generally a nonpenetrating blow such as that delivered by a baseball or softball. This can occur in the absence of underlying cardiac disease and leads to instantaneous cardiac arrest. Research indicates that the trauma must be delivered during the vulnerable phase of the cardiac cycle, which is described as 15 to 30 ms before and after the T wave.

Typical clinical scenario: An 11-year-old boy playing baseball is pitched a ball errantly and takes a blow to the chest. He falls to the ground pulseless.

Prosthetic Valve

Bioprostheses

These are made of animal or human tissue, which may be unmounted or mounted in a frame. Different types include 1) homograft (human tissue), either aortic or pulmonary; 2) heterograft (porcine valve), for example, Hancock or Carpentier-Edwards; and 3) pericardial (bovine valve), for example, Ionescu-Shiley. Tissue valves have the advantage that they are not as thrombogenic as mechanical valves; thus, most patients in sinus rhythm do not require anticoagulation in the long term, although they will need it for the first 3 to 6 months after valve replacement. There is a risk of systemic embolism, however, with biologic prostheses in patients with atrial fibrillation, particularly with a mitral prosthesis. The disadvantage is that tissue valves degenerate and calcify, and thus patients need reoperation. Approximately 50% of patients need valve replacement at 10 to 15 years. In young patients (20 years or younger), these valves may calcify very rapidly. Tissue valves last a little longer in the tricuspid position than in positions on the left side of the heart. Aortic valves have a slightly better durability than mitral valves. Prosthesis failure can be detected by clinical evaluation and two-dimensional and Doppler echocardiography.

- Tissue valves are not as thrombogenic as mechanical valves.
- Most patients with tissue valves who are in sinus rhythm do not require anticoagulation.
- Tissue valves degenerate and calcify.
- About 50% of patients need valve replacement 10 to 15 years after original valve placement.

Mechanical Valves

An example of a *ball valve* is the Starr-Edwards. It has excellent longevity and is a so-called high-profile valve. Newer valves such as the *bileaflet* St. Jude or *tilting disc valve* (i.e., Björk-Shiley) have a lower profile. All mechanical valves have a risk of thromboembolism and necessitate long-term anticoagulation. Hemolysis may occur with mechanical prostheses, especially if there is a perivalvular leak. Anticoagulation complications include hemorrhage, especially when the international normalized ratio is too high, and thrombosis, when the ratio is subtherapeutic. The rate of minor hemorrhages is 2% to 4% per year, and that of major hemorrhages is 1% to 2% per year. Risk of complications from mechanical prostheses, including endocarditis, is approximately 1% per year. All patients with a valvular prosthesis require antibiotic prophylaxis for endocarditis.

- All mechanical valves have a risk of thromboembolism.
- Hemolysis may occur with mechanical prostheses, especially in association with perivalvular leak.
- Anticoagulation can be associated with hemorrhage and thrombosis.
- All patients with a valvular prosthesis require antibiotic prophylaxis for endocarditis.

Tumors of the Heart

Most cardiac tumors are metastatic. The most common primary cardiac tumor is myxoma.

Cardiac Myxoma

Most cardiac myxomas are sporadic, but there have been some reports of familial occurrence. A syndrome of cardiac myxomas with lentiginosis (spotty pigmentation) and recurrent myxomas has been recognized. About 75% are in the left atrium, 18% are in the right atrium, and the rest are in the ventricles. Most of the atrial tumors arise from the atrial septum, usually adjacent to the fossa ovalis. About 95% are single. Most myxomas have a short stalk, are gelatinous and friable, and tend to embolize. They occasionally calcify, so they may be visible on a chest radiograph.

The main clinical features are obstruction to blood flow, embolization, and systemic effects. Left atrial tumors prolapse into the mitral valve orifice and produce mitral stenosis. They mimic mitral valvular stenosis, with symptoms of dyspnea, orthopnea, cough, pulmonary edema, and hemoptysis. Classically, symptoms occur with a change in body position. Physical findings suggest mitral stenosis. Pulmonary hypertension also may occur. An early diastolic sound, the tumor "plop," may be heard. This has a lower frequency than an opening snap.

- Most cardiac tumors are metastatic.
- The most common primary cardiac tumor is myxoma.
- About 75% of cardiac myxomas are in the left atrium and 18% are in the right atrium; the rest are in the ventricles.
- Clinical features are obstruction to blood flow, embolization, and systemic effects.
- Symptoms occur with a change in body position.
- An early diastolic sound, the tumor "plop," may be heard.

Embolization

Systemic emboli may occur in 30% to 60% of patients with left-sided

myxoma, frequently to the brain and lower extremities. Histologic examination of embolized material is important. Coronary embolization is rare, but it should be considered in a young patient with no known previous cardiac disease. Systemic effects are fatigue, fever, weight loss, and arthralgia. Systemic effects may be associated with an increased sedimentation rate, leukocytosis, hypergammaglobulinemia, and anemia. Increased immunoglobulins are usually of IgG class.

Echocardiography is the preferred approach to diagnosis. Transesophageal echocardiography helps delineate the precise site of origin and accurately assesses tumor size and degree of mobility. Operation is indicated when the diagnosis is made.

- Systemic emboli occur in 30% to 60% of cases of left-sided myxoma, frequently to the brain and lower extremities.
- Coronary embolization is rare.
- Systemic effects: fatigue, fever, weight loss, and arthralgia.
- Systemic effects may be associated with an increased sedimentation rate, leukocytosis, hypergammaglobulinemia, and anemia.
- Increased immunoglobulins are usually of IgG class.
- Echocardiography is the preferred approach to diagnosis.
- Operation is indicated.

Primary Cardiac Neoplasm

Rhabdomyoma is most common in women and children. It can produce obstruction of cardiac valves, simulating other abnormalities, and can cause cardiac arrhythmias. Other tumors, such as Kaposi sarcoma associated with acquired immunodeficiency syndrome (AIDS), do not usually cause cardiac symptoms.

Secondary tumors most often originate from bone, breast, lymphoma, leukemia, and thyroid. More than half of patients with malignant melanoma have metastases to the heart.

- Rhabdomyoma is most common in women and children.
- More than half of patients with malignant melanoma have metastases to the heart.

Imaging in Cardiology

An important part of cardiology is the appropriate choice of an imaging method to aid in the diagnosis, quantification, and prognosis of various diseases. The most commonly ordered test is assessment of left ventricular function. Various techniques are available, as outlined in Table 3-9. It is important for the clinician to have a focused question and subsequently choose the most appropriate technique to answer the clinical question.

Contrast Angiography

This imaging method was the first to visualize the cardiac chambers and directly assess left ventricular size and function with x-rays by injecting radiopaque material (iodine dye) into the cardiac chamber. Intracardiac access usually is required, and thus it is an invasive procedure, although new techniques (intravenous digital subtraction angiography) may allow a more noninvasive approach. With use of a 30° right ventricular oblique and an orthogonal (60°) left anterior oblique view (sometimes with a 20°-30° cranial tilt to avoid foreshortening of the left ventricle), biplane views are obtained over several cycles to assess left ventricular volumes and regional wall motion abnormalities. Several algorithms have been developed to extrapolate the information of these two views to the entire heart. This requires certain assumptions about the ventricular shape (regularity) and contraction pattern (concentric), which may not hold true in ischemia with resting wall motion abnormalities and previous myocardial infarction. Other concerns include the need for ionizing radiation, possible allergies to iodine, and impairment of renal function. These usually are managed with appropriate preparation (hydration, corticosteroids, antihistamine, acetylcysteine) and by minimizing the amount of contrast agent used. Because coronary angiography, that is, the selective visualization of the coronary arteries, is the reference technique to assess the location (not necessarily the hemodynamic significance) of coronary artery stenosis, assessment of left ventricular function by contrast ventriculography should be performed only during

Table 3-9 Cardiac Imaging Methods

Method	Variable assessed				Cost effectiveness*
	LVEF	RV function	LV mass	RWMA	
Contrast angiography	Yes	No	No	Yes	++++†
Two-dimensional echocardiography	Yes	Yes	Yes	Yes	++
First-pass RNA	Yes	Yes, quantitative‡	No	No	+
Blood pool RNA	Yes	No	No	Yes	+
Magnetic resonance imaging	Yes	Yes, quantitative‡	Yes	Yes	+++/+
Electron beam computed tomography	Yes	Yes, quantitative‡	Yes	Yes	+++

LV, left ventricular; LVEF, left ventricular ejection fraction; RNA, radionuclide angiography; RV, right ventricular; RWMA, regional wall motion abnormalities.

*+, Least expensive; ++++, most expensive.

†If performed without coronary angiography.

‡Quantitative, absolute measurements of global ventricular volumes possible to facilitate measure of RV ejection fraction.

accompanying coronary angiography. If the dye load needs to be minimized (renal failure), an alternative technique should be considered to save approximately 20 to 50 mL of contrast agent.

Echocardiography

Echocardiography uses a high-frequency (2-10 MHz) ultrasonic beam produced by a piezoelectric crystal from a transducer to generate images and acquire and process the various acoustic echoes. Currently, three methods are readily available: M-mode, two-dimensional, and Doppler-color Doppler. A single cursor (beam) traverses the object of interest and traces its motion through time and gives excellent temporal-spatial resolution for timing of motion of structures in the cardiac cycle. M-mode echocardiography provides only limited information about the structures and has largely been replaced by two-dimensional echocardiography.

Two-Dimensional Echocardiography

Two-dimensional imaging provides a beat-to-beat tomogram of the heart. Outlining the endocardial and epicardial borders allows determination of left ventricular volumes in end-diastole and end-systole and subsequently stroke volume, ejection fraction, cardiac output, and muscle mass. The algorithms used are similar to those used in contrast ventriculography, requiring certain assumptions about ventricular shape and contraction. The technique is, however, completely noninvasive and thus lends itself to serial image acquisition. Its easy availability has made it the most widely used imaging technology in cardiology today. With assessment of endocardial motion and wall thickening from various transducer positions, regional wall motion abnormalities also can be assessed. The morphologic features of valves (pliability, degree of calcification, morphologic abnormalities, i.e., flail segments) and intracardial and pericardial structures also can be analyzed. With exercise or pharmacologic (usually dobutamine) stress, regional wall motion can be assessed both at rest and at stress for the diagnosis of coronary artery disease. Regional wall motion analysis requires a highly skilled interpreter, particularly in the presence of preexisting regional wall motion abnormalities.

Doppler-Color Doppler Echocardiography

Doppler-color Doppler echocardiography allows direct measurements of blood velocities across valves and along conduits (left ventricular outflow tract, vessels), which permit calculation of stroke volume, cardiac output, valve gradients, and severity of regurgitant lesions and semiquantitation of intracardiac and extracardiac shunts.

The crucial element for optimal echocardiographic image acquisition is the availability of appropriate acoustic "windows" to allow proper directing of the ultrasound beam to the structure of interest. Obese patients, very cachectic patients, and patients with extensive lung disease (smokers, chronic obstructive pulmonary disease, restrictive lung disease) may pose insurmountable problems for transthoracic echocardiography in a small percentage of cases. Transesophageal echocardiography may overcome this problem, but it is an invasive approach. Echocardiography also requires the most operator experience and is more dependent on the operator for both image acquisition and interpretation. Neither technique can currently visualize the coronary arteries in the way that angiography does.

Contrast Echocardiography

Contrast echocardiography is a new technology, enhancing the echocardiographic signal with injection of an enhancing agent. Some of these agents are now smaller than red blood cells and cross the pulmonary vascular bed. Applications in the clinical arena include better visualization of endocardium that is not conducive to sonographic access (caused by obesity, emphysema, chest deformities). Work is also progressing to use echocardiographic contrast agents as "flow" agents to assess myocardial perfusion, an additional, independent factor complementing regional wall motion analysis and cardiac function. Standardization of testing algorithms is in progress.

Radionuclide Imaging

Radionuclide imaging principally uses two techniques: labeling erythrocytes with an isotope to assess endocardial motion or using perfusion tracers (thallium, sestamibi) to assess differences between resting and stress blood flow.

Radionuclide Angiography

Erythrocytes are labeled with technetium, which can be imaged by a gamma camera, which usually is placed in the anteroposterior, left anterior oblique, and lateral positions. Sufficient photon capture is ensured by acquiring images over multiple cardiac cycles. This procedure requires electrocardiographic gating, which opens the aperture of the camera for fractions during the cardiac cycle. Patients with atrial fibrillation and markedly variable RR intervals are not suited for this approach. Quantification of left ventricular function is based on the number of photons in the ventricle at end-diastole and end-systole. This count-based method obviates any geometric assumptions and thus provides a very accurate assessment of left ventricular function, especially in patients with poor function. Because radionuclide angiography is dependent on the number of photons available at end-diastole and end-systole, there is a very good signal with little noise in large, poorly contractile ventricles, allowing excellent discrimination between low ejection fractions, particularly during serial assessment. In contrast, echocardiography relies on the endocardial inward motion, which is poor in severely dysfunctional ventricles, introducing a higher signal-to-noise ratio that makes discrimination between low ejection fractions difficult.

First-Pass Radionuclide Angiography

Recently, techniques have been developed to follow the passage of a radioisotope bolus through the right and left cardiac system, allowing assessment of left ventricular function. Subsequently, the tracer distributes according to coronary blood flow, and perfusion images are obtained. This technique, based on dye-dilution and videodensitometric principles, allows easy, economical assessment of both right and left ventricular function. Drawbacks are difficulties in administering the bolus (poor intravenous access), which lead to early diffusion of the bolus with poor discrimination of the dextrophase and levo-phase. Similar to radionuclide angiography, first-pass radionuclide angiography is extremely sensitive to arrhythmias, particularly when they occur during the calculation phase of the first-pass acquisition.

Myocardial Perfusion Imaging

The two most commonly applied isotopes are thallium and sestamibi, which distribute to the myocardium according to blood flow. They are avidly taken up by the myocytes. These isotopes can subsequently be imaged at rest and after exercise (Fig. 3-13). Images are acquired by a planar technique in which the camera is positioned similar to that in radionuclide angiography in three positions. More accurate is a single photon emission computed tomography (SPECT) approach in which a camera rotates around the patient and takes images at certain narrow-angle intervals to compose a complete three-dimensional image of the entire heart without superpositrons. The views are then commonly displayed as short-axis tomograms spanning the entire heart (Fig. 3-13, upper left at stress; upper right at rest). The images are then compared with each other. During stress (exercise or pharmacologic), there is usually reduced uptake in the affected myocardium. Subsequently, at rest, there is redistribution of the isotope (thallium) where a preferential washout of the previously normal myocardium and a preferential uptake of the previously hypoperfused myocardium take place. With sestamibi, the isotope is taken up essentially irreversibly into the myocardium, and a repeat resting injection is mandatory to reflect the resting flow conditions. The extent and the severity of the perfusion defect provide additional important information in regard to the prognosis of the disease which goes beyond the mere diagnosis of the presence or absence of coronary artery disease. It is also helpful to assess residual ischemia in patients with previous myocardial infarction and to assess therapeutic efficacy in patients treated medically or by intervention. The result of the imaging studies should always be viewed in conjunction with the data available from the exercise or stress electrocardiogram.

Gated Sestamibi Imaging

Improved imaging techniques and shortened image acquisition time due to dual- or triple-camera configurations have made gated imaging available, a technique similar to radionuclide angiography. Unlike multiple-gated acquisition scanning, in which the isotope remains in the left ventricular cavity (a "lumenogram"), with gated SPECT imaging the motion of myocardium is imaged throughout the cardiac cycle. This allows regional wall motion analysis similar to that of echocardiography. Because of technical circumstances, post-stress images are acquired with a considerable time delay and thus reflect mostly resting contractility.

Magnetic Resonance Imaging

Magnetic resonance imaging (MRI) is a noninvasive, three-dimensional imaging technique that allows noninvasive assessment of left ventricular size, function, and muscle mass. The technique is extremely precise. Recent technical advances have considerably shortened the acquisition time. Clinical applications are emerging aside from study

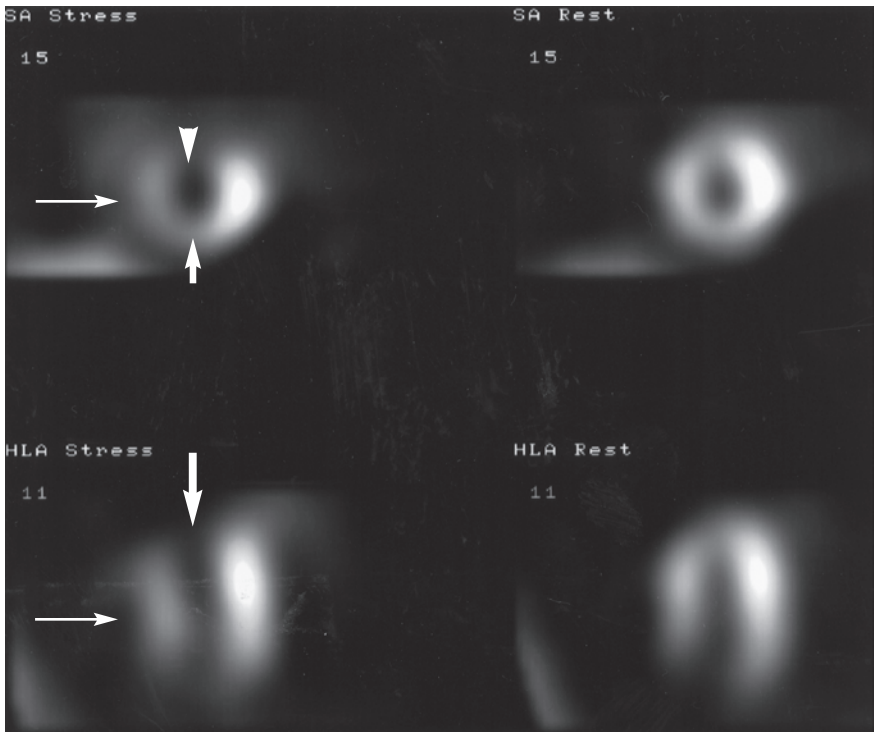

Fig. 3-13. Patient with exertional angina (class III) of recent onset. Low-level exercise with 1-mm ST-segment depression at 2 minutes into exercise. The left column depicts the stress images with a representative short-axis tomogram (upper left panel) and the horizontal long axis (lower left panel). In the right column are the rest images, with corresponding short-axis tomogram in the right upper panel and the corresponding horizontal long-axis tomogram in the right lower panel. Note the severely reduced uptake in the apical (thick arrow), septal (thin arrows), anterior (arrowhead), and inferior (short arrow) segments. At rest there is nearly complete normalization in all segments. Subsequent angiography indicated complete occlusion of the right coronary artery and 80% stenosis in the proximal left anterior descending coronary artery. The circumflex coronary artery did not show a critical lesion.

of left ventricular function and anatomical structure. It has the potential to differentiate plaque composition and thus may be able to identify vulnerable plaques. Additional work indicates its usefulness for assessing myocardial perfusion and, although MRI for this purpose is not yet widely available, it will undoubtedly add to our diagnostic armamentarium in the near future.

Electron Beam Computed Tomography

Electron beam computed tomography (EBCT) uses a scanner without any movable parts in which an electron beam is deflected via magnetic fields rapidly on several rings around the patient, allowing high-fidelity, high-resolution, three-dimensional images of the entire heart in rapid succession. Like all complex imaging techniques it is dependent on electrocardiographic gating; however, it requires only one beat to complete a cycle. Because the entire heart is encompassed in the scan, no geometric assumptions need to be made. It is ideally suited for serial studies in left ventricular remodeling because of its high precision and accuracy. Drawbacks are the requirements for a contrast agent to be administered into a peripheral vein and for ionizing radiation.

EBCT has raised considerable interest for the early detection of coronary atherosclerosis because it opens the possibility for early, effective, and targeted intervention (primary prevention). It is currently the most widely used technique in this field because of its ease of application (rapid acquisition time, no contrast agent) and standardized imaging and analysis algorithms. It detects coronary calcium, an essential component of coronary plaque. Databases are being generated to assess the degree of calcification in relation to age, sex, and ethnic background. This information has been correlated with future risk for cardiac events, surpassing any currently available algorithm containing the conventional risk factor array (such as lipid profile, smoking history, family history, hypertension, and diabetes). Interest in the early detection of atherosclerosis has resulted in other scanning technology. It is not yet clear whether these other scanners are equivalent in their predictive accuracy.

Positron Emission Tomography

Positron emission tomography depends on the detection of a simultaneous pair of photons radiating into exact opposite directions. This principle, not unlike radionuclide angiography, allows high-spatial and temporal resolution imaging. Positron emission tomography currently is the reference standard for the assessment of myocardial viability. However, the complexity of the technology and the cost currently limit its use to tertiary academic centers.

Part II

Peter A. Brady, MD

Mechanisms of Arrhythmias

Abnormal cardiac rhythm may be due to reentry, triggered activity, and abnormal automaticity (including parasystole).

Reentry

Reentry is the most common mechanism responsible for cardiac arrhythmias. Reentrant rhythms may be micro-reentrant or macro-reentrant. Examples of micro-reentrant circuits include the sinus node, atrioventricular (AV) node, or injured myocardium bordering a myocardial infarction (myocardial scar). Macro-reentrant circuits include reentry within the atrium (as in atrial flutter), AV conduction system, ventricle, or an accessory pathway (as in Wolff-Parkinson-White syndrome).

For reentry to occur, three conditions must be met (Fig. 3-14 and 3-15): 1) two or more anatomically or functionally distinct pathways (connected proximally and distally to form a closed circuit) must be present (e.g., slow and fast pathways in patients with supraventricular tachycardia due to AV nodal reentry), 2) unidirectional block must occur in one pathway, and 3) slowed conduction must occur in the second pathway to an extent that conduction in the first pathway has recovered by the time the impulse reaches its distal connection.

- Reentry is the most common mechanism for cardiac arrhythmias.

Triggered Activity

This mechanism is so-named because each abnormal complex is generated (triggered) by the preceding beat (complex). During normal depolarization of the cardiac cell, partial (abnormal) depolarization may occur which "triggers" complete depolarization of the cell, initiating an (early) abnormal complex. Two types of triggered activity exist depending on whether they arise before (*early afterdepolarization*) or after (*delayed afterdepolarization*) normal action potential recovery. Delayed afterdepolarizations arising during the resting phase of the action potential (phase 4) are believed to underlie arrhythmias due to digitalis toxicity. In contrast, early afterdepolarizations arise during the plateau (phase 2) or repolarization (phase 3) of the action potential and may be responsible for the polymorphic ventricular tachycardia (torsades de pointes) caused by antiarrhythmic drugs such as quinidine.

Automaticity

Individual cardiac cells are able to discharge spontaneously, a property termed "physiologic automaticity." Cells in the region of the sinus node discharge with the highest frequency and therefore act as the dominant pacemaker of the heart. The rate of impulse formation is determined by the slope of spontaneous depolarization (Fig. 3-16). Factors that enhance automaticity by altering the slope of spontaneous depolarization are listed in Table 3-10.

Predominant discharge of cells outside the region of the sinus node which causes abnormal heart rhythms is termed "abnormal automaticity" and is due to accelerated phase 4 depolarization. This mechanism is thought to be the cause of atrial tachycardia and multifocal atrial tachycardia (which occurs most commonly in patients

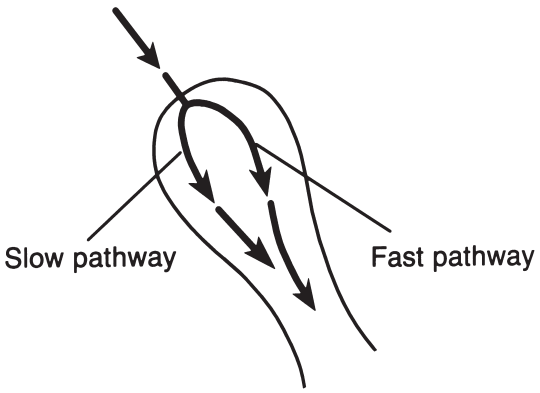

Fig. 3-14. Reentry within the atrioventricular (AV) node shows the two limbs of reentrant circuit. Recent evidence suggests that a portion of the reentrant pathway is separate from the AV node.

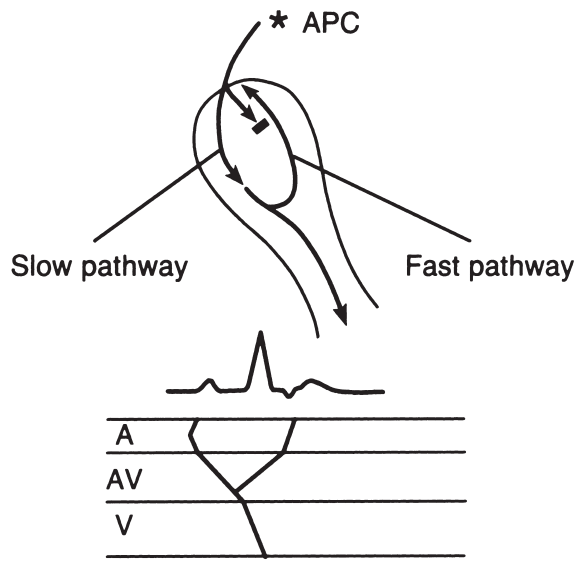

Fig. 3-15. Atrioventricular (AV) nodal reentrant tachycardia. An atrial premature complex (APC) blocks in fast pathway but conducts over slow pathway to ventricle. Impulse then returns to atria over recovered fast pathway and can reenter slow pathway and initiate tachycardia. A, atrium; V, ventricle.

Table 3-10 Factors That Enhance Automaticity

Autonomic changes
Increased sympathetic tone
Decreased parasympathetic tone
Metabolic or ischemic changes
Increased carbon dioxide
Decreased oxygen
Increased acidity
Mechanical factors
Increased stretch
Drugs
Isoproterenol
Electrolyte alterations
Decreased potassium
Increased calcium

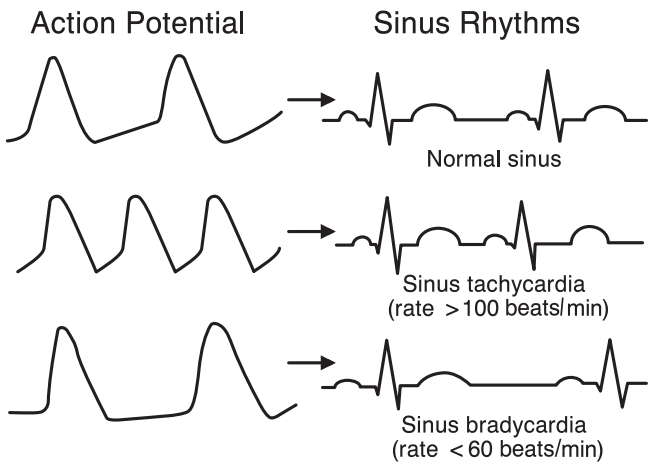

Fig. 3-16. Action potential corresponding to electrocardiographic manifestation of sinus node activity. Under physiologic conditions, sinus rate is a function of the slope of spontaneous depolarization during phase 4 of the action potential. A steep slope of the spontaneous depolarization corresponds to a faster sinus rate (sinus tachycardia). A flat slope of phase 4 depolarization corresponds to a slower sinus rate (sinus bradycardia).

with decompensated lung disease) and of ventricular ectopy occurring early after myocardial infarction (idioventricular rhythm). Automaticity is enhanced by increased sympathetic tone, hypoxia, acid-base and electrolyte disturbances, and atrial or ventricular stretch. Accelerated idioventricular rhythm also may be due to abnormal automaticity.

- Automaticity is enhanced by increased sympathetic tone, hypoxia, acid-base and electrolyte disturbances, and atrial or ventricular stretch.

Parasystole

Parasystole is a special type of abnormal automaticity and occurs when an ectopic focus in the atrium or ventricle is isolated from the rest of the myocardium. Cells within a parasystolic focus are protected from the influence of surrounding cells and therefore are not constantly "reset" by the sinus node or other focus and manifest on the surface electrocardiogram as ectopy independent of the dominant rhythm. This mechanism accounts for approximately 3% of premature ventricular complexes (PVCs) noted during routine monitoring and is, in general, benign.

- Parasystole is due to an independently discharging ectopic focus in the atrium or ventricle.
- Parasystole causes 3% of PVCs during routine monitoring.
- Parasystole is generally benign.

Investigations Commonly Used in the Evaluation and Management of Patients With Suspected Rhythm Disorders

Electrocardiography

Electrocardiography (ECG) remains a valuable tool in the evaluation of heart rhythm disorders. In many cases, ECG performed during symptoms of tachycardia is diagnostic of the tachycardia mechanism and is all that is needed to plan management. In other cases, ECG may provide clues to the probable diagnosis of symptoms. Whenever possible, a current ECG should be compared with previous recordings.

Ambulatory ECG Monitoring and Transtelephonic Event Recording

Ambulatory (Holter) monitoring is useful for the evaluation of both symptomatic and asymptomatic rhythm disturbances and their relationship to daily activity (e.g., exercise). Symptoms, if present, must, however, occur frequently enough to be recorded during the 24- or 48-hour recording period. A diary in which patients record their activity and specific symptoms and precise duration of both allows correlation with heart rhythm recordings.

Ambulatory monitoring is also useful for assessing the impact of treatment on arrhythmias (e.g., determining the adequacy of ventricular rate control during drug therapy for atrial fibrillation because control at rest may not reflect response during exercise or daily activity). In addition, ambulatory monitoring also can help assess pacemaker function (although newer devices can do this without the need for external monitoring) and confirm episodes of myocardial ischemia, most of which are not usually associated with the typical symptoms of angina.

- Ambulatory monitoring allows correlation of (frequent) symptoms with heart rhythm and helps assess response to treatment and pacemaker function.

Transtelephonic event recording is similar to ambulatory recording but is more useful for documenting heart rate and rhythm when

symptoms are less frequent (less than one episode per 24-48 hours). Typically, patients either wear the recording device continuously for several days or weeks or briefly attach it to themselves during symptoms. The ECG is permanently stored in memory when the device is activated during symptoms by the patient. In most cases, continuous loop recorders record the ECG obtained 30 seconds to 4 minutes before the activation button is depressed. This feature is useful in patients whose symptoms are brief or of sudden onset. When convenient, the ECG then can be transmitted over the telephone for evaluation. In most cases, depending on the specific population of patients in which the device is used, about 20% of transmissions document abnormal heart rhythm. However, even when completely normal, transmissions can be helpful for patient management when a normal rhythm is identified. Implantable loop event recorders also may be used when symptoms are more infrequent or are of such sudden onset that activation is not possible. These devices, which are implanted subcutaneously in the pectoral region, can be programmed to provide information regarding rhythm disturbances over several months.

- Transtelephonic event recording documents heart rate during symptoms that occur infrequently.
- About 20% of transmissions document abnormal heart rhythm.
- Transtelephonic event recording is often helpful for patient management even if a normal rhythm is identified.

Implantable Loop Recorder

For patients with infrequent and sudden-onset symptoms, activation of a loop recorder may be difficult. In such cases, an implantable loop recorder should be considered. An implantable loop recorder is inserted subcutaneously in the anterior part of the chest and can be programmed to record both patient-activated and automatically activated events. Event data can be retrieved noninvasively (much like a pacemaker), allowing correlation with symptoms and rhythm.

Exercise Testing

Treadmill exercise testing is useful when symptoms occur during exercise because it allows evaluation of cardiac rhythm in a controlled setting with ECG monitoring. Exercise testing is also useful to determine whether the beneficial effect of a drug at rest is reversed with exercise. For example, patients with atrial fibrillation may have adequate control of heart rate at rest but poor control with moderate exercise. Similarly, patients with ventricular tachycardia or complex ventricular ectopy may have adequate suppression of the arrhythmia at rest in response to medical therapy only to have ventricular tachycardia with exercise. Not infrequently, proarrhythmic effects of antiarrhythmic drugs may be provoked by exercise testing. This is particularly the case for class IC drugs (flecainide and propafenone) because of use-dependence (i.e., the pharmacologic effect of a drug is affected by heart rate) and their long unbinding times from the sodium channel.

- Exercise testing allows evaluation of cardiac rhythm disturbance during exercise.
- Exercise testing is useful for assessing whether the effect of a drug is reversed with exercise.

PVCs occur during exercise testing in 10% of patients without and 60% of those with coronary artery disease. The response of PVCs *during* exercise does not predict the severity of coronary artery disease. Elimination of PVCs with exercise is not an indication that coronary artery disease is less severe. Recent data suggest that appearance of frequent PVCs (defined as seven or more per minute, ventricular bigeminy or trigeminy, ventricular couplets or triplets, ventricular tachycardia or flutter, torsades de pointes, or ventricular fibrillation) during the recovery phase of treadmill exercise testing may be a better predictor of outcome than PVCs occurring during exercise.

- PVCs occur during exercise in 10% of patients without and in 60% of those with coronary artery disease.
- The response of PVCs during exercise does not predict the severity of coronary artery disease.
- Elimination of PVCs with exercise does not indicate less severe coronary artery disease.

Exercise testing is useful for assessing sinus node function, for diagnosing chronotropic incompetence in a patient who complains of dyspnea on exertion or fatigue, and for assessing AV block. Exercise testing is most useful for assessing second-degree AV block in which the site of block is unknown (i.e., within the AV node vs. His-Purkinje system). This distinction is important because AV block occurring within the AV node (Wenckebach [Mobitz I]) is usually benign and does not require pacing. Characteristically, block within the AV node improves with exercise because increased catecholamines enhance AV node conduction. In contrast, AV block due to failure of conduction in the His-Purkinje system (Mobitz II) has a worse prognosis and a high incidence of progression to complete heart block and thus is an indication for permanent pacing. In contrast to block within the AV node, Mobitz II block typically worsens during exercise because enhanced AV node conduction increases the frequency of activation of the diseased His-Purkinje system, thus putting greater strain on the already diseased conducting system.

- Exercise testing is useful for assessing sinus node function.
- Mobitz I block usually improves with exercise.
- Mobitz II block usually worsens with exercise.
- Mobitz II block frequently progresses to complete AV block and therefore requires permanent pacing.

Electrophysiologic Testing

Electrophysiologic study involves the placement of electrode catheters in the heart to record and to stimulate heart rhythm. In most cases, pacing and recording electrodes (catheters) are positioned in the high right atrium, across the tricuspid valve in the region of the AV node and His bundle, and in the right ventricular apex (Fig. 3-17). In select patients, additional catheters are placed (most commonly within the coronary sinus) to record from the left atrium and ventricle. Electrophysiologic testing is indicated in patients with cardiogenic syncope of undetermined origin, for determining the mechanism of supraventricular tachycardia, for assessing symptomatic patients with Wolff-Parkinson-White syndrome, and for evaluating patients with sustained ventricular tachycardia and survivors of out-of-hospital

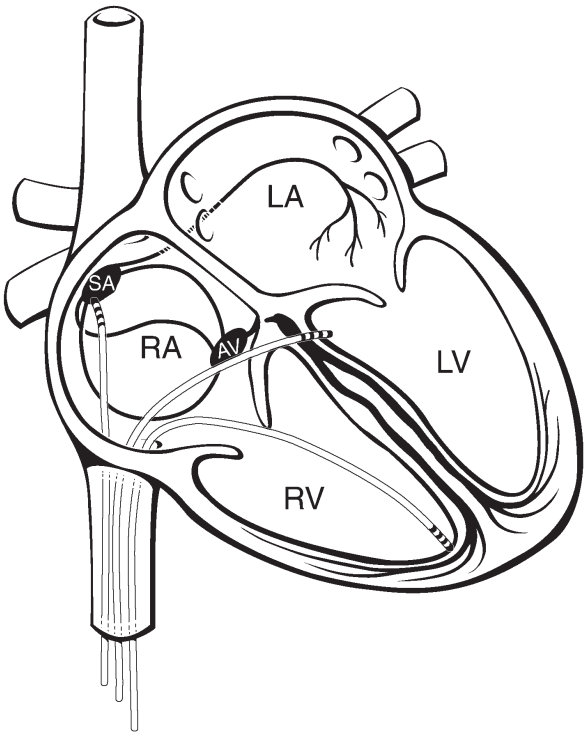

Fig. 3-17. Locations of intracardiac catheters for pacing and during cardiac electrophysiologic study. AV, atrioventricular node; LA, left atrium; LV, left ventricle; RA, right atrium; RV, right ventricle; SA, sinoatrial node.

cardiac arrest. As part of the evaluation of patients with syncope, electrophysiologic study (including measurement of sinus and AV nodal function and ventricular stimulation to exclude ventricular arrhythmias), when normal, also can be used in combination with tilt-table testing. Complications resulting from electrophysiologic study are infrequent, occurring in less than 0.5% to 1.0% of cases. Most common complications include vascular injury and hematoma at the puncture site.

- Electrophysiologic testing is invasive.
- Indications for electrophysiologic study include a history of syncope suggestive of cardiogenic syncope or to determine the mechanism of a clinically documented or suspected heart rhythm disorder.
- Complications are uncommon and usually minor.

Therapy for Heart Rhythm Disorders

Several therapeutic options are available for heart rhythm disorders. These include drug therapy, radiofrequency ablation, and device therapy (pacing for bradyarrhythmias and implantable cardioverter-defibrillators for tachyarrhythmias).

Antiarrhythmic Drugs

Therapeutic range, half-life, and routes of metabolism of antiarrhythmic drugs are listed in Table 3-11. The relative effectiveness of these drugs for treating PVCs, ventricular tachycardia, paroxysmal tachycardia that uses the AV node as part of the reentrant circuit,

Table 3-11 Properties of Antiarrhythmic Drugs

Drug	Therapeutic range, µg/mL	Half-life, h	Route of metabolism	
			Hepatic, %	Renal, %
Class IA				
Quinidine	2-5	6-8	80	20

and atrial fibrillation is given in Table 3-12. The predominant target of the antiarrhythmic drugs is shown in Figure 3-18.

Half-life is an important concept in the use of antiarrhythmic drugs. It is the time required for 50% of the drug within the body to be eliminated. It takes 5 half-lives for a drug to reach steady state or to be eliminated completely. If a drug has a half-life of 90 minutes (e.g., lidocaine), a steady state will be reached in 6 hours; therefore, a loading dose is given to achieve a therapeutic level more promptly.

- Half-life is an important concept in the use of antiarrhythmic drugs.
- Half-life is the time required for 50% of the drug within the body to be eliminated.
- It takes 5 half-lives for a drug to reach steady state or to be eliminated completely.

Proarrhythmic effect (Table 3-13), a common problem of all antiarrhythmic drugs, occurs when the drug creates an adverse rhythm disturbance (Fig. 3-19), including sinus node suppression and sinus bradycardia, AV block, or increased frequency of or new-onset atrial or ventricular arrhythmias. It was first described in association with quinidine and causes quinidine syncope, which occurs in an estimated 3% of patients who take this drug. In such patients, a rapid

polymorphic ventricular tachycardia, termed "torsades de pointes," develops. The frequency of proarrhythmia is higher in patients with decreased ventricular function and a history of sustained ventricular tachycardia or ventricular fibrillation. Unfortunately, it is these patients who most often require antiarrhythmic drugs. Also, proarrhythmia can occur in structurally normal hearts.

- Proarrhythmic effect occurs when a drug creates a rhythm disturbance.
- Proarrhythmic effect is common to all antiarrhythmic drugs.
- Quinidine syncope due to polymorphic ventricular tachycardia (torsades de pointes) is an example of a proarrhythmic effect.

The results of recent pharmacologic trials for the prevention of sudden cardiac death are summarized in Table 3-14.

Class I Antiarrhythmic Drugs

The Cardiac Arrhythmia Suppression Trial (CAST) was a landmark study that evaluated the use of flecainide, encainide, and moricizine to suppress asymptomatic or mildly symptomatic ventricular ectopy after myocardial infarction. The hypothesis tested was that patients in whom spontaneous ventricular ectopy could be suppressed would have improved outcome. In fact, patients who received class I agents showed a decrease in survival rates despite the adequate suppression of ventricular ectopy when compared with placebo. At the time, this

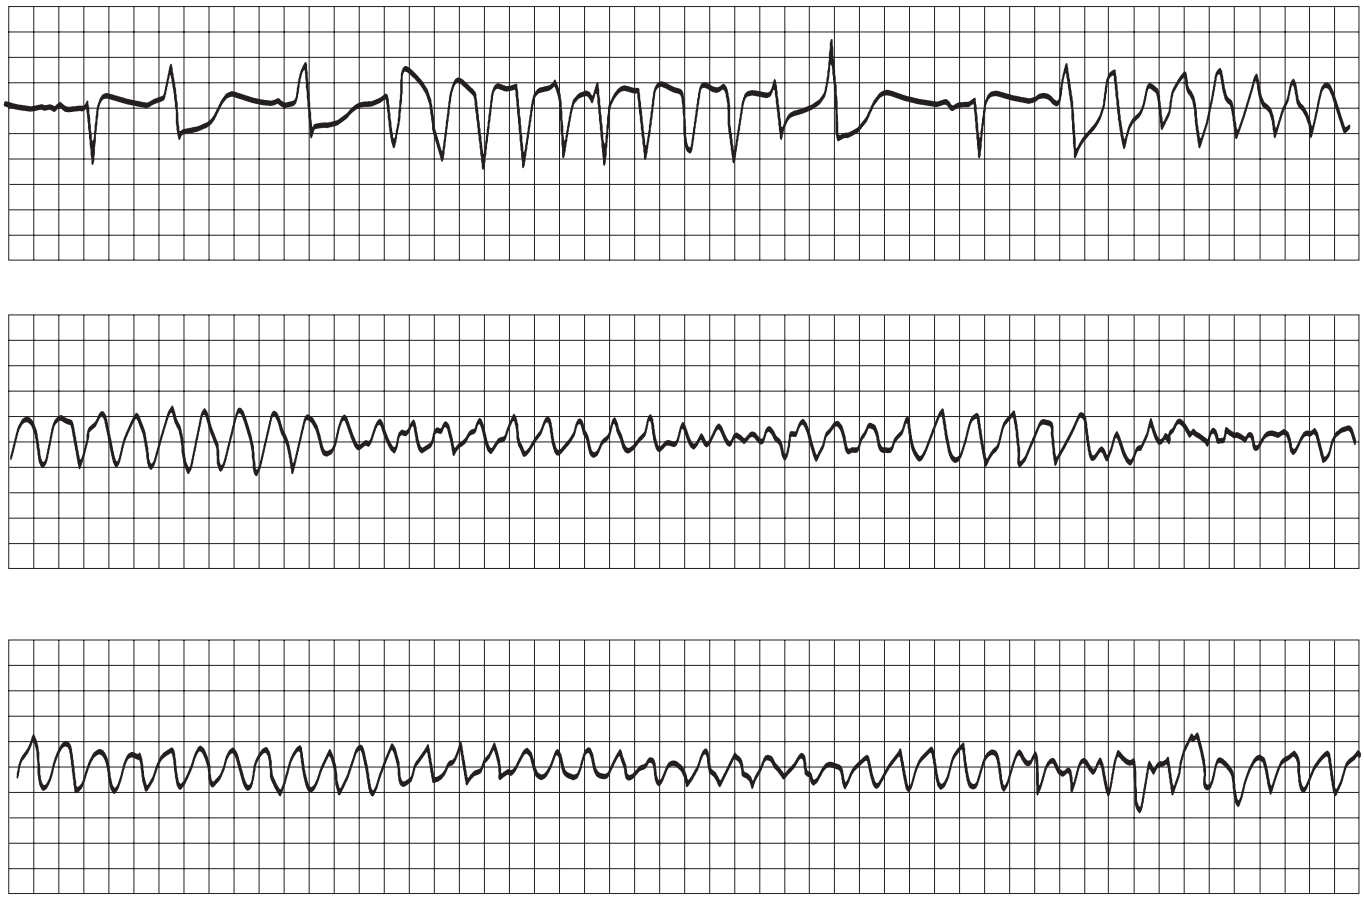

Fig. 3-19. Proarrhythmic response to quinidine. Quinidine resulted in prolongation of QT interval, and late-coupled premature ventricular complex initiated polymorphic ventricular tachycardia, termed "torsades de pointes."

Table 3-14 Results of Trials on Pharmacologic Prevention of Primary Sudden Cardiac Death

Trial	Patients	No.	Drug	Follow-up, mo	Total mortality, %		Significance
					Placebo	Drug	
Julian et al., 1982	MI <2 wk	1,456	*d*-, *l*-Sotalol	12	8.9	7.3	No
CAST, 1989	MI, EF <55%, >6 PVCs/h	1,455	Flecainide Encainide	10	3.0	7.7	Yes
CAST II, 1992	MI, EF ≤40%, >6 PVCs/h	1,155	Moricizine	18	12.4	15.0	No
SWORT, 1996	MI, EF ≤40%	3,121	*d*-Sotalol	5	3.1	5.0	Yes
Diamond-MI, 1997	MI	1,510	Dofetilide	≥12	32.0	31.0	No

was a totally unexpected and alarming finding. Similar results have been reported with class IA drugs (quinidine, procainamide, and disopyramide) and the class IB drug mexiletine.

- CAST reported decreased survival rate with drug therapy in patients with asymptomatic ventricular ectopy after infarction.

Amiodarone

Results from two randomized trials of amiodarone after myocardial infarction (European Myocardial Infarction Amiodarone Trial [EMIAT] and Canadian Amiodarone Myocardial Infarction Arrhythmia Trial [CAMIAT]) suggested that amiodarone may decrease arrhythmia-related death. However, overall mortality was not improved. Results from amiodarone trials among patients with congestive heart failure are also mixed. The Survival Trial of Antiarrhythmic Therapy in patients with Congestive Heart Failure arrhythmia (STAT-CHF) study showed that overall mortality was not significantly different between patients treated with amiodarone and those receiving placebo. In contrast, the Gruppo de Estudio de la Sobrevida en la Insuficiencia Cardiaca en Argentina (GESICA) study (randomized trial of low-dose amiodarone in severe congestive heart failure) showed that low-dose amiodarone therapy reduced total mortality in comparison with placebo therapy in patients with congestive heart failure. The differences in outcome may be explained by differences in patient population. In the STAT-CHF study, approximately 70% of the study population had coronary artery disease, compared with 30% in the GESICA study. Currently, the routine use of amiodarone after myocardial infarction or in unselected patients with congestive heart failure is not recommended. However, if patients have frequent and complex PVCs associated with documented symptoms in the setting of compromised left ventricular dysfunction, it is not unreasonable to consider a trial of amiodarone therapy.

- The routine use of amiodarone after myocardial infarction or in unselected patients with congestive heart failure for PVC suppression or primary prevention of sudden cardiac death is not recommended.

Adenosine

Adenosine slows conduction in the AV node and is eliminated by uptake in endothelial cells and erythrocytes. Its half-life is 10 seconds. Adenosine is indicated in supraventricular reentrant tachycardia that uses the AV node as part of the reentrant circuit (i.e., AV nodal reentry or reentry using an accessory pathway). The drug does not terminate atrial fibrillation, flutter, or tachycardia, and it slows the ventricular rate for only a few seconds because of its short half-life. Both adenosine and verapamil have equal efficacy at the highest recommended doses (adenosine, 12 mg; verapamil, 10 mg). Because of the short half-life of adenosine, approximately 10% of patients have recurrent supraventricular tachycardia after its administration, whereas recurrent supraventricular tachycardia is rare after termination by verapamil. In patients who present with wide QRS tachycardia (ventricular tachycardia) or atrial fibrillation and associated Wolff-Parkinson-White syndrome, hemodynamic collapse is common when they are given verapamil. This hemodynamic collapse is not associated with adenosine. The cost of adenosine is approximately twice that of verapamil.

- Adenosine slows conduction in the AV node.
- Adenosine can terminate supraventricular reentrant tachycardia that relies on conduction through the AV node.
- Adenosine does not terminate atrial fibrillation, flutter, or atrial tachycardia (exceptions exist, so adenosine should not be used to "diagnose" atrial tachycardia by exclusion).
- The efficacy of 12 mg of adenosine is equal to that of 10 mg of verapamil.
- The cost of adenosine is twice that of verapamil.

Electrophysiology Study

Because of the widespread availability and use of implantable cardioverter-defibrillators, electrophysiologic testing is less commonly used. Most commonly, an electrophysiologic study is performed to attempt induction of a suspected heart rhythm disorder in patients who present with syncope.

Among patients presenting with ventricular tachycardia due to coronary disease, the chance of inducing clinical tachycardia in the laboratory is 95% but decreases to 75% in patients with dilated cardiomyopathy or valvular heart disease. Among patients who present with out-of-hospital cardiac arrest or ventricular fibrillation, the chance of life-threatening ventricular arrhythmia being induced at testing decreases to 70%.

Transcatheter Radiofrequency Ablation

Transcatheter ablation therapy using a radiofrequency energy source to heat tissue has revolutionized the treatment of almost all heart rhythm disorders. With currently available technology, supraventricular tachycardias such as AV nodal reentrant tachycardia or tachycardia due to an accessory pathway (such as Wolff-Parkinson-White syndrome) are completely curable with radiofrequency ablation in more than 95% of cases. Ectopic atrial tachycardias are curable in more than 90% of cases. Table 3-15 lists heart rhythm disorders amenable to catheter ablation therapy. In addition, considerable progress has been made in recent years in the treatment of atrial fibrillation (especially paroxysmal atrial fibrillation) and ventricular tachycardia due to reentry around a scar after myocardial infarction.

The technique of radiofrequency ablation is similar to that described for electrophysiologic testing and, in most cases, is performed during the same procedure if an abnormal rhythm is found or has been documented clinically. When an area of tissue critical for initiating or sustaining the abnormal rhythm has been identified (mapped), a specially designed electrode catheter capable of delivering radiofrequency energy is maneuvered in proximity and radiofrequency energy is delivered. This procedure prevents further conduction of electrical impulses and prevents the abnormal rhythm from occurring.

- Supraventricular tachycardia due to AV nodal reentrant tachycardia, accessory pathway in Wolff-Parkinson-White syndrome, automatic atrial focus, atrial flutter, and some cases of atrial fibrillation and ventricular tachycardia can be cured with radiofrequency ablation.

Table 3-15 Heart Rhythms Amenable to Catheter Ablation

Rhythm	Curable	Treatable
SVT	AVNRT AVRT (bypass tract) EAT AFL (without fibrillation)	AF
Ventricular	RV outflow tract tachycardia Idiopathic LV tachycardia	VT due to coronary disease and scar after MI

AF, atrial fibrillation; AFL, atrial flutter; AVNRT, atrioventricular node reentry tachycardia; AVRT, atrioventricular reentry tachycardia; EAT, ectopic atrial tachycardia; LV, left ventricular; MI, myocardial infarction; RV, right ventricular; SVT, supraventricular tachycardia; VT, ventricular tachycardia.

- Ablation is performed with radiofrequency energy passed through a catheter.

About 1% to 2% of patients experience complications, including vascular injury at the site of catheter insertion, cardiac perforation, and infection. In addition, if the site of the critical area, such as an accessory pathway, is close to the normal conduction system, or if AV nodal reentrant tachycardia is ablated, there is a 5% risk of creating complete heart block that requires permanent pacing. When compared with previous surgical approaches for the treatment of similar tachycardias, the technique has reduced the hospital stay from 7 days to 1 to 2 days and the time to return to work or school from 6 to 8 weeks to 3 to 5 days. The cost is approximately 40% of the surgical cost.

- Catheter ablation is successful in 95% of cases of accessory pathway or reentrant tachycardia in the AV node.
- The complication rate is 1%-2%.
- Catheter ablation reduces hospital stay to 1-2 days.
- The cost is 40% of the surgical cost.

Catheter ablation also may be used to achieve complete heart block in some cases of supraventricular tachycardias (usually atrial fibrillation or atrial flutter) that are refractory to medications and associated with rapid ventricular rates. With either direct-current ablation or radiofrequency ablation, complete heart block can be achieved in more than 95% of patients. In such cases, permanent pacing is required. In select patients, this approach results in substantial improvement in symptoms (because of regularization of the heart rate) and in exercise capacity with use of rate-responsive pacing. However, one disadvantage is that patients are pacemaker-dependent and require long-term follow-up.

- Catheter ablation achieves complete heart block in supraventricular tachycardias that are refractory to medication and associated with rapid ventricular rate.
- Catheter ablation results in heart block in >95% of patients; permanent pacing then is required.
- Symptoms improve substantially.

Current therapeutic interventions available to patients with symptoms due to tachycardia are summarized in Table 3-16.

Device Therapy

Device therapy is used for abnormal heart rhythms due to bradycardias (permanent cardiac pacemaker implantation) and tachycardias (implantable cardioverter-defibrillators [ICDs]).

Permanent Cardiac Pacemaker Implantation

An internationally recognized four-letter system is used to classify different types of implantable pacemakers and ICDs (Table 3-17). The initial letter is used to denote the chamber paced, the second letter the chamber sensed, and the third letter the programmed mode of response of the pacemaker (inhibited, triggered, or both). Recently, a fourth letter was added to denote whether rate-responsiveness is possible. In a pacemaker with rate-responsiveness, the programmed rate automatically increases in response to sensor-detected activity. Usually, the sensor is located within the pulse-generator or is part of the implanted lead system. Common pacing modes include VVI (ventricular paced, ventricular sensed, inhibited in response to a ventricular event), VVIR (same as previous entry but also has rate responsiveness), DDD (atrial and ventricular pacing and sensing with triggered and inhibited response to a sensed atrial or ventricular event), and DDDR (same as previous entry but also has rate responsiveness). The precise choice of pacemaker used depends in large part on clinical circumstances.

Physiologic pacing (with a DDD pacemaker) attempts to maintain heart rate with normal AV synchrony and to increase heart rate in response to physical activity. In patients with normal sinus node activity, DDD pacemakers can "track" atrial activation. This has the advantage that as sinus node activity increases (e.g., in response to exercise or some other stress), the pacemaker rate increases accordingly

Table 3-16 Summary of Tachyarrhythmia Therapy

Supraventricular tachycardia	Drug	Ablation	ICD
AVNRT	+	++	-
AVRT	+	++	-
EAT	+	+	-
IAST	++	o	-
Typical A flutter	+	++	-
AFib	++	+	o

Symbols: +, effective; ++, preferred; o, investigational; -, no indication.
A, atrial; AFib, atrial fibrillation; AVNRT, atrioventricular nodal reciprocating tachycardia; AVRT, atrioventricular reciprocating tachycardia; EAT, ectopic atrial tachycardia; IAST, inappropriate sinus tachycardia; ICD, implantable cardioverter-defibrillator.

Table 3-17 Code of Permanent Pacing

Chamber(s) paced	Chamber(s) sensed	Mode(s) of response	Programmable capabilities
V = Ventricle A = Atrium D = Dual (atrium and ventricle)	V = Ventricle A = Atrium D = Dual (atrium and ventricle) O = None	T = Triggered I = Inhibited D = Dual (triggered and inhibited) O = None	R = Rate modulated

so that the ventricle is paced at the appropriate rate but with normal AV conduction delay (PR interval). In patients with chronic atrial fibrillation, rate-modulated pacing (the "R" in VVIR) is used to increase heart rate in response to physical demand. In such cases, a sensor that responds to body motion, respiratory rate, blood temperature, or some other variable is used to drive the pacemaker so that the rate at which pacing occurs is appropriate to metabolic demands. Patients fitted with this type of pacemaker have increased exercise endurance during treadmill testing. Patients with both sinus node dysfunction and AV conduction system disease benefit most from DDDR pacing.

- Physiologic pacing maintains heart rate with normal AV synchrony and increases the rate during physical activity.
- Rate-modulated pacing increases exercise endurance during treadmill testing.

Complications of Permanent Pacing

Complications of device therapy (pacing and ICD) may be classified as early (usually within 30 days of implant) or late. Early complications are most commonly related to vascular injury, hematoma, pneumothorax, dislodgment of the lead, and extracardiac stimulation (e.g., diaphragmatic stimulation). In most cases, repositioning of the lead or reprogramming of the device remediates the problem. Late complications include lead fracture or insulation defect, infection, pacemaker syndrome, and pacemaker-mediated tachycardia.

Pacemaker syndrome may develop during dominant ventricular pacing in a minority of patients with intact retrograde conduction between the ventricle and the atrium (Fig. 3-20). When the ventricle is paced, the impulse conducts retrogradely to the atrium and simultaneous atrial and ventricular contraction results. Because the atria are contracting against closed tricuspid and mitral valves, the atrial contribution to ventricular filling is prevented and the atria are distended. The increased atrial pressure distends the neck veins, leading to a sensation of "fullness in the neck" and symptoms due to decreased forward cardiac output such as light-headedness and fatigue. Symptoms and signs due to pacemaker syndrome can be eliminated with dual-chamber pacing.

- In pacemaker syndrome, atria contract against closed tricuspid and mitral valves, resulting in backward blood flow and decreased forward blood flow (cardiac output).
- Symptoms are typically "fullness in the neck," light-headedness, and fatigue.
- Dual-chamber pacing eliminates symptoms.

Pacemaker-mediated tachycardia is a well-recognized complication of dual-chamber pacemakers (DDD pacing) and occurs when retrograde conduction between the ventricle and atrium is intact. In this type of tachycardia, the pacemaker generator acts as one limb of the reentrant circuit. Typically, a spontaneous PVC occurs which conducts retrogradely to the atrium. This early retrograde atrial activity is sensed by the pacemaker, which awaits the normal AV delay and then paces the ventricle. The "early" ventricular activity generated by the pacemaker then conducts retrogradely to the atrium, and the reentrant circuit is completed. Typically, the tachycardia rate is close to the upper rate limit of the device. Most pacemaker devices possess algorithms that recognize and attempt to abort pacemaker-mediated tachycardia. Alternatively, the device can be programmed to reduce or eliminate it.

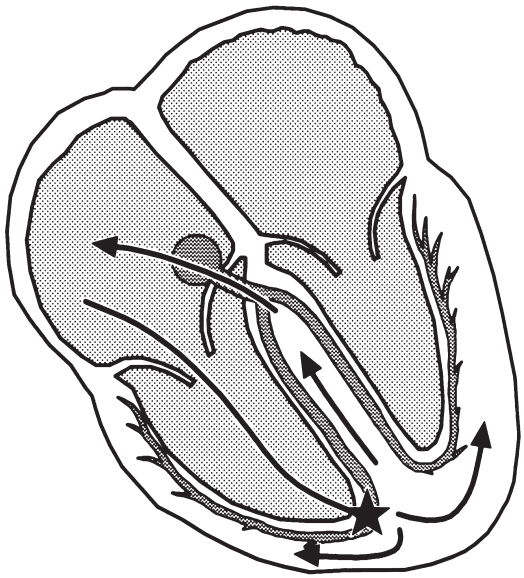

Fig. 3-20. Pacemaker syndrome with retrograde atrial activation during ventricular pacing (star), resulting in simultaneous atrial and ventricular contractions.

- Pacemaker-mediated tachycardia occurs with DDD pacing when there is intact retrograde conduction between the ventricle and atrium.
- The abnormality is corrected by programming changes of the pacemaker generator.

Indications for Permanent Pacemaker Implantation

Guidelines for permanent pacemaker implantation are well established. Indications for specific conduction system diseases are listed in Table 3-18. Indications are generally grouped according to the following classification: class I indication—conditions for which there is general agreement that permanent pacemakers should be implanted; class II—conditions for which permanent pacemakers are frequently used but opinions differ about the necessity of implantation; and class III—conditions for which there is general agreement that pacemakers are not necessary. Clinical symptoms such as syncope, presyncope, or exercise intolerance that can be correlated with and attributed to a bradycardia disorder usually constitute a class I indication for permanent pacemaker implantation. If symptoms cannot be correlated with bradycardia, it is less certain that permanent pacemaker implantation is indicated.

Table 3-18 Indications for Pacemaker Implantation

Sinus node dysfunction
Class I
Documented symptomatic bradycardia
Class II
HR <40 beats/min, symptoms present but not clearly correlated with bradycardia
Class III
Asymptomatic bradycardia (<40 beats/min)
AV block
Class I
Symptomatic 2° or 3° AV block, permanent or intermittent
Congenital 3° AV block with wide QRS
Advanced AV block 14 d after cardiac surgery
Class II
Asymptomatic type II 2° or 3° AV block with ventricular rate >40 beats/min
Class III
Asymptomatic 1° and type I 2° AV block
Myocardial infarction
Class I
Recurrent type II 2° AV block and 3° AV block with wide QRS
Transient advanced AV block in presence of BBB
Class II
Persistent advanced AV block with narrow QRS
Acquired BBB in absence of AV block
Class III
Transient AV block in absence of BBB

AV, atrioventricular; BBB, bundle branch block; HR, heart rate.

Implantable Cardioverter-Defibrillators

ICDs continuously monitor heart rhythm and can detect and treat abnormal ventricular arrhythmia with overdrive pacing (antitachycardia pacing), low-energy cardioversion, or up to 30- to 40-J shocks. In most cases, an ICD can be implanted in the pectoral region in a fashion similar to that of permanent pacemakers. Moreover, with improvements in ICD technology, earlier problems with limited battery life, larger pulse generators, and frequent inappropriate shocks (often due to atrial fibrillation with rapid ventricular response being confused with a rapid ventricular tachycardia) are rapidly being resolved.

ICDs improve mortality outcomes among patients who survive a sudden cardiac death episode when compared with historical controls. Historically, such patients had a 70% survival rate at 1 year without treatment or with empiric antiarrhythmic drug therapy. Use of the ICD has improved the overall 1-year survival rate to 90%; recurrent sudden cardiac death occurs in 2% of patients at 1 year and in 4% of patients at 4 years. In terms of secondary prevention, the Antiarrhythmic Versus Implantable Defibrillator (AVID) trial reported that an ICD is superior for reducing overall mortality in comparison with empiric amiodarone therapy in patients with a history of out-of-hospital cardiac arrest or symptomatic sustained ventricular tachycardia (secondary sudden cardiac death prevention).

Several trials have reported on the role of the ICD among patients at high risk of sudden cardiac death (i.e., primary prevention). One of the first was the Multicenter Automatic Defibrillator Implantation Trial (MADIT), which found that patients with prior myocardial infarction, ejection fraction less than 35%, and nonsustained ventricular tachycardia with electrophysiologically inducible sustained monomorphic ventricular tachycardia not suppressible with procainamide had improved survival with ICD when compared with the best medical (including antiarrhythmic) therapy. Similar observations were confirmed in the Multicenter Unsustained Tachycardia Trial (MUSTT). MADIT II addressed prophylactic implantation of an ICD in a group of patients with prior myocardial infarction and reduced ejection fraction (<30%), without additional risk stratification, and found improved survival with ICD therapy compared with best medical therapy. Recently reported ICD trials include the Sudden Cardiac Death in Heart Failure Trial (SCD-HeFT), which enrolled patients with mild to moderate congestive heart failure (New York Heart Association [NYHA] class II and III) and depressed left ventricular ejection fraction (≤35%) with both ischemic and nonischemic cardiomyopathy but with no prior history of ventricular arrhythmia. ICD therapy was associated with a significant reduction in risk of death compared with medical therapy.

Current Indications for ICD Implantation

The following are indications for ICD implantation:

1. Documented episode of cardiac arrest due to ventricular fibrillation, not due to a transient or reversible cause
2. Documented sustained ventricular tachyarrhythmia, either spontaneous or induced by an electrophysiology study, not associated with an acute myocardial infarction and not due to a transient or reversible cause
3. Documented familial or inherited conditions with a high

risk of life-threatening ventricular tachycardia, such as long QT syndrome or hypertrophic cardiomyopathy

4. Coronary artery disease with a documented prior myocardial infarction, a measured left ventricular ejection fraction less than 35%, and inducible, sustained ventricular tachycardia or ventricular fibrillation at electrophysiologic study. The myocardial infarction must have occurred more than 4 weeks before defibrillator insertion. The electrophysiologic test must be performed more than 4 weeks after the qualifying myocardial infarction
5. Documented prior myocardial infarction and a measured left ventricular ejection fraction less than 30%
6. Ischemic dilated cardiomyopathy, documented prior myocardial infarction, NYHA class II and III heart failure, and measured left ventricular ejection fraction less than 35%
7. Nonischemic dilated cardiomyopathy for more than 9 months, NYHA class II and III heart failure, and measured left ventricular ejection fraction less than 35%

   Patients must not have:

   a. Cardiogenic shock or symptomatic hypotension while in a stable baseline rhythm
   b. Had a coronary artery bypass graft or percutaneous transluminal coronary angioplasty within the past 3 months
   c. Had an acute myocardial infarction within the past 40 days
   d. Clinical symptoms or findings that would make them a candidate for coronary revascularization
   e. Irreversible brain damage from preexisting cerebral disease
   f. Any disease, other than cardiac disease (e.g., cancer, uremia, liver failure), associated with a likelihood of survival less than 1 year

Part III

Peter A. Brady, MD

Specific Arrhythmia Problems

Sinus Node Dysfunction

Sinus node dysfunction, also called "sick sinus syndrome," includes sinus bradycardia, sinus pauses, tachycardia-bradycardia syndrome (Fig. 3-21), and sinus arrest. It usually is associated with conduction system disease and lack of an appropriate junctional escape focus during sinus pause or sinus bradycardia. The diagnosis is made from the medical history and results of electrocardiographic (ECG) and Holter monitoring, which are the most useful diagnostic tests. Electrophysiologic testing generally is not helpful for evaluating patients with a history consistent with sinus node disease because it has low sensitivity. In some cases, prolonged monitoring with an event recorder may be required to correlate symptoms with bradycardia. If a patient is able to exercise, a treadmill test is useful for determining whether the sinus node rate can increase appropriately to meet metabolic need.

- Sinus node dysfunction includes sinus bradycardia, sinus pauses, tachycardia-bradycardia syndrome, and sinus arrest.
- Sinus node dysfunction is associated with conduction system disease.
- The diagnosis is made from the history and the results of ECG and Holter monitoring.
- Electrophysiologic testing is reserved for patients in whom the arrhythmia mechanism cannot be determined by ECG or Holter monitoring.

Asymptomatic patients with sinus node dysfunction are followed without specific therapy. Symptomatic patients usually are treated with a pacemaker. Often, patients with tachycardia-bradycardia have atrial fibrillation that at times presents with rapid ventricular rates and at other times with inappropriate, symptomatic bradycardia. Pacemakers are used to prevent the bradycardia, and drugs may be used to slow conduction through the atrioventricular (AV) node and to prevent episodes of rapid ventricular rate.

- Asymptomatic patients with sinus node dysfunction are followed without specific therapy.
- Symptomatic patients with sinus node dysfunction are treated with pacemakers.

Conduction System Disorders

First-degree AV block results in a prolonged PR interval. If the QRS is narrow, the conduction delay is most likely within the AV node. In patients with associated bundle branch block, the conduction delay may be distal to the AV node in the His-Purkinje system or bundle branches. Two subtypes of second-degree AV block are described: Mobitz I (Wenckebach) manifests as gradual prolongation of the PR interval before a nonconducted P wave. Classically, the PR interval after the nonconducted P wave is shorter than the PR interval before the nonconducted P wave (Fig. 3-22 and 3-23). Also, the RR interval that encompasses the nonconducted P wave is shorter than two RR intervals between conducted beats. Wenckebach conduction is frequently observed after an inferior myocardial infarction, which can result in ischemia of the AV node. Generally, this does not require pacing (temporary or permanent) unless hemodynamic problems are associated with the slow heart rate.

- First-degree AV block results in a prolonged PR interval.
- Second-degree AV block of Mobitz I type results in gradual prolongation of the PR interval before the nonconducted P wave.
- Wenckebach conduction may accompany inferior myocardial infarction.
- Wenckebach conduction does not require pacing unless hemodynamic problems are associated with slow heart rate.

Mobitz II second-degree AV block usually is caused by conduction block within the His-Purkinje system and frequently is associated with bundle branch block (Fig. 3-24). This conduction abnormality is shown on the ECG as a sudden failure of a P wave to conduct to the ventricle, with no change in the PR interval either before or after the nonconducted P wave. This problem may herald complete heart

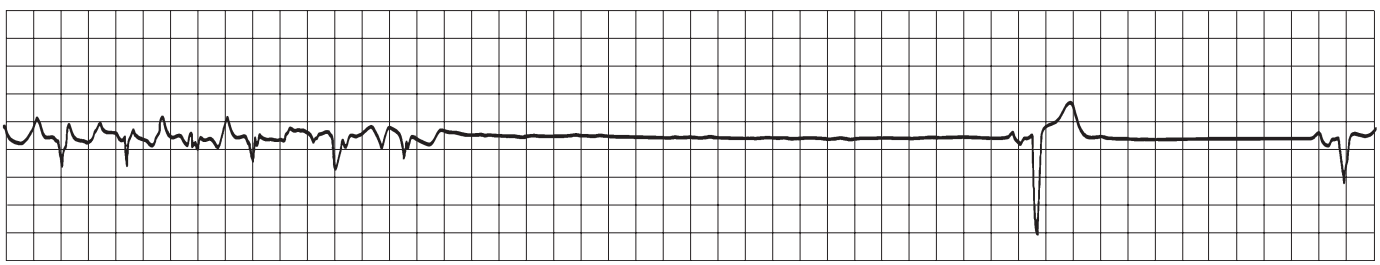

Fig. 3-21. Tachycardia-bradycardia with episode of atrial fibrillation terminating spontaneously, followed by a 4.5-second pause until the sinus node recovers. (From MKSAP IX: Part C, Book 1, 1992. American College of Physicians. Used with permission.)

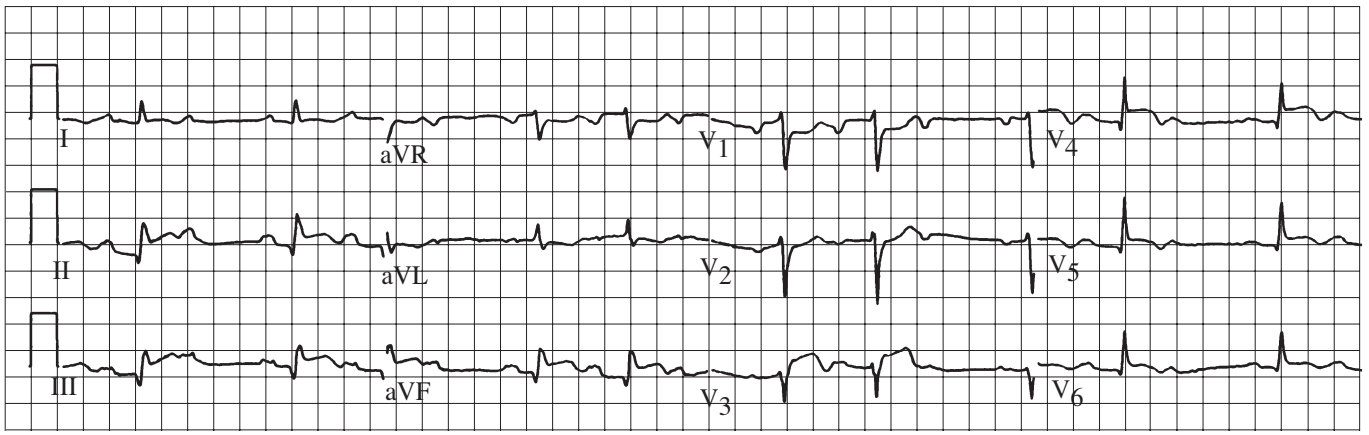

Fig. 3-22. 3:2 Mobitz I (or Wenckebach) second-degree atrioventricular block in a patient with acute inferior myocardial infarction.

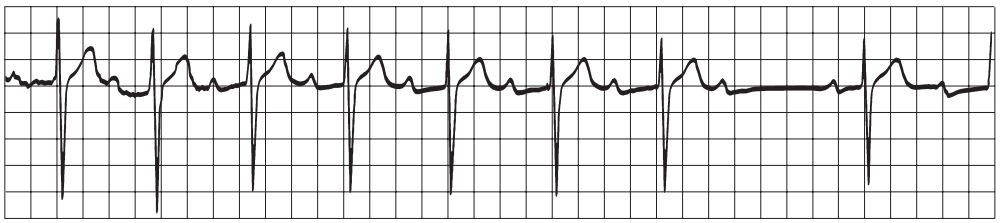

Fig. 3-23. Mobitz I second-degree atrioventricular block; note gradual PR prolongation. The PR interval after a nonconducted P wave is shorter than the PR interval preceding the nonconducted P wave.

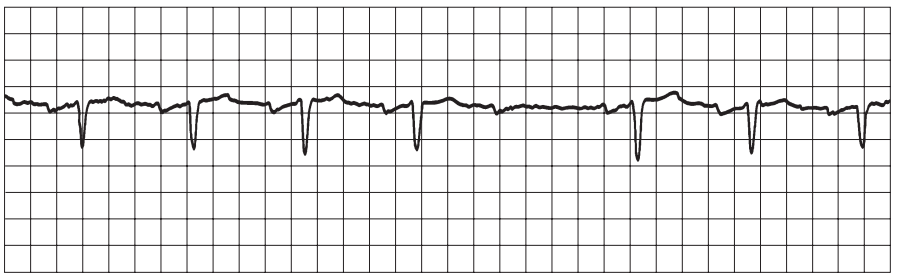

Fig. 3-24. Mobitz II second-degree atrioventricular block with no change in the PR interval before or after a nonconducted P wave.

block, and therefore strong consideration should be given to permanent pacing. Complete heart block is diagnosed when there is no relation between the atrial rhythm and the ventricular rhythm and *the atrial rhythm is faster than the ventricular escape rhythm* (Fig. 3-25). The ventricular escape rhythm is either a junctional escape focus, with a conduction pattern similar to that seen during normal rhythm, or a ventricular escape focus, with a wide QRS conduction pattern. In most cases, complete heart block is treated with permanent pacing.

- Second-degree AV block of Mobitz II type usually is due to conduction disease in the His-Purkinje system.
- It often heralds complete heart block; permanent pacing should be considered.
- Complete heart block: no relation between atrial rhythm and ventricular rhythm, and atrial rhythm is faster than ventricular escape rhythm. Treatment is with pacing.

"Bifascicular block" refers to left bundle branch block, right bundle branch block with left anterior fascicular block (marked left-axis deviation), or right bundle branch block with left posterior fascicular block (right-axis deviation). Bifascicular block usually is associated with underlying structural heart disease and has a 1% chance of progressing to complete heart block in asymptomatic persons. Patients presenting with syncope and bifascicular block may have intermittent complete heart block caused by conduction system disease or ventricular tachycardia caused by the underlying myocardial disease. Permanent pacing can be used to treat syncope due to complete

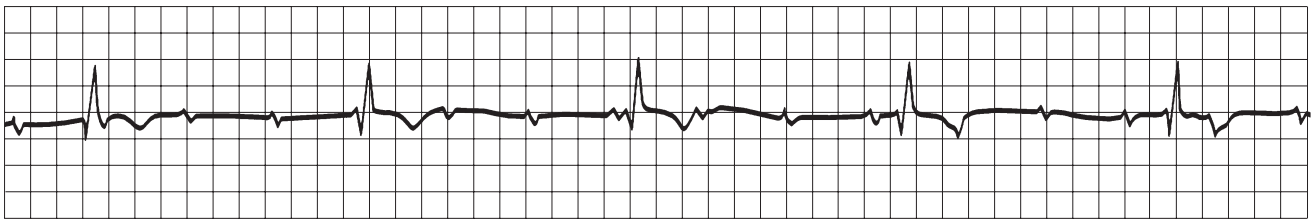

Fig. 3-25. Complete heart block with an atrial rate at 70 beats/min and a ventricular escape rhythm at 30 beats/min.

heart block. In patients with impaired left ventricular function (most commonly ejection fraction ≤40%), syncope may be due to ventricular tachycardia or fibrillation. Typically, such patients are candidates for an electrophysiology study and, if results are positive, an implantable defibrillator. Patients with syncope and bifascicular block should have electrophysiologic testing (especially if the ejection fraction is decreased) to determine whether they have ventricular tachycardia, because this rhythm occurs in 40% of these patients. Patients with syncope, bifascicular block, and ventricular tachycardia who receive only permanent pacing have improvement in syncope but no decrease in risk of sudden death.

- Bifascicular block usually is associated with structural heart disease.
- Bifascicular block progresses to complete heart block in 1% of asymptomatic persons.
- Permanent pacing is used to treat syncope in complete heart block.
- Syncope due to ventricular tachycardia typically is treated with an implantable defibrillator.
- Patients with syncope, bifascicular block, and ventricular tachycardia who receive only permanent pacing have improvement in syncope but no decrease in risk of sudden death.

High-degree AV block is diagnosed when there is a 2:1 or higher AV conduction block (Fig. 3-26). It can be due to a Wenckebach or Mobitz II mechanism. A Wenckebach mechanism is more likely if the QRS conduction (duration) is normal, and a Mobitz II-type mechanism is more likely if the QRS complex demonstrates additional conduction disease, such as bundle branch block.

Carotid Sinus Syndrome

Carotid sinus massage is performed to identify carotid sinus hypersensitivity (Fig. 3-27). Approximately 40% of patients older than 65 have a hyperactive carotid sinus reflex (3-second pause or a decrease in systolic blood pressure of 50 mm Hg), although most of these patients do not have spontaneous syncope. Carotid sinus massage should be performed over the carotid bifurcation at the angle of the jaw in patients without evidence of carotid bruit on carotid auscultation or a history of cerebrovascular disease. Carotid sinus massage is performed with moderate pressure over the carotid bifurcation for 5 seconds while monitoring heart rate and blood pressure. Approximately 35% of patients with a hyperactive carotid sinus reflex have a pure cardioinhibitory component manifested only by a pause in ventricular activity exceeding 3 seconds. Fifteen percent of patients have a pure vasodepressor component, with a normal heart rate maintained but a decrease in systolic blood pressure of more than 50 mm Hg. Sixty percent of patients have a combined response of both cardioinhibitory and vasodepressor components. In such patients, permanent pacing may prevent the cardioinhibitory response, but the vasodepressor response continues to produce symptoms.

- Carotid sinus massage is used to identify carotid sinus hypersensitivity.
- About 40% of patients >65 years have a hyperactive carotid sinus reflex (3-second pause or decrease in systolic blood pressure of 50 mm Hg).

Rarely, neck abnormalities, such as lymph node enlargement, prior neck surgery, or a regional tumor, can cause a carotid sinus syndrome. Often, surgical techniques to treat this condition are unsuccessful, and the primary form of therapy is AV sequential pacing for the cardioinhibitory component and elastic stockings for the vasodepressor component. Occasionally, the condition responds to anticholinergic medications.

Summary of Indications for Pacemakers

Symptomatic bradycardia is a class I indication for pacemaker implantation. Commonly, this is due to AV block (second-degree Mobitz II, high-grade, or third-degree), sinus node dysfunction, and carotid sinus hypersensitivity. Correlation of symptoms and bradycardia is important but may not be possible in some cases (class II indication). In asymptomatic patients, pacing should be considered in complete heart block (particularly with escape <40 beats/min or pauses >3 seconds), Mobitz II block (especially associated with bifascicular or trifascicular block), and postoperative AV block.

- Pacing is indicated for symptomatic bradycardias due to second- or third-degree heart block, sinus node dysfunction, and carotid sinus hypersensitivity.
- Asymptomatic patients with complete heart block, Mobitz II AV block, or postoperative AV block should also be considered for pacing.

Atrial Flutter

Atrial flutter is identified by the characteristic sawtooth pattern of atrial activity at a rate of 240 to 320 beats/min. Patients with normal conduction systems maintain 2:1 AV conduction; thus, the

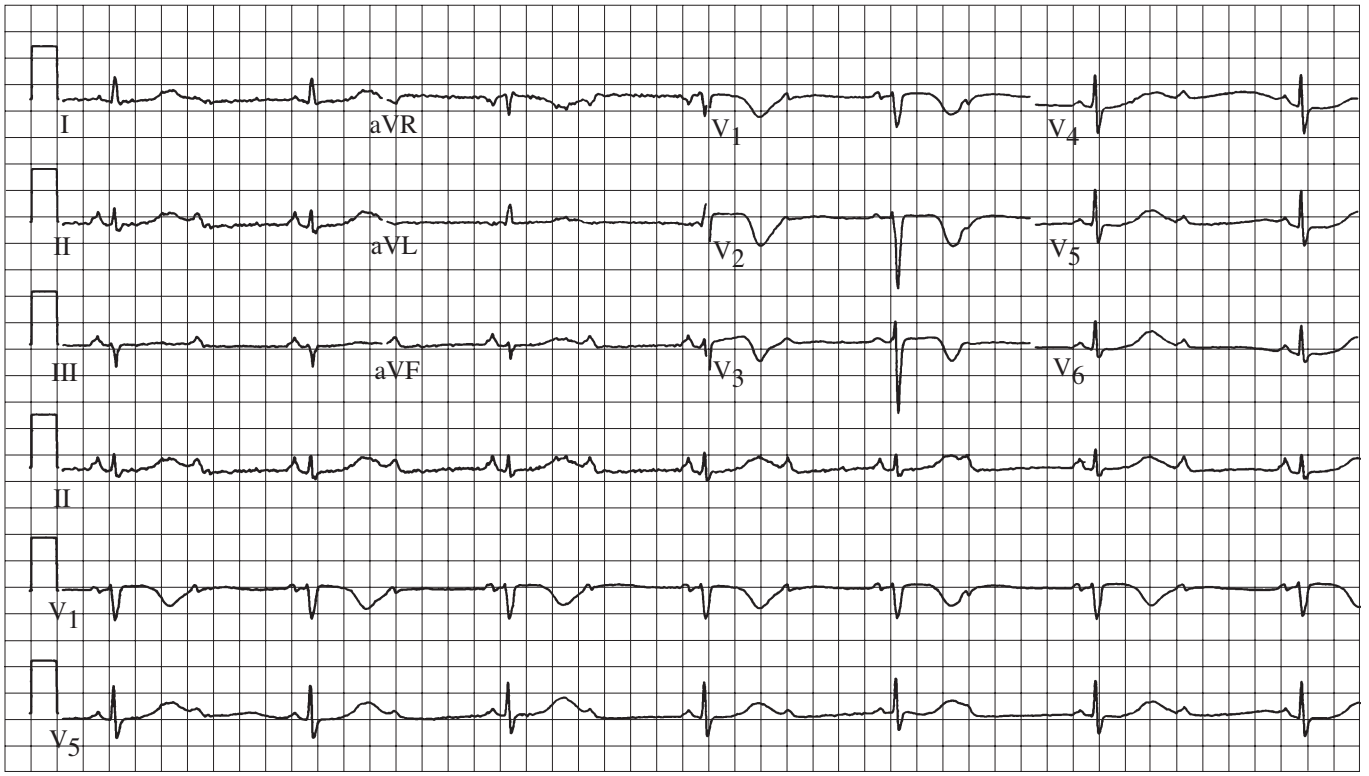

Fig. 3-26. High-grade 2:1 atrioventricular conduction block.

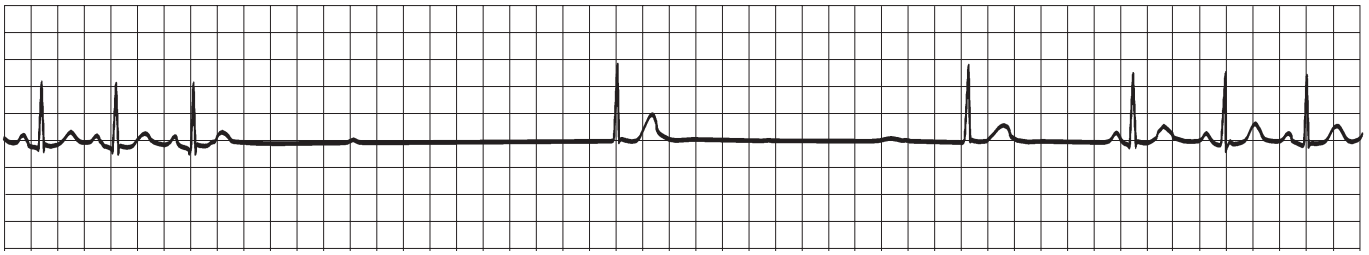

Fig. 3-27. Carotid sinus massage resulting in sinus pause with junctional escape beats before sinus rhythm returns.

ventricular rate is often close to 150 beats/min. Higher degrees of AV block (3:1 or higher) in the absence of drugs that slow AV nodal conduction (digoxin, β-adrenergic blocker, calcium antagonist) suggest the presence of intrinsic AV conduction disease (Fig. 3-28). In patients with 2:1 AV conduction and a heart rate of 150 beats/min, one of the flutter waves is often buried in the QRS complex. Carotid sinus massage (or use of adenosine to transiently block AV conduction) may be helpful for revealing the flutter waves and establishing the diagnosis.

- Atrial flutter is atrial activity at 240-320 beats/min.
- The ventricular rate is close to 150 beats/min.

Pharmacologic therapy for atrial flutter is used to slow AV node conduction and to control the ventricular rate or to control the flutter itself. The same medications used to treat atrial fibrillation (discussed below) are used to treat atrial flutter. Success rates for the control of atrial flutter are 30% to 50%.

Nonpharmacologic therapy for typical atrial flutter has been well established. Unlike atrial fibrillation, which is composed of multiple reentrant wavelets that travel through the atria, typical atrial flutter consists of a single reentrant circuit that follows the tricuspid valve annulus (Fig. 3-29). This fixed reentrant pathway results in a surface ECG with very stable flutter waves (Fig. 3-28) and provides a target for ablation. Radiofrequency catheter ablation of this single circuit has a success rate higher than 90%. Ablation is performed within the atrium between the tricuspid annulus and the inferior vena cava to interrupt the artial flutter circuit. Other options include ablation of the AV node and permanent pacemaker implantation (which is also useful in atrial fibrillation). In this case, the atria continue to fibrillate but symptoms are often much improved due to slower ventricular rate and regularity. Atrial flutter is associated with a similar risk of thromboembolism as atrial fibrillation and should be treated similarly to atrial fibrillation with regard to anticoagulation.

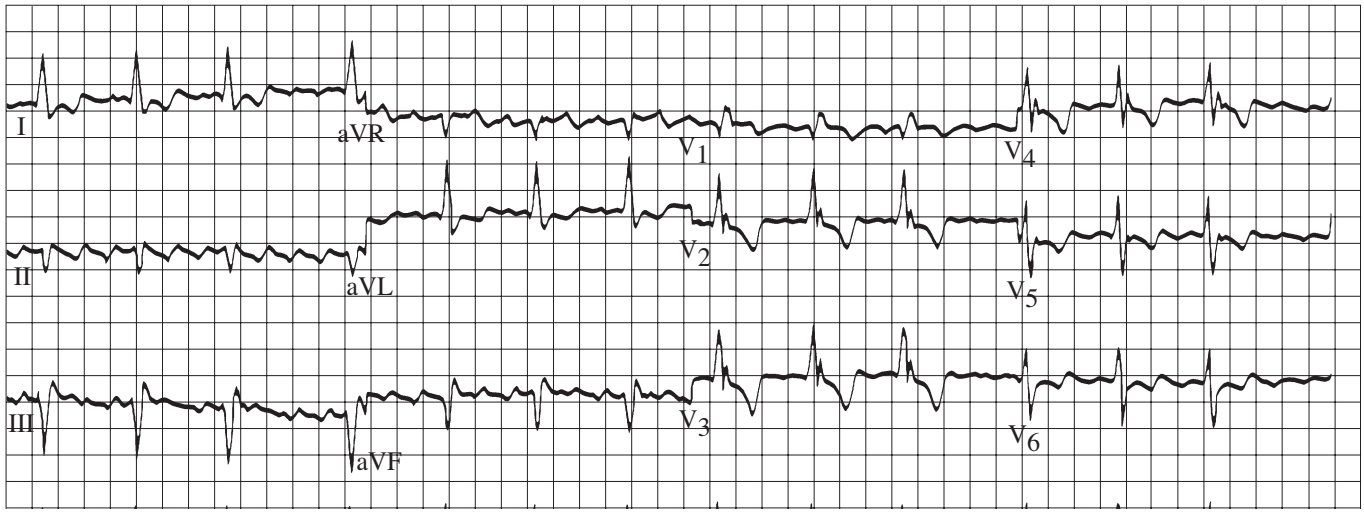

Fig. 3-28. Atrial flutter with 3:1 conduction in a patient with atrioventricular conduction disease.

- Typical atrial flutter ablation has a success rate >90%.
- Atrial flutter is associated with a similar risk of thromboembolism as atrial fibrillation and should be treated similarly to atrial fibrillation with regard to anticoagulation.

Atrial Fibrillation

Atrial fibrillation is the most common arrhythmia encountered in clinical practice. Its frequency increases with age. Atrial fibrillation is characterized by continuous and irregular activity of the ECG baseline caused by swarming electrical currents in the atria. According to population-based studies, its prevalence is 5% among persons 65 or older. Common causes and associated conditions include hypertension, cardiomyopathy, valvular heart disease (particularly mitral stenosis), sick sinus syndrome, Wolff-Parkinson-White syndrome (especially in young patients), alcohol use ("holiday heart"), and thyrotoxicosis. The presence of these conditions should be sought in the history and physical examination of patients with atrial fibrillation. Atrial fibrillation can have a discrete focal source or trigger. These triggers are often from the muscle in the proximal portions of the pulmonary veins. Atrial fibrillation must be distinguished from atrial flutter (uniform flutter waves) and multifocal atrial tachycardia (isoelectric interval between premature atrial contractions that have three or more different morphologic forms).

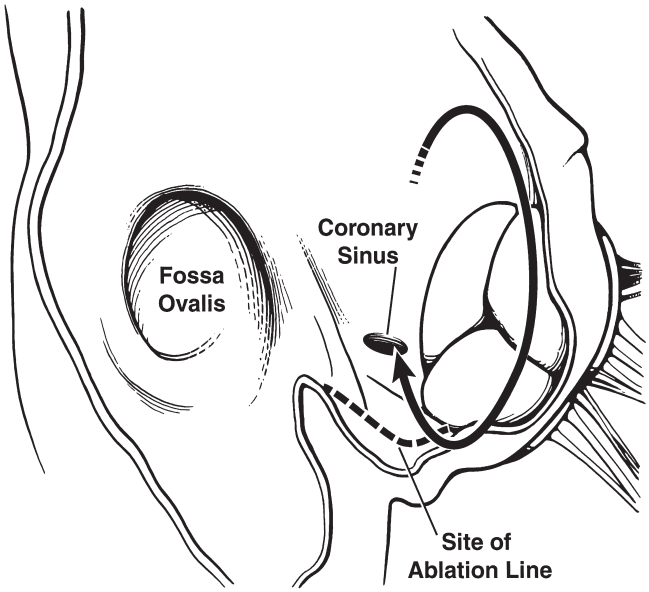

Fig. 3-29. View of the right atrium, with the tricuspid valve on the right. The atrial flutter circuit is confined to the path depicted by the circular arrow adjacent to the valve. An ablation lesion along the dashed line ("Site of Ablation Line") interrupts the circuit, eliminating atrial flutter. In contrast to atrial flutter, atrial fibrillation has wandering wavefronts throughout the atria which will not respond to the flutter ablation line.

- Common causes of atrial fibrillation include hypertension, cardiomyopathy, valvular heart disease, sick sinus syndrome, Wolff-Parkinson-White syndrome, thyrotoxicosis, and alcohol use.
- Atrial fibrillation must be distinguished from atrial flutter (uniform flutter waves) and multifocal atrial tachycardia (isoelectric interval between premature atrial contractions that have three or more different morphologic forms).

Therapy for Atrial Fibrillation

Therapy for atrial fibrillation can be divided into two broad strategies: rate control strategy (by pharmacologic agents or ablation to slow conduction through the AV node) with stroke prophylaxis (for ongoing atrial fibrillation) in patients at risk of stroke (*c*ongestive heart failure, *h*ypertension, *a*ge >75 years, *d*iabetes, and previous *s*troke; CHADS score) and rhythm control strategy with both pharmacologic and nonpharmacologic (usually catheter ablation) approaches to restore and maintain normal sinus rhythm. The choice of the approach depends for the most part on the presence and severity of symptoms, age, and comorbid conditions. In the absence of symptoms, a rate control strategy has been shown to have outcomes similar, in terms of mortality, to those of a rhythm control strategy.

For the purposes of clinical management, atrial flutter should be considered the same as atrial fibrillation. Initial management of atrial fibrillation usually involves rate control with use of AV nodal blocking agents and anticoagulation before deciding on long-term strategy, which needs to be individualized.

- It is important to know which agents are useful for rate control and which for rhythm control (Table 3-19).
- Treatment of atrial fibrillation is based on the presence or absence of symptoms.
- Adequate rate control (with anticoagulation therapy if risk of stroke is increased) is associated with outcomes similar to those of a rhythm control strategy.
- Initial management of atrial fibrillation usually involves rate control with use of AV nodal blocking agents and anticoagulation before deciding on long-term strategy, which needs to be individualized.

Rate Control and Anticoagulation

The three main categories of drugs used to blunt the AV node response in atrial fibrillation are digitalis glycosides, β-adrenergic blocking agents, and calcium channel blockers. These are summarized in Table 3-19. None of these agents have been shown to be effective for the prevention of recurrent atrial fibrillation.

Digoxin acts indirectly by increasing vagal tone and at therapeutic concentration has no direct effect in slowing AV node conduction. Because of its mechanism of action, digoxin is less effective than β-blockers or calcium channel blockers, particularly with exercise, when an increase in sympathetic tone results in more rapid AV node conduction. Thus, the optimal role for digoxin in atrial fibrillation is therapy for patients with left ventricular dysfunction (because of the drug's positive inotropy) or adjunctive therapy for patients receiving β-blockers or calcium channel blockers. Digoxin alone is no better than placebo for terminating atrial fibrillation.

- Digoxin alone is no better than placebo for terminating atrial fibrillation.
- Digoxin is less effective than β-blockers or calcium channel blockers in controlling ventricular rate and is best used as an adjunctive agent for its inotropic effect in patients with impaired ventricular function.

β-Blockers such as propranolol, metoprolol, and atenolol are effective in slowing AV node conduction and may be particularly useful when atrial fibrillation complicates hyperthyroidism or myocardial infarction (in which case they reduce the risk of death from myocardial infarction). β-Blockers also decrease the risk of postoperative myocardial infarction, making them well suited for postoperative atrial fibrillation. Carvedilol decreases mortality of patients with chronic heart failure and may be a good choice in that setting. Esmolol, because of its intravenous formulation and short half-life, is particularly useful for acute management of atrial fibrillation.

- β-Blockers are effective for slowing ventricular rate in atrial fibrillation, but they do not terminate atrial fibrillation (although they may prevent it postoperatively).

Table 3-19 Pharmacologic Therapy for Atrial Fibrillation

Agents	Comments
Control of ventricular rate	
β-Blockers (e.g., atenolol, metoprolol, propranolol, carvedilol)	Ideal postoperatively and in hyperthyroidism, acute MI, and chronic CHF (especially carvedilol)
Calcium channel blockers (verapamil, diltiazem)	Nifedipine, amlodipine, and felodipine are not useful for slowing AV conduction
Digoxin	Less effective than β-blockers and calcium channel blockers, especially with exercise Useful in heart failure
Maintenance of sinus rhythm	
Class IA: quinidine, disopyramide, procainamide	Enhance AV conduction—rate must be controlled before use Monitor QTc
Class IC: propafenone, flecainide	Slow AV conduction Often first choice for patients with normal heart Monitor QRS duration
Class III: sotalol, amiodarone	Amiodarone is agent of choice for ventricular dysfunction and after MI

AV, atrioventricular; CHF, congestive heart failure; MI, myocardial infarction.

- β-Blockers are particularly useful postoperatively and in hyperthyroidism, acute myocardial infarction, and chronic heart failure.

Calcium channel blockers are broadly divided into two groups: dihydropyridines (nifedipine, amlodipine, felodipine) and nondihydropyridines (diltiazem, verapamil). Dihydropyridine agents have little or no effect on AV node conduction and no role in the management of atrial fibrillation. Verapamil and diltiazem are both available as intravenous and oral preparations and are well suited for acute and chronic rate control. Also, both agents have negative inotropic effects and should be used cautiously in congestive heart failure.

- Diltiazem and verapamil are both effective for rate control in atrial fibrillation; nifedipine, amlodipine, and felodipine are not and have no role in the management of atrial fibrillation.

Adenosine is very effective at slowing AV node conduction; however, because of its short half-life, it has no role in the treatment of atrial

fibrillation. It can be useful diagnostically by slowing ventricular rate transiently, permitting visualization of atrial activity if the diagnosis is in question.

Nonpharmacologic AV Node Rate Control

If rate control using pharmacologic agents fails (whether due to persistent symptoms or intolerance of medications), catheter ablation of the AV junction may be considered. The advantages of this approach are that it is more than 95% effective for controlling symptoms due to atrial fibrillation and for preventing tachycardia-induced cardiomyopathy (a reversible form of ventricular dysfunction that can occur with long-standing poorly controlled ventricular rates of more than 110 beats/min) and it can be performed with minimal risk. A disadvantage of this approach is that it creates dependence on ventricular pacing and is effectively irreversible. For patients in whom this approach is adopted, a single-lead ventricular pacemaker (programmed to VVIR mode) is implanted if atrial fibrillation is permanent (chronic), and a dual-chamber pacemaker is used for paroxysmal atrial fibrillation. The dual-chamber pacemaker has a mode-switching function. This device permits the tracking of P waves during sinus rhythm and reverts to VVIR (or DDIR) pacing when atrial fibrillation recurs. With ablation of the AV node, the risk of thromboembolism is unchanged because the fibrillation itself persists in the atria and risk factors remain; thus, appropriate stroke prophylaxis must be prescribed.

A new catheter-based ablation approach aimed at cure of atrial fibrillation, based on the discovery of discrete triggers in the pulmonary vein, may be appropriate for patients with significant symptoms attributable to atrial fibrillation. In this procedure, the source for the fibrillation is ablated in the pulmonary vein. The chance of a successful cure is 70% to 80%. This procedure has rapidly become popular because AV node conduction is not impaired and permanent pacing is not required.

Rhythm Control

Rhythm control (maintenance of sinus rhythm) can control symptoms effectively. However, maintaining sinus rhythm has not been shown to decrease the likelihood of thromboembolism, nor has it been shown to prolong survival. In fact, some drugs used to prevent recurrences may cause new arrhythmias (proarrhythmias).

Class IA agents (quinidine, procainamide, and disopyramide) can be associated with torsades de pointes, particularly at the time of reversion of atrial fibrillation to normal sinus rhythm, and treatment should be initiated in a monitored setting. Class IA agents also enhance AV node conduction; thus, before these agents are used, rate control agents should be administered. Class IB agents (lidocaine, mexiletine, tocainide) have no marked effect in treating atrial fibrillation and should not be used for that purpose. For patients with a normal heart, class IC agents (propafenone, flecainide) are often a good first choice and often can be given safely in an outpatient setting (with ECG and treadmill testing at 3 days to exclude proarrhythmia). Amiodarone is safe for patients who have had myocardial infarction and those with systolic dysfunction and is preferable in these situations.

Stroke Prevention

Acute Cardioversion to Normal Sinus Rhythm

Electrical cardioversion from atrial fibrillation is commonly used to control atrial fibrillation. According to current guidelines, patients with atrial fibrillation lasting more than 2 days should receive anticoagulation before cardioversion. Several weeks of warfarin therapy before cardioversion significantly decreases the incidence of cardioversion-associated thromboembolism to 0% to 1.6% (compared with up to 7% in the absence of anticoagulation). Anticoagulation should be continued for a minimum of 4 weeks after cardioversion because of the increased risk of thromboembolism in the weeks after cardioversion or indefinitely in select patients with risk factors for stroke. Although few data are available about cardioversion in the absence of anticoagulation for atrial fibrillation of recent onset (<48 hours), current guidelines do not mandate anticoagulation in this setting. Anticoagulation guidelines for atrial flutter are identical to those for atrial fibrillation. An alternative approach for patients who have had atrial fibrillation for more than 2 days is transesophageal echocardiography with cardioversion (if no thrombus is found) followed by anticoagulation for 3 to 4 weeks.

- Patients who have had atrial fibrillation for more than 2 days must receive anticoagulation for 3 weeks before cardioversion and for 4 weeks afterward.
- An alternative approach for patients who have had atrial fibrillation for more than 2 days is transesophageal echocardiography with cardioversion (if no thrombus is found) followed by anticoagulation for 3-4 weeks.

Chronic Stroke Prevention

Patients with atrial fibrillation due to rheumatic valvular disease have a markedly increased risk of stroke and should receive warfarin therapy. Most patients encountered in clinical practice have nonrheumatic atrial fibrillation. Warfarin decreases the incidence of thromboembolism close to 80% in this population. Risk of thromboembolism is determined by clinical and echocardiographic risk factors (Table 3-20). The risk factors are advanced age, previous transient ischemic

Table 3-20 Risk Factors for Thromboembolism in Non- rheumatic Atrial Fibrillation

Clinical risk factors	Echocardiographic risk factors
Advanced age (>65 y)	Left ventricular dysfunction
Previous TIA or stroke	
Hypertension	
Diabetes (in pooled analysis)	
Congestive heart failure	
Other high-risk clinical settings	
Prosthetic heart valves	
Thyrotoxicosis	

TIA, transient ischemic attack.

attack or stroke, history of hypertension, diabetes mellitus, and congestive heart failure. Echocardiographic risk factors include depressed left ventricular function and left atrial enlargement. Patients who are younger than 60 years and have no clinical heart disease or hypertension are at extremely low risk and require no treatment, although some physicians recommend aspirin. Thus, a strategy based on age and risk factors has emerged and is summarized in Table 3-21. Patients younger than 65 (60 in some reports) with no risk factors can be given no therapy or aspirin. Patients older than 75 or those with risk factors should be given warfarin. For patients given warfarin, the international normalized ratio (INR) should be maintained in the range of 2.0 to 3.0 (although 2.0-2.5 may be preferable for those older than 75). INR values are preferable to prothrombin times for management because prothrombin time assays vary among laboratories.

- Clinical risk factors for stroke in nonrheumatic atrial fibrillation include age >75 years, previous transient ischemic attack or stroke, history of hypertension, diabetes mellitus, and congestive heart failure.
- The echocardiographic risk factors are depressed ventricular function and left atrial enlargement.
- Patients <60 years with structurally normal hearts and no hypertension are at low risk for thromboembolism and require no specific therapy.
- Warfarin should be used to maintain an INR of 2.0-3.0 (although 2.0-2.5 is preferable in the elderly).
- Studies have shown no difference between paroxysmal and chronic atrial fibrillation in stroke rate risk.

Supraventricular Tachycardia

Paroxysmal supraventricular tachycardia (PSVT) refers to cardiac arrhythmias of supraventricular origin using a reentrant mechanism with an abrupt onset and termination, a regular RR interval, and a narrow QRS complex, unless there is a rate-related or preexisting bundle branch block (Fig. 3-30). In patients with a normal QRS during sinus rhythm (lack of preexcitation), PSVT is due to reentry within the AV node in 60%, reentry using a concealed accessory pathway in 30%, and reentry in the sinus node or atrium in the other 10% (Fig. 3-31). Episodes usually respond to vagal maneuvers; if these fail, intravenously administered adenosine or verapamil terminates the arrhythmia in 90% of patients.

- PSVT is an arrhythmia with an abrupt onset and termination.
- Acutely, PSVT usually responds to vagal maneuvers; if not, adenosine or verapamil terminates the arrhythmia in 90% of patients.

PSVT generally is not a life-threatening arrhythmia and only occasionally is associated with near-syncope or syncope. The rhythm is more serious when it is associated with severe heart disease and cardiac decompensation results, with the sudden increase in heart rate. This can occur in patients with congenital heart disease, cardiomyopathy, or ischemic heart disease.

- PSVT generally is not a life-threatening arrhythmia; it often occurs in an otherwise normal heart.
- PSVT is more serious when associated with heart disease.

Although long-term treatment of PSVT can include drugs that suppress AV node conduction (digoxin, β-blockers, and calcium antagonists) and antiarrhythmic drugs (class IA [quinidine, procainamide, disopyramide], IC [propafenone, flecainide], and III [amiodarone, sotalol]), most forms of PSVT can be "cured" permanently with catheter ablation, which has success rates of more than 90%. For young patients in whom β-blocker or calcium channel blocker therapy fails or who choose not to take these agents, catheter ablation usually is preferred over class I or class III antiarrhythmic drugs. For patients with PSVT and hypertension, in whom catheter ablation is not feasible or preferred, β-blockers or calcium channel blockers may be useful in hope of treating both conditions.

- PSVT responds to long-term treatment with most antiarrhythmic drugs.
- PSVT usually can be "cured" permanently with catheter ablation.

Multifocal atrial tachycardia is an automatic atrial rhythm diagnosed when three or more distinct atrial foci (P waves of different morphology) are present and the rate exceeds 100 beats/min (Fig. 3-32).

Table 3-21 Recommended Management of Patients With Nonrheumatic Atrial Fibrillation

Age, y	Risk factors	Recommendations
<65	Present	Warfarin INR 2-3
	No risk factors	Aspirin or nothing
65-75	Present	Warfarin INR 2-3
	No risk factors	Warfarin or aspirin (based on discussion with patient of relatively low risk of stroke, decrease in risk with warfarin, monitoring needs, etc.)
>75		Warfarin INR 2-3 (but should be kept closer to 2.0-2.5 because of increased risk of hemorrhage in this age group)

INR, international normalized ratio.

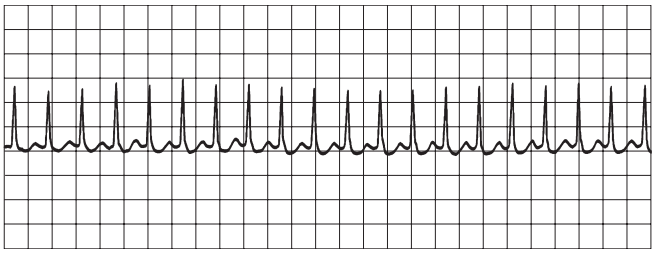

Fig. 3-30. Paroxysmal supraventricular tachycardia.

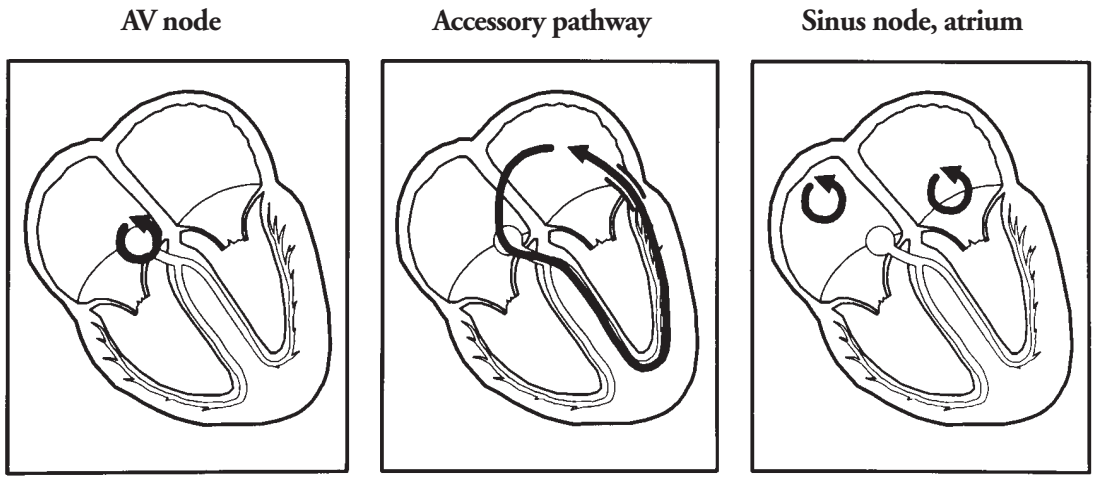

Fig. 3-31. Mechanisms of paroxysmal supraventricular tachycardia in patients with a normal electrocardiogram during sinus rhythm. AV, atrioventricular.

The rhythm occurs primarily in patients with decompensated lung disease and associated hypoxia, increased catecholamines (exogenous and endogenous), atrial stretch, and local tissue acid-base and electrolyte disturbances. This rhythm is made worse by digoxin, which shortens atrial refractoriness, but it does respond to improved oxygenation and slow channel blockade with verapamil or diltiazem.

- Digoxin worsens multifocal atrial tachycardia.
- Multifocal atrial tachycardia is best treated with calcium channel blockers and correction of the underlying medical illnesses.

Differentiating Supraventricular Tachycardia With Aberrancy From Ventricular Tachycardia

Wide QRS tachycardia may be due to supraventricular tachycardia with aberrancy or to ventricular tachycardia. Useful findings to identify ventricular tachycardia are listed in Table 3-22.

Approximately 85% of wide QRS tachycardias are ventricular in origin and are often well tolerated. The absence of hemodynamic compromise during tachycardia is not a clue that the tachycardia is supraventricular in origin. In patients with a wide QRS tachycardia and a history of ischemic heart disease (angina, myocardial infarction, Q wave on ECG), the tachycardia is ventricular in origin in 90% to 95%. Therefore, most wide QRS complex tachycardias are ventricular tachycardia (Fig. 3-33).

- About 85% of wide QRS tachycardias are ventricular in origin.
- In patients with wide QRS tachycardia and ischemic heart disease, tachycardia is ventricular in origin in 90%-95%.

Intravenous administration of verapamil should be avoided in patients with a wide QRS tachycardia unless the tachycardia is supraventricular in origin. Most patients with a wide QRS tachycardia have

Fig. 3-32. Simultaneous recordings from a patient with multifocal atrial tachycardia showing three or more P waves of different morphology. (*Lower tracing*, From MKSAP IX: Part C Book, 1, 1992. American College of Physicians. Used with permission.)

Table 3-22 Findings That Identify Ventricular Tachycardia

Evidence of AV dissociation with P waves "marching through" the QRS complexes
A QRS width >0.14 s if the tachycardia has a right bundle branch block pattern and >0.16 s if the tachycardia has a left bundle branch block pattern
Northwest axis (axis between −90° and −180°)
A different QRS morphology in patients with a preexisting bundle branch block
A history of structural heart disease

AV, atrioventricular.

ventricular tachycardia, and verapamil causes hemodynamic deterioration that requires cardioversion in more than half of the patients. The use of verapamil results in peripheral vasodilatation, further increase in catecholamines, and decreased cardiac contractility—all of which contribute to adverse hemodynamics.

- Intravenously administered verapamil should be avoided for wide QRS tachycardia.
- Verapamil causes hemodynamic deterioration requiring cardioversion in ventricular tachycardia.

Wolff-Parkinson-White Syndrome

This abnormality is defined as 1) symptomatic tachycardia, 2) short PR interval (<0.12 second), 3) a delta wave, and 4) prolonged QRS interval (>0.12 second).

In Wolff-Parkinson-White syndrome, normal activation of the ventricle is a fusion complex. Part of the activation is due to conduction over the accessory pathway, and the remaining activation is due to conduction through the normal His-Purkinje conduction system. Not all patients with preexcitation have a short PR interval. Normal PR conduction may occur if the accessory pathway is far removed from the AV node. In patients with a far left lateral accessory pathway, the heart is activated through the AV node before atrial activation reaches the accessory pathway. Thus, the PR interval may be normal before the onset of the delta wave.

Ventricular activation is abnormal in patients with Wolff-Parkinson-White syndrome. Infarction, ventricular hypertrophy, and ST-T wave changes should not be interpreted after the diagnosis is established, because these changes are usually due to the abnormal pattern of ventricular activation.

- In Wolff-Parkinson-White syndrome, the PR interval may be normal before the onset of the delta wave.
- Ventricular activation is abnormal in Wolff-Parkinson-White syndrome.

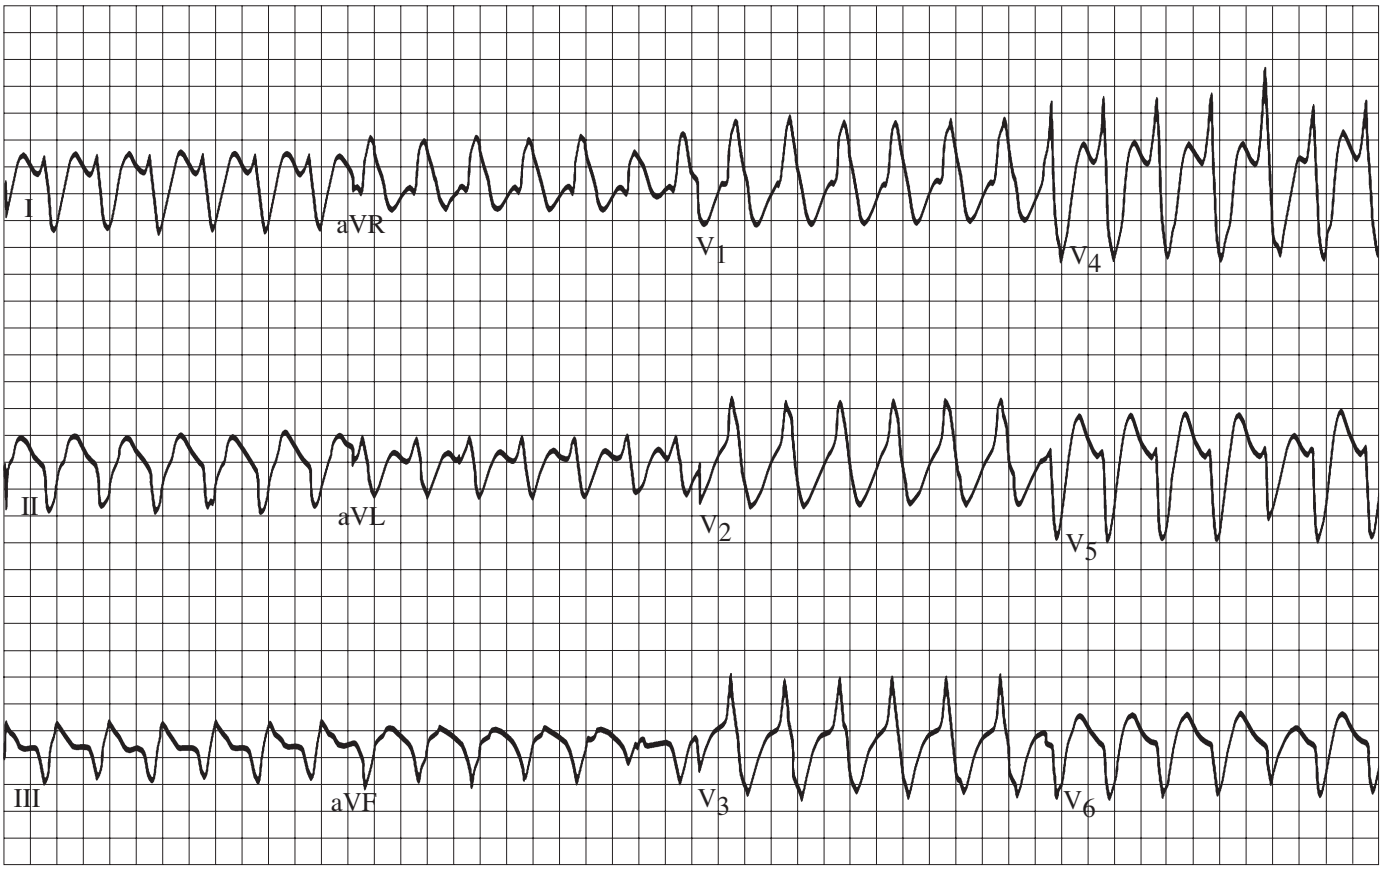

Fig. 3-33. Ventricular tachycardia with a wide QRS complex, northwest axis, and fusion complexes in a patient with normal blood pressure.

Preexcitation occurs in about 2 of 1,000 patients; tachycardia subsequently develops in 70%. Of patients with tachycardia, 70% have PSVT and 30% have atrial fibrillation. The atrial fibrillation often occurs after a short episode of PSVT. Elimination of the accessory pathway with catheter ablation or surgery eliminates atrial fibrillation in most cases. The most serious rhythm disturbance is the onset of atrial fibrillation with rapid ventricular conduction over the accessory pathway resulting in ventricular fibrillation (Fig. 3-34). Most asymptomatic patients do not benefit from risk stratification with electrophysiologic testing, including induction of atrial fibrillation, unless they have a high-risk occupation. Patients who are asymptomatic have a negligible chance of sudden death; for patients who are symptomatic, the incidence of sudden death is 0.0025 per patient-year.

- Preexcitation occurs in 2/1,000 patients; tachycardia develops in 70%.
- Of patients with tachycardia, 70% have PSVT and 30% have atrial fibrillation.
- Asymptomatic patients have a negligible chance of sudden death.
- For symptomatic patients, the incidence of sudden death is 0.0025 per patient-year.

Wolff-Parkinson-White syndrome comprises 1) preexcitation on the surface ECG "delta wave" (Fig. 3-35) due to anterograde conduction over the accessory pathway (an accessory pathway may be concealed such that it is capable of conducting only in the retrograde direction and, thus, the surface ECG in sinus rhythm is normal) and 2) palpitations. Both manifest and concealed accessory pathways have the same mechanism of reentrant tachycardia, in which conduction over the normal conduction system results in a normal QRS complex (unless there is rate-related bundle branch block) and conduction continues through the ventricle, returns over the accessory pathway, and continues through the atrium to complete the reentrant circuit. This mechanism is often termed "orthodromic AV reentry" (Fig. 3-36). Up to 5% of patients may have reentrant tachycardia that goes in the reverse direction ("antidromic AV reentry"), in which ventricular activation over the accessory pathway activates the ventricle from an ectopic location; the result is a wide QRS complex tachycardia that is often confused with ventricular tachycardia (Fig. 3-37).

Electrophysiologic testing is indicated in patients with *symptomatic* Wolff-Parkinson-White syndrome to identify pathway location and to determine whether it is an integral part of the reentrant circuit and not an innocent bystander (i.e., the arrhythmia is AV node reentry). Ultimately, electrophysiologic study is aimed at elimination of the pathway to prevent symptoms due to reentry.

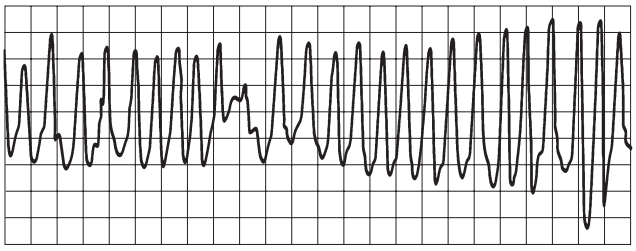

Fig. 3-34. Atrial fibrillation in a patient with Wolff-Parkinson-White syndrome shows a wide QRS complex and irregular RR intervals.

Atrial Fibrillation in Wolff-Parkinson-White Syndrome

Wolff-Parkinson-White syndrome frequently has an association with atrial fibrillation, which is thought to be related to the presence of the accessory pathway because catheter ablation of the accessory pathway results, in most cases, in resolution of atrial fibrillation. Because the accessory pathway does not slow conduction in the same manner as the AV node, the ventricular response to atrial fibrillation can be very rapid and may precipitate ventricular fibrillation. During "preexcited" atrial fibrillation, wide, irregular, and rapid ventricular complexes are seen because activation down the accessory pathway does not use the normal His-Purkinje system (Fig. 3-35). The use of agents such as calcium channel blockers, β-blockers, or digoxin can result in an even more rapid ventricular response due to blocking of conduction down the AV node (which can limit concealed conduction into the pathway). Therefore, the agent of first choice is procainamide, which slows accessory pathway and intra-atrial conduction. Should a patient with Wolff-Parkinson-White syndrome and atrial fibrillation become hypotensive, cardioversion should be performed.

- Atrial fibrillation in Wolff-Parkinson-White syndrome should not be treated with digoxin, adenosine, β-blockers, or calcium channel blockers.
- In atrial fibrillation in Wolff-Parkinson-White syndrome, procainamide can be given to slow the ventricular rate (by slowing atrial and accessory pathway conduction) and to restore sinus rhythm.

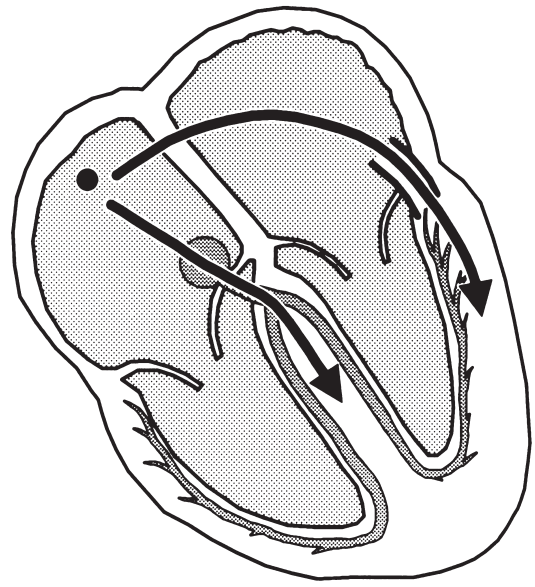

Fig. 3-35. Conduction of sinus impulses in Wolff-Parkinson-White syndrome. The ventricles are activated over the normal atrioventricular node–His-Purkinje system and accessory pathway; the result is a fusion complex (QRS and delta wave).

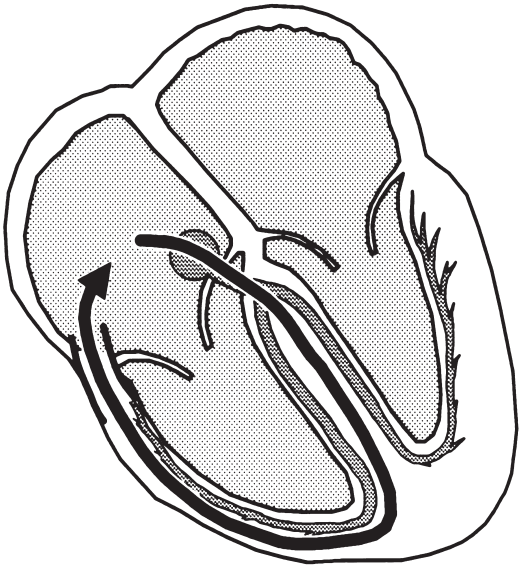

Fig. 3-36. Typical mechanism of supraventricular tachycardia in patients with Wolff-Parkinson-White syndrome (orthodromic atrioventricular reentry): the result is a narrow QRS complex because ventricular activation is over the normal conduction system.

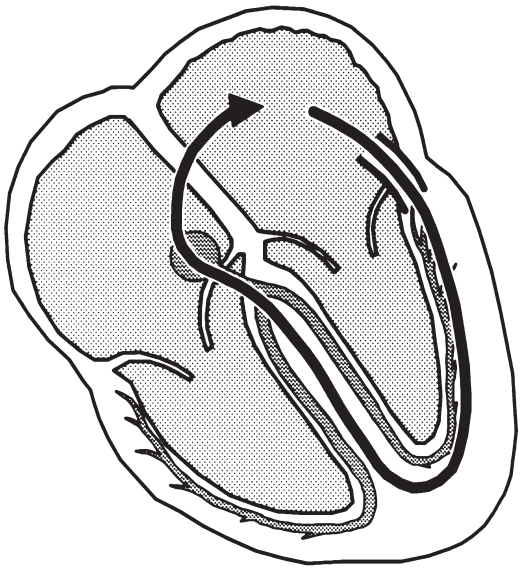

Fig. 3-37. Unusual mechanism of supraventricular tachycardia in patients with Wolff-Parkinson-White syndrome; the result is a wide QRS complex because ventricular activation is over an accessory pathway. This arrhythmia is difficult to distinguish from ventricular tachycardia.

- If the heart rate is rapid and there is hemodynamic compromise, cardioversion should be performed.

PSVT in patients with an accessory pathway often terminates with vagal maneuvers or intravenously administered adenosine or verapamil. Additional episodes can be prevented with a β-blocker, a calcium antagonist, and class IA (quinidine, procainamide, disopyramide), class IC (propafenone, flecainide), and class III (amiodarone, sotalol) antiarrhythmic drugs. Radiofrequency ablation is used to ablate the accessory pathway and to cure the tachycardia, thus eliminating the need for medical therapy.

- Additional PSVT is prevented with a β-blocker, a calcium antagonist, and class IA, IC, and III antiarrhythmic drugs.
- Radiofrequency ablation is used to cure tachycardia and should be strongly considered for symptomatic patients.

Tachycardia-Mediated Cardiomyopathy

Persistent atrial fibrillation with a rapid ventricular rate may lead to progressive ventricular dysfunction (termed tachycardia-induced cardiomyopathy). This condition is reversible in most cases because control of the ventricular rate improves ventricular function. One issue in patients who present with tachycardia and congestive heart failure, or who are found to have left ventricular dysfunction during evaluation, is determining whether the heart failure is causing the tachycardia or the tachycardia has caused the heart failure. In a patient with heart failure who has a rhythm with an abnormal P-wave axis, tachycardia-mediated cardiomyopathy should be suspected.

Ventricular Ectopy and Nonsustained Ventricular Tachycardia

Management of frequent ventricular ectopy and nonsustained ventricular tachycardia is predicated on the underlying cardiac lesion. For patients with structurally normal hearts, the long-term prognosis is excellent and no specific therapy is warranted in the absence of symptoms. If symptoms are present, management includes reassurance, β-blockers or calcium channel blockers for disturbing symptoms, and, in rare cases of frequent monomorphic symptomatic ventricular ectopy, catheter ablation.

In patients with previous myocardial infarction, depressed ventricular function (ejection fraction ≤35%), and nonsustained ventricular tachycardia, electrophysiologic study can stratify risk, even in the absence of symptoms. If, in this population, tachycardia is inducible, the mortality rate is decreased with implantation of a defibrillator. In patients with nonischemic (dilated) cardiomyopathy with ejection fraction less than 35%, recent evidence suggests potential mortality benefit with use of an implantable cardioverter-defibrillator. Use of amiodarone is not associated with mortality benefit in this population, as had previously been suggested.

- Patients with a structurally normal heart and complex ectopy or nonsustained ventricular tachycardia have an excellent prognosis; management includes reassurance or, if bothersome symptoms persist, calcium channel blockers or β-blockers.
- Patients with depressed ventricular function and nonsustained ventricular tachycardia are at increased risk for sudden cardiac death; patients with previous myocardial infarction can be risk stratified with electrophysiologic study.

Ventricular Tachycardia and Fibrillation

Patients who present with ventricular tachycardia or fibrillation or who survive sudden cardiac death (out-of-hospital cardiac arrest who were successfully resuscitated) have lethal ventricular arrhythmias and a substantial risk of recurrence. Survivors of sudden cardiac death have a risk of death approaching 30% in the first year after hospital dismissal. Current guidelines support the use of implantable cardioverter-defibrillators in this population. Antiarrhythmic drug therapy has not been shown to have benefit. Use of an implantable cardioverter-defibrillator reduces the recurrence rate of sudden death to 2% at 1 year and to 4% at 4 years; the overall mortality rate is 10% at 1 year and 20% at 4 years.

- Patients with ventricular tachycardia or fibrillation who survive sudden cardiac death have a substantial risk of recurrence.
- Survivors of sudden cardiac death have a risk of death of 30% at 1 year after hospital dismissal.
- Implantable cardioverter-defibrillator therapy improves outcome.

Torsades de Pointes

This is a form of ventricular tachycardia with a characteristic polymorphic morphology described as a "twisting of the points" (torsades de pointes) (Fig. 3-19) and occurs in the setting of QT interval prolongation. Typically, polymorphic ventricular tachycardia is initiated by a late-coupled premature ventricular contraction. Common causes include medications (quinidine, procainamide, disopyramide, sotalol, tricyclic antidepressants), electrolyte disturbance (hypokalemia), or bradycardia (especially after myocardial infarction). After the tachycardia has been converted to sinus rhythm (electrically or spontaneously), treatment should be aimed at shortening the QT interval until the offending drug can be metabolized or the electrolyte disturbance or bradycardia corrected. Treatment options include temporary overdrive pacing, isoproterenol infusion, or magnesium. Patients with a prolonged QT interval in the absence of medications, electrolytes, or bradycardia have a congenital form of this problem and are usually treated with a β-blocker.

- Torsades de pointes is a form of ventricular tachycardia involving a prolonged QT interval.
- Torsades de pointes usually is due to a medication, an electrolyte disturbance, or bradycardia.
- Treatment includes temporary overdrive pacing, isoproterenol, or magnesium.

Ventricular Arrhythmias During Acute Myocardial Infarction

Prevention of myocardial ischemia and the use of β-blockers are essential during and after acute myocardial infarction to decrease the frequency of life-threatening ventricular arrhythmias. Asymptomatic complex ventricular ectopy, including nonsustained ventricular tachycardia, should not be treated empirically in the acute phase of myocardial infarction because the risk of proarrhythmia outweighs the potential benefit of therapy for reducing the incidence of sudden cardiac death after hospital dismissal.

The routine use of lidocaine or amiodarone in suppressing ventricular arrhythmias in the acute phase of myocardial infarction is not recommended.

Ventricular tachycardia and fibrillation occurring within 24 hours after myocardial infarction are independent risk factors for in-hospital mortality at the time of the acute myocardial infarction but are not risk factors for subsequent total mortality or mortality due to an arrhythmic event after hospital dismissal and do not require antiarrhythmic therapy.

Ventricular tachycardia and fibrillation occurring 24 hours or longer after an acute myocardial infarction in the absence of reinfarction are independent risk factors for increased total mortality and death due to an arrhythmic event after hospital dismissal. Patients should be assessed with electrophysiologic testing, and the treatment option is usually an implantable cardioverter-defibrillator.

Episodes of refractory ventricular tachycardia and fibrillation during acute myocardial infarction should be treated with intravenously administered lidocaine, procainamide, bretylium, or amiodarone, and patients should have adequate oxygenation and normal electrolyte values. Recent data suggest that amiodarone may be a reasonable choice if lidocaine fails to control the arrhythmia. If these drugs are ineffective, alternative therapies to prevent recurrences of tachycardia include overdrive pacing if the tachycardia follows a bradycardia event, intra-aortic balloon pump, and coronary revascularization.

- Refractory ventricular tachycardia and fibrillation during acute myocardial infarction should be treated with intravenously administered lidocaine, procainamide, bretylium, or amiodarone.
- Alternative therapies are overdrive pacing and coronary revascularization.

Role of Pacing in Acute Myocardial Infarction

Among patients with an acute inferior myocardial infarction, 5% to 10% have Mobitz I second-degree or third-degree block in the absence of bundle branch block, and the site commonly is in the AV node. This usually is transient, tends not to recur, and requires pacing only if there are symptoms as a result of bradycardia.

Bundle branch block occurs in 10% to 20% of patients with an acute myocardial infarction; in half of these patients, it is detected at the initial presentation, often representing preexisting conduction system disease. The appearance of a new bundle branch block is an indication for prophylactic temporary pacing.

Death of patients with myocardial infarction and bundle branch block usually is due to advanced heart failure and ventricular arrhythmias rather than to the development of complete heart block. Patients in whom transient complete heart block develops in association with a bundle branch block are at risk for recurrent complete heart block and should undergo permanent pacing. A new bundle branch block that never progresses to complete heart block is not an indication for permanent pacing.

- Death of patients with myocardial infarction and bundle branch block usually is due to advanced heart failure.

- New bundle branch block that never progresses to complete heart block is not an indication for permanent pacing.
- Second-degree (Mobitz II) block with bilateral bundle branch block and third-degree AV block warrants pacing.

Syncope

Syncope is a transient loss of consciousness with spontaneous recovery. It is a frequent clinical syndrome that requires medical evaluation. Causes of syncope can be categorized as cardiovascular, noncardiovascular, and unexplained (Table 3-23). It is estimated that 30% of cases of syncope have a cardiogenic cause (bradycardia or tachycardia), 35% have a vasovagal cause, and 10% to 25% are related to a miscellaneous disorder such as orthostatic or situational syncope or seizures or are drug-related episodes. In 10% to 25% of cases, the cause is—and often remains—unknown.

The most important aspect of evaluation for syncope is the clinical history and physical examination, which provide key information in 40% to 75% of the patients for whom a diagnosis is eventually established. The factors associated with increased cardiogenic causes for syncope are listed in Table 3-24. In patients with increased risk of cardiogenic syncope, electrophysiologic testing should be considered. If an arrhythmogenic cause (bradycardia or tachycardia) for syncope has been established by noninvasive tests such as ECG, Holter monitoring, or transtelephonic monitoring, electrophysiologic testing is not indicated unless other arrhythmias are suspected. In patients at low risk for cardiogenic syncope, a noninvasive approach should be considered.

Tilt-table testing is effective in eliciting a vasovagal response. For diagnostic purposes, tilt-table testing is indicated for patients with recurrent syncope without evidence of structural cardiac disease or for those with structural heart disease but after other causes of syncope have been excluded by appropriate testing. Tilt-table testing generally is not indicated for patients with a single episode of syncope without injury or in a high-risk setting with clear-cut vasovagal clinical features. Recommendations for evaluation of patients with syncope are outlined in Figure 3-38.

After the diagnosis of syncope has been established, the treatment usually is straightforward. Pacemaker therapy is appropriate for sinus node dysfunction and AV conduction disease. Various treatment options for tachyarrhythmias are discussed above. Pharmacologic therapy can be effective in selected patients with marked symptomatic vasovagal syncope. These therapeutic options include β-blockers, anticholinergic drugs, vasoconstrictors, increased intravascular volume, and maneuvers to prevent venous pooling. Recent reports suggest that serotonin reuptake blockers may be effective in a subgroup of patients. Pacemaker therapy can be effective for preventing syncope in patients with a predominant cardioinhibitory subtype of vasovagal syncope and may be effective in patients with very frequent recurrent vasovagal syncope.

Part IV

Abhiram Prasad, MD
Steve R. Ommen, MD

Ischemic heart disease, principally myocardial infarction, accounts for approximately one of three deaths in the United States, or nearly 600,000 deaths annually. The substantial decrease in the death rate from acute myocardial infarction that has occurred in the past 4 decades (Fig. 3-39) is attributed to efforts in primary prevention and new interventions in the treatment of myocardial infarction. The variable presentation of patients with coronary heart disease includes patients who are asymptomatic (with or without silent ischemia), patients who have stable or unstable angina or myocardial infarction, and patients with sudden death.

- About one-third of the deaths annually in the United States are due to myocardial infarction.
- The substantial decrease in death from acute myocardial infarction in the past 4 decades is due to primary prevention and new treatments of myocardial infarction.

Prevention of Coronary Heart Disease

Risk factors for coronary artery disease, for which intervention has been proved to reduce cardiac events, include tobacco abuse, serum low-density lipoprotein (LDL) cholesterol level, and hypertension. Factors that clearly increase the risk of coronary artery disease, which intervention likely decreases, include diabetes mellitus, physical inactivity, obesity, serum high-density lipoprotein level, and serum triglyceride levels. Factors for which intervention may improve subsequent risk include psychosocial factors (anxiety and depression), homocysteine level, and alcohol intake. The nonmodifiable risk factors for coronary artery disease are age, sex, and family history. Primary prevention includes modification of certain risk factors (J Am Coll Cardiol. 2003;41:159-68):

- Smoking more than doubles the incidence of coronary heart disease and increases mortality by 50%.
- The relative risk of smokers who have quit smoking decreases rapidly, approaching the levels of nonsmokers within 2-3 years.
- Plasma levels of total cholesterol and LDL cholesterol are important risk factors for coronary heart disease. This relationship is strongest at high levels of cholesterol.
- A 1% decrease in total serum cholesterol yields a 2%-3% decrease in the risk of coronary heart disease.
- Lowering increased plasma levels of LDL cholesterol slows progression and promotes regression of coronary atherosclerosis.
- Lowering increased plasma levels of LDL cholesterol prevents coronary events, presumably because of stabilization of lipid-laden plaques.
- The estimated decreased risk of myocardial infarction is 2%-3% for each 1-mm Hg decrease in diastolic blood pressure.

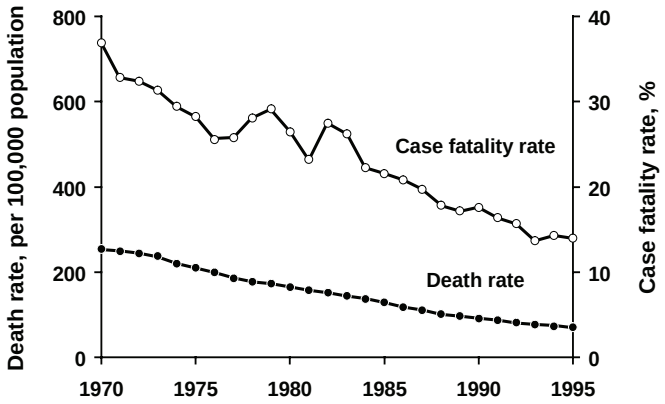

Fig. 3-39. Death rate and case fatality rate for acute myocardial infarction among persons 45 to 64 years of age in the United States, 1970 through 1995. (From Levy D, Thom RJ. Death rates from coronary disease: progress and a puzzling paradox [editorial]. N Engl J Med. 1998;339:915-7. Used with permission.)

- The estimated decrease in the risk of myocardial infarction with the maintenance of an active compared with a sedentary lifestyle is 35%-55%.
- The adjusted mortality rates for coronary heart disease are 2 to 3 times higher in men with diabetes mellitus and 3 to 7 times higher in women with diabetes mellitus.
- Estrogen replacement therapy is not indicated in women with cardiovascular disease, and it may be harmful.
- Although heavy alcohol use increases the risk of cardiovascular disease, moderate consumption decreases the risk of heart disease.
- Metabolic syndrome is present in 20% of the U.S. population, its prevalence is increasing, and it is associated with twofold to threefold increase in mortality from cardiovascular disease.

Secondary prevention refers to efforts to prevent recurrent ischemic events in patients with known coronary artery disease. The role of antiplatelet agents, β-adrenergic blockers, and angiotensin-converting enzyme inhibitors is discussed below. Aggressive treatment of cholesterol levels is of value. The statin drugs reduce events after myocardial infarction to a greater degree than would be expected from their effect on atherosclerosis progression alone. This result may be related to stabilization of lipid-rich plaques, which are prone to rupture. In patients who have had a myocardial infarction and have increased levels of cholesterol (>220 mg/dL), treatment with a statin drug decreases overall mortality by 30% and disease mortality from coronary events by 42%. In patients who have had a myocardial infarction and have "average" levels of cholesterol (cholesterol, <240 mg/dL; LDL, >125 mg/dL), treatment with a statin drug reduces

the chance of fatal heart disease or recurrent myocardial infarction by 24%.

Current indications for instituting cholesterol-lowering therapy are as follows (J Am Coll Cardiol. 2004;44:720-32):

- Known coronary artery disease (or diabetes mellitus): LDL >100 mg/dL. Goal LDL <100 mg/dL (optimal < 70 mg/dL).
- Risk factors for coronary artery disease: LDL >130 mg/dL.
- Others: LDL >160 mg/dL.

Newer "risk factors" have been proposed for the diagnosis and management of patients with coronary heart disease. Abnormal levels of lipoprotein (a), homocysteine, and fibrinogen may be markers for coronary artery disease in patients who may not have the conventional risk factors. In patients with known coronary artery disease, inflammatory or infectious markers have been associated with adverse outcomes. These include inflammatory markers such as C-reactive protein, tumor necrosis factor-α, interleukin-1 and -6, and infectious agents such as *Chlamydia*, cytomegalovirus, and *Helicobacter*. New data suggest that increased levels of C-reactive protein are associated with a twofold to threefold increase in the rate of myocardial infarction. There is the suggestion that some drugs (i.e., statins) may be beneficial in patients with inflammatory markers, although the data are preliminary.

Mechanism of Atherosclerosis

The "response to injury" hypothesis is the most prevalent explanation of atherosclerosis (N Engl J Med. 1992;326:242-50). According to this hypothesis, chronic minimal injury to the arterial endothelium is caused mainly by a disturbance in the pattern of blood flow (stage I injury), potentiated by high cholesterol levels, inflammation, infections, and tobacco smoke. Stage I injury leads to the accumulation of lipids, which are modified by oxidation and glycation. The modified LDL induces an inflammatory response in the vessel wall that results in the accumulation of macrophages and other leukocytes. Scavenger receptors on the macrophages mediate the uptake of the modified LDL into the cells to form macrophage foam cells. The release of toxic products by macrophages produces stage II injury, which is characterized by the adhesion of platelets. Macrophages and platelets with endothelial-release growth factors cause migration and proliferation of smooth muscle cells, which form a fibrointimal lesion or lipid lesion. Disruption of a lipid lesion that has a thin capsule causes stage III damage, with thrombus formation. The thrombus may organize and contribute to the growth of the atherosclerotic lesion or become totally occluded, culminating in unstable angina or myocardial infarction (Fig. 3-40). Lipid-laden coronary artery lesions with less severe angiographic stenosis are more prone to rapid progression because of atherosclerotic plaque disruption. In up to two-thirds of cases of unstable angina or myocardial infarction, the culprit lesion is at a site with less than 50% stenosis.

- The most prevalent explanation for atherosclerosis is the "response to injury" hypothesis.
- Stage II injury is characterized by the adhesion of platelets.
- Stage III damage is disruption of a lipid lesion leading to thrombus formation.
- Lipid-laden coronary artery lesions with less severe angiographic stenosis are more prone to rapid progression because of atherosclerotic plaque disruption.
- In up to two-thirds of cases of unstable angina or myocardial infarction, the culprit lesion is at a site with <50% stenosis.

Chronic Stable Angina

Pathophysiology

In chronic stable angina, myocardial ischemia is caused by a mismatch between myocardial oxygen demand and myocardial oxygen supply. Less important factors are perfusion pressure (aortic–to–right atrial gradient), autoregulation (maintenance of coronary blood flow through a physiologic range of perfusion pressures), autonomic tone, and compressive effect (high left ventricular end-diastolic pressure decreases subendocardial flow). Normally, coronary blood flow can increase up to 5 times to meet effort-related increases in myocardial oxygen demands. Ischemia occurs when flow reserve is inadequate, usually the result of fixed coronary artery disease. Restriction of resting blood flow to levels sufficient to cause ischemia at rest does not occur unless vessel stenosis is greater than 95%. However, a decrease in overall flow reserve begins to occur with about 60% stenosis, at which point symptoms of exercise-induced ischemia may begin.

The four factors that determine myocardial oxygen consumption (demand) are heart rate, afterload, contractility, and wall tension [wall tension = (left ventricular radius) × (left ventricular pressure)]. With a dilated, poorly contractile left ventricle, the contribution of wall tension to myocardial oxygen consumption outweighs the other factors. The temporal sequence of events includes metabolic ischemia → diastolic dysfunction → perfusion abnormalities → regional wall motion abnormalities → electrocardiographic (ECG) changes → pain.

- In chronic stable angina, myocardial ischemia is caused by increased myocardial oxygen demand.
- Normally, coronary blood flow can increase up to 5 times to meet myocardial oxygen demand.
- Resting blood flow does not cause ischemia unless stenosis is >95%.
- The four factors of myocardial oxygen consumption: heart rate, afterload, contractility, and wall tension.
- The temporal sequence of events: ischemia → diastolic dysfunction → perfusion abnormalities → regional wall motion abnormalities → ECG changes → pain.

Clinical Presentation

Symptomatic Chronic Coronary Artery Disease

Typical angina is defined by the presence of all three of the following: characteristic retrosternal pain, the pain occurs with stress, and the pain is relieved by rest or nitroglycerin. Atypical angina is defined by the presence of two of these features. Noncardiac chest pain is defined by the presence of one or none of these features. Many

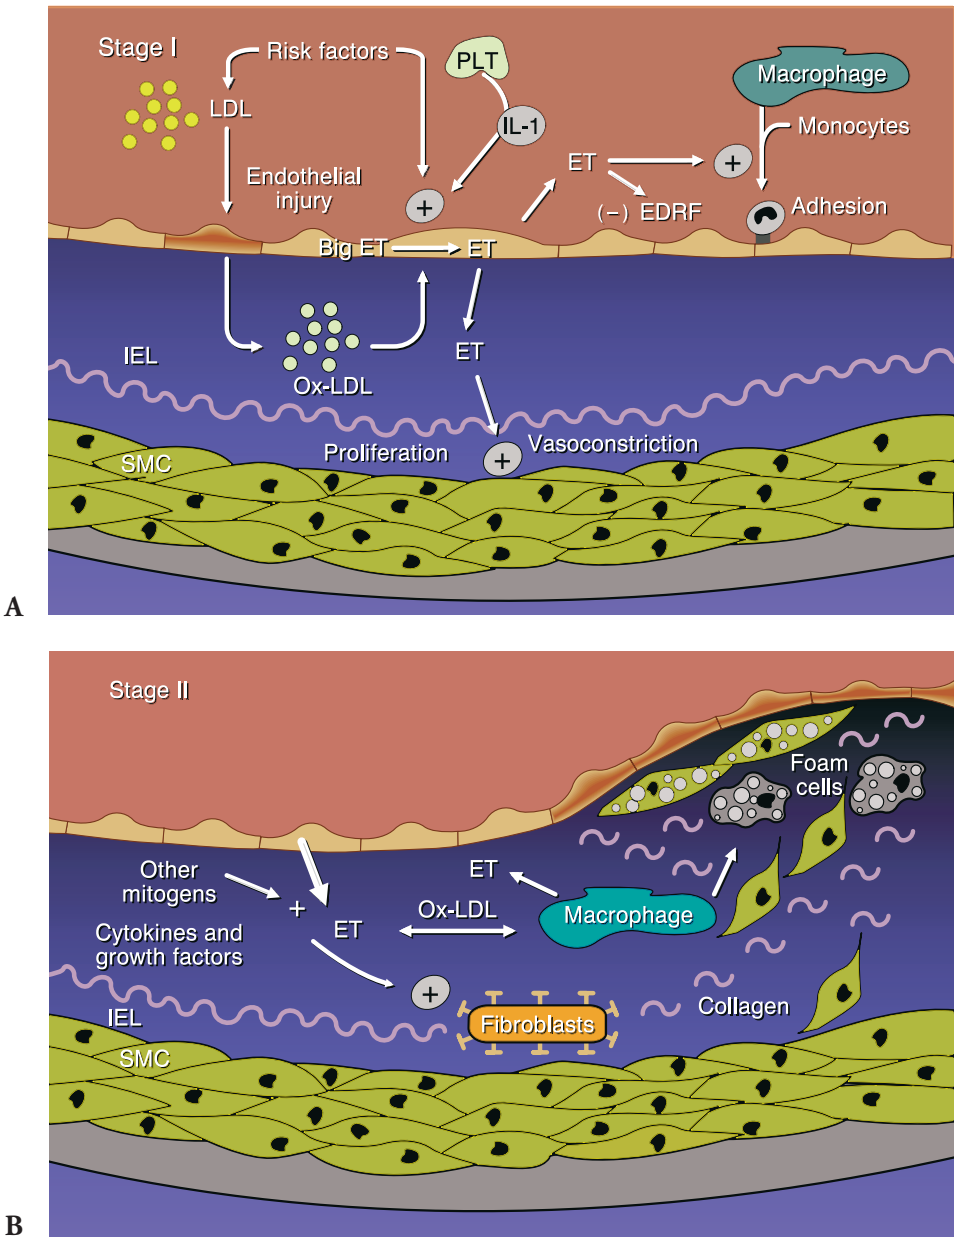

Fig. 3-40. *A*, Stage I vascular injury. *B*, Stage II vascular injury. Interaction of endothelin (ET) and the atherosclerotic plaque. EDRF, endothelium-derived relaxing factor; IEL, internal elastic lamina; IL-1, interleukin 1; LDL, low-density lipoprotein particles; Ox-LDL, oxidized LDL particles; PLT, platelet; SMC, smooth muscle cell. "+" indicates stimulation. (From Lerman A. The endothelium. In Murphy JG, editor. Mayo Clinic cardiology board review. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2000. p. 99-112. Used with permission of Mayo Foundation for Medical Education and Research.)

patients have symptoms of angina pectoris during physical activity. The pain is described variously as "pressure," "burning," "stabbing," "ache," "hurt," or "shortness of breath." It can be substernal or epigastric and radiate to the neck, jaw, shoulder, elbow, or wrist. In chronic stable angina, the pain lasts 2 to 30 minutes and is usually relieved by rest. It generally is precipitated by any activity that increases myocardial oxygen consumption. Physical signs that occur with the pain include the onset of a fourth heart sound and mitral regurgitant murmur due to papillary muscle dysfunction. ST-segment depression may be found on the ECG, indicating subendocardial ischemia. The double product [(heart rate) × (systolic blood pressure)] is useful for defining myocardial oxygen demand. Nocturnal angina can be caused by unstable angina and also by increased wall tension with left ventricular dysfunction.

- Typical angina is defined by the presence of all three of the following: characteristic retrosternal pain, the pain occurs with stress, and the pain is relieved by rest or nitroglycerin. Atypical angina is

defined by the presence of two of these features. Noncardiac chest pain is defined by the presence of one or none of these features.
- Physical signs occurring with the pain are a fourth heart sound and mitral regurgitant murmur due to papillary muscle dysfunction.
- The double product [(heart rate) × (systolic blood pressure)] is useful for defining myocardial oxygen demand.

Silent Ischemia

Silent ischemia is common in patients with symptomatic stable coronary artery disease or unstable angina or after myocardial infarction. It is diagnosed by the presence of ST-segment depression in the absence of symptoms. The treatment is similar to that for chronic stable angina: risk factor modification, aspirin, and β-adrenergic blockers are effective. Whether percutaneous transluminal coronary angioplasty or coronary artery bypass grafting should be performed for silent ischemia alone is debated unless there are other markers of exceptionally high risk. The prognosis for this condition is the same as that for symptomatic ischemia.

- Silent ischemia is common in patients with symptomatic stable coronary artery disease or unstable angina or after myocardial infarction.
- Silent ischemia is diagnosed by the presence of ST-segment depression in the absence of symptoms.
- Treatment is similar to that for chronic stable angina.
- β-Adrenergic blockers are effective therapeutic agents in silent ischemia.
- Whether coronary angioplasty or bypass grafting should be performed for silent ischemia is debated.
- The prognosis for silent ischemia is the same as that for symptomatic ischemia.

Noninvasive Testing

Ancillary tests for coronary artery disease include measurement of left ventricular function, stress testing, and coronary angiography. Left ventricular function is the most important predictor of prognosis and should be measured in all patients with two-dimensional echocardiography, radionuclide angiography, or left ventricular angiography. Exercise testing is performed with the treadmill or bicycle exertion test in conjunction with ECG monitoring, thallium or technetium-sestamibi scanning (perfusion of the myocardium), radionuclide angiography (left ventricular function), or echocardiography (left ventricular function) to assess for ischemia (J Am Coll Cardiol. 2002;40:1531-40). During a standard treadmill test (i.e., exercise with stepped increases in workload every 2-3 minutes), heart rate, blood pressure, and the onset of subjective symptoms are monitored. The cardiac rhythm and the 12-lead ECG are monitored continuously. The ECG is positive for ischemia if there is a flat or downsloping ST-segment depression of 1 mm or more. The ECG response is uninterpretable when there is more than 1 mm of resting ST-segment depression, left bundle branch block, left ventricular hypertrophy, paced rhythm, digoxin therapy, or preexcitation (Wolff-Parkinson-White syndrome). For interpreting the results of any test, Bayes theorem is important. According to this theorem, the predictive value of a test depends on the prevalence of the disease in the population studied.

- The most important predictor of prognosis is left ventricular function.
- The ECG is positive for ischemia if there is a flat ST-segment depression of ≥1 mm.
- Complete left bundle branch block, resting ST-segment depression >1 mm, left ventricular hypertrophy, paced rhythm, digoxin therapy, or preexcitation render the exercise ECG uninterpretable.
- Bayes theorem: the predictive value of a test depends on the prevalence of the disease in the population studied.

ECG treadmill exertion testing has a sensitivity of about 70% and specificity of about 75%. Thus, a young patient with atypical chest pain and no risk factors (patient A in Fig. 3-41) has a low pretest probability (5%) of coronary artery disease. If the test results are negative, the probability decreases to 3%. However, if the results are positive, the probability is less than 15%. In comparison, an older man (patient B in Fig. 3-41) with typical chest pain and multiple risk factors has a high pretest probability (90%) of coronary artery disease, and even with negative test results the probability is higher than 70%. Thus, stress tests should not be used for the *diagnosis* of coronary artery disease in patients at high or low risk. Pretest probability of disease can be estimated with the following clinical criteria: age (men >40 years and women >60 years), male sex, and symptom status (in decreasing order of risk: typical angina, atypical angina, noncardiac chest pain, asymptomatic).

Several different types of cardiac imaging methods add to the sensitivity and specificity of ECG treadmill exertion testing. In thallium

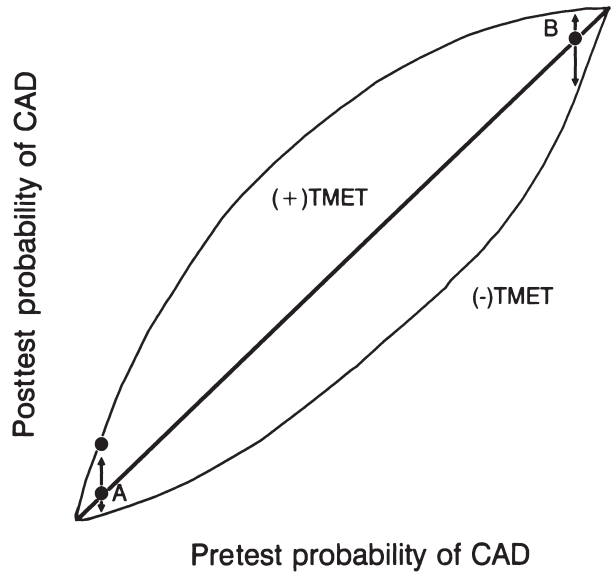

Fig. 3-41. The effect of Bayes theorem on the ability of treadmill exertion testing (TMET) to diagnose coronary artery disease (CAD). Representative patients A and B are described in the text.

imaging, thallium 201 injected at peak exercise labels areas of perfusion; "cold spots" are nonperfused regions. Scanning is repeated 3 to 24 hours later. Persistent cold spots indicate previous infarction, and reperfused areas indicate ischemia. Single-photon emission computed tomography thallium scanning (use of multiple tomographic planes) is more accurate than planar thallium scanning. In patients with left bundle branch block and severe left ventricular hypertrophy, thallium and sestamibi scanning give false-positive results during exercise stress.

Sestamibi scanning uses an isotope with a half-life different from that of thallium. Also, because this isotope has higher photon energy than thallium, it is routinely used in women and obese patients to avoid artifact. However, the results are interpreted in the same way as those of thallium scanning, with cold spots indicating lack of perfusion.

In radionuclide angiography (multiple gated acquisition scanning), erythrocytes are labeled with technetium Tc 99m and the left ventricular cavity is imaged during the cardiac cycle to measure (at rest and at peak exercise) left ventricular volume, ejection fraction, and regional wall motion abnormalities. The test result is positive if the ejection fraction decreases or new regional wall motion abnormalities appear. Because multiple cycles are gated, the test cannot be used with irregular rhythms.

In exercise echocardiography, two-dimensional echocardiography is performed at rest and at peak exercise. Digital acquisition allows side-by-side comparisons of images from the same view. The test is positive for ischemia if global systolic function decreases or new regional wall motion abnormalities appear.

- The sensitivity and specificity of ECG treadmill exertion testing are about 70% and 75%, respectively.
- The treadmill exertion test should not be used to make the diagnosis of coronary artery disease.
- Thallium or sestamibi scanning gives false-positive results during exercise in patients with left bundle branch block and severe left ventricular hypertrophy.
- Multiple gated acquisition scanning is positive if the ejection fraction decreases or new regional wall motion abnormalities appear.
- Two-dimensional echocardiography is positive for ischemia if global systolic function decreases or new regional wall motion abnormalities appear.

All these imaging methods are more expensive than the ECG treadmill exertion test. Because Bayes theorem applies, imaging methods should not be used instead of ECG treadmill testing to diagnose coronary artery disease except in cases of an uninterpretable ECG or false-positive ECG results or for localizing specific regions of ischemia (for future revascularization procedures).

Pharmacologic stress tests that provoke ischemia have been developed for patients who cannot exercise. These tests include the use of dipyridamole thallium, which redistributes flow away from ischemic myocardium. Adenosine thallium works in the same way as dipyridamole. In dobutamine echocardiography, the myocardial oxygen demand is increased. Pacing echocardiography increases heart rate.

Treadmill exertion testing identifies high-risk patients. A patient is at high risk if the following results are obtained: a positive test in stage I of the Bruce protocol or at a heart rate less than 120 beats/min, ST-segment depression more than 2 mm, ST-segment depression more than 6 minutes in duration after stopping, decreased blood pressure, multiple perfusion defects, and a decrease in ejection fraction more than 20%. In patients with poor prognostic factors, it is reasonable to proceed with coronary angiography to define the anatomy of the coronary arteries and the need for intervention. However, in patients who achieve a good workload without significant ST-segment depression and have appropriate blood pressure and heart rate responses, medical management may be indicated because of the excellent prognosis. The treadmill exertion test should not be performed on patients with high-risk unstable angina, patients who have had an acute myocardial infarction in the previous 2 days, or patients with symptomatic severe aortic stenosis, uncontrolled heart failure, uncontrolled arrhythmia, or severe aortic stenosis.

- The major usefulness of stress testing is to identify high-risk patients, not to diagnose coronary artery disease.
- The treadmill exertion test should not be performed on patients with high-risk unstable angina, patients who have had an acute myocardial infarction in the previous 2 days, or patients with symptomatic severe aortic stenosis, uncontrolled heart failure, uncontrolled arrhythmia, or severe aortic stenosis.

Coronary Angiography

Although coronary angiography has many limitations, it is the standard method for defining the severity and extent of coronary artery disease. Subjective visual estimation of the percentage of stenosis may grossly underestimate the severity of the disease, especially if it is diffuse, because angiography outlines only the vessel lumen. The risk of serious complications of coronary angiography is approximately 0.2%. These complications include myocardial infarction (0.1%), stroke (0.1%), and death (0.1%). The risk is greater for older patients or for those with severe left ventricular dysfunction, left main coronary artery disease, or other coexistent diseases. Other complications include vascular complications (0.5%) and renal failure.

- Coronary angiography is the standard method for defining the severity of coronary artery disease.
- Visual estimation of the percentage of stenosis may grossly underestimate disease severity.
- The risk of serious complications in coronary angiography is <1%.

Medical Therapy

Medical treatment for chronic stable angina should be given in a stepwise manner according to symptoms. Sublingual nitroglycerin should be given as needed. A first-line drug should be increased to the optimal dosage before a second or third drug is added. β-Adrenergic blockers are the most effective drugs for patients with coronary artery disease and should be the first-line drug of choice. They relieve angina mainly by decreasing heart rate, reducing

contractility, and decreasing afterload (blood pressure). They are the most effective drugs for reducing the double product (heart rate × blood pressure) with exercise. Also, these drugs may improve survival for some patients with known coronary artery disease, particularly those who have had a myocardial infarction and those with depressed left ventricular systolic function. β-Adrenergic blockers should not be prescribed if the patient has marked bronchospastic disease, severely symptomatic congestive heart failure, or bradycardia. However, they can and should be given to patients with left ventricular systolic dysfunction in the absence of overt heart failure. They should be given at a dosage that keeps the resting heart rate less than 70 beats/min.

Long-acting nitrates should be added sequentially if symptoms continue. Nitrates relieve angina mainly by producing venodilatation, which decreases wall tension. Nitrate tolerance can occur with continuous exposure (use a nitrate-free interval with dosing three times daily). Isosorbide dinitrate, at least 20 to 30 mg three times daily, needs to be given.

Calcium channel blockers are effective for relieving angina by decreasing afterload, heart rate, and contractility; they may be used as a third-line drug. However, short-acting calcium channel blockers, specifically the dihydropyridines, may increase mortality of patients with ischemic heart disease. This detrimental effect probably does not occur with the longer-acting calcium channel blockers in patients with normal systolic function, but the use of these agents should be avoided if the patient has left ventricular systolic dysfunction. If a calcium channel blocker is required for patients with left ventricular systolic dysfunction, amlodipine should be given.

Treatable underlying factors that contribute to ischemia (anemia, thyroid abnormalities, and hypoxia) should always be sought. For patients with left ventricular dysfunction and nocturnal angina, diuretics and angiotensin-converting enzyme inhibitors may be helpful for decreasing wall tension. They may be beneficial for preventing future cardiovascular events in high-risk patients with known coronary artery disease regardless of the level of systolic function.

- The initial therapy for chronic stable angina is β-adrenergic blockade with sublingual nitroglycerin as needed.
- Long-acting nitrates should be added sequentially if symptoms continue.
- Nitrates relieve angina by producing venodilatation, which decreases wall tension.
- β-Adrenergic blockers relieve angina by decreasing heart rate, reducing contractility, and decreasing afterload (blood pressure).
- β-Adrenergic blockers are the most effective drugs for reducing the double product.
- Nitrate tolerance can occur with continuous exposure.
- β-Adrenergic blockers should not be prescribed if the patient has marked bronchospastic disease, severely symptomatic congestive heart failure, or bradycardia.
- β-Adrenergic blockers should be given at a dosage to keep the resting heart rate <70 beats/min.
- Treatable underlying factors contributing to ischemia should be sought.
- Diuretics and angiotensin-converting enzyme inhibitors may be helpful for patients with left ventricular dysfunction and nocturnal angina.
- Short-acting calcium channel blockers should be avoided if the patient has coronary artery disease.
- For patients with left ventricular dysfunction, all calcium channel blockers except amlodipine should be avoided.

Antiplatelet agents may be helpful in patients with chronic stable angina pectoris. A low dose of aspirin probably does not prevent progression of atherosclerosis, but it may prevent acute myocardial infarction in patients with known coronary artery disease. In two large primary prevention trials, aspirin produced a 33% decrease in the risk for first, nonfatal myocardial infarction in men. The data are conflicting about the potential for a sex difference in the antithrombotic effects of aspirin; however, there is clear benefit for both men and women when aspirin is used in a secondary prevention strategy. The role of aspirin in primary prevention of stroke or overall cardiovascular mortality is uncertain.

- A low dose of aspirin probably does not prevent progression of atherosclerosis, but it may prevent acute myocardial infarction in patients with known coronary artery disease.
- The role of aspirin in primary prevention of stroke or overall cardiovascular mortality is uncertain.

Percutaneous Coronary Intervention

Percutaneous coronary intervention (PCI), a treatment for coronary artery disease, is performed at the time of coronary angiography. During percutaneous transluminal coronary angioplasty (PTCA), which is PCI with only a balloon, a small balloon is placed across a coronary stenosis and inflated to increase the area of the lumen at the site of stenosis. The mechanism of PTCA is a combination of "splitting" the atheroma and stretching the noninvolved segment of artery. In experienced laboratories, the success rate now is more than 95%. The potential complications include myocardial infarction (<5%), vascular complications (<5%), emergency coronary artery bypass grafting (<1%), and mortality (1%). The risks of the procedure are increased in long, tubular eccentric lesions that are calcified, and the risk is also increased in older women. Overall, more than 500,000 catheter-based therapies are performed annually in North America. The major problem with PTCA is restenosis, which occurs in 30% to 40% of patients within 6 months. Treatment with antiplatelet agents before PTCA may decrease the rate of acute closure but does not prevent restenosis. Glycoprotein IIb/IIIa inhibitors may decrease acute complications in high-risk patients but probably do not prevent restenosis. Other catheter-based therapies such as atherectomy, rotoblator, and laser have been used but they (and other therapies) have a high restenosis rate, similar to that of PTCA.

Placement of an intracoronary stent at the time of PCI is the only procedure that has been shown to decrease restenosis. The restenosis rate after successful bare-metal stent implantation is 20% to 30%. Stents also are effective for treating the acute complications of PTCA such as acute dissection and have decreased the need for emergency bypass operation. However, for patients who have

restenosis within a stent, the restenosis rate is high (>60%) if another procedure is performed. Coronary brachytherapy with gamma and beta radiotherapy decreases this high rate of recurrent restenosis, but the long-term outcome of the procedure is not known and the risk of subacute and delayed thrombosis is slightly increased. Radiation at the time of initial stent implantation has been associated with higher rates of subacute stent thrombosis. Drug-eluting stents that are coated with and elute drugs such as sirolimus (Rapamycin) and paclitaxel (Taxol) have been shown to significantly decrease the rate of restenosis (5%-10%). Drug-eluting stents are rapidly replacing bare-metal stents in the United States. Their use has resulted in a marked decrease in restenosis and the use of brachytherapy.

It is important to emphasize that for the treatment of chronic stable angina, PCI clearly relieves symptoms but does not reduce the risk of subsequent myocardial infarction or death.

- PTCA is a combination of splitting the atheroma and stretching the uninvolved segment of artery.
- Currently, the initial success rate is >95%.
- Restenosis is a major problem of PTCA.
- Stents, particulary drug-eluting stents, can decrease the rate of restenosis.
- Antiplatelet agents reduce the problem of acute events but do not prevent restenosis.

Surgical Treatment

The surgical treatment for severely symptomatic patients with chronic stable angina is coronary artery bypass grafting (CABG) with either saphenous vein or internal mammary artery grafts. CABG provides excellent relief from symptoms (partial relief in >90% of patients and complete relief in >70%). In-hospital mortality after CABG varies widely from less than 1% to 30%. Mortality increases with age, poor ventricular function, female sex, left main coronary artery disease, unstable angina, and diabetes mellitus. Complications of CABG include sternal wound infection (especially in patients with diabetes mellitus), severe left ventricular dysfunction (from perioperative myocardial infarction or inadequate cardioprotection), and late constrictive pericarditis. The procedure is not without latent problems. Closure rates of saphenous vein grafts are 20% at 1 year and 50% at 5 years. The patency rate is higher for internal mammary arteries, possibly up to 90% patency at 5 years. A minithoracotomy with a left internal mammary artery–left anterior descending artery anastomosis may shorten hospitalization, but long-term follow-up is needed.

- CABG provides excellent relief from symptoms.
- CABG gives partial relief in >90% of patients and complete relief in >70%.
- In-hospital mortality after CABG varies widely from <1%-30%.
- Mortality increases with age, poor ventricular function, female sex, left main coronary artery disease, unstable angina, and diabetes mellitus.
- Closure rates of saphenous vein grafts are 20% at 1 year and 50% at 5 years.

Several randomized trials have compared CABG with medical therapy, and the intermediate-term follow-up results are as follows:

- CABG does not prevent myocardial infarction.
- CABG does not uniformly improve left ventricular function.
- CABG does not decrease ventricular arrhythmias.
- CABG improves survival only for patients with 1) left main coronary artery disease, 2) three-vessel disease and moderately depressed left ventricular function, 3) three-vessel disease and severe symptoms of ischemia at a low workload, and 4) multivessel disease with involvement of the proximal left anterior descending artery. For all other subsets of patients, CABG should not be performed to improve survival.
- The indications for CABG instead of medical therapy are 1) relieving symptoms in patients who have limiting symptoms unresponsive to medical management and 2) prolonging the life of the subsets of patients listed above.
- These recommendations were based on the randomized trials of CABG vs. medical therapy, which all had a small number of patients and limited use of internal mammary artery grafts. In larger meta-analyses, there was a survival benefit for CABG vs. medical therapy for all patients with three-vessel disease.

Medical Versus Catheter-Based Versus Surgical Therapy

The decision about which therapy to use for a patient with chronic stable angina is individualized and must be based on the patient's age, lifestyle, and personal preference. However, randomized trials have compared the medical, catheter-based, and surgical therapies, and the results help in guiding decisions about which therapy to use for a selected subset of patients. The following summarizes the results of these trials.

1. Medical therapy versus PCI (one-vessel disease):

- PCI is associated with a similar or higher incidence of myocardial infarction and emergency CABG.
- PCI does not decrease the future risk of myocardial infarction.
- PCI does not improve resting left ventricular function.
- PCI does not increase survival.

2. PCI versus surgical therapy (multivessel disease—excluding left main coronary artery disease and totally occluded vessels):

- The rates of procedure-related mortality are similar (1%-2%).
- There are more procedure-related Q-wave infarctions with CABG than with PCI (4.6% vs. 2.1%), but events are well tolerated.
- The duration of initial hospitalization is longer with CABG than with PCI.
- The overall rates of death or myocardial infarction are similar at 5-year follow-up (85%-90% free of death and 80% free of myocardial infarction).
- Patients who have CABG have less angina, require less antianginal medication, and are less likely to need a repeat revascularization procedure than those who have PCI (8% vs. 54% at 5-year follow-up).

- For patients with diabetes mellitus, 5-year survival is higher with CABG than with PCI (80% vs. 65%). Increased survival is associated with a patent left internal mammary artery–left anterior descending artery graft.

Postcardiotomy Syndrome

Postcardiotomy syndrome occurs 2 weeks to 2 years postoperatively and consists of fever, pericarditis, and increased erythrocyte sedimentation rate. Rarely, it can present as pericardial tamponade. It probably is an autoimmune process (associated with antimyocardial antibodies); treatment is with aspirin and nonsteroidal anti-inflammatory drugs. Postperfusion syndrome is also characterized by fever and pericarditis, but it is associated with increased results on liver function tests and atypical lymphocytes, presumably due to cytomegalovirus syndrome. If a patient has fever and pleuritic chest pain postoperatively, the erythrocyte sedimentation rate should be measured and a special blood smear done to check for postperfusion or postcardiotomy syndrome.

- Postcardiotomy syndrome occurs 2 weeks-2 years postoperatively.
- It consists of fever, pericarditis, and increased erythrocyte sedimentation rate.
- It probably is an autoimmune process (associated with antimyocardial antibodies).
- Treatment: aspirin and nonsteroidal anti-inflammatory drugs.
- Postperfusion syndrome: fever, pericarditis, increased values on liver function tests, and atypical lymphocytes.
- If the patient has fever and pleuritic chest pain postoperatively, the erythrocyte sedimentation rate should be measured and a special blood smear performed to check for postcardiotomy or postperfusion syndrome.

Coronary Artery Spasm

The vasomotor tone of coronary arteries is important in the pathogenesis of coronary artery disease. Coronary artery vasoconstriction is a response to arterial injury. The endothelium affects vascular tone by releasing relaxing factors, for example, prostacyclin and endothelium-derived relaxing factor, which prevent vasoconstriction and platelet deposition. With dysfunctional endothelium, these factors are absent and the coronary arteries may be more prone to spasm. Most clinical episodes of coronary artery spasm are superimposed on atherosclerotic plaques. However, patients may have primary coronary artery spasm and angiographically normal coronary arteries.

- Endothelium affects vascular tone by releasing relaxing factors (e.g., prostacyclin and endothelium-derived relaxing factor).
- With dysfunctional endothelium, coronary arteries may be more prone to spasm.
- Most episodes of spasm are superimposed on atherosclerotic plaques.
- Patients may have primary coronary artery spasm and angiographically normal coronary arteries.

The typical presentation of coronary artery spasm consists of recurrent episodes of rest pain in association with ST-segment elevation, which reverses with administration of nitrates. Coronary angiography with ergonovine or methylergonovine challenge has been used to diagnose coronary artery spasm, but the sensitivity and specificity are not known. The use of acetylcholine to provoke spasm may be helpful because it directly examines the status of the endothelium. ST-segment elevation on the resting 12-lead ECG during an episode of rest pain is the standard criterion for diagnosing coronary artery spasm. Coronary artery spasm is treated with long-acting nitrates or calcium channel blockers (or both).

- The typical presentation of coronary artery spasm is recurrent episodes of rest pain and ST-segment elevation that is reversed with nitrates.

Acute Coronary Syndromes

The term "acute coronary syndrome" refers to any constellation of clinical symptoms that are compatible with acute myocardial ischemia (Fig. 3-42). Acute coronary syndromes encompass acute myocardial infarction (ST-segment elevation and depression, Q-wave, and non–Q-wave) and unstable angina. Patients with these syndromes have to be differentiated from those with noncardiac chest pain on the basis of the clinical assessment (Table 3-25).

The resting ECG is essential in the evaluation of a patient presenting with an acute coronary syndrome. Patients without ST-segment elevation and myocardial ischemia may have unstable angina or they may have development of non–Q-wave myocardial infarction. Unstable angina and non–ST-segment elevation myocardial infarction have a similar pathogenesis. Patients with ST-segment elevation most likely have complete occlusion of an epicardial coronary artery that causes transmural injury. If untreated, a Q-wave myocardial infarction eventually develops. In a small proportion of patients with non–ST-segment elevation myocardial infarction, Q-wave myocardial infarction develops. In patients who have ST-segment elevation and receive thrombolytic therapy, non–Q-wave myocardial infarction may develop. Acute coronary syndromes should be considered a continuous spectrum of diseases in patients who present with myocardial ischemia.

Table 3-25 Clinical Features Increasing the Likelihood of an Acute Coronary Syndrome

History	Examination	Investigation findings
Typical angina chest pain Age >70 y Male sex Diabetes mellitus	Pulmonary edema Hypotension Extracardiac vascular disease	Pathologic Q waves Abnormal ST segments T-wave inversion ≥0.02 mV Increased cardiac biomarkers

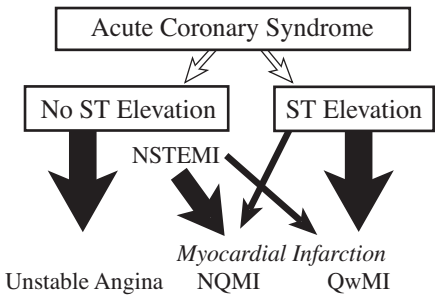

Fig. 3-42. Nomenclature of acute coronary syndromes. Patients with ischemic discomfort may present with or without ST-segment elevation on the electrocardiogram. In the majority of patients with ST-segment elevation (large arrows) a Q-wave anterior myocardial infarction (QwMI) ultimately develops, whereas in a small proportion (small arrow) a non–Q-wave anterior myocardial infarction (NQMI) develops. Patients who present without ST-segment elevation are experiencing either unstable angina or non–ST-segment elevation myocardial infarction (NSTEMI). The distinction between these two diagnoses is ultimately made on the basis of the presence or absence of a cardiac marker detected in the blood. In most patients with NSTEMI, a Q wave does not develop on the 12-lead electrocardiogram, and they are subsequently referred to as having "sustained a non–Q-wave myocardial infarction" (NQMI). In only a small proportion of patients with NSTEMI does a Q wave develop, and Q-wave myocardial infarction is later diagnosed. Not shown is Prinzmetal angina, which presents with transient chest pain and ST-segment elevation but rarely with myocardial infarction. The spectrum of clinical conditions that range from unstable angina to NQMI and QwMI is referred to as "acute coronary syndromes." (From the Committee on the Management of Patients With Unstable Angina: ACC/AHA guidelines for the management of patients with unstable angina and non-ST-segment elevation myocardial infarction. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines. J Am Coll Cardiol. 2000;36:970-1062. Used with permission.)

Early risk stratification is essential (Table 3-26). Patients presenting with a suspected acute coronary syndrome should be evaluated immediately in the emergency department, and those who have ST-segment elevation should be treated immediately (see below, ST-Segment Elevation Myocardial Infarction). For patients who do not have ST-segment elevation, chest pain units have been developed in emergency departments that allow dismissal of low-risk patients, observation of intermediate-risk patients, and admission of high-risk patients (Fig. 3-43).

- "Acute coronary syndrome" refers to clinical symptoms compatible with acute myocardial ischemia.
- Early risk stratification is essential.

Unstable Angina and Non–ST-Segment Elevation Myocardial Infarction

These conditions are characterized by an imbalance between myocardial oxygen supply and demand. They may be caused by an increased myocardial oxygen demand in the presence of a fixed myocardial oxygen supply. They also may be caused by a decrease in myocardial oxygen supply, which usually results from narrowing of the coronary artery due to a nonocclusive thrombus that developed on a disrupted atherosclerotic plaque. Superimposed spasm also may cause this syndrome.

All patients with the tentative diagnosis of an acute coronary syndrome should have continuous ECG monitoring and treatment to improve the myocardial oxygen demand-supply mismatch (J Am Coll Cardiol. 2002;40:1366-74). Sedation should be used to decrease anxiety and catecholaminergic stimulation of the heart. β-Adrenergic blocker is the treatment of choice for decreasing myocardial oxygen demand. Antiplatelet agents, such as aspirin, should be given immediately because they are effective for decreasing the incidence of progression to myocardial infarction. Heparin also decreases the incidence of progression to myocardial infarction and should be given to all patients who do not have contraindications to this treatment. Continuous intravenous administration of unfractionated heparin or subcutaneous injections of low-molecular-weight heparin can be given. Glycoprotein IIb/IIIa inhibitors should be prescribed for patients who are at high risk (ongoing chest pain, transient ST-segment depression with angina at rest, marked increase in troponin levels), particularly if PCI is likely.

Unstable angina and non–ST-segment elevation myocardial infarction are differentiated on the basis of cardiac enzymes. Previously, creatine kinase-MB was the principal serum marker used in the evaluation of acute coronary syndromes. However, monoclonal antibody-based immunoassays have been developed to detect cardiac-specific troponin T and cardiac-specific troponin I. An increase in the level of these enzymes in patients with an acute coronary syndrome indicates myocardial necrosis and identifies patients who are at high risk for future events.

There are two accepted therapeutic pathways for patients who present with unstable angina or non–ST-segment elevation myocardial infarction (Fig. 3-44). The first is a conservative approach in which aggressive medical management is used to stabilize the patient's condition. Coronary angiography is indicated if 1) additional ischemic episodes occur despite optimal medical therapy, 2) there is left ventricular dysfunction or heart failure, and 3) serious arrhythmias occur.

Table 3-26 High-Risk Features in Patients With Non–ST-Segment Elevation Acute Coronary Syndrome

Age >75 y
Accelerating ischemic symptoms over 48 h
Ongoing rest pain for >20 min
Recurrent ischemic pain during observation
Hypotension
Reduced ejection fraction (<40%)
Pulmonary edema
Severe arrhythmia
ST-segment depression >0.05 mV
Increased cardiac biomarkers

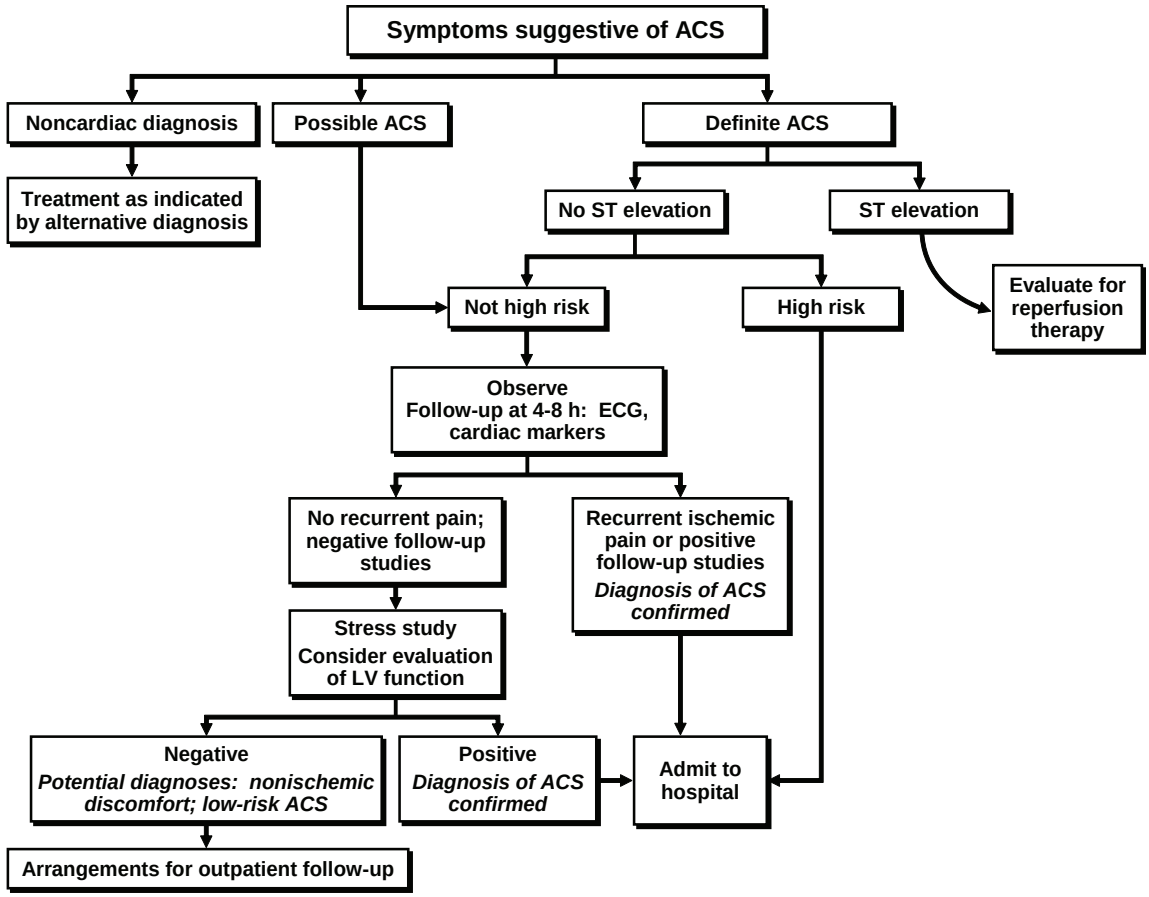

Fig. 3-43. Algorithm for evaluation and management of patients suspected of having acute coronary syndrome (ACS). ECG, electrocardiography; LV, left ventricular. (Modified from Braunwald E, Antman EM, Beasley JW, Califf RM, Cheitlin MD, Hochman JS, et al. ACC/AHA 2002 guideline update for the management of patients with unstable angina and non–ST-segment elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee on the management of patients with unstable angina]. 2002 [cited 2006 March 1]. Available from: http://www.acc.org/clinical/guidelines/unstable/unstable.pdf. Used with permission.)

The second accepted therapeutic pathway is an early invasive approach in which all high-risk patients have coronary angiography within 48 hours and high-grade coronary lesions are treated. If the conservative pathway is taken, patients should undergo stress testing before dismissal, and patients with positive results of stress testing should also have coronary angiography. The early invasive strategy is preferred in high-risk patients.

- Unstable angina differs from non–ST-segment elevation myocardial infarction in that cardiac-specific enzyme values are increased in the latter.
- An early invasive strategy is preferred in high-risk patients with a non–ST-elevation acute coronary syndrome.

ST-Segment Elevation Myocardial Infarction

The underlying pathogenesis of ST-segment elevation myocardial infarction is usually rupture of an intracoronary plaque. This leads to platelet adhesion, aggregation, thrombus formation, and sudden, complete occlusion of an epicardial coronary artery. Without collateral circulation, 90% of the myocardium that is supplied by the occluded coronary artery is infarcted within 3 hours. If untreated, transmural myocardial infarction develops. Patients with ST-segment elevation myocardial infarction require urgent diagnosis and therapy to preserve the myocardium. It is for this group of patients that aggressive reperfusion therapy has improved survival.

- ST-segment elevation myocardial infarction usually implies acute occlusion of an epicardial coronary artery.
- If untreated, a transmural myocardial infarction will develop within 3 hours.

Myocardial infarction accounts for a large percentage of morbidity and mortality in the United States. More than 500,000 patients are admitted annually to a hospital because of myocardial infarction. More than 50% of patients who have a myocardial infarction die before reaching the hospital. With the advent of coronary care units 4 decades ago, mortality from myocardial infarction decreased, primarily because of treatment of ventricular arrhythmias. β-Adrenergic blockade has further decreased in-hospital and posthospital mortality by 30% to 40%. In the 1980s, reperfusion

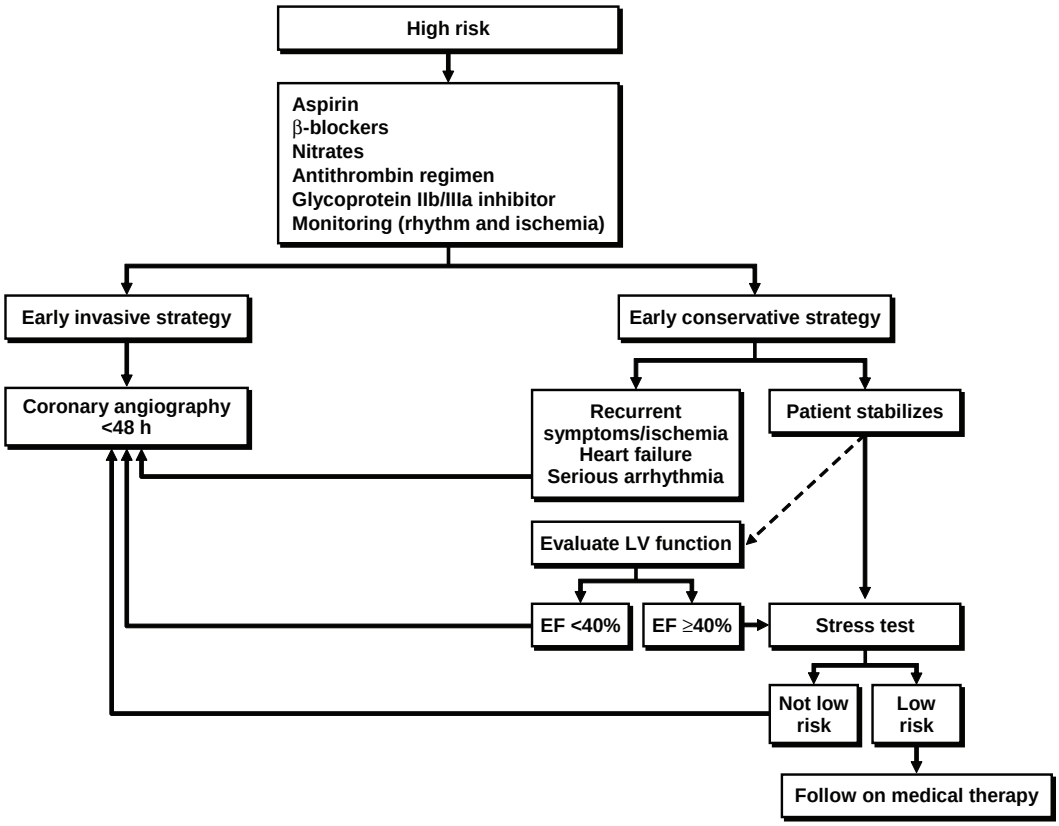

Fig. 3-44. Acute ischemia pathway. EF, ejection fraction; LV, left ventricular. (Modified from Braunwald E, Antman EM, Beasley JW, Califf RM, Cheitlin MD, Hochman JS, et al. ACC/AHA 2002 guideline update for the management of patients with unstable angina and non–ST-segment elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee on the management of patients with unstable angina]. 2002 [cited 2006 March 1]. Available from: http://www.acc.org/clinical/guidelines/unstable/unstable.pdf. Used with permission.)

therapy became the standard of care and has been shown to further improve survival. Currently, the overall in-hospital mortality for a patient with ST-segment elevation myocardial infarction is 5% to 10%.

Several new concepts about myocardial infarction have arisen in the past 2 decades: stunned myocardium, ischemia at a distance, and infarct remodeling. *Stunned myocardium* occurs when a coronary artery is completely occluded and then opened, and transient akinesis of the myocardium occurs. If reperfusion occurs early enough, systolic contraction of the affected myocardium may be decreased after the event, but the myocardium is viable. Systolic contraction returns hours to days later. Currently, no clinical test differentiates stunned myocardium from infarcted, dead myocardium. *Ischemia at a distance* refers to infarction occurring in the distribution of one coronary vessel and ischemia and subsequent hypokinesis developing in the distribution of a second vessel that has a high-grade stenosis. When this is found on echocardiography, the prognosis is poor because of recurrent myocardial infarction and increased mortality. *Infarct remodeling* occurs mainly after a large anteroapical myocardial infarction. An area of infarction may undergo thinning, dilatation, and dyskinesis. This remodeling is associated with a high incidence of congestive heart failure and posthospital mortality. Angiotensin-converting enzyme inhibitors may help prevent infarct remodeling.

- Stunned myocardium: a coronary artery is completely occluded and then opened, and transient akinesis of the myocardium occurs.
- Ischemia at a distance: infarction occurs in the distribution of one coronary artery and ischemia and subsequent hypokinesis develop in the distribution of a second vessel that has a high-grade stenosis.
- Infarct remodeling: occurs after a large anteroapical myocardial infarction.
- Angiotensin-converting enzyme inhibitors may help prevent infarct remodeling.

Presentation and Diagnosis

The usual presentation of ST-segment elevation myocardial infarction is angina-like pain that lasts longer than 30 to 45 minutes and is associated with typical ECG changes and increased levels of creatine kinase-MB fraction or troponin (Fig. 3-45). However, more than 25% to 30% of myocardial infarctions are silent and present later as new ECG abnormalities or regional wall motion abnormalities. Silent myocardial infarctions occur especially in patients with

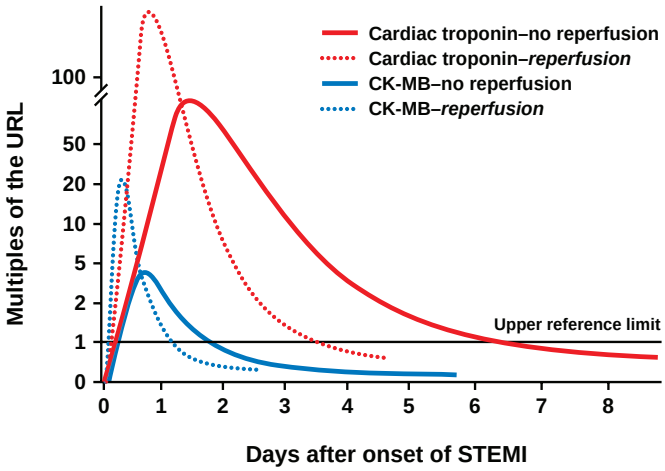

Fig. 3-45. Cardiac biomarkers in ST-segment elevation myocardial infarction (STEMI). Typical cardiac biomarkers that are used to evaluate patients with STEMI include the MB isoenzyme of creatine kinase (CK-MB) and cardiac-specific troponins. The horizontal line depicts the upper reference limit (URL) for the cardiac biomarker in the clinical chemistry laboratory. The URL is that value representing the 99th percentile of a reference control group without STEMI. The kinetics of release of CK-MB and cardiac troponin in patients who do not undergo reperfusion are shown in the solid blue and red curves as multiples of the URL. Note that when patients with STEMI undergo reperfusion, as depicted in the dashed blue and red curves, the cardiac biomarkers are detected sooner, increase to a higher peak value, but decline more rapidly, resulting in a smaller area under the curve and limitation of infarct size. (From Antman EM, Anbe DT, Armstrong PW, Bates ER, Green LA, Hand M, et al. ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee to Revise the 1999 Guidelines for the management of patients with acute myocardial infarction]. J Am Coll Cardiol. 2004;44:E1-E211. Used with permission.)

diabetes mellitus and in the elderly. The increased incidence of myocardial infarction in the early morning is perhaps related to increased platelet aggregation. The pain of myocardial infarction mimics that of other diseases, for example, gastrointestinal tract or pericardial disease or musculoskeletal pain.

- More than 25%-30% of myocardial infarctions are silent.
- Silent myocardial infarctions occur especially in patients with diabetes mellitus and in the elderly.
- The increased incidence of myocardial infarction in the early morning is perhaps related to increased platelet aggregation.
- The pain of myocardial infarction mimics that of other diseases.

Basic and Drug Treatments

Bed rest and sedation are essential and beneficial in the acute stage of myocardial infarction for decreasing myocardial oxygen demand. Analgesics, particularly morphine, are beneficial for recurrent pain. Currently, prolonged bed rest is not recommended, and the effort to shorten hospitalization is increasing. Many physicians recommend a gradual increase in activity level over 3 to 6 days for an uncomplicated myocardial infarction. During the acute 3- to 4-day period, ECG monitoring is recommended for both tachyarrhythmias and bradyarrhythmias. Oxygen can be given at the initial presentation but has little benefit after 2 or 3 hours unless hypoxia (oxygen saturation < 90%) is present. However, modest hypoxemia is not uncommon, even with uncomplicated myocardial infarction, and is due to ventilation-perfusion lung mismatch.

- Prolonged bed rest is not recommended for myocardial infarction.
- Oxygen has little benefit beyond 3 hours after the initial presentation unless hypoxia is present.

Heparin is important for treating acute myocardial infarction. It prevents recurrent infarction (especially after thrombolytic therapy), deep venous thrombosis, and intracardiac thrombus formation. Historically, intracardiac thrombus formation occurred in up to 40% of patients with anterior myocardial infarction in whom patency of the occluded vessel is not restored, and almost 50% of these patients had a systemic embolic event. Intravenous unfractionated heparin therapy is indicated for higher-risk patients (large or anterior myocardial infarction, atrial fibrillation, previous embolus, reperfusion therapy not given or unsuccessful). Low-molecular-weight heparin given subcutaneously may be more effective. Thromboembolism is uncommon in patients in whom reperfusion therapy is successful. Aspirin decreases recurrent infarction by 50% in patients not receiving thrombolytic therapy. It also reduces mortality when given in addition to thrombolytic therapy.

- Heparin is important for treating acute myocardial infarction.
- Heparin prevents recurrent infarction, deep venous thrombosis, and intracardiac thrombus formation.
- Intracardiac thrombus formation occurs in up to 40% of patients with anterior myocardial infarction in whom patency of the occluded vessel is not restored.
- Aspirin decreases recurrent infarction by 50% in patients not receiving thrombolytic therapy.

Nitroglycerin is useful for subsets of patients with myocardial infarction—for those with heart failure (by decreasing wall tension) and for those with continued pain. To prevent acute decreases in blood pressure in the early stages of myocardial infarction, intravenous nitroglycerin should be given instead of long-acting oral nitrates. Intravenous nitroglycerin may reduce infarct size by decreasing wall tension and affecting remodeling. Also, it may decrease susceptibility to ventricular fibrillation. If the mean blood pressure is more than 80 mm Hg, intravenous nitroglycerin may reduce mortality by 10% to 25%, specifically among patients with anterior myocardial infarction and poor left ventricular function. However, for patients with low blood pressure and those with inferior and right ventricular infarctions, nitroglycerin may decrease blood pressure too much, increasing mortality. The dosage of intravenous nitroglycerin is a 15-μg bolus and an initial infusion of 10 μg/min. This infusion

should be increased every 5 to 10 minutes, up to a maximum of 150 to 200 μg/min, until blood pressure decreases 10% to 15%. Mean blood pressure should be kept higher than 80 mm Hg. Nitrate intolerance develops with infusions that last longer than 24 hours. Intravenous nitroglycerin should not be given to patients with low blood pressure (systolic <90 mm Hg), patients with right ventricular infarction, and patients who have received a phosphodiesterase inhibitor for erectile dysfunction within the previous 24 hours (48 hours for tadalafil).

- Nitroglycerin is useful for patients with myocardial infarction who have heart failure and for those with continued pain.
- Intravenous nitroglycerin may reduce infarct size by decreasing wall tension and affecting remodeling.
- Nitroglycerin may decrease susceptibility to ventricular fibrillation.
- Nitrate intolerance occurs with infusions that last longer than 24 hours.
- Intravenous nitroglycerin should not be given to patients with low blood pressure or right ventricular infarction or to patients who have received a phosphodiesterase inhibitor for erectile dysfunction within the previous 24 hours (48 hours for tadalafil).
- Intravenous nitroglycerin may improve mortality for patients with a large anterior myocardial infarction and congestive heart failure.

β-Adrenergic blockers are useful during acute myocardial infarction and after myocardial infarction. If given early, they decrease infarct size and in-hospital mortality. If given after myocardial infarction has been completed, β-adrenergic blockers can reduce posthospital reinfarction and mortality. In an acute setting, the typical dosage of metoprolol is 5 mg given intravenously three times, 5 minutes apart, followed by 100 mg given orally twice daily. β-Adrenergic blockers decrease pain and the incidence of ventricular fibrillation. The beneficial effects are probably multifactorial but include decreased myocardial oxygen demand, increased threshold for ventricular fibrillation, decreased platelet aggregability, and decreased sympathetic effects on the myocardium. β-Adrenergic blockers are most beneficial for patients with a large infarction, that is, those at higher risk for complications. Acute intravenous β-adrenergic blockers are also beneficial for patients receiving thrombolytic therapy. β-Adrenergic blockers are especially useful for patients with hyperdynamic circulation and continued postinfarction pain and should be given to patients presenting with less than 12 hours of pain who do not have contraindications, especially those with anterior myocardial infarction. Contraindications to β-adrenergic blockers are bradycardia, atrioventricular block, hypotension, severe heart failure, and inferior myocardial infarction with high vagal tone.

- Acute intravenous β-adrenergic blockers decrease infarction size and in-hospital mortality.
- Acute intravenous β-adrenergic blockers decrease the incidence of ventricular fibrillation.
- Contraindications to β-adrenergic blockers are bradycardia, atrioventricular block, hypotension, severe heart failure, and inferior myocardial infarction with high vagal tone.

Calcium channel blockers have been used to treat myocardial infarction, but their routine use has no proven benefit. Routine use of verapamil and nifedipine has no benefit and may increase mortality. However, by producing coronary vasodilatation and decreasing myocardial oxygen demand, calcium channel blockers may be beneficial for treating postinfarction angina if β-adrenergic blockade is ineffective or cannot be used.

- Routine use of calcium channel blockers for myocardial infarction has no proven benefit.
- Routine use of verapamil and nifedipine to treat myocardial infarction may increase mortality.

In most patients, magnesium does not seem to have a therapeutic role after myocardial infarction. Although initial studies suggested that it may decrease infarct size, subsequent studies have not borne out this effect. Magnesium should be given only if a patient has documented hypomagnesemia (from diuretics) or for the treatment of torsades de pointes.

Angiotensin-converting enzyme inhibitors have been studied extensively in patients with ST-segment elevation myocardial infarction. These inhibitors seem to prevent the infarct remodeling, especially after a large anteroapical myocardial infarction. Although these drugs should not be given acutely intravenously, data support the initiation of this therapy within the first 24 hours after a myocardial infarction as long as blood pressure is stable and for chronic use. Angiotensin receptor blockers are recommended as an alternative in patients who are intolerant to angiotensin-converting enzyme inhibitors. However, current data support their use in patients with heart failure or ejection fraction less than 40%. Long-term aldosterone blockade (spironolactone or eplerenone) is indicated for patients without renal dysfunction (creatinine, 2.0 mg/dL) or hyperkalemia (potassium, 5.0 mEq/L) who are receiving therapeutic doses of angiotensin-converting enzyme inhibitors and have symptomatic heart failure or diabetes mellitus with an ejection fraction of 40%.

Other medications are being studied for treating ST-segment elevation myocardial infarction. Although glycoprotein IIb/IIIa inhibitors are given routinely to high-risk patients with non–ST-segment elevation myocardial infarction, there are conflicting data regarding their use either alone or in combination with other treatments during an ST-segment elevation myocardial infarction. There appears to be a modest benefit when abciximab is administered during primary PCI. Several direct thrombin inhibitors have been studied in patients with acute ST-segment elevation myocardial infarction, but they are not yet approved for the treatment of acute coronary syndromes. Bivalirudin is approved for use for unstable angina during PCI and is also an acceptable alternative to unfractionated heparin for patients who have heparin-induced thrombocytopenia and require anticoagulation.

Reperfusion Therapy

Early reperfusion therapy has had a tremendous effect on the treatment of acute myocardial infarction. Overall, mortality is decreased 27%±3% when reperfusion is given early. For more than 50,000 patients in the Third International Study in Infarct Survival (ISIS-3)

and Gruppo Italiano per lo Studio della Sopravvivenza nell'Infarcto Miocardico (GISSI-2) studies, the 35-day in-hospital mortality was only 10% with thrombolytic therapy. Time is of the essence when giving reperfusion therapy. The sooner the reperfusion, the better the extent of myocardial salvage and the better the effect on mortality. Without collaterals, 90% of the myocardium at risk is infarcted within 3 hours after occlusion. Very early reperfusion has a major effect on direct myocardial salvage. In a study in which thrombolysis was given less than 90 minutes after the onset of pain, mortality was 1%. In most U.S. studies, the average time from pain onset to artery opening is 3.7 hours. The delay is in patient presentation (22%), transport (21%), in-hospital institution of the drug (35%), and reperfusion drug time (19%). Reperfusion at 2 to 6 hours salvages the peri-infarction zone, depending on the degree of collateral circulation. Thus, there is a lesser effect on myocardial salvage but an important effect on survival. The "open artery concept" describes a benefit in improvement in posthospital mortality in the presence of an open artery after thrombolytic therapy that is not reflected in improved ventricular function. The reason for this is unclear, but it may be related to improved electrical stability or prevention of ventricular remodeling.

- Overall, mortality is decreased 27%±3% when reperfusion is given early.
- For more than 50,000 patients, the 35-day in-hospital mortality was 10% with thrombolytic therapy.
- The sooner the reperfusion, the better the extent of myocardial salvage.
- Without collaterals, 90% of the myocardium at risk is infarcted within 3 hours after occlusion.

Reperfusion therapy with either fibrinolytics or primary PCI is indicated for patients presenting within 12 hours of onset of symptoms and either 1 mm of ST-segment elevation in two adjacent leads or new or presumably new left bundle branch block (J Am Coll Cardiol. 2004;44:671-719). ECG changes of a true posterior myocardial infarction also qualify for reperfusion therapy. Intravenous thrombolysis is not as effective (65%-70%) for restoring normal coronary blood flow (TIMI grade 3) as PCI (90%). However, this disadvantage is counterbalanced by faster administration of intravenous thrombolysis and wider availability of the fibrinolytics. Fewer than 10% of all hospitals have the capability of performing emergency PCI, and these centers must be able to provide rapid treatment, with door-to-balloon time of less than 90 minutes. Thus, the preferred strategy depends on 1) time since the onset of symptoms, 2) time required for transportation to a skilled PCI catheterization laboratory, 3) risk of ST-segment elevation myocardial infarction (Table 3-27), and 4) presence of contraindications to fibrinolytics (Table 3-28). At most medical centers that do not have the resources for primary PCI, intravenous thrombolysis is the treatment of choice for patients with acute myocardial infarction. Emergency PCI may be used for patients with 1) immediate access to a high-volume catheterization laboratory, 2) a contraindication for intravenous thrombolysis, 3) high-risk ST-segment elevation myocardial infarction (cardiogenic shock or pulmonary edema), or 4) continued ischemia after thrombolytic therapy (rescue PCI). Routine PCI after successful thrombolytic therapy is not indicated in the absence of ongoing symptoms or ischemia.

Thrombolytic therapy seems to be less beneficial for patients older than 75 years. Reperfusion therapy is not indicated for patients who have other ECG abnormalities (ST-segment depression) or for those who present late (>12 hours) and are asymptomatic.

Major complications of intravenous thrombolysis include major bleeding (5%-6% of patients), intracranial bleeding (0.5%), major allergic reaction (0.1%-1.7%), and hypotension (2%-10%). A higher incidence of myocardial rupture may occur in patients who are given thrombolytic therapy late (>12 hours after pain onset).

- Major complications of intravenous thrombolysis are major bleeding (5%-6% of patients), intracranial bleeding (0.5%), major allergic reaction (0.1%-1.7%), and hypotension (2%-10%).
- A higher incidence of myocardial rupture may occur in patients given thrombolytic therapy late (>12 hours after pain onset).

Table 3-27 Thrombolysis in Myocardial Infarction (TIMI) Risk Score for ST-Segment Elevation Myocardial Infarction*

Variable	Points	Risk score	Odds of death by 30-day mortality†	
Historical		0	0.8	Low risk
Age		1	1.6	
≥75 y	3	2	2.2	
65-74 y	2	3	4.4	
DM or HTN or angina	1	4	7.3	
Examination		5	12	
SBP <100 mm Hg	3	6	16	
HR >100 bpm	2	7	23	
Killip II-IV	2	8	27	
Weight <67 kg (150 lb)	1	>8	36	
Presentation				
Anterior STE or LBBB	1			
Time to Rx >4 h	1			
Risk score = total points (0-14)				

DM, diabetes mellitus; HR, heart rate; HTN, hypertension; LBBB, left bundle branch block; Rx, therapy; SBP, systolic blood pressure; STE, ST-segment elevation.

*Entry criteria: chest pain >30 min, ST ↑, symptom onset <6 h, fibrinolytic-eligible.

†Referenced to average mortality (95% confidence interval).

Table 3-28 Contraindications and Cautions for Fibrinolysis Use in ST-Segment Elevation Myocardial Infarction

Absolute contraindications
Any prior ICH
Known structural cerebral vascular lesion
Known malignant intracranial neoplasm
Ischemic stroke within 3 months *except* acute ischemic stroke within 3 h
Suspected aortic dissection
Active bleeding or bleeding diathesis (excluding menses)
Significant closed head or facial trauma within 3 mo
Relative contraindications
History of chronic severe, poorly controlled hypertension
Severe uncontrolled hypertension on presentation (SBP >180 mm Hg or DBP >110 mm Hg)*
History of prior ischemic stroke >3 mo, dementia, or known intracranial pathology not covered in contraindications
Traumatic or prolonged (>10 min) CPR or major surgery (less than 3 weeks)
Recent (within 2 to 4 weeks) internal bleeding
Noncompressible vascular punctures
For streptokinase/anistreplase: prior exposure (more than 5 days ago) or prior allergic reaction to these agents
Pregnancy
Active peptic ulcer
Current use of anticoagulants: the higher the INR, the higher the risk of bleeding

CPR, cardiopulmonary resuscitation; DBP, diastolic blood pressure; ICH, intracranial hemorrhage; INR, international normalized ratio; SBP, systolic blood pressure.

*Could be an absolute contraindication in low-risk patients with ST-segment elevation myocardial infarction.

From Antman EM, Anbe DT, Armstrong PW, Bates ER, Green LA, Hand M, et al. ACC/AHA guidelines for the management of patients with ST-elevation myocardial infarction: executive summary: a report of the ACC/AHA Task Force on Practice Guidelines (Committee to Revise the 1999 Guidelines on the Management of Patients With Acute Myocardial Infarction). J Am Coll Cardiol. 2004;44:671-719. Used with permission.

Several agents are available for intravenous thrombolysis. Streptokinase, a nonselective thrombolytic agent, combines with circulating plasminogen to split circulating and thrombus-bound plasminogen into plasmin, which splits fibrin. It lyses circulating fibrinogen and thus has systemic effects. The dosage is a 250,000-U bolus and 1.5×10^6 U in 1 hour. Tissue plasminogen activator binds preferentially to preformed fibrin and lyses it without activating plasminogen in the general circulation. Thus, it has less effect on circulating fibrinogen and is "fibrin-specific." It has the fastest onset of action. The dosage is 100 mg over 90 minutes. Anisoylated plasminogen streptokinase activator complex is composed of anisoylated plasminogen and streptokinase bound together and inactivated by plasminogen. It requires spontaneous deacylation, which occurs in the plasma before the active plasminogen–streptokinase complex is generated, splitting plasminogen to plasmin. Thus, anistreplase is a more stable agent and may be given as a single intravenous bolus. The dosage is 30 U over 5 minutes. Newer thrombolytic agents such as recombinant and tenecteplase tissue plasminogen activator offer better selectivity for active thrombus, but they seem to be equivalent in efficacy to tissue plasminogen activator in clinical trials. However, the greatest advantage is that they can be administered as a bolus, which reduces drug errors and speeds delivery.

The large European trials did not demonstrate any benefit of one thrombolytic therapy over the others. In the Global Utilization of Strategies To Open Occluded arteries (GUSTO) trial, the mortality rate was lower when an accelerated dose of tissue plasminogen activator was given with intravenous heparin than with streptokinase. Compared with streptokinase, tissue plasminogen activator is more expensive and has a slightly increased risk of cerebral hemorrhage, especially in the elderly. It is reasonable to give tissue plasminogen activator preferentially to younger patients who present very early with a large myocardial infarction.

After intravenous thrombolysis, a high-grade residual lesion is usually present. Reocclusion or ischemia occurs in 15% to 20% of patients and reinfarction occurs in 2% to 3%. In the United States, both heparin and aspirin are given after intravenous thrombolysis with the specific tissue plasminogen activators to prevent reinfarction. After administration of tissue plasminogen activator, heparin is given as a bolus injection, followed by a continuous infusion to keep the activated partial thromboplastin time at 50 to 70 seconds. The indication for coronary angiography or PCI after intravenous thrombolysis is continued pain or ischemia documented on functional testing. No benefit results from routine intervention in all patients.

- After intravenous thrombolysis, reocclusion or ischemia occurs in 15%-20% of patients and reinfarction occurs in 2%-3%.
- Both aspirin and heparin are given after intravenous thrombolysis to prevent reinfarction.
- The benefit is clear with aspirin but not with heparin.
- Streptokinase is the least expensive thrombolytic therapy.
- Tissue plasminogen activator is the most clot-specific thrombolytic therapy.
- The least amount of antigenicity is with tissue plasminogen activator.

Acute Mechanical Complications of Myocardial Infarction

Cardiogenic shock after myocardial infarction has a high rate of mortality, but with newer interventions the mortality rate has decreased from 90% to 60%. However, it is important to determine the cause of cardiogenic shock. Although most cases are due to extensive left ventricular dysfunction, there are other causes, for example, right ventricular infarction and mechanical complications of myocardial infarction. Pulmonary artery catheterization and two-dimensional echocardiography may help in determining the cause (Table 3-29).

- Cardiogenic shock after myocardial infarction approaches 90% mortality.

Table 3-29 Diagnosis of Cause of Cardiogenic Shock

Cause	Pulmonary artery catheterization			Catheterization findings	Two-dimensional echocardiography
	RA	PAWP	CO		
Left ventricular dysfunction	↑	↑↑	↓↓		Poor left ventricle
Right ventricular infarction	↑↑	↓	↓↓		Dilated right ventricle
Tamponade	↑↑	↑↑	↓↓	End-equalization	Pericardial tamponade
Papillary muscle rupture	↑	↑↑	↓↓	Large V	Severe mitral regurgitation
Ventricular septal defect	↑	↑↑	↑	Step-up	Defect seen
Pulmonary emboli	↑↑	=	↓	PADP > PAWP	Dilated right ventricle

CO, cardiac output; PADP, pulmonary artery diastolic pressure; PAWP, pulmonary artery wedge pressure; RA, right atrial pressure.

- Most cases of cardiogenic shock are due to extensive left ventricular dysfunction.
- Pulmonary artery catheterization and two-dimensional echocardiography may help determine other causes of cardiogenic shock.

Right ventricular infarction occurs in up to 40% of patients with inferior myocardial infarction and is diagnosed from increased jugular venous pressure in the presence of clear lung fields. It can present anywhere from hours to several days after the onset of infarction. ST-segment elevation in a V_4R lead is diagnostic of a large right ventricular infarction and portends a high mortality rate. In extreme circumstances, right ventricular infarction can cause cardiogenic shock because the right ventricle is not able to effectively pump enough blood to fill the left ventricle. Treatment includes large amounts of fluids given intravenously and infusion of dobutamine. If right ventricular infarction is recognized early, reperfusion therapy is indicated.

- Right ventricular infarction occurs in up to 40% of patients with inferior myocardial infarction and presents with increased jugular venous pressure with clear lung fields.

Myocardial free wall rupture may occur and cause abrupt decompensation. Free wall rupture occurs in 85% of all ruptures. It occurs suddenly, usually 2 to 14 days after transmural myocardial infarction, most commonly in elderly hypertensive women, and usually presents as electromechanical dissociation or death. If rupture is contained in the pericardium, tamponade may occur. If the diagnosis can be made by emergency echocardiography, surgery should be performed. If the rupture is sealed off, a pseudoaneurysm may occur; surgical treatment is required because of the high incidence of further rupture.

- Free wall rupture occurs in 85% of all ruptures.
- It occurs suddenly, usually 2-14 days after transmural myocardial infarction.

Papillary muscle rupture occurs in 5% of all ruptures and usually 2 to 10 days after myocardial infarction. It is associated with inferior myocardial infarction because of the single blood supply to the posteromedial papillary muscle. Rupture of papillary muscle is heralded by the sudden onset of dyspnea and hypotension. Although a murmur may be present, it may not be audible because of equalization of left atrial and left ventricular pressures. The diagnosis is made with echocardiography or pulmonary artery catheterization, which demonstrates a large V wave on pulmonary artery wedge pressure. The treatment is intra-aortic balloon pump and an emergency operation.

- Papillary muscle rupture occurs in 5% of all ruptures.
- It usually occurs 2-10 days after myocardial infarction.
- It is associated with inferior myocardial infarction.
- It is heralded by sudden dyspnea and hypotension.
- It is diagnosed with echocardiography or pulmonary artery catheterization.

Ventricular septal defects occur in 10% of all ruptures, usually 1 to 20 days after myocardial infarction, and are equally frequent in inferior and anterior myocardial infarctions. Ventricular septal defects associated with inferior myocardial infarctions have a poorer prognosis because of the serpiginous nature of the rupture and associated ventricular infarction. They are indicated by the sudden onset of dyspnea and hypotension. A loud murmur and systolic thrill are always present. The diagnosis is made with echocardiography or pulmonary artery catheterization, which demonstrates a step-up in oxygen saturation from the right atrium to the pulmonary artery. Treatment is intra-aortic balloon pump and an emergency operation.

- Ventricular septal defects occur in 10% of all ruptures.
- They are equally frequent in inferior and anterior myocardial infarctions.
- They are indicated by the sudden onset of dyspnea and hypotension.
- A ventricular septal defect almost always has a thrill and loud murmur.

Prehospital Dismissal Evaluation

For proper evaluation of a patient with myocardial infarction before dismissal from the hospital, the predictors of mortality

must be determined. These include status of the left ventricle, ventricular arrhythmias, and presence of continued myocardial ischemia.

After myocardial infarction, most patients should have rehabilitation treadmill exertion testing to detect continued ischemia, particularly patients who did not have thrombolytic therapy. A submaximal treadmill test can be performed before dismissal, within 4 to 6 days after myocardial infarction. Alternatively, a symptom-limited treadmill test can be performed safely 10 to 21 days after myocardial infarction. If a submaximal treadmill test is performed before dismissal, a late symptom-limited treadmill test should be performed at follow-up evaluation 3 to 6 weeks after myocardial infarction. High-risk patients identified by treadmill exertion testing have an ST-segment depression greater than 1 mm, a decrease in blood pressure, or an inability to achieve 4 metabolic equivalents on the exercise test. Imaging exercise tests may identify additional high-risk patients by demonstrating multiple areas of ischemia. Pharmacologic stress tests (dobutamine echocardiography, dipyridamole thallium scanning, or adenosine thallium scanning) may be useful for patients unable to exercise. The role of stress testing for patients after thrombolytic therapy is less clear because most of them do well without intervention. However, stress testing is of value in providing an exercise prescription to patients.

- After myocardial infarction, most patients should undergo rehabilitation treadmill testing.
- It is a low-risk test for properly selected patients.

To prevent infarct remodeling and expansion, angiotensin-converting enzyme inhibitors should be given to all patients who have large anterior myocardial infarctions. In patients with an ejection fraction less than 40%, this therapy prevents future congestive heart failure and improves mortality. Data suggest that angiotensin-converting enzyme inhibitors may be beneficial for preventing recurrent myocardial infarction and cerebrovascular accidents in all high-risk patients who have coronary artery disease.

Coronary angiography is indicated after myocardial infarction if the results of a rehabilitation treadmill exertion test are highly positive or postinfarction angina occurs. Patients with these findings usually have substantial regions of myocardium at risk, and the coronary anatomy should be defined to determine whether they should undergo either catheter-based therapy or CABG. Coronary angiography is indicated in patients who have had hemodynamic instability. Patients who have had heart failure during hospitalization are at high risk and should be considered for coronary angiography. Because CABG improves mortality for patients with three-vessel disease and depressed systolic function, it has been suggested that coronary angiography be performed in all patients who have a depressed ejection fraction to look for severe three-vessel or left main coronary artery disease.

- Coronary angiography is indicated if the results of a rehabilitation treadmill exertion test are positive or postinfarction angina occurs.

No randomized trials have examined the benefit of PTCA or bypass grafting after myocardial infarction. However, in high-risk patients (i.e., those with continued ischemia or positive results on a treadmill exertion test), it is reasonable to proceed with intervention. PTCA can be undertaken if there is a single-vessel high-grade lesion amenable to the procedure. CABG should be performed if there is left main coronary artery or proximal three-vessel disease or two- or three-vessel disease that supplies a large portion of the myocardium, especially when associated with moderate depression in left ventricular function.

Aggressive modification of risk factors is essential in the treatment of patients who have had a myocardial infarction. An exercise program, weight loss, and diet are mandatory for all patients after myocardial infarction. Many physicians determine the cholesterol level on admission to the hospital. The goal of treatment is to decrease LDL cholesterol to less than 100 (optimal <70) mg/dL. If LDL cholesterol is more than 100 mg/dL, the trend is to start treatment with a statin drug before dismissal, even before instituting diet and weight loss.

The following apply to patients who survive acute myocardial infarction:

- Aspirin decreases recurrent myocardial infarction by 31% and late mortality by 15%, more so in cases of non–ST-segment elevation myocardial infarction.
- Warfarin may cause a similar decrease in mortality and reinfarction, but it is not used routinely in the United States.
- Statin drugs reduce recurrent events and mortality in patients with increased cholesterol levels (total cholesterol >200 mg/dL).
- Statin drugs reduce recurrent events in patients with "average" cholesterol levels (LDL >125 mg/dL).
- β-Adrenergic blockers improve survival after myocardial infarction.
- β-Adrenergic blockers are most effective in high-risk patients (i.e., decreased left ventricular function and ventricular arrhythmias) and may not be required for low-risk patients.
- β-Adrenergic blockers are also effective after thrombolytic therapy.
- Because antiarrhythmic agents are associated with increased mortality, they should not be used to suppress ventricular ectopy.
- Angiotensin-converting enzyme inhibitors decrease mortality after anterior myocardial infarction and depressed left ventricular function, presumably by inhibiting infarct remodeling.
- A rehabilitation program is essential for the patient's well-being and cardiovascular fitness.
- An automatic implantable cardioverter-defibrillator should be considered if the ejection fraction is <30% 1 month after a myocardial infarction in patients with an expected survival of at least 1 year.

Part V

Barry L. Karon, MD

Heart Failure

Heart failure is a clinical syndrome characterized by the inability of the heart to maintain adequate cardiac output to meet the metabolic demands of the body while still maintaining normal or near-normal ventricular filling pressures. For correct treatment of heart failure, the mechanism, underlying cause, and any reversible precipitating factors must be identified. Typical manifestations of heart failure are dyspnea and fatigue that limit activity tolerance and fluid retention leading to pulmonary or peripheral edema. These abnormalities do not necessarily dominate the clinical picture at the same time. Dyspnea may be due to impaired output or increased filling pressures or both.

Heart failure may result from abnormalities of the pericardium, myocardium, endocardium, cardiac valves, or vascular or renal systems. Most commonly, however, it is due to impaired left ventricular myocardial function. In approximately half of cases, the left ventricle is enlarged and there is abnormal contractile function with demonstrable reduction in ejection fraction. This is referred to as dilated cardiomyopathy. In the other half of cases, the heart failure is occurring in the setting of normal ejection fraction; this is referred to as heart failure with preserved ejection fraction. Although isolated right ventricular failure can occur, the majority of cases of heart failure involve either the left ventricle alone or the left ventricle with secondary right ventricular dysfunction. High ventricular filling pressures can cause dyspnea and edema.

- Heart failure is the inability of the heart to maintain adequate cardiac output to meet the metabolic demands of the body while still maintaining normal filling pressures.
- Cardinal symptoms of heart failure are fatigue (related to impaired output) and fluid retention (resulting in pulmonary or peripheral edema). Dyspnea may be due to impaired output or increased filling pressures or both.
- The most common cause of heart failure is left ventricular myocardial dysfunction.
- High ventricular filling pressures cause dyspnea and edema.
- Myocardial dysfunction with preserved ejection fraction is as important as dilated cardiomyopathy in causing heart failure.

Ventricular diastolic function is a complex process. Three of its major components are relaxation, passive filling, and atrial contraction. Relaxation is an active, energy-requiring process in which calcium is removed from the actin-myosin filaments, causing contracted muscle to return to its original length. Relaxation properties are dynamic and are normally transiently enhanced during physical exertion. In disease states (e.g., hypertension, ischemia), relaxation rates may not be able to augment or may even worsen. After active relaxation, filling of the ventricle continues along the pressure gradient from the left atrium to the left ventricle (passive filling). The amount of filling during this phase is determined by left atrial pressure and left ventricular compliance; compliance is the increase in ventricular volume per unit of driving pressure. Thus, abnormally low compliance impairs filling and produces high end-diastolic pressure. Ventricular filling is also affected by the duration of diastolic filling. The contribution from atrial contraction further increases ventricular volume by as much as 15% to 20% in normal subjects and 45% to 50% in those with abnormal ventricular relaxation and passive filling (Table 3-30).

- Three major components of ventricular diastolic function are relaxation, passive filling, and atrial contraction.
- Relaxation is impaired in myopathic ventricles and can worsen transiently in the setting of ischemia or hypertension.
- Impaired ventricular compliance means higher pressures are needed to produce volume changes.
- Atrial contraction takes on greater importance in patients with reduced ventricular relaxation or compliance.

Managing Heart Failure

Managing patients with heart failure requires a disciplined thought process. One possible algorithm is shown in Figure 3-46.

Diagnosis of Heart Failure

Heart failure is a clinical diagnosis made on the basis of symptoms, physical findings, and chest radiography. The symptoms typically include some combination of dyspnea, fatigue, and fluid retention. The dyspnea may be with exertion or with recumbency. Physical findings include evidence of low output or volume overload or both. These include narrow pulse pressure, poor peripheral perfusion, jugular venous distention, hepatojugular reflux, peripheral edema, ascites, and dull lung bases suggestive of pleural effusions. Lung crackles usually represent atelectatic compression by pleural fluid rather than fluid in the alveoli, which would be more common in acute heart failure. Edema usually affects the lower extremities but can also affect the abdomen. Cardiac findings include abnormalities

Table 3-30 Abnormal Diastolic Function in Myocardial Disease

Phase	Influencing factors	Treatment
Relaxation	Ischemia, hypertrophy	Treat ischemia, hypertension
Passive filling	Myocardial compliance, heart rate	Slow heart rate
Atrial contraction	Atrial contraction, atrioventricular synchrony	Maintain sinus rhythm

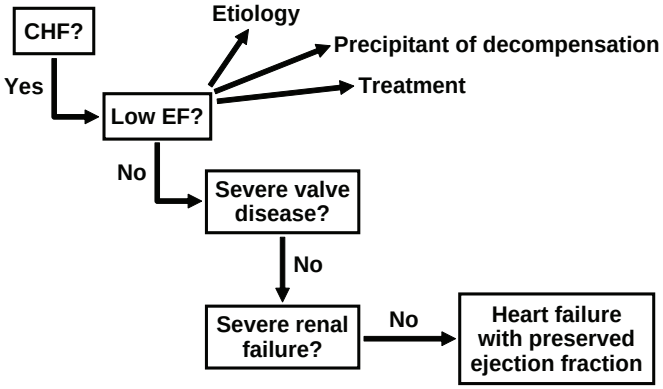

Fig. 3-46. Algorithm used to determine mechanism of heart failure. CHF, congestive heart failure; EF, ejection fraction.

of the cardiac apex (enlarged, displaced, sustained) and gallop rhythms. The liver may be enlarged, pulsatile, and tender.

Both the symptoms and signs of heart failure described above are nonspecific and can occur in other conditions. Use of the modified Framingham criteria for the clinical diagnosis of congestive heart failure retains an important place in clinical cardiology (Table 3-31).

By this scheme, the simultaneous presence of two major or one major and two minor criteria satisfies the clinical diagnosis of congestive heart failure. It is important to recognize that exertional dyspnea does not have the same weight as paroxysmal nocturnal dyspnea or orthopnea, and edema does not have the same weight as increased venous pressure. Patients with low-output heart failure may not have findings of volume overload (congestion) and thus may not satisfy Framingham criteria.

Natriuretic peptides are substances produced by the heart in increased amounts when there is increased intracardiac pressure or chamber dilatation. Accordingly, measurement of B-type natriuretic peptide or N-terminal pro-brain natriuretic peptide complements the clinical diagnosis of heart failure. In general, the degree of increase reflects the degree of myocardial dysfunction. Increased levels of these peptides do not distinguish systolic from diastolic, left from right, or acute from chronic cardiac dysfunction. Interpreting these levels has caveats (Table 3-32).

The utility of the natriuretic peptides for diagnosing heart failure has been best shown in patients without prior known cardiac disease. It can be difficult to interpret intermediately increased levels in patients with a prior history of ventricular dysfunction or heart failure who are receiving medical treatment.

- Heart failure is a clinical diagnosis based primarily on symptoms and physical findings.
- Use of the modified Framingham criteria can assist in diagnosing heart failure but will not be as helpful in patients with low-output heart failure without associated congestion.
- Natriuretic peptide levels are increased in patients with heart failure, although there are circumstances in which values may be higher or lower than expected. They are most useful in patients without a prior diagnosis of heart failure and in patients not receiving treatment for heart failure.

Mechanisms of Heart Failure

The mechanism and causes of heart failure must be defined to select proper therapy. A simple categorical framework is given in Table 3-33.

Clinically, the most common cause of heart failure is left ventricular myocardial dysfunction. Because the treatment and prognosis are different for other causes of heart failure, accurate diagnosis is essential and is initially based on physical examination and noninvasive testing, such as echocardiography or radionuclide angiography.

Precipitating Factors

The new appearance of or worsening of previous heart failure symptoms may merely represent natural disease progression. Often, however, one or more precipitating factors are responsible for symptomatic deterioration (Table 3-34). If these factors are not identified and corrected, symptoms of heart failure frequently return after initial therapy. The most common precipitants are dietary indiscretion (sodium, fluid, alcohol) and medication noncompliance (cost, regimen complexity, patient understanding). The evaluation of each patient with heart failure follows these steps: 1) a medical history (include sodium and fluid intake, medication use and compliance, and sleep history from bedroom partners), 2) chest radiography to look for pneumonitis, 3) electrocardiography and measurement of cardiac biomarkers to document the rhythm and identify ischemia or myocardial injury, and 4) culture specimens of blood, urine, and sputum as appropriate from the history. Other tests should include determination of complete blood cell count and thyroid-stimulating hormone and creatinine levels.

Table 3-31 Framingham Criteria for Clinical Diagnosis of Congestive Heart Failure*

Major criteria	Minor criteria
PND	Peripheral edema
Orthopnea	Night cough
Increased JVP	DOE
Rales	Hepatomegaly
S_3	Pleural effusion
Chest radiography	Heart rate >120 beats/min
Cardiomegaly	Weight loss ≥4.5 kg in 5 days with diuretic
Pulmonary edema	

DOE, dyspnea on exertion; JVP, jugular venous pressure; PND, paroxysmal nocturnal dyspnea.

*Validated congestive heart failure if two major or one major and two minor criteria are present concurrently.

Modified from Ho KKL, Anderson KM, Kannel WB, Grossman W, Levy D. Survival after the onset of congestive heart failure in Framingham heart study subjects. Circulation. 1993;88:107-15. Used with permission.

Table 3-32 Pitfalls in the Interpretation of Natriuretic Peptide Value

NP higher than expected	NP lower than expected
Women	Obesity
Elderly	Acute heart failure
Renal failure	Heart failure due to mitral stenosis
	Constriction

NP, natriuretic peptide.

- For different causes and mechanisms of heart failure, treatment and prognosis are different.
- For every patient with heart failure, precipitating factors must be sought and treated.

Acute Heart Failure Syndromes

Acute heart failure syndromes are almost always related to left heart failure and usually present as pulmonary edema with or without shock. The most common causes are ischemic heart disease and severe hypertension, often coexistent. Ischemic syndromes presenting as acute heart failure usually result from large infarction, widespread global ischemia, or acute severe ischemic mitral regurgitation. Rarely, valvular disease such as endocarditis with perforation can present as acute heart failure. Myocarditis-dilated cardiomyopathies can present as acute heart failure, although a subacute presentation is more common.

Clinical hallmarks of acute heart failure include variable hypotension, tachycardia, and significant dyspnea. Murmurs may be unimpressive even in the setting of significant valvular disease because of high intracardiac pressures and low systemic pressures making regurgitant valvular pressure gradients lower and the resultant murmurs softer.

The evaluation and management of acute heart failure are performed simultaneously. Laboratory studies should include determination of blood counts and electrolyte, cardiac enzyme, and blood gas values. Electrocardiography and chest radiography are standard. Urgent echocardiography can be extremely helpful for distinguishing myocardial, valvular, and pericardial disease. Further evaluation might require pulmonary artery catheterization, especially for patients in shock or needing inotropes or pressors. Coronary angiography is generally appropriate if there is ischemia or infarction. Concomitant therapy includes oxygen, diuretics, afterload reduction with nitroprusside, or nitrates if ischemia is present and blood pressure is adequate.

- Acute heart failure is usually due to severe ischemic heart disease (infarction or global ischemia) or hypertension or both.
- Heart murmurs may be subtle in acute heart failure, even when severe valvular disease exists.
- Prompt identification of the mechanism of acute heart failure is imperative and often requires emergency cardiac imaging (echocardiography, coronary angiography).

Cardiomyopathies

According to the 1995 World Health Organization Task Force, a cardiomyopathy is a disease of myocardium associated with cardiac

Table 3-33 Causes of Heart Failure and Treatment

Cause	Treatment
Myocardial	
Dilated cardiomyopathy (including ischemic)	Angiotensin-converting enzyme inhibitors, angiotensin receptor blockers, β-adrenergic blockers (carvedilol, metoprolol, bisoprolol), diuretics, aldosterone antagonists, nitrates, digoxin, nitrates and hydralazine in combination, transplantation, coronary revascularization, left ventricular aneurysmectomy
Hypertrophic cardiomyopathy	β-Adrenergic blockers, verapamil, disopyramide, surgical myectomy, septal alcohol ablation, dual-chamber pacing
Restrictive cardiomyopathy	Diuretics, heart transplant, treatment of underlying systemic disease
Pericardial	
Tamponade	Pericardiocentesis
Constrictive pericarditis	Pericardiectomy
Valvular	Valve repair or replacement
Hypertension	Antihypertensive treatment
Pulmonary hypertension	Prostacyclin infusion, calcium channel blockers, heart-lung transplant, endothelin antagonists
High output	Correction of underlying cause
Hyperthyroidism, Paget disease, arteriovenous fistula	

Table 3-34 Precipitating Factors in Heart Failure

Diet (excessive sodium or fluid intake, alcohol)
Noncompliance with medication or inadequate dosing
Sodium-retaining medications (NSAIDs)
Infection (bacterial or viral)
Myocardial ischemia or infarction
Arrhythmia (atrial fibrillation, bradycardia)
Breathing disorders of sleep
Worsening renal function
Anemia
Metabolic (hyperthyroidism, hypothyroidism)
Pulmonary embolus

NSAIDs, nonsteroidal anti-inflammatory drugs.

dysfunction. Major categories are dilated, hypertrophic, restrictive, arrhythmogenic right ventricular, and unclassified cardiomyopathies. The task force also defined several specific cardiomyopathies, but pathophysiologically all of these behave as dilated, hypertrophic, or restrictive cardiomyopathies. The different anatomical and pathophysiologic processes for each cardiomyopathy are listed in Table 3-35.

Dilated Cardiomyopathy

Etiology

The major abnormality in dilated cardiomyopathy is a remodeled left ventricle characterized by dilatation with a reduced ejection fraction. Left ventricular end-diastolic pressure typically is increased. The increased filling pressures and low cardiac output produce symptoms of shortness of breath and fatigue.

An idiopathic dilated cardiomyopathy indicates left ventricular dysfunction without any known cause. Many of the cases are genetic; at least one affected family member can be identified in up to 30% of cases. Other causes of left ventricular dysfunction include severe coronary artery disease ("hibernating myocardium"), previous infarction, uncontrolled hypertension, ethanol abuse, hyperthyroidism or hypothyroidism, postpartum cardiomyopathy, toxins and drugs (including doxorubicin and trastuzumab), tachycardia-induced cardiomyopathy, infiltrative cardiomyopathy (i.e., hemochromatosis, sarcoidosis), acquired immunodeficiency syndrome (AIDS), and pheochromocytoma.

- In dilated cardiomyopathy, the major abnormality is enlarged left ventricle with reduced ejection fraction.
- Other causes of left ventricular dysfunction: severe coronary artery disease ("hibernating myocardium"), previous infarction, uncontrolled hypertension, ethanol abuse, thyroid disease, postpartum cardiomyopathy, toxins and drugs, and tachycardia-induced cardiomyopathy.

Clinical Presentation

The presentation of dilated cardiomyopathy is highly variable. The patient may be asymptomatic and the diagnosis then is based on examination, chest radiography, electrocardiography (ECG), or echocardiography. Patients may have symptoms of mild to severe heart failure (New York Heart Association [NYHA] functional class II-IV). Atrial and ventricular arrhythmias are common in dilated cardiomyopathy. The following may be found on physical examination: jugular venous pressure is increased (if there is right heart involvement), low-volume upstroke of the carotid artery, displaced and sustained left ventricular impulse (possibly with a rapid filling wave), audible third or fourth heart sounds, and an apical systolic murmur of mitral regurgitation. Pulmonary examination often has normal results but may reveal crackles or evidence of pleural effusion.

- Presentation of dilated cardiomyopathy is highly variable.
- Carotid volume is low, third heart sound is often present, and the apex is displaced and sustained.

ECG frequently shows left ventricular hypertrophy, intraventricular conduction delay, or bundle branch block. Rhythm abnormalities may include premature atrial contractions, atrial fibrillation, premature ventricular contractions, or short bursts of ventricular tachycardia. The chest radiograph often shows left ventricular enlargement and

Table 3-35 Anatomical and Pathophysiologic Processes for Each Cardiomyopathy

Type	Left ventricular cavity size	Left ventricular wall thickness	Systolic function	Diastolic function	Other
Dilated cardiomyopathy	↑	N/↑	↓	↓	
Hypertrophic cardiomyopathy	↓/N	↑	↑	↓	Left ventricular outflow obstruction
Restrictive cardiomyopathy	N/↑	N	N	↓	

↓, decreased; N, normal; ↑, increased.

pulmonary venous congestion. The diagnosis is made on the basis of left ventricular enlargement and reduced ejection fraction, which can be measured with echocardiography, radionuclide angiography, left ventriculography, cine computed tomography, or magnetic resonance imaging.

- ECG may show left ventricular hypertrophy, intraventricular conduction delay, or bundle branch block.
- Atrial and ventricular rhythm disturbances are common.
- The chest radiograph often shows left ventricular enlargement and pulmonary venous congestion.
- The diagnosis requires demonstration of left ventricular enlargement and reduced ejection fraction by any cardiac imaging method.

Evaluation

After impaired left ventricular contractile function is diagnosed, treatable secondary causes of left ventricular dysfunction should be excluded. Sensitive thyroid-stimulating hormone level should be determined to exclude hyperthyroidism or hypothyroidism. Transferrin levels should be measured to screen for hemochromatosis. The serum angiotensin-converting enzyme level should be measured if sarcoidosis is a possibility. The metanephrine level should be measured if there is a history of severe labile hypertension or unusual spells. A history of ethanol or drug abuse must be sought.

In severe coronary artery disease, reversible left ventricular dysfunction can be caused by hibernating myocardium. However, with revascularization, left ventricular function may improve gradually. Identifying affected patients is difficult. Currently, the reference standard is positron emission tomography, which can show metabolic activity. Viability protocols used in stress echocardiography and radionuclide perfusion imaging are more widely available than positron emission tomography and are also useful for identifying hibernating myocardium.

Tachycardia-induced cardiomyopathy can occur in patients with prolonged periods of tachycardia (usually atrial fibrillation, flutter, or incessant atrial tachycardia). This is an important cause to establish because systolic dysfunction can be completely reversed after the tachycardia is treated.

- After depressed left ventricular function is diagnosed, treatable causes of reversible left ventricular dysfunction should be sought.
- Blood tests should be performed for thyroid dysfunction, sarcoidosis, and hemochromatosis, which are reversible causes of cardiomyopathy.
- Hibernating myocardium is a reversible cause of left ventricular dysfunction.
- Tachycardia-induced cardiomyopathy is reversible.

Some patients have left ventricular dysfunction caused by acute myocarditis. The natural history of these patients is unknown. Many patients have development of permanent left ventricular dysfunction, whereas others experience improvement with time. Thus, it is necessary to remeasure left ventricular function 3 to 6 months after making the diagnosis and initiating treatment. Although endomyocardial biopsy may help diagnose myocarditis, immunosuppressive therapy has not been shown to improve outcome and should be reserved for patients with giant cell arteritis, concomitant skeletal myositis, or clinical deterioration despite standard pharmacologic therapy.

Pathophysiology

For understanding the treatment of heart failure associated with dilated cardiomyopathy, the hemodynamic, pathophysiologic, and biologic aspects of heart failure must be appreciated.

Preload can be thought of as the ventricular end-diastolic volume. The relationship of stroke volume to preload is shown on the Starling curve in Figure 3-47. *Afterload* is the tension, force, or stress acting on the fibers of the ventricular wall after the onset of shortening. Left ventricular afterload is increased by aortic stenosis and systemic hypertension but is decreased by mitral regurgitation. Importantly, afterload is increased by ventricular enlargement and therefore the compensatory preload adjustment to contractile dysfunction (i.e., cardiac enlargement) has a putative effect on stroke volume through its effects on afterload.

Figure 3-48 illustrates the neurohormonal hemodynamic response to decreased myocardial contractility. Decreased cardiac output activates baroreceptors and the sympathetic nervous system. Sympathetic nervous system stimulation causes an increased heart rate and contractility. α-Stimulation of the arterioles causes an increase in afterload. The renin-angiotensin system is activated by sympathetic stimulation, decreased renal blood flow, and decreased renal sodium. This system in turn activates aldosterone, causing increased renal retention of sodium and, thus, more pulmonary congestion. A low

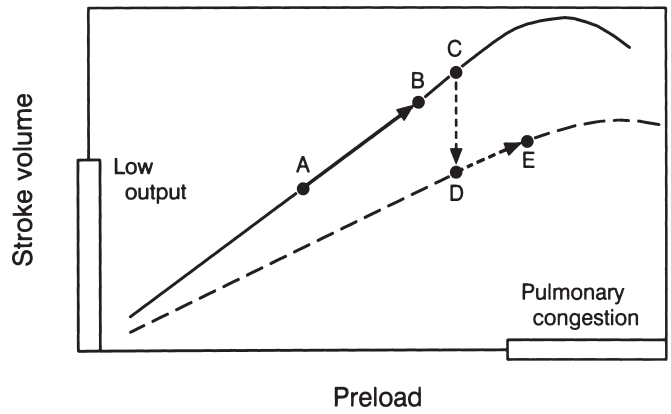

Fig. 3-47. Starling curve. Solid line is patient with normal contractility, and dotted line is one with depressed systolic function. Normally, stroke volume depends on preload of the heart. Increasing preload increases stroke volume (*A* to *B*). Myocardial dysfunction causes a shift of the curve downward and to the right (*C* to *D*), causing a severe decrease in stroke volume, which leads to symptoms of fatigue and lethargy. The compensatory response to decrease in stroke volume is an increase in preload (*D* to *E*). Because the diastolic pressure-volume relationship is curvilinear, increased left ventricular volume produces increased left ventricular end-diastolic pressure, causing symptoms of pulmonary congestion. Note flat portion of the curve at its upper end; here, there is little increase in stroke volume for increase in preload.

rate of renal blood flow results in renal retention of sodium. An increased level of angiotensin II causes vasoconstriction and an increase in afterload. In congestive heart failure, the compensatory mechanisms that increase preload eventually cause a malcompensatory increase in afterload, in turn causing further decrease in stroke volume.

Importantly, in the subacute and chronic stages of heart failure, neurohormonal (adrenergic, angiotensin II) and other signaling pathways lead to altered myocyte gene expression, impaired myocyte function, and progressive myocyte loss. Increased collagen production leads to progressive cardiac fibrosis. This progressive myocardial dysfunction and remodeling are the natural history of untreated myocardial dysfunction.

- Within physiologic limits, an increase in preload causes an increase in stroke volume.
- An increase in afterload (which can result from hypertension, aortic valve stenosis, or increased left ventricular mass) decreases stroke volume.
- Either an increase in afterload or a decrease in myocardial contractility can shift the Starling curve downward and to the right.
- Initial compensatory neurohormonal mechanisms lead to long-term malcompensatory increase in afterload, with a further decrease in stroke volume.
- Neurohormonal activation modifies myocyte function with ultimate myocyte death and also increases myocardial fibrosis. This is known as remodeling.

Treatment

In the treatment of dilated cardiomyopathy, it is important to identify and remove precipitating factors. Treatment of congestive heart failure in patients with dilated cardiomyopathy should be based on the pathophysiologic mechanisms described above (Fig. 3-49).

Nonpharmacologic treatment is crucial to patient management. It includes sodium and fluid restriction, avoidance of alcohol, daily patient monitoring of weight (with a definition of, and plan for responding to, excessive gain), and regular aerobic exercise. Ongoing patient and family education and regular outpatient follow-up (often with nurse specialists) reduce heart failure exacerbations, emergency department visits, and hospitalizations.

The mainstays of pharmacologic therapy are angiotensin-converting enzyme (ACE) inhibitors, β-adrenergic blockers, and diuretics. By blocking conversion of angiotensin I to angiotensin II, ACE inhibitors decrease afterload by inhibition of angiotensin II and decrease sodium retention by inhibition of aldosterone. ACE inhibitors also directly affect myocyte gene expression, growth, and remodeling in a positive manner through the suppression of angiotensin and also by increasing bradykinin and vascular nitric oxide (Fig. 3-50).

Overall, ACE inhibitors provide symptomatic improvement in patients with NYHA functional class II-IV failure and improve mortality in patients with moderate and severe heart failure. In asymptomatic patients, ACE inhibitors prevent onset of heart failure and reduce the need for hospitalization.

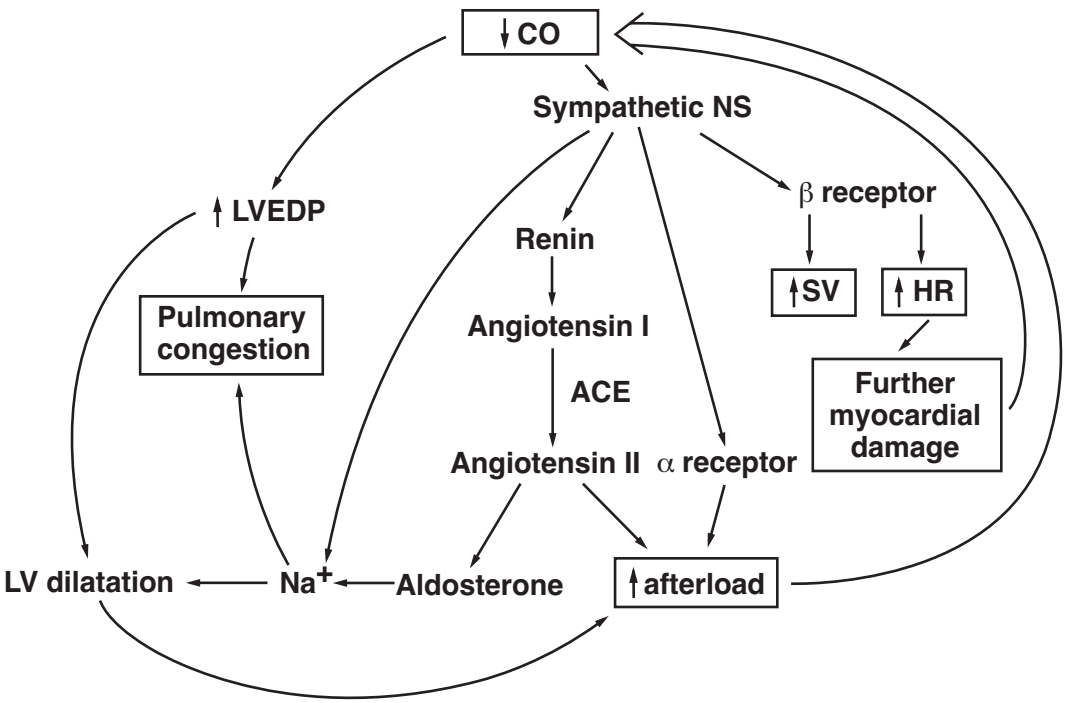

Fig. 3-48. Neurohormonal response to decreased myocardial contractility. ACE, angiotensin-converting enzyme; CO, cardiac output; HR, heart rate; LV, left ventricular; LVEDP, left ventricular end-diastolic pressure; NS, nervous system; SV, stroke volume.

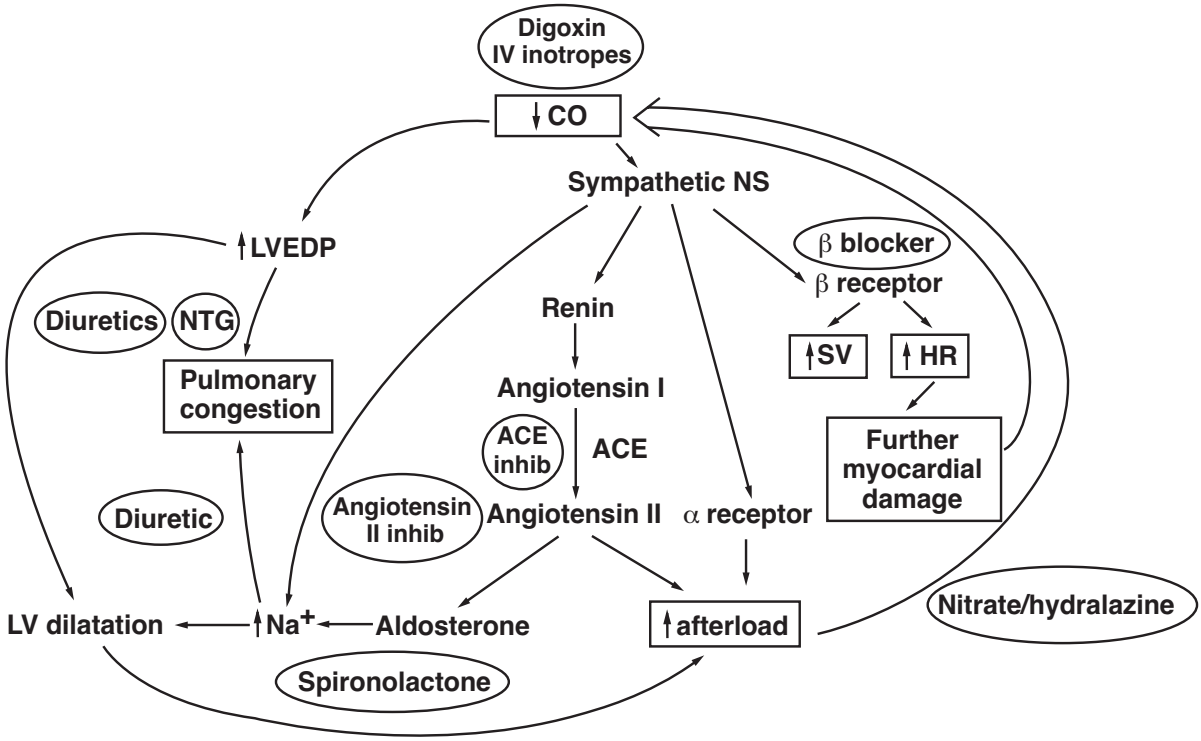

Fig. 3-49. The effect of various drugs used to treat heart failure in patients with dilated cardiomyopathy. inhib, inhibitor; IV, intravenous; NTG, nitroglycerin. Other abbreviations as in Figure 3-48.

- ACE inhibitors decrease afterload, decrease sodium retention, and directly reduce adverse biologic effects on myocytes.
- ACE inhibitor use decreases mortality in patients with moderate and severe heart failure.
- ACE inhibitors provide symptomatic improvement in patients with NYHA class II-IV heart failure symptoms.
- In asymptomatic patients, ACE inhibitors reduce the incidence of heart failure and reduce the need for hospitalization.

ACE inhibitors are given initially in small doses because of possible hypotensive effects. Dosage should be titrated up as tolerated on the basis of symptoms and blood pressure, potassium, and creatinine measurements. Even if a patient is clinically compensated on a low or intermediate ACE inhibitor dose, upward dose adjustment as tolerated is beneficial. For optimal ACE inhibitor doses to be achieved, the diuretic dose may need to be reduced. Common side effects of ACE inhibitors include hypotension, hyperkalemia, azotemia, cough, angioedema (mild or severe), and dysgeusia. The benefits and potential side effects of ACE inhibitors are thought to be a class effect.

- ACE inhibitor doses are initially low but should be titrated upward; concomitant diuretic dose may need reduction.
- ACE inhibitor side effects: hypotension, hyperkalemia, azotemia, cough, angioedema, and dysgeusia.

Angiotensin II receptor blockers provide hemodynamic benefits similar to those of ACE inhibitors in patients with dilated cardiomyopathy. They cause less cough and angioedema than ACE inhibitors and should be tried in patients who cannot tolerate ACE inhibitors because of these bradykinin-mediated side effects. Because they provide less reverse remodeling than ACE inhibitors, they remain second-line treatment, to be reserved for patients who cannot tolerate ACE inhibitors.

β-Adrenergic blockers (β-blockers) are effective adjuncts to ACE inhibitor therapy in patients with dilated cardiomyopathy; they improve symptoms, reverse remodeling of ventricles with improvement in ejection fraction, and decrease hospitalizations and mortality. Although acutely they may have unwanted hemodynamic effects (negatively inotropic, attenuation of heart rate response that may be maintaining cardiac output in the setting of reduced stroke volume), they provide long-term (may take up to 6 months) benefit by modifying the unfavorable biologic effects of enhanced adrenergic tone. These drugs are most useful for patients with asymptomatic left ventricular dysfunction and NYHA class II or III symptoms. They can be given cautiously to patients with class IV symptoms who have mild volume overload but should not be given to patients with more significant volume overload or cardiogenic shock. Initial dosing should be low, clinical follow-up should be close, and upward titration of the β-blocker dose should be slow and cautious. Well-studied β-blockers with established benefit for patients with heart failure include metoprolol succinate, carvedilol, and bisoprolol (although only metoprolol succinate and carvedilol currently have the approval of the U.S. Food and Drug Administration for the treatment of heart failure). The benefits of β-blocking agents are not necessarily class effects.

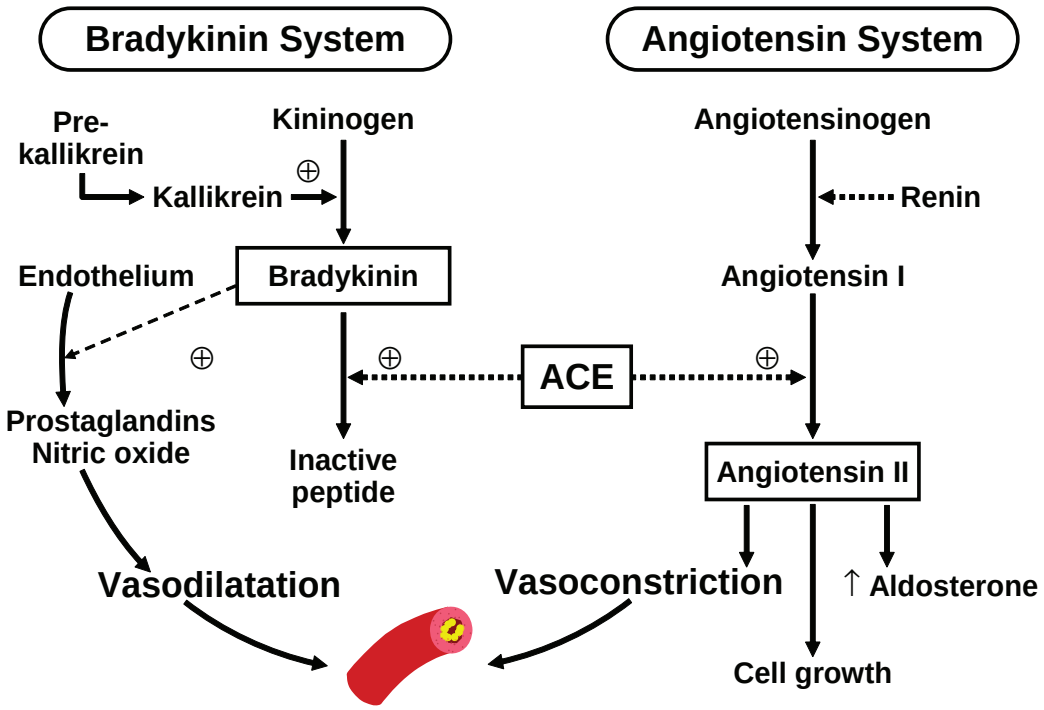

Fig. 3-50. Action of angiotensin-converting enzyme (ACE) on the bradykinin and angiotensin system.

- β-Blockers have been shown to be effective as adjunctive therapy to ACE inhibitors in patients with dilated cardiomyopathy.
- β-Blockers have a long-term beneficial effect on ventricular function and slow or reverse pathologic remodeling in dilated cardiomyopathy.
- β-Blockers need to be given carefully to avoid left ventricular decompensation.
- β-Blocker therapy is contraindicated in severely decompensated heart failure, especially when there is significant volume overload.

Diuretics are part of the routine management of patients with heart failure and either symptoms of pulmonary congestion or physical or radiographic evidence of fluid overload. Diuretic doses should be minimized because regular diuretic use causes neurohormonal activation and electrolyte imbalances. Mild fluid overload is initially treated with thiazide diuretics if renal function is normal. Loop diuretics are needed if there is significant fluid overload, renal dysfunction, or fluid overload resistant to thiazides. Occasionally, a combination of thiazides and loop diuretics is needed for severe fluid retention. The addition of spironolactone can help in patients with hypokalemia and may provide additional benefit by blocking aldosterone-mediated effects, as described below.

- Diuretics should be used for patients with heart failure and volume overload.
- Diuretic dose should be minimized so the renin-angiotensin-aldosterone system is not unnecessarily stimulated and to minimize unwanted metabolic side effects.

Drugs that directly affect contractility include digoxin and phosphodiesterase inhibitors (milrinone and amrinone). Digoxin provides symptomatic relief when the ejection fraction is less than 40%, but it does not improve survival. Because digoxin trials included few patients receiving β-blockers, it is not clear whether its benefit is maintained in the setting of contemporary therapy. Because digoxin is excreted by the kidneys, its dosage needs to be decreased with increased levels of creatinine and in older patients. The typical dosage is 0.25 mg/day but should be decreased to 0.125 mg/day if creatinine clearance is less than 70 mL/min. In patients with chronic renal failure, the digoxin dose is adjusted on the basis of trough digoxin levels and is ideally around 1.0 ng/dL. Because of drug-drug interactions, digoxin dosage should be decreased with concomitant administration of amiodarone, verapamil, and quinidine. Although short-term parenteral inotropic agents (milrinone and amrinone) may improve symptoms, long-term use increases mortality, and therefore these drugs should be used transiently and only in severe cases of congestive heart failure.

- Digoxin and phosphodiesterase inhibitors (milrinone and amrinone) directly affect contractility.
- Digoxin dosage needs to be decreased in azotemic and older patients and should be guided by trough digoxin levels.
- Digoxin dosage should be decreased with concomitant administration of amiodarone, verapamil, and quinidine.

Aldosterone antagonists may have added benefits mediated through inhibition of fibrosis and combating mechanical and electrical remod-

eling. A large study of spironolactone showed significant survival benefit in patients with NYHA class III and IV heart failure. There was little use of β-blocker therapy in these patients. In another study using selective aldosterone inhibitor, eplerenone was given to patients who had had infarction and had left ventricular dysfunction and either heart failure or diabetes; they had survival benefit at 30 days and 1 year. Both studies excluded patients with baseline renal failure and hyperkalemia; use of potassium supplements and potassium-sparing diuretics was discontinued. Nevertheless, there was still significant risk of hyperkalemia. Thus, these drugs need to be given carefully with cautious follow-up of laboratory values, avoidance of nonsteroidal anti-inflammatory drugs, and prompt attention to illnesses predisposing patients to dehydration.

- Aldosterone antagonists can be used in highly symptomatic patients already receiving baseline therapy or in patients with either heart failure or diabetes early after infarction.
- Patients with hyperkalemia or renal dysfunction should not receive these drugs.
- Patients treated with aldosterone antagonists need very careful laboratory follow-up.

Angiotensin receptor blockers can be used in combination with ACE inhibitor and β-blocker therapy in an effort to more completely block the renin-angiotensin-aldosterone pathway. This approach has been shown to reduce the combined end point of death and hospitalization for heart failure. Electrolyte disturbances and hypotension are more common with this approach, and it is not considered standard therapy. Routine use of combined therapy with ACE inhibitors, angiotensin receptor blockers, and aldosterone antagonists should be avoided.

Nitrates reduce preload and afterload through venodilatation. They also are anti-ischemic agents, may improve endothelial function, and combat ventricular remodeling. They should be given with a nitrate-free interval to prevent nitrate tolerance. Hydralazine may potentiate nitrate therapy by reducing nitrate tolerance when they are used in combination.

The combination of high-dose nitrates and hydralazine provides symptomatic improvement and improved mortality in patients with heart failure. However, the rate of intolerance to the necessary doses of medications is high, and their demonstrated mortality benefit is less than that achieved with ACE inhibitors. They are used in patients unable to tolerate ACE inhibitors or angiotensin receptor blockers. They have also been shown to benefit African-American patients when given as adjuvant therapy to ACE inhibitors and β-blockers.

- Diuretics and nitrates reduce pulmonary congestion.
- Nitrates reduce preload and afterload.
- Nitrate tolerance is best avoided by providing a nitrate-free interval.
- The combination of nitrates and hydralazine improves symptoms and mortality.

A 48-hour infusion of dobutamine may give symptomatic relief, but the effect is often temporary and mortality may be increased. Milrinone also may be used in this fashion and is preferred over dobutamine in patients who are chronically receiving β-blockers. Those therapies are reserved for severely symptomatic patients who are unresponsive to other therapies; they may receive continuous outpatient infusions.

Amlodipine and felodipine are safe in patients with dilated cardiomyopathy but do not provide any survival benefit. First-generation calcium channel blockers (verapamil, diltiazem, nifedipine), however, are relatively contraindicated because of their negative inotropic effects.

Anticoagulation with warfarin is recommended for patients in atrial fibrillation and those with intracardiac thrombus or a history of systemic or pulmonary thromboembolism. In two prospective studies, prophylactic warfarin use was not shown to decrease the composite end point of death, nonfatal stroke, or infarction when given to patients with dilated cardiomyopathy. Retrospective studies have suggested that aspirin may diminish the benefits of ACE inhibitors by blocking prostaglandin-induced vasodilatation. In addition, these studies showed an increased incidence of hospitalizations for heart failure in patients with dilated cardiomyopathy receiving aspirin. Accordingly, most advise aspirin use in small doses only in patients with coronary artery disease. Alternatively, clopidogrel may be given.

- Anticoagulation with warfarin is recommended in patients with atrial fibrillation, intracardiac thrombus, or a history of thromboembolism.
- Aspirin therapy should be reserved for patients with coronary artery disease.

Recapitulation of Drug Therapy for Dilated Cardiomyopathy

- ACE inhibitors and β-blockers improve symptoms and decrease mortality in patients with symptomatic dilated cardiomyopathy.
- ACE inhibitors and β-blockers prevent deterioration and subsequent hospitalizations in patients with asymptomatic dilated cardiomyopathy.
- Angiotensin receptor blockers can be used in patients intolerant of ACE inhibitors. There use in addition to ACE inhibitor and β-blocker therapy is less well established.
- Aldosterone antagonists have shown survival benefit in certain subgroups of patients with dilated cardiomyopathy but should not be used when hyperkalemia or renal failure is present.
- The combination of high-dose nitrates and hydralazine improves symptoms and survival (although the survival benefit is less than with ACE inhibitors), but intolerance to the high doses limits their usefulness.
- Nitrates should be used with a nitrate-free interval to prevent nitrate tolerance.
- Digoxin is useful for symptomatic treatment of patients with dilated cardiomyopathy but provides no survival benefit, and its role in patients receiving β-blockers is undefined.
- Phosphodiesterase inhibitors and prolonged infusion of dobutamine directly increase contractility and may improve symptoms transiently, but they probably increase mortality.

Device Therapy

Implanted defibrillators improve survival as primary prevention in patients with ischemic and nonischemic dilated cardiomyopathies who have ejection fractions less than 30%. They should be offered to patients whose 1-year survival is not otherwise threatened. Patients should be thoroughly counseled about the role of these devices relative to survival and heart failure symptoms.

Patients with ventricular asynchrony may benefit from biventricular pacing, also known as cardiac resynchronization therapy. Current implantation criteria are sinus rhythm, QRS duration more than 120 ms, NYHA class III-IV, ejection fraction less than 35%, and optimal medical management. Cardiac resynchronization therapy results in improvement in approximately 70% of patients.

- Patients receiving optimal medical management who have persistent qualifying degrees of left ventricular dysfunction should be considered for cardiac defibrillator or cardiac resynchronization therapy if they meet other selection criteria.

Cardiac Replacement Therapy

Heart transplantation is the procedure of choice for patients with severe dilated cardiomyopathy and severe symptoms. With successful transplantation, the 1-year survival is 90%. The major contraindication for transplantation in an otherwise healthy patient is a high pulmonary arteriolar resistance. Long-term complications after heart transplantation include rejection, infection, hypertension, hyperlipidemia, malignancy, and accelerated coronary vasculopathy. In the United States, donor availability is the major limiting factor; in selected patients, left ventricular assist devices are used either as a bridge to transplantation or as final ("destination") therapy.

- The procedure of choice for patients with severely symptomatic dilated cardiomyopathy despite optimal medical management is heart transplantation. With successful transplantation, 1-year survival is 90%.
- Ventricular assist devices are an option for selected patients either as a bridge to transplantation or as destination therapy.

Heart Failure With Preserved Ejection Fraction

Approximately half of patients with a new diagnosis of heart failure have a normal ejection fraction. Although many, if not all, of these patients have contractile abnormalities that could be identified by more sophisticated evaluation techniques, the ejection fraction is the most widely available measure of systolic function and remains the standard in daily practice. This is a heterogeneous group and includes patients with hypertrophic and restrictive cardiomyopathies, infiltrative cardiac disorders, and constrictive pericarditis; all of these are further discussed below.

The remaining patients have some other form of diastolic dysfunction. Some patients have fairly normal diastolic filling properties at rest, but exertional hypertension or ischemia or both cause their diastolic filling properties to deteriorate (or at least the relaxation does not augment) with resultant increase in filling pressure. Others have abnormal baseline diastolic compliance with superimposed volume overload, which increases the diastolic filling pressures. Others have exhuberant heart rate responses to exercise with inadequate diastolic filling periods, and others rely on the atrial contribution to ventricular filling and suffer when atrial fibrillation develops. Thus, it is highly desirable to try to understand the mechanism of diastolic dysfunction in any given patient in an effort to tailor the most effective treatment, which might include some combination of hypertension or ischemia treatment, diuretic treatment, ventricular rate slowing, or restoration of sinus rhythm.

- Heart failure with preserved ejection fraction represents a heterogeneous group of problems.
- There is not a standard therapy for heart failure with preserved ejection fraction; ideally, a tailored approach is applied.

Hypertrophic Cardiomyopathy

Etiology

Hypertrophic cardiomyopathy is a genetically and phenotypically heterogeneous family of disorders characterized by defects involving myocyte proteins with hypertrophy as a compensatory response. There may or may not be obstruction in the left ventricular outflow tract or mid-ventricular cavity. The diagnosis currently is based on the echocardiographic finding of increased myocardial wall thickness in the absence of an underlying cause such as hypertension, aortic stenosis, chronic renal failure, or infiltrative disease. Because hypertrophic cardiomyopathy is a hereditary disease, all patients should have their first-degree relatives screened, and genetic counseling is advised for potential parents.

- Hypertrophic cardiomyopathy is a heterogeneous family of genetic disorders of myocyte proteins with compensatory myocardial hypertrophy.
- Dynamic left ventricular outflow tract or mid-cavity obstruction occurs in some, but not all, patients.
- Diagnosis is based on the echocardiographic finding of increased myocardial wall thickness in the absence of a cause.
- Family screening and genetic counseling are advised.

Symptoms

Hypertrophic cardiomyopathy has several different manifestations. There appears to be a bimodal distribution of age at presentation. Young males (usually in the teens or early 20s) have a high propensity for syncope and sudden death. Older patients (in their 50s and 60s) present with symptoms of shortness of breath and angina and may have a better prognosis than young patients. The classic presentation of the younger group is a young athlete undergoing a physical examination to participate in sports who is found to have a heart murmur or left ventricular hypertrophy on ECG. The classic presentation of the older group is an older woman in whom pulmonary edema develops after noncardiac surgery and whose condition worsens with diuresis, afterload reduction, and inotropic support (all of which worsen dynamic left ventricular outflow tract obstruction). The classic symptom triad is syncope, angina, and dyspnea (symptoms similar to those of valvular aortic stenosis). Some hypertensive patients have a small hyperdynamic left ventricle with hypertrophy and

dynamic left ventricular outflow tract obstruction—hypertensive hypertrophic cardiomyopathy. Although the pathophysiology is the same as in hypertrophic cardiomyopathy, these patients are not at increased risk for sudden death and ventricular fibrillation.

There is a 1.5% per year frequency of evolution from hypertrophic to dilated cardiomyopathy. This may reflect either the natural history or a superimposed secondary process such as ischemia. The treatment of a "burnt-out hypertroph" is then the same as that for other dilated cardiomyopathies.

- The classic presentation of hypertrophic cardiomyopathy is the triad of angina, syncope, and dyspnea.
- There is a bimodal distribution of presentation: young males with high incidence of sudden death and older patients with dyspnea and angina.
- The prognosis for older patients may be better than that for younger patients.
- Patients with hypertension may have hypertrophy and dynamic left ventricular outflow tract obstruction similar to those of patients with hypertrophic cardiomyopathy.

Pathophysiology

Signs and symptoms of hypertrophic cardiomyopathy are caused by four major abnormalities: diastolic dysfunction, left ventricular outflow tract obstruction, mitral regurgitation, and ventricular arrhythmias.

Diastolic dysfunction is caused by many mechanisms. Marked abnormality in calcium metabolism causes abnormal ventricular relaxation. High afterload due to left ventricular tract obstruction also delays ventricular relaxation. Severe hypertrophy and increased muscle mass produce decreased compliance so that there is increased pressure per unit volume entering the left ventricle during diastole. These combine to cause increased left ventricular diastolic pressure, which leads to angina and dyspnea.

In many patients, dynamic left ventricular tract obstruction is caused by the hypertrophied septum encroaching into the left ventricular outflow tract. This subsequently "sucks in" the anterior leaflet of the mitral valve (systolic anterior motion), creating left ventricular outflow tract obstruction. Because of this pathophysiologic process, dynamic outflow tract obstruction increases dramatically with decreased preload, decreased afterload, or increased contractility.

Systolic anterior motion of the mitral valve distorts the mitral valve apparatus during systole and may cause significant mitral regurgitation. Thus, the degree of mitral regurgitation is also dynamically influenced by the degree of left ventricular outflow tract obstruction. Patients with severe mitral regurgitation usually have severe symptoms of dyspnea.

Because of cellular disarray in patients with hypertrophic cardiomyopathy, the electrical conduction system is dispersed, leading to a high propensity for ventricular arrhythmias. The frequent occurrence of ventricular arrhythmias may cause sudden death or syncope.

- A major pathophysiologic abnormality in patients with hypertrophic cardiomyopathy is diastolic dysfunction.
- Left ventricular outflow tract obstruction and mitral regurgitation are caused by distortion of the mitral valve apparatus (systolic anterior motion), and they are dynamically influenced by preload, afterload, and contractility.
- The propensity for ventricular arrhythmias causing syncope and sudden death is high.

Examination

Hypertrophic cardiomyopathy is suspected on the basis of abnormal carotid artery upstroke and left ventricular impulse. The carotid artery upstroke is rapid compared with that of patients with aortic stenosis. If left ventricular outflow tract obstruction is extensive, the carotid artery upstroke has a bifid quality. The left ventricular impulse is sustained, indicating considerable left ventricular hypertrophy. It frequently has a palpable *a* wave. Patients with excessive left ventricular outflow tract obstruction may have a triple apical impulse. The first heart sound is normal, and the second heart sound is paradoxically split. A loud systolic ejection murmur indicates left ventricular outflow tract obstruction. The murmur changes in intensity with changes in loading conditions (Table 3-36). A holosystolic murmur of mitral regurgitation may be present; it increases in intensity with increases in the dynamic left ventricular outflow tract obstruction. Maneuvers affect the mitral regurgitant murmur of hypertrophic obstructive cardiomyopathy differently than other mitral regurgitant murmurs. When mitral regurgitation is not due to hypertrophic obstructive cardiomyopathy, it increases with increasing afterload and varies little with changes in contractility and preload. When mitral regurgitation is due to hypertrophic cardiomyopathy, however, increased afterload decreases the dynamic left ventricular outflow obstruction and thus the amount of secondary mitral regurgitation.

In patients with hypertrophic obstructive cardiomyopathy, the intensity of the ejection murmur increases whereas the arterial pulse volume decreases on the beat following a premature ventricular contraction. This is called the Brockenbrough sign, and it is due to post-ectopic increased contractility and decreased afterload, resulting in more dynamic obstruction. In contradistinction, in patients with fixed left ventricular outflow tract obstruction (e.g., aortic stenosis), both the murmur intensity and the pulse volume increase with the beat following a premature contraction.

- The diagnosis of hypertrophic cardiomyopathy is suspected by palpating a sustained left ventricular impulse and rapid upstroke of the carotid artery.
- The outflow murmur intensity and carotid upstroke change with changes in loading conditions of the heart.
- In hypertrophic obstructive cardiomyopathy, the secondary mitral regurgitation murmur changes in the same direction as that of the left ventricular outflow obstruction murmur under different loading conditions. This differs from the auscultatory findings when mitral regurgitation is due to other conditions.

Diagnostic Testing

Patients with hypertrophic cardiomyopathy usually have an abnormal ECG, which shows considerable left ventricular hypertrophy

Table 3-36 Dynamic Left Ventricular Outflow Tract Obstruction

Increased obstruction
Decreased afterload
Amyl nitrite
Vasodilators
Increased contractility
Postpremature ventricular contraction beat
Digoxin
Dopamine
Decreased preload
Squat-to-stand
Nitrates
Diuretics
Valsalva maneuver (strain phase)
Decreased obstruction
Increased afterload
Handgrip
Stand-to-squat
Decreased contractility
β-Adrenergic blockers
Verapamil
Disopyramide
Increased preload
Fluids

(Fig. 3-51). Because ECG abnormalities may precede echocardiographically detected phenotypic expression, surveillance echocardiography is appropriate in patients with suspicious ECG results. Apical hypertrophic cardiomyopathy is a variant of hypertrophic cardiomyopathy in which the hypertrophy is localized at the apex of the left ventricle. Although patients with apical hypertrophic cardiomyopathy do not have outflow tract obstruction (no murmur or secondary mitral regurgitation), they do have diastolic dysfunction and a predisposition to ventricular arrhythmias. The ECG in these patients typically has large, diffuse, symmetric T-wave inversions across the precordium (Fig. 3-52).

Hypertrophic cardiomyopathy is diagnosed with echocardiography, which shows severe hypertrophy of the myocardium (left ventricular wall thickness >16 mm in diastole) without any known cause. Formerly, asymmetric septal hypertrophy was required for the diagnosis, but it is now recognized that hypertrophy can be in any part of the myocardium. Doppler echocardiography can be used to diagnose left ventricular outflow tract obstruction, measure its severity, and detect mitral regurgitation. Cardiac catheterization is no longer necessary for diagnosing dynamic left ventricular outflow tract obstruction because all diagnostic data can be obtained with two-dimensional and Doppler echocardiography.

Sudden death is a problem in patients with hypertrophic cardiomyopathy. Because of a strong association between ventricular arrhythmias and sudden death, 48- to 72-hour Holter monitoring is recommended for all patients with hypertrophic cardiomyopathy. Predictors of sudden death include a personal or family history of sudden death, left ventricular hypertrophy, ventricular tachycardia at electrophysiologic study, young male, history of syncope, and nonsustained ventricular tachycardia. Genetic markers may identify patients with a strong propensity for sudden death. In some patients, carefully supervised stress testing also is indicated to search for ventricular tachycardia, to objectify symptom threshold, and to evaluate the variables contributing to symptoms.

- ECG usually shows evidence of left ventricular hypertrophy in cases of hypertrophic cardiomyopathy.
- Apical hypertrophy is suspected in the presence of large symmetric inverted T waves in precordial leads on ECG.
- The diagnosis of hypertrophic cardiomyopathy is made with echocardiography, which shows hypertrophy in the absence of any known cause.
- Predictors of sudden death: personal or family history of sudden death, young male, history of syncope, nonsustained ventricular tachycardia, massive left ventricular hypertrophy, and sustained ventricular tachycardia at electrophysiologic study.
- 48- to 72-Hour Holter monitoring is recommended for all patients with hypertrophic cardiomyopathy.

Treatment

Symptomatic Patients

For symptomatic patients with hypertrophic cardiomyopathy, initial treatment is with drugs that decrease contractility in an attempt to decrease left ventricular outflow tract obstruction (Fig. 3-53). The most effective medication is a high dose of β-blockers (>240 mg equivalent of propranolol/day). Although verapamil may be used if β-adrenergic blockade fails, it may cause sudden hemodynamic deterioration in patients with high resting left ventricular outflow tract gradients because of its vasodilating properties. Disopyramide may improve symptoms by decreasing left ventricular outflow tract obstruction, but anticholinergic side effects limit its use. All drugs that reduce afterload or preload and those that increase contractility must be avoided in patients with hypertrophic cardiomyopathy. Cautious diuretic use for volume-overloaded states is permitted.

Septal reduction therapy (either surgical myectomy or alcohol septal ablation) is reserved for patients who are severely symptomatic despite optimal medical therapy and produces dramatic symptomatic relief. Mortality associated with surgical myectomy is less than 5% overall in experienced centers and less than 1% in patients younger than 40 years. Its complications are rare but include complete heart block, aortic regurgitation, and ventricular septal defect. Myectomy is a highly operator-dependent procedure and should be performed only at medical centers that specialize in this procedure. Alcohol septal ablation complications include complete heart block and ventricular arrhythmias. The long-term outcome of this procedure is unknown.

Dual-chamber pacing is an alternative to septal reduction therapy for occasional patients with hypertrophic cardiomyopathy and severe left ventricular outflow tract obstruction. Dual-chamber pacing can produce a reduction in gradient and symptomatic improvement in

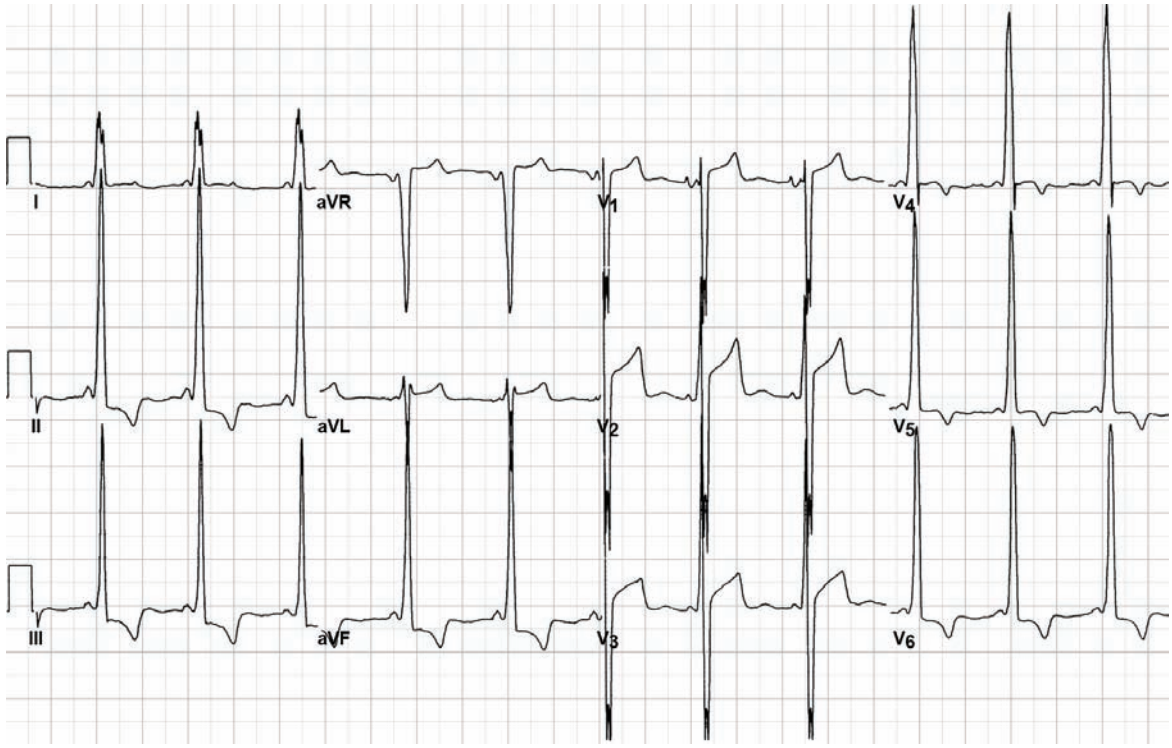

Fig. 3-51. Electrocardiogram in hypertrophic cardiomyopathy, showing marked left ventricular hypertrophy.

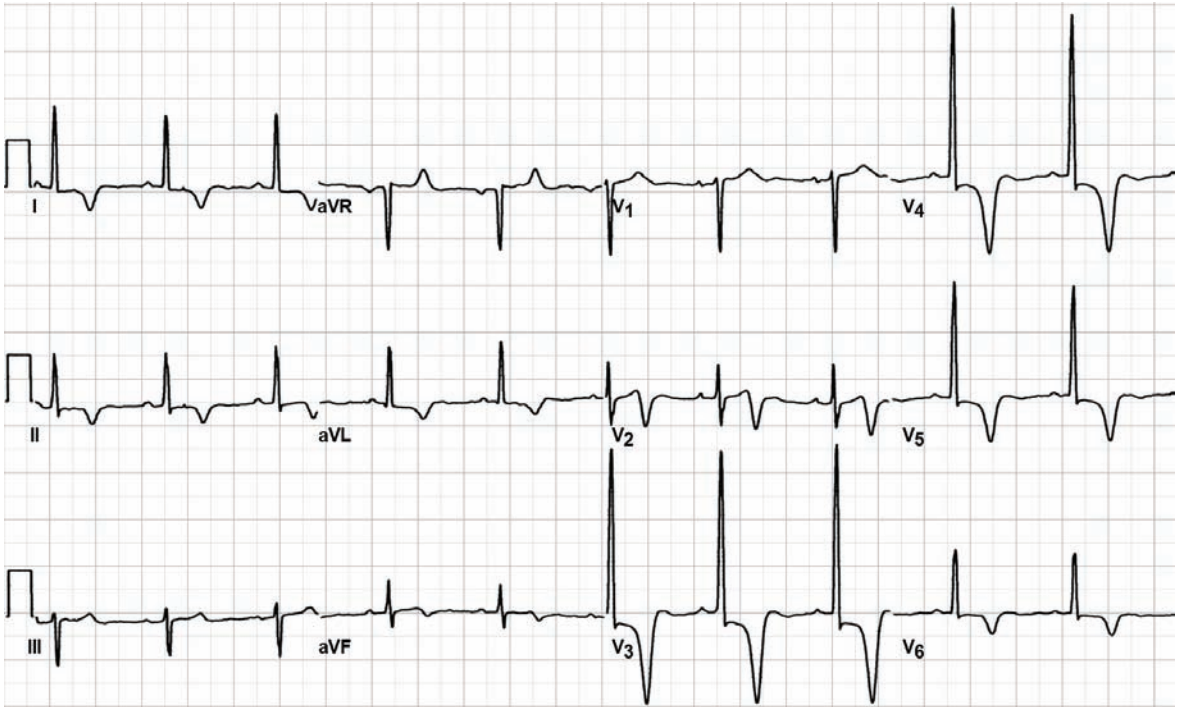

Fig. 3-52. Electrocardiogram in apical hypertrophic cardiomyopathy with deep symmetric T-wave inversions in precordial leads.

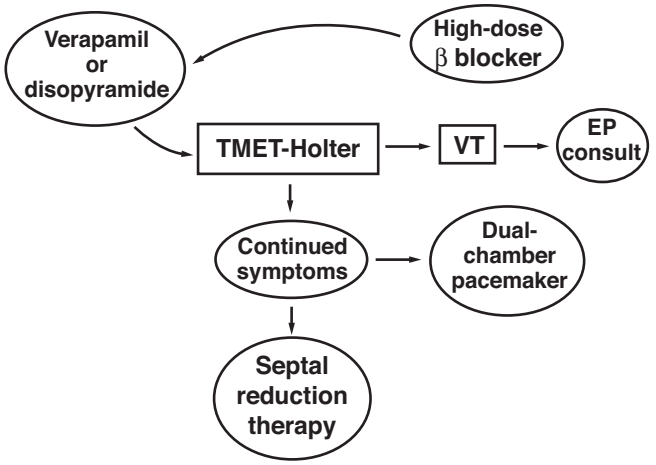

Fig. 3-53. Treatment of symptomatic patients with hypertrophic cardiomyopathy. EP, electrophysiologic; TMET, treadmill exercise test; VT, ventricular tachycardia.

some patients, but this approach is not recommended for all patients with symptomatic hypertrophic obstructive cardiomyopathy.

Asymptomatic Patients

Whether to treat asymptomatic patients with nonsustained ventricular tachycardia is controversial (Fig. 3-54). No antiarrhythmic agent is uniformly effective, and any may make the arrhythmia worse. In selected patients with multiple risk factors for sudden death, empiric amiodarone or an automatic implantable cardiac defibrillator might be chosen. In patients who have already had an out-of-hospital arrest, the treatment of choice is an automatic implantable cardiac defibrillator.

- β-Blockade is the treatment of choice for patients with symptomatic hypertrophic cardiomyopathy.
- Verapamil may cause sudden hemodynamic deterioration in patients with high resting left ventricular outflow tract obstruction because of its vasodilating properties.
- Septal reduction therapy is reserved for severely symptomatic patients unresponsive to medical therapy.
- Dual-chamber pacing is an accepted treatment strategy in rare situations.
- No antiarrhythmic agent is uniformly effective, and any may worsen the arrhythmia.
- Automatic implantable cardiac defibrillator is the treatment of choice for patients with out-of-hospital arrest.

Restrictive Cardiomyopathy

Definition

The primary abnormality in restrictive cardiomyopathy is diastolic dysfunction, usually including abnormal relaxation, high compliance, and ineffectual atrial contribution to filling. Diastolic dysfunction causes abnormal left ventricular filling such that a greater than usual increase in filling pressure is required to fill the ventricle. This is reflected back to the pulmonary and systemic circulations, causing symptoms of shortness of breath and edema. In addition, the ventricle cannot fill adequately to meet its preload requirements, thus resulting in low cardiac output (Starling mechanism), fatigue, and lethargy. Normal or near normal ejection fraction is present in most patients with restrictive cardiomyopathy.

- In restrictive cardiomyopathy, the primary abnormality is diastolic dysfunction.
- Diastolic dysfunction means a greater pressure per unit volume is required to fill the ventricle, causing dyspnea and edema.
- The left ventricle cannot fill to meet its preload requirements, causing low output, fatigue, and lethargy.

The cause of primary restrictive cardiomyopathy is unknown. There are two major categories: idiopathic restrictive cardiomyopathy and endomyocardial fibrosis. In idiopathic restrictive cardiomyopathy, there is progressive fibrosis of the myocardium. Familial cases, often with peripheral myopathy as well, have been reported. Endomyocardial fibrosis is probably an end stage of eosinophilic syndromes in which there is intracavitary thrombus filling of the left ventricle. This restricts filling and causes increased diastolic pressures. This fibrosis also may involve the mitral valve, causing severe mitral regurgitation. There may be two different forms of endomyocardial fibrosis: active inflammatory eosinophilic myocarditis in temperate zones and chronic endomyocardial fibrosis in tropical zones.

Diseases that cause infiltration of the myocardium (such as amyloidosis) have a presentation and pathophysiology similar to those of primary restrictive cardiomyopathy. Signs and symptoms similar to those of restrictive cardiomyopathy also may develop after radiation therapy and anthracycline chemotherapy. Although other infiltrative diseases (sarcoidosis, hemochromatosis) initially may mimic

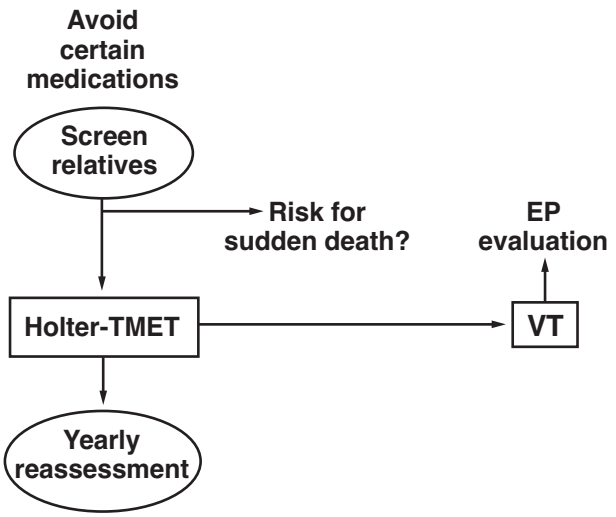

Fig. 3-54. Treatment of asymptomatic patients with hypertrophic cardiomyopathy. Abbreviations as in Figure 3-53.

restrictive cardiomyopathy, they usually have progressed to a dilated cardiomyopathy by the time they cause cardiac symptoms.

- Restrictive cardiomyopathy may be idiopathic or due to infiltrative diseases (amyloidosis).
- Endomyocardial fibrosis is probably an end stage of eosinophilic syndromes.
- Secondary fibrosis may involve the mitral valve, causing severe mitral regurgitation.

Signs and Symptoms

Patients with restrictive cardiomyopathy usually present with edema, dyspnea, ascites, and low output symptoms. Atrial arrhythmias due to passive atrial enlargement are frequently present, and the patient may present with atrial fibrillation. Jugular venous pressure is almost always increased, with rapid X and Y descents. The precordium is quiet, and heart sounds are soft. There may be an apical systolic murmur of mitral regurgitation and a left sternal border murmur of tricuspid regurgitation. A third heart sound may be present. Dullness at the bases of the lungs is consistent with bilateral pleural effusions. ECG is usually low or normal voltage with atrial arrhythmias. Chest radiography shows pleural effusions with normal cardiac silhouette or atrial enlargement.

- Restrictive cardiomyopathy: biventricular failure, dyspnea, edema, and low output symptoms.
- Atrial arrhythmias are frequently present.
- Jugular venous pressure is increased, with rapid X and Y descents.

Diagnosis

Restrictive cardiomyopathy is diagnosed with echocardiography. Typical findings are normal left ventricular cavity size and function and marked enlargement of both atria. If there is right heart failure, the inferior vena cava is enlarged. Echocardiography is usually nonspecific about the cause except in two instances. First, in amyloid heart disease, echocardiography demonstrates thickened myocardium with a scintillating appearance as well as pericardial effusion and thickened regurgitant valves. Second, in endomyocardial fibrosis, there is an apical thrombus (without underlying apical akinesis) or thickening of the endocardium under the mitral valve, which often tethers the valve, causing mitral regurgitation. Cardiac catheterization shows elevation and end-equalization of all end-diastolic pressures. A typical "square-root sign" or "dip-and-plateau" pattern consistent with early rapid filling is present. Endomyocardial biopsy usually is not helpful unless there is a systemic disease that has caused infiltration of the myocardium (i.e., amyloidosis).

- Restrictive cardiomyopathy is diagnosed with echocardiography.
- Typical findings are normal left ventricular cavity size and function and marked enlargement of both atria.
- In amyloid heart disease, thickened myocardium has scintillating appearance, pericardial effusion, valvular regurgitation.
- In endomyocardial fibrosis, there is thrombus in left ventricular apex (without apical akinesis) or posterior mitral leaflet tethering causing mitral regurgitation.

Treatment

There is no medical treatment for idiopathic restrictive cardiomyopathy. Diuretics decrease filling pressures and give symptomatic relief, but this may be at the expense of further decreasing cardiac output. Digoxin usually is not helpful, because systolic contractility is maintained. Heart transplantation is the only proven therapy for patients with severe restrictive cardiomyopathy. Corticosteroids and cytotoxic drugs are appropriate during the early stages of eosinophilic endocarditis. Endomyocardial fibrosis can be surgically resected and the mitral valve can be replaced, although mortality is significant.

- There is no medical treatment for idiopathic restrictive cardiomyopathy.
- Diuretics decrease filling pressures.
- Digoxin usually is not helpful.
- Heart transplantation is the only proven therapy for severe restrictive cardiomyopathy.
- Medical therapy is used for early stages of eosinophilic endocarditis, and operation is used for endomyocardial fibrosis in selected cases.

It is important to differentiate restrictive cardiomyopathy from constrictive pericarditis. Both have similar presentations and findings on clinical examination and diagnostic studies. However, in constrictive pericarditis, pericardiectomy produces symptomatic improvement and, frequently, survival. Therefore, exploratory thoracotomy may be indicated in patients with normal left ventricular systolic function, large atria, and severe increase of diastolic filling pressures if doubt remains after anatomical (cine computed tomography or magnetic resonance imaging) and other tests (echocardiography, cardiac catheterization).

- It is important to differentiate restrictive cardiomyopathy from constrictive pericarditis.
- In constrictive pericarditis, pericardiectomy produces symptomatic improvement and may prolong survival.

Cardiology Pharmacy Review

Narith N. Ou, PharmD, Jeffrey J. Armon, PharmD, Lance J. Oyen, PharmD

Drugs Commonly Used for Cardiac Resuscitation

Drug	Primary use	Toxic/adverse effects	Comments: precautions (P) and contraindications (C)
Adenosine	Narrow complex PSVT	Chest pain, ischemia, bronchoconstriction, increased ICP, VF (infants)	Wide complex tachycardia (P) Drug/poison-induced arrest (C)
Amiodarone	Pulseless VT/VF, stable VT of unknown origin, AF	AV block, hypotension, proarrhythmias	Dose-related hypotension (P) Renal failure (P) Concomitant use of QT-prolonging drugs (e.g., procainamide) (P)
Atropine	Sinus bradycardia, type IIa AVB, asystole	Tachyarrhythmias, ischemia	Hypothermic bradycardia (C) Avoid in advanced infranodal (type II) AVB or new 3rd-degree AVB with wide QRS (C)
β-Adrenergic blockers (atenolol, metoprolol, esmolol)	Myocardial infarction, supraventricular tachycardia	Bronchospasm, hypotension, bradycardia, exacerbation of heart failure	Bradycardia (<60 bpm) or 2nd- or 3rd-degree heart block (C) Poison/drug-induced arrest (C) Concomitant calcium channel blocker (P) Severe reactive airway disease (P) Wolff-Parkinson-White syndrome (P)
Calcium channel antagonists (diltiazem, verapamil)	Supraventricular tachycardia	AV block, hypotension, bradycardia, exacerbation of heart failure	Wolff-Parkinson-White syndrome (C) Ventricular arrhythmia (P) Concomitant use of β-blocker (P)
Catecholamines (dobutamine, dopamine, epinephrine, norepinephrine)	Bradycardia, hypotension (except dobutamine), asystole (epinephrine)	Hypertension, tachycardia, ischemia, arrhythmia, hypotension (dobutamine)	Evolving MI (P) Peripheral administration may cause severe extravasation (P) Use only after volume resuscitation (P) SBP <100 mm Hg and signs of shock (dobutamine) (P)
Digoxin	Supraventricular tachycardia	Proarrhythmia	Hypokalemia, hypercalcemia, or hypomagnesemia (C) Concomitant defibrillation (P) Wolff-Parkinson-White syndrome (P) AV block (P)
Lidocaine	Ventricular tachyarrhythmias	Proarrhythmia, seizures, exacerbation of heart failure	Prophylaxis after MI (C) Liver dysfunction or CHF (P) Evolving myocardial ischemia = more proarrhythmic (P)

Cardiology Pharmacy Review (continued)

Drugs Commonly Used for Cardiac Resuscitation (continued)

Drug	Primary use	Toxic/adverse effects	Comments: precautions (P) and contraindications (C)
Procainamide	Ventricular & supraventricular tachyarrhythmias	Proarrhythmias (torsades de pointes), hypotension, exacerbation of heart failure	Low magnesium or potassium (P) Evolving myocardial ischemia = more proarrhythmic (P) Hypotension: slow infusion important (P) Polymorphic VT (C)
Vasopressin	Pulseless VT/VF, vasodilatory shock	Bradycardia, ?ischemia	Coronary artery disease (P)

AF, atrial fibrillation; AV, atrioventricular; AVB, atrioventricular block; bpm, beats/minute; CHF, congestive heart failure; ICP, intracranial pressure; MI, myocardial infarction; PSVT, paroxysmal supraventricular tachycardia; SBP, systolic blood pressure; VF, ventricular fibrillation; VT, ventricular tachycardia.

Cardiology Pharmacy Review (continued)

Drugs Commonly Used in Cardiology

Drug	Toxic/adverse effects
Aldosterone antagonists (spironolactone, eplerenone)	Serious hyperkalemia if renally impaired, gynecomastia (less with eplerenone)
Angiotensin-converting enzyme inhibitors	Angioedema, renal failure, hypotension, hyperkalemia, hepatitis, neutropenia, cough, rashes, taste disturbance
Angiotensin II receptor antagonists	Rarely angioedema (38% cross-reaction if h/o angiotensin-converting enzyme inhibitor angioedema), hepatitis, headache, dizziness, fatigue
β-Adrenergic blockers	Bronchospasm, hypotension, bradycardia, decompensated heart failure, CNS effects (lipophilic agents > nonlipophilic: depression, psychosis, dizziness, weakness, fatigue, vivid dreams, insomnia), GI effects, reduced peripheral vascular perfusion, impotence, hypo-/hyperglycemia
Calcium channel antagonists	Hypotension, bradycardia (verapamil, diltiazem), worsening of heart failure symptons (verapamil, diltiazem), dizziness, flushing, peripheral edema, constipation, postural hypotension, taste disturbances
Centrally acting agents (clonidine, methyldopa)	Withdrawal hypertension, hypotension, hepatitis (methyldopa), bradycardia (clonidine), frequent CNS effects (depression, sedation), GI effects, sexual dysfunction, xerostomia (clonidine)
Digoxin	Cardiovascular effects (heart block, ectopic arrhythmias, ventricular extra beats, ventricular tachycardia, paroxysmal supraventricular tachycardia), GI effects (anorexia, nausea, vomiting, diarrhea), CNS effects (drowsiness, dizziness, confusion, vision abnormalities, photophobia)
Direct thrombin inhibitors (lepirudin, argatroban, bivalirudin)	Bleeding (no available antidote for reversal), allergic reaction to reexposure and antibody formation (lepirudin)
Hydralazine	Hypotension, hepatitis, neuropathy, flushing, GI effects, LLS
Loop diuretics	Dehydration, hypokalemia, hyponatremia, pancreatitis, jaundice, deafness (high dose), thrombocytopenia, serious skin disorders, dizziness, postural hypotension, gout
Nesiritide (Natrecor)	Dose-related hypotension, headache, renal impairment, increased mortality
Organic nitrates	Syncope, TIAs, headache, flushing, palpitations, peripheral edema
Potassium-sparing diuretics	Hyperkalemia, dehydration, GI effects (nausea, vomiting, diarrhea), CNS effects (headache, weakness), rashes, gynecomastia in men and breast enlargement/soreness in women (spironolactone)
Thiazide diuretics	Dehydration, rarely thrombocytopenia, cholestatic jaundice, pancreatitis, hepatic encephalopathy (in patients with cirrhosis), dizziness, gout, hyperglycemia, orthostasis, hypokalemia, hypermagnesemia, hypercalcemia, GI effects
Warfarin	Abnormal bleeding, rarely necrosis or gangrene of skin and other tissues, purple toe syndrome (cholesterol microembolization), osteoporosis

CNS, central nervous system; GI, gastrointestinal tract; h/o, history of; LLS, lupus-like syndrome; TIA, transient ischemic attack.

Cardiology Pharmacy Review (continued)

Selected Important Cardiac Drug Interactions

Drug	Drug	Net effect and suggested actions
Amiodarone	Digoxin	Amiodarone increases serum digoxin levels Reduce digoxin dose by 25%-50% (monitor digoxin levels)
	Cyclosporine	Amiodarone increases serum cyclosporine Monitor cyclosporine levels
	Dofetilide	Amiodarone must be withdrawn for at least 3 mo or amiodarone level <0.3 mg/mL before initiating dofetilide therapy
	Fosphenytoin or phenytoin	Phenytoin level can increase × 2-3, amiodarone levels may decrease by >30% Monitor amiodarone effectiveness & phenytoin levels
	Procainamide	Amiodarone increases procainamide level; 20% reduction of procainamide dose is suggested Monitor procainamide levels; combination is rarely used
	Quinidine	Amiodarone increases quinidine levels; 50% reduction of quinidine dose is suggested Monitor quinidine levels; rarely used together
	Simvastatin	Amiodarone increases risk of myopathy or rhabdomyolysis with simvastatin. If >20 mg per day of simvastatin required, different agent is recommended
	Warfarin	Amiodarone increases warfarin effect Decrease warfarin dose by 25%-50%; monitor INR
Digoxin	Amiodarone	Amiodarone increases serum digoxin levels Reduce dose of digoxin by 25%-50% (monitor digoxin levels)
	Propafenone	Propafenone increases digoxin levels Empirically reduce digoxin dose; monitor levels and signs of increased digoxin
	Quinidine	Quinidine may increase digoxin levels Monitor ECG and digoxin levels
	Verapamil	Verapamil increases serum digoxin levels Reduction of digoxin dose may be required; monitor digoxin levels & signs of elevated digoxin
Dofetilide	Amiodarone	Torsades de pointes risk Amiodarone must be withdrawn for at least 3 mo or amiodarone level <0.3 mg/mL before initiating dofetilide therapy
	Class I & III antiarrhythmic agents	Torsades de pointes risk Washout period of at least 3 half-lives of other antiarrhythmics before starting dofetilide
	Cimetidine	Cimetidine is contraindicated because increased serum level of dofetilide = torsades de pointes effect
	Hydrochlorothiazide	Hydrochlorothiazide is contraindicated because increased serum level of dofetilide and decreased potassium = risk of torsades de pointes
	Ketoconazole	Ketoconazole is contraindicated because increased serum level of dofetilide = torsades de pointes effect
	Megestrol	Megestrol is contraindicated because increased serum level of dofetilide = torsades de pointes effect
	Prochlorperazine	Prochlorperazine is contraindicated because increased serum level of dofetilide = torsades de pointes effect

Cardiology Pharmacy Review (continued)

Selected Important Cardiac Drug Interactions

Drug	Drug	Net effect and suggested actions
Dofetilide (continued)	Trimethoprim-sulfamethoxazole	Trimethoprim-sulfamethoxazole is contraindicated because increased serum level of dofetilide = torsades de pointes risk
	Trimethoprim	Trimethoprim is contraindicated because increased serum level of dofetilide = torsades de pointes risk
	Verapamil	Verapamil is contraindicated because increased serum level of dofetilide = torsades de pointes risk
	Ziprasidone	Ziprasidone is contraindicated because increased serum level of dofetilide = risk of torsades de pointes
Propafenone	Digoxin	Propafenone increases digoxin levels Empirically reduce digoxin dose; monitor levels & signs of elevated digoxin
	Metoprolol	Propafenone increases metoprolol level 1.5-5 times Monitor cardiac function (especially blood pressure)
	Warfarin	Propafenone increases warfarin effect by 25% Monitor INR when adding/withdrawing propafenone
Warfarin	Amiodarone	Amiodarone increases warfarin effect Decrease warfarin dose by 25%-50% & monitor INR
	Cholestyramine	Cholestyramine decreases effectiveness of warfarin Use colestipol as alternative
	Cyclooxygenase-2 inhibitors (celecoxib [Celebrex], rofecoxib [Vioxx])	These inhibitors increase INR (monitor INR closely)
	Propafenone	Propafenone increases warfarin effect by 25% Monitor INR when adding/withdrawing propafenone
	Glycoprotein IIb/IIIa inhibitors (abciximab [ReoPro], eptifibatide [Integrilin], tirofiban [Aggrastat])	These inhibitors increase hemorrhagic risk (use with caution) Abciximab contraindicated if PT>1.2 × control
	Thrombolytics	Thrombolytics increase hemorrhagic risk (use with caution) Alteplase contraindicated if PT>15 s

ECG, electrocardiogram; INR, international normalized ratio; PT, prothrombin time.

Critical Care Medicine

Steve G. Peters, MD

Critical care medicine encompasses multidisciplinary aspects of the management of severely ill patients. All areas of medicine may have relevance for critically ill patients, but this review focuses on aspects of cardiopulmonary monitoring and life support, technologic interventions, and disease states typically managed in the intensive care unit (ICU).

Respiratory Failure

Effective functioning of the respiratory system requires normal central nervous system control, neuromuscular transmission and bellows function, and gas exchange at the alveolar-capillary level. Respiratory failure may result from disease at any of these levels.

Physiologic Definitions and Relationships

Lung Volumes

"Total lung capacity" (TLC) is the total volume of gas in the chest at the end of a maximal inspiration. "Vital capacity" (VC) is the volume of a maximal breath (expired or inspired). "Tidal volume" (V_T) is the volume of a normal breath. "Functional residual capacity" (FRC) is the lung volume at the end of a normal expiration. FRC reflects the relaxation point of the respiratory system, which is the point at which outward recoil of the chest wall is balanced by inward recoil of the lungs.

Compliance and Resistance

"Compliance" (C) of the lungs or respiratory system is defined by the change in volume (ΔV) for a given change in pressure (ΔP):

$$C_{STATIC} = \frac{\Delta V}{\Delta P}$$

where ΔV is measured in liters (L) and ΔP in centimeters of water (cm H_2O). Compliance is considered a static measurement because it is a characteristic of the lungs, independent of airflow. Normal compliance is approximately 0.2 L/cm H_2O. Emphysema causes the loss of recoil and, thus, increased compliance. Most other disease states, particularly interstitial diseases, fibrosis, pulmonary edema, and acute respiratory distress syndrome (ARDS), cause decreased compliance (i.e., "stiff" lungs, or increased transpulmonary pressure for a given volume change).

- Normal compliance is approximately 0.2 L/cm H_2O.
- Emphysema causes the loss of recoil and increased compliance.
- Interstitial diseases, fibrosis, pulmonary edema, and ARDS cause decreased compliance.

Resistance (R) to airflow is defined by the change in pressure (ΔP) for a given change in flow ($\Delta \dot{V}$):

$$R = \frac{\Delta P}{\Delta \dot{V}}$$

where ΔP is measured in cm H_2O and $\Delta \dot{V}$ in L/s. Common causes of increased airway resistance include bronchospasm and airway secretions.

- Common causes of increased airway resistance are bronchospasm and airway secretions.

The total pressure required to inflate the respiratory system (spontaneously or with a mechanical ventilator) is the pressure required to overcome elastic recoil (due primarily to the lungs and chest wall) plus the pressure to overcome flow resistance (due primarily to the airways and endotracheal tube):

$$P_{inflation} = \underbrace{\frac{\Delta V}{C_{STATIC}}}_{\text{(Elastic Load)}} + \underbrace{R \times \Delta \dot{V}}_{\text{(Resistive Load)}}$$

Evaluation of Hypoxia

Gas exchange requires alveolar ventilation for the elimination of carbon dioxide, oxygen uptake across the alveolar-capillary membrane, and the delivery of oxygen to tissues. Hypoxemia may result from

1) a decrease in the inspired partial pressure of oxygen (e.g., high altitude, including air travel), 2) hypoventilation, 3) ventilation-perfusion ($\dot{V}/Q$) mismatch, 4) shunting, or 5) a diffusion barrier. Estimation of the alveolar-arterial (A-a) gradient for oxygen is essential in analyzing the cause of hypoxemia. Important relationships include the following:

The partial pressure of carbon dioxide ($PaCO_2$) in the blood is directly proportional to the amount of carbon dioxide produced ($\dot{V}CO_2$) and inversely proportional to alveolar ventilation ($\dot{V}A$):

$$PaCO_2 = k \frac{\dot{V}CO_2}{\dot{V}A}$$

Alveolar ventilation is equal to total ventilation ($\dot{V}E$) minus dead space ventilation ($\dot{V}D$). Thus, physiologic dead space is defined by the portion of a breath that does not participate in gas exchange. Dead space volume ($\dot{V}D$) may be anatomical (conducting airways) or alveolar (areas of ventilation that receive no perfusion):

$$\dot{V}A = \dot{V}E - (VD \times f)$$

where f = breaths/min.

Calculation of Dead Space Ventilation

$$\frac{VD}{VT} + \frac{PaCO_2 - P_ECO_2}{PaCO_2}$$

(Bohr equation)

$\frac{VD}{VT}$ normally is <0.25 to 0.30

where P_ECO_2 is the partial pressure of expired carbon dioxide. The ratio of dead space to tidal volume is calculated by measuring the partial pressure of carbon dioxide in an arterial blood gas sample ($PaCO_2$) and an expired gas sample (P_ECO_2). The greater the dead space, the greater the difference between $PaCO_2$ and P_ECO_2.

- Physiologic dead space is defined by the portion of breath not participating in gas exchange.
- Increased dead space leads to decreased elimination of carbon dioxide at any given level of total minute ventilation.

Calculation of PAO_2

Alveolar gas consists of inspired gases saturated with water vapor. The alveolus also contains carbon dioxide delivered from the blood. The sum of the partial pressures of all gases present equals the ambient barometric pressure. The alveolar air equation defines this relationship:

$$PAO_2 = FIO_2 (PB - PH_2O) - \frac{PaCO_2}{R}$$

where PA is alveolar partial pressure, FIO_2 is fraction of inspired oxygen, PB is barometric pressure (about 760 mm Hg at sea level), PH_2O is water vapor pressure (47 mm Hg), and R is the respiratory quotient ($\dot{V}CO_2/\dot{V}O_2$, normally about 0.8). The simplified equation is

$$PAO_2 = FIO_2 (PB - 47) - \frac{PaCO_2}{0.8}$$

When room air ($FIO_2 = 0.21$) is breathed at sea level

$$PAO_2 = 150 - \frac{40}{0.8}$$

or normal PAO_2 is approximately equal to 100 mm Hg.

The A-a Gradient

The A-a oxygen difference is defined by PAO_2 minus PaO_2, which is normally less than 10 to 20 mm Hg when room air is breathed. The A-a gradient normally increases to approximately 50 to 100 mm Hg as the FIO_2 increases from 0.21 to 1.0, and it also increases slightly with age. Hypoxemia due to hypoventilation is characterized by increased $PaCO_2$ and decreased PaO_2 but by a relatively normal A-a gradient. Hypoxemia due to ventilation-perfusion mismatch shows an increased A-a gradient.

- Hypoxemia due to hypoventilation: increased $PaCO_2$, decreased PaO_2, normal A-a gradient.

Shunt Fraction and the Fick Equation

A shunt is defined by perfusion (Q) in the absence of ventilation ($\dot{V}$) (i.e., $\dot{V}/Q = 0$). With a pure shunt, PaO_2 does not increase even though FIO_2 is increased to 100%. Normal shunt fraction is less than 3% to 5% of total cardiac output. The shunt fraction is measured with the person breathing 100% oxygen and is expressed as follows:

$$\frac{Qs}{Qt} = \frac{CC'O_2 - CaO_2}{CC'O_2 - C\bar{V}O_2} = \frac{P(A\text{-}a)O_2 \times 0.003}{P(A\text{-}a)O_2 \times 0.003 + (Ca - C\bar{V})O_2}$$

where Qs is the portion of cardiac output shunted, Qt is the total cardiac output, $CC'O_2$ is capillary oxygen content, CaO_2 is arterial oxygen content, and $C\bar{V}O_2$ is venous oxygen content.

The content of oxygen in the blood is the total amount of oxygen bound to hemoglobin (Hgb) plus the amount dissolved.

$$O_2 \text{ content: } CxO_2 = \underset{\text{(Bound)}}{(1.34 \times Hgb \times S_xO_2)} + \underset{\text{(Dissolved)}}{(0.003 \times P_xO_2)}$$

where x may be arterial, venous, or capillary.

Under steady state conditions, the amount of oxygen used by the tissues equals the amount taken up by the lungs. The oxygen uptake, $\dot{V}O_2$, can be defined by the amount of oxygen leaving the lungs in pulmonary venous blood minus the amount of oxygen

coming into the lungs in the pulmonary arteries. This should be familiar as the Fick equation:

$$\dot{V}O_2 = CO\ (CaO_2 - C\bar{v}O_2)$$

where CO is cardiac output.

- A shunt is defined by perfusion in the absence of ventilation, i.e., $\frac{\text{Ventilation}}{\text{Perfusion}} = 0$.
- The normal shunt fraction is <3%-5% of total cardiac output.
- A shunt leads to hypoxemia that shows little improvement after supplemental oxygen.

Mixed Venous Oxygen Saturation

Many applications of the Fick equation are important in managing critically ill patients. One application involves continuous monitoring of mixed venous oxygen saturation by a specialized type of pulmonary artery catheter. Expressing oxygen content in terms of saturation and rearranging the Fick equation to solve for $S\bar{v}O_2$ yields the following:

$$S\bar{v}O_2 = SaO_2 - \frac{\dot{V}O_2}{CO \times Hgb \times 1.34}$$

where SaO_2 is arterial saturation, CO is cardiac output, and Hgb is hemoglobin.

Note that decreased mixed venous oxygen saturation may be due to decreased arterial saturation, increased oxygen consumption, decreased cardiac output, or decreased hemoglobin. Certain disease states, particularly early sepsis, may be characterized by normal or increased mixed venous oxygen saturation because cardiac output initially increases along with impaired oxygen uptake by the tissues. Later in sepsis, mixed venous $S\bar{v}O_2$ typically decreases because of decreased oxygen delivery.

- Decreased mixed venous oxygen may be due to decreased arterial saturation, increased oxygen consumption, decreased cardiac output, or decreased hemoglobin.
- Early sepsis: normal or increased mixed venous oxygen saturation.

Oxygen Delivery

Under normal circumstances, oxygen demand by the tissues is met by the supply. Oxygen delivery is defined by cardiac output (CO) times arterial oxygen content (CaO_2):

$$O_2 \text{ delivery} = CO \times CaO_2$$

Although cardiac output may decrease, $\dot{V}O_2$ of the tissues may be maintained by increased oxygen extraction.

- Oxygen delivery = cardiac output × arterial oxygen content.

Acid-Base Balance and Arterial Blood Gases

The production of acid byproducts is the normal result of cellular metabolism. An acid is defined as a hydrogen ion (H^+) or proton donor. A base (A^-) accepts protons. The dissociation constant (K) for an acid (HA) may be defined as

$$K = \frac{[H^+][A^-]}{[HA]}$$

Buffer systems minimize the changes in pH associated with the addition of acid or base. For carbonic acid:

$$H_2O + CO_2 \leftrightarrow H_2CO_3 \overset{K}{\leftrightarrow} H^+ + HCO_3^-$$

$$\text{and } K = \frac{[H^+][HCO_3^-]}{[H_2CO_3]}$$

This relationship gives the Henderson-Hasselbalch equation:

$$pH = pK + \log \frac{[HCO_3^-]}{[H_2CO_3]}$$

where $pH = -\log [H^+]$ and $pK = -\log K$. The pK for carbonic acid is 6.1. $[H_2CO_3]$ is often measured by taking $0.03 \times PaCO_2$ (i.e., dissolved carbon dioxide). So the Henderson-Hasselbalch equation can be rewritten as

$$pH = 6.1 + \log \frac{[HCO_3^-]}{0.03 \times PaCO_2}$$

Hydrogen ions are buffered by several mechanisms in different body fluid compartments. In plasma and interstitial fluid, bicarbonate is the major buffer, with proteins and phosphate compounds contributing to a lesser extent. In erythrocytes, hemoglobin is the major buffer, but bicarbonate contributes approximately 30% and phosphate 10% of the buffering capacity. The kidney eliminates organic acid and also contributes by 1) reabsorbing bicarbonate from tubular fluids, 2) forming titratable acid, and 3) eliminating hydrogen ions as ammonium ions.

- Bicarbonate is the major buffer in plasma and interstitial fluid.
- In erythrocytes, hemoglobin is the major buffer.
- The kidney eliminates organic acid and reabsorbs bicarbonate from tubular fluids.

Given the importance of the carbonic acid–bicarbonate system, many acid-base problems involve some method for solving variables of the Henderson-Hasselbalch equation. Because pK is constant, if only two of the three values for pH, PCO_2, and HCO_3^- are known,

the missing variable can be calculated. Graphic displays are commonly used; two of the variables are plotted as constant values for the third variable (e.g., the Davenport diagram).

Patterns of Acid-Base Disorders

Common acid-base disorders and associated clinical scenarios are listed in Table 4-1.

Respiratory Acidosis

Acute respiratory acidosis is defined by the rapid development of carbon dioxide retention ($PaCO_2$ >45 mm Hg) with a concomitant decrease in pH (<7.35). Common causes include respiratory depression by drugs such as narcotics, central nervous system injury, acute diaphragm or neuromuscular weakness, severe parenchymal respiratory failure, and cardiac failure. Because carbon dioxide diffuses quickly into cells and the cerebrospinal fluid, the physiologic effects of acidosis may occur rapidly. Confusion, obtundation, and signs of cerebral edema are commonly observed. Chronic respiratory acidosis typically occurs in patients with severe chronic obstructive pulmonary disease (COPD), particularly chronic bronchitis or bronchiectasis, and in other states associated with chronic alveolar hypoventilation. Chronic respiratory acidosis may be compensated partly by renal mechanisms, that is, increased reabsorption of bicarbonate and excretion of acid in the urine.

- Acute respiratory acidosis: rapid onset of carbon dioxide retention with concomitant decrease in pH.
- Chronic respiratory acidosis typically occurs in patients with severe COPD or in other states associated with chronic alveolar hypoventilation.

Table 4-1 Common Acid-Base Disorders and Associated Clinical Scenarios

Acid-base disorder	Typical clinical scenario
Respiratory acidosis	Severe COPD, narcotic ingestion
Respiratory alkalosis	Pulmonary embolism, anxiety
Normal anion gap metabolic acidosis	Diarrhea, renal tubular acidosis
Increased anion gap metabolic acidosis	Diabetic ketoacidosis, lactic acidosis, uremia
Metabolic alkalosis	Vomiting
Respiratory and metabolic acidosis	Severe shock
Respiratory acidosis and metabolic alkalosis	COPD being treated with diuretics or corticosteroids
Metabolic acidosis and respiratory alkalosis	Sepsis, salicylate overdose
Metabolic alkalosis and respiratory alkalosis	Mechanical ventilation in a patient with metabolic alkalosis

COPD, chronic obstructive pulmonary disease.

Respiratory Alkalosis

Acute respiratory alkalosis is the result of a rapid decrease in $PaCO_2$ due to hyperventilation. Hyperventilation usually is associated with anxiety or pain. Important causes also include early shock states, pulmonary embolism, other causes of hypoxemia, hyperthermia, salicylate intoxication, liver failure, and disorders of the central nervous system. Patients with unexplained hypocapnia should be evaluated for these disorders. In mechanically ventilated patients, respiratory alkalosis may result from inadvertent overventilation, that is, excessive tidal volume or respiratory rate (or both), especially in a volume preset assist-control ventilator mode.

- Respiratory alkalosis is the result of alveolar hyperventilation.
- Common causes include anxiety, pain, shock, pulmonary embolism, hypoxemia, fever, salicylate overdose, liver failure, and mechanical overventilation.

Metabolic Acidosis

Metabolic acidosis results from the accumulation of organic acids such as lactate, pyruvate, or keto acids. Acidosis may develop by increased acid production or decreased renal excretion of acid. Conditions causing metabolic acidosis are further characterized by the anion gap, that is,

$$[Na^+] - ([Cl^-] + [HCO_3^-])$$

with a normal value of 8 to 14 mEq/L.

A normal anion gap or non–anion gap acidosis is characterized by an increase in chloride balancing the loss of bicarbonate. Causes include gastrointestinal tract losses of bicarbonate (diarrhea), urinary diversion procedures, and intestinal fistulas. Renal losses of bicarbonate (renal tubular acidosis) are also associated with a normal anion gap. Causes of acidosis associated with other anions—increased anion gap disorders—are diabetic ketoacidosis, lactic acidosis, uremia, and toxins (e.g., ethylene glycol, methanol, paraldehyde, and salicylate).

The "delta gap" is a useful calculation that assists in defining the presence of a complicated anion gap metabolic acidosis. It is defined as follows:

Delta gap = (deviation of anion gap from normal) – (deviation of bicarbonate from normal)

In uncomplicated anion gap metabolic acidosis, the expected delta gap is 0 (±6).

A positive delta gap would be due to the presence of a concomitant metabolic alkalosis or (chronic) respiratory acidosis. A negative delta gap would be due to a concomitant non–anion gap metabolic acidosis or (chronic) respiratory alkalosis.

- Metabolic acidosis: result of accumulation of organic acids, e.g., lactate, pyruvate, and keto acids.
- Normal anion gap or non–anion gap acidosis is characterized by an increase in chloride balancing the loss of bicarbonate (diarrhea and renal tubular acidosis).
- Increased anion gap disorders: diabetic ketoacidosis, lactic acidosis, uremia, toxins (e.g., ethylene glycol, methanol, paraldehyde, and salicylate).

- An abnormal "delta gap" reveals the presence of a complicated anion gap metabolic acidosis.

Metabolic Alkalosis

Primary metabolic alkalosis is characterized by increased bicarbonate and pH. Hypokalemia and hypochloremia are commonly associated and further perpetuate the alkalosis. Common causes are volume contraction states, particularly those associated with the loss of chloride and hydrogen ion (e.g., vomiting and nasogastric suctioning). Diuretic therapy and mineralocorticoids are also common contributing factors. Although respiratory compensation (hypoventilation) for metabolic alkalosis might seem counterproductive, it can occur and may contribute to hypoxemia. As with other acid-base disorders, therapy is directed at the underlying cause, but support with volume and potassium and chloride replacement are important.

- Primary metabolic alkalosis is characterized by increased bicarbonate and pH.
- Hypokalemia and hypochloremia are commonly associated and further perpetuate alkalosis.
- Common causes are volume contraction states, particularly those associated with further loss of chloride and hydrogen ion (e.g., vomiting and nasogastric suctioning).

Mixed Acid-Base Disorders

Mixed disorders are characterized by a combination of the primary abnormalities described above or by a primary disorder and compensatory changes in $PaCO_2$ or bicarbonate. For example, combined respiratory and metabolic acidosis may occur in patients with depressed respiration and tissue hypoperfusion, as would occur with severe shock, after cardiorespiratory arrest, or with status epilepticus. In these situations, pH is severely depressed and immediate therapy is necessary. Treatment includes assisted ventilation plus measures to improve cardiac output and organ perfusion. Sodium bicarbonate might be given for severe acidemia (pH <7.0-7.1), but treatment must be directed at the underlying cause of the primary disorder.

- Combined respiratory and metabolic acidosis leads to severe acidemia.
- Treatment should be directed at the underlying disorder.

Respiratory acidosis and metabolic alkalosis typically occur in patients with COPD or chronic alveolar hypoventilation. Secondary bicarbonate retention may be augmented by concomitant corticosteroid therapy or diuretics. Because a given blood gas measurement showing increased $PaCO_2$ and increased bicarbonate (with pH near 7.4) could occur by many mechanisms, the clinical history is essential for determining the most likely pathophysiologic mechanism. If patients with chronic hypercarbia are mechanically ventilated, there is a risk of severe alkalemia if the ventilator settings are adjusted to "normalize" the $PaCO_2$ at approximately 40 mm Hg without recognizing the chronic compensatory nature of the increase in bicarbonate.

- Respiratory acidosis plus metabolic alkalosis is seen most commonly in patients who have chronic respiratory insufficiency plus bicarbonate retention.

Metabolic acidosis and respiratory alkalosis may occur in patients who have tissue hypoperfusion and respiratory stimulation, as is commonly seen with early shock states, sepsis, and liver or renal failure. This pattern is also typical of salicylate intoxication.

- The combination of metabolic acidosis and respiratory alkalosis is commonly seen in shock states, sepsis, or salicylate overdose.

Metabolic alkalosis and respiratory alkalosis rarely occur in spontaneously breathing patients but can develop quickly with mechanical ventilation. This usually is the result of a disorder that causes respiratory alkalosis, as described above, combined with a metabolic alkalosis induced by volume contraction, gastric suctioning, hypokalemia, diuretics, or corticosteroids. Seizures or cardiac arrhythmias or both may result from severe alkalemia. Treatment usually requires replacement of volume, potassium, and chloride.

Clinical Approach to Arterial Blood Gases

Problems of acid-base balance and gas exchange can be assessed in several ways. When interpreting arterial blood gases, the following approach is useful:

1. Consider the pH. Are conditions normal (pH 7.35-7.45), acidemic (<7.35), or alkalemic (>7.45)?
2. Assess $PaCO_2$. Does the $PaCO_2$ change (from 40 mm Hg) account for the pH change (from 7.40)? The evaluation of this relation requires calculation, graphic display, or a rule of thumb such as the following: an acute change in $PaCO_2$ of 10 mm Hg should be associated with a pH change in the opposite direction of approximately 0.08 unit. If an abnormal pH can thus be accounted for by the change in $PaCO_2$, a simple acute respiratory disturbance is present. If not, a mixed acid-base disorder is present.
3. The change in bicarbonate will confirm whether a metabolic disturbance is present. That is, base deficit or excess should confirm the conditions already defined by pH and $PaCO_2$. Is the anion gap increased? If an anion gap is present, is the delta gap appropriate?
4. Consider PaO_2. If hypoxemia is present, estimate the A-a gradient. If this is normal and $PaCO_2$ is increased, hypoventilation alone should account for the hypoxemia. The A-a gradient should be increased in conditions of ventilation-perfusion mismatching, shunting, or diffusion barrier.
5. Compare the PaO_2 and the arterial saturation, SaO_2. The SaO_2 should correspond to the expected values for a normal oxygen-hemoglobin dissociation curve. If saturation is lower than expected, consider the presence of other hemoglobin forms, for example, carboxyhemoglobin or methemoglobin. As examples, use the above approach to match the following arterial blood gas values with the clinical scenarios listed below:

	pH	$PaCO_2$	HCO_3^-	PaO_2 (room air)	SaO_2
A.	7.35	60	32	50	85%
B.	7.50	46	34	85	94%
C.	7.18	70	26	55	89%
D.	7.28	31	15	110	99%
E.	7.38	30	18	105	75%

1. 20-year-old woman with diabetic ketoacidosis
2. 20-year-old man with acute narcotic overdose
3. 60-year-old man 1 week after an abdominal operation, with continuous nasogastric suction and diuretic therapy
4. 60-year-old woman with severe emphysema
5. 60-year-old man with carbon monoxide intoxication

(Answers: 1. D, 2. C, 3. B, 4. A, 5. E)

- Consider the pH.
- Assess $PaCO_2$.
- The change in bicarbonate should confirm the conditions already defined by pH and $PaCO_2$.
- Consider PaO_2 and the A-a gradient.

Airway Management

Endotracheal intubation allows control of the airway, enables the delivery of specific inspired oxygen and positive pressure ventilation, and provides protection from aspiration. Indications for intubation include airway protection in cases of obstruction or loss of normal gag and cough reflexes, central nervous system injury or sedation with loss of normal control of ventilation, and any cause of respiratory failure requiring positive pressure–assisted ventilation. Oral-tracheal intubation is usually achieved through direct visualization with a laryngoscope. In experienced hands, this procedure should be relatively quick and safe. Complications may include vomiting and aspiration, hypoxemia during the procedure, and inadvertent intubation of the esophagus. The major contraindication for laryngoscopic intubation is an unstable cervical spine (due to trauma or degenerative conditions such as rheumatoid arthritis). In such cases, fiberoptic intubation (passing a tube over a bronchoscope) or tracheostomy may be necessary. In semiconscious and spontaneously breathing patients, nasotracheal intubation may be accomplished "blindly" and may be more comfortable for patients. Complications include bleeding, obstruction of sinus drainage with sinusitis, and damage to nasal structures.

- Endotracheal intubation allows control of the airway.
- Contraindication: unstable cervical spine (trauma or rheumatoid arthritis).
- In semiconscious, spontaneously breathing patients, nasotracheal intubation may be an alternative.

In emergency situations in which airway control is required, cricothyrotomy may be lifesaving. This procedure involves identifying and puncturing the cricothyroid membrane. For patients who require prolonged mechanical ventilation or airway support, the timing of tracheostomy is controversial. The use of high-volume, low-pressure endotracheal tube cuffs has decreased the frequency of tracheal injury and stenosis caused by prolonged intubation. Tracheostomy has the advantages of decreased laryngeal injury, increased patient comfort, ease of suctioning, and, in certain patients, allowance for oral ingestion and speech. Complications may include tracheal injury and stenosis, bleeding, tracheoesophageal fistula, and possibly increased bronchial or pulmonary infections. Tracheostomy is commonly considered for patients who have needed or are expected to need intubation and mechanical ventilation for more than 2 to 4 weeks.

- In emergency situations, cricothyrotomy may be lifesaving.
- High-volume, low-pressure endotracheal tube cuffs have decreased the frequency of tracheal injury and stenosis.
- Tracheostomy is considered for patients who have needed or are expected to need intubation and mechanical ventilation for >2 to 4 weeks.

Mechanical Ventilation

Mechanical ventilation may be valuable in various conditions of respiratory failure, including loss of respiratory control, neuromuscular or respiratory pump failure, and disorders of gas exchange. Many specific variables that have been suggested as criteria (or general guidelines) for ventilator support are listed in Table 4-2.

Complications of Mechanical Ventilation

Complications of mechanical ventilation may be related to airway access, physiologic responses to positive pressure, and complications related to other organ systems. Examples are given in Table 4-3.

Other complications, such as pulmonary embolism or malnutrition, may also reflect the underlying disease state. Management of these complications requires ongoing surveillance and recognition. Pneumonia may be difficult to diagnose in patients who are receiving mechanical ventilation because pulmonary infiltrates are frequently present, tracheal secretions may be colonized by bacteria, and signs such as fever and leukocytosis are frequently blunted. In this setting, quantitative cultures of secretions obtained from bronchoalveolar lavage or protected specimen brush may aid in the diagnosis of ventilator-associated pneumonia. Prophylaxis is commonly given to reduce stress-related gastritis and ulceration. The hemodynamic complications of increased intrathoracic pressure may be overcome with the administration of fluid; however, there is often a coexisting condition of capillary leak and pulmonary edema that may worsen.

- Pneumonia may be difficult to diagnose in patients receiving mechanical ventilation.
- Prophylaxis is commonly given to reduce stress-related gastritis and ulceration.

An important and occasionally subtle complication of positive pressure ventilation is called "intrinsic positive end-expiratory pressure" (PEEP), "auto-PEEP," "breath-stacking," or "dynamic hyperinflation." This refers to a phenomenon of inadequate time during the expiratory phase of the respiratory cycle so that a mechanically assisted breath is delivered before passive expiration of the lungs is complete. Thus, a new machine breath is delivered before the previous breath is completely exhaled. This may worsen hyperinflation, increase intrathoracic pressure, reduce venous return, and worsen the associated

Table 4-2 Criteria for Ventilator Support

Respiratory rate >30/min
Minute ventilation >10 L/min
Maximal inspiratory pressure < –20 cm H_2O
Vital capacity <10 mL/kg
PaO_2 <60 mm Hg with FIO_2 >0.60
PaO_2/FIO_2 <100-150
$P(A\text{-}a)O_2$ >300 mm Hg with FIO_2 = 1.0
V_D/V_T >0.60
$PaCO_2$ >50 mm Hg

complications (e.g., barotrauma), especially in patients with airway obstruction. Intrinsic PEEP may exist in spontaneously breathing patients with obstructive airway disease, but the effect is most important in mechanically ventilated patients. Treatment typically involves optimizing bronchodilator therapy and altering the ventilator cycle to allow maximal expiratory time.

Pulmonary oxygen toxicity appears to be the result of direct exposure to high tensions of inspired oxygen or alveolar oxygen. For adults, oxygen toxicity is not believed to be a major clinical concern below an FIO_2 of 0.40 to 0.50. Higher levels of inspired oxygen may be associated with acute tracheobronchitis (most likely an irritant effect). After several days of exposure, a syndrome of diffuse alveolar damage and lung injury may develop. The pathologic features may resemble those of ARDS.

- Pulmonary oxygen toxicity is the result of direct exposure to high tensions of inspired oxygen or alveolar oxygen.
- A syndrome of diffuse alveolar damage and lung injury may develop.

Modes of Mechanical Ventilation

"Modes of mechanical ventilation" refers to the pattern of cycling of the machine breath and its relation to the spontaneous breaths of the patient, for example, assist/control mode, intermittent mandatory ventilation, and pressure support ventilation. "Volume preset assist/control mode" is defined by a machine-assisted breath for every inspiratory effort by the patient. If no spontaneous breaths occur during a preset time interval, a controlled breath of predetermined tidal volume is delivered by the ventilator. The backup rate determines the minimum minute ventilation the patient will receive. The advantage of assist/control mode ventilation is that it should allow maximal rest for the patient and maximal control of ventilation. The disadvantage is that hyperventilation or air trapping (or both) can occur in patients making rapid inspiratory efforts.

"Volume preset intermittent mandatory ventilation" (IMV) allows a preset number of machine-assisted breaths of a given tidal volume. Between machine breaths, patients may breathe spontaneously. The IMV mode was developed as a mode for weaning patients from the ventilator so that the number of mechanical breaths could be decreased gradually, allowing for increasing spontaneous ventilation. However, recent trials suggest that this mode of weaning is inferior to weaning via T-piece trials or pressure support ventilation.

- Assist/control mode ventilation: machine-assisted breath for every inspiratory effort by the patient (a mandatory minimal frequency is set).
- Assist/control mode advantage: allows maximal rest for the patient and maximal control of ventilation.
- Assist/control mode disadvantage: hyperventilation or air trapping or both occur in patients making rapid inspiratory efforts.
- IMV: allows a preset number of machine-assisted breaths of a given tidal volume.
- Between machine breaths, patients may breathe spontaneously.
- IMV is not superior to other weaning techniques (T-piece trials or pressure support).

"Pressure support ventilation" may be used to assist spontaneously breathing patients, with or without IMV breaths. In this technique, for each inspiratory effort by the patient, the ventilator delivers a high rate of flow of inspired gas, up to a preset pressure limit. This pressure support occurs only during the spontaneous inspiratory effort, so that the rate and pattern of respiration are determined by the patient.

- With pressure support ventilation, for each inspiratory effort of the patient, the ventilator delivers a high flow of inspired gas, up to a preset pressure limit.

Use of PEEP in Mechanical Ventilation

PEEP is intended to increase functional residual capacity, recruit partially collapsed alveoli, improve lung compliance, and improve ventilation-perfusion matching. An adverse effect of PEEP is an excessive increase in intrathoracic pressure with decreased cardiac output. Overdistention of lung units may also worsen gas exchange because of ventilator-induced lung injury. At levels of PEEP greater than 10 to 15 cm H_2O, barotrauma is of particular concern. The optimal, or best, PEEP may be defined as the lowest level of PEEP needed to achieve satisfactory oxygen delivery at a nontoxic FIO_2.

Table 4-3 Complications of Mechanical Ventilation

Airway injury, bleeding, infection
Ventilator malfunction—leaks, power loss, incorrect settings, or alarm failures
Barotrauma; pneumothorax; interstitial, subcutaneous, or mediastinal air
Decreased right ventricular filling, increased right ventricular afterload, decreased cardiac output, hypotension
Gastrointestinal tract bleeding, stress gastritis, ulceration
Decreased urine output
Alteration in intracranial pressure

- PEEP: to increase functional residual capacity, recruit partially collapsed alveoli, improve lung compliance, and improve ventilation-perfusion matching.
- Adverse effect of PEEP: excessive increase in intrathoracic pressure with decreased cardiac output.
- Overdistention of lung units may also worsen ventilation-perfusion matching and gas exchange.
- Optimal, or best, PEEP: lowest level of PEEP needed to achieve satisfactory oxygenation at a nontoxic FIO_2.

Acute Respiratory Distress Syndrome

Diffuse lung injury with acute hypoxic respiratory failure may result from various injuries. Acute lung injury is a frequent primary cause of critical illness and may occur as a complication or a coexisting feature of multisystem disease. "ARDS" is commonly defined as diffuse acute lung injury with the following major features: diffuse pulmonary infiltrates, severe hypoxemia due to shunting and ventilation-perfusion mismatch, and normal or low pulmonary capillary wedge pressure (i.e., noncardiogenic pulmonary edema). Criteria for the diagnosis of ARDS are listed in Table 4-4. Mortality from all causes averages about 50%. For nearly 30 years after this syndrome was described, no single therapy was shown to alter outcome, although gradual improvement in overall mortality was attributed to multidisciplinary ICU management. Recently, prospective, controlled trials have found that a strategy of mechanical ventilation with reduced tidal volumes is associated with improved survival (discussed below).

- Diffuse lung injury with hypoxic respiratory failure may result from various injuries.
- Mortality from all causes averages approximately 50%.

ARDS Etiology, Pathophysiology, and Prognosis

ARDS was described initially as a post-traumatic or shock-induced injury, but it occurs with various states, as outlined in Table 4-5.

Table 4-4 Criteria for Diagnosis of Acute Respiratory Distress Syndrome

Appropriate setting
Pulmonary injury, shock, trauma
Acute event
Clinical respiratory distress, tachypnea
Diffuse pulmonary infiltrates on chest radiography
Interstitial and/or alveolar pattern
Hypoxemia
PaO_2/FIO_2 ratio <150
Exclude
Chronic pulmonary disease accounting for the clinical features
Left ventricular failure (most series require pulmonary artery wedge pressure measurement <18 mm Hg)

The relative risks of developing ARDS have been estimated from studies of predisposed groups. The greatest frequency is among patients with sepsis (approximately 40%), gastric aspiration (30%), multiple transfusions (25%), pulmonary contusion (20%), disseminated intravascular coagulation (20%), pneumonia requiring ICU management (12%), and trauma with long-bone or pelvic fractures (5%).

The pathophysiologic mechanism of ARDS depends on damage to the alveolar-capillary unit. The earliest histologic changes are endothelial swelling, followed by edema and inflammation. Mononuclear inflammation, loss of alveolar type I cells, and protein deposition in the form of hyaline membranes may occur within 2 or 3 days. Fibrosis may develop after days or weeks of the process. Damage to type II alveolar cells leads to loss of surfactant. The surfactant that is produced may be inactivated by proteins present in the airways. Alveolar filling and collapse cause intrapulmonary shunting and ventilation-perfusion mismatch with hypoxemia.

Death from ARDS is not usually caused by isolated hypoxemic respiratory failure. The most frequent causes of death are complications of infection, sepsis, and failure of other organ systems. In addition to the clinical risk factors listed above, specific variables associated with death include less than 10% band forms on a peripheral blood smear, persistent acidemia, bicarbonate less than 20 mEq/L, and blood urea nitrogen greater than 65 mg/dL. Therefore, the systemic effects associated with ARDS may be important to outcome.

- Death from ARDS is not usually caused by isolated hypoxemic respiratory failure.
- Infection, sepsis, and failure of other organ systems are the usual causes of death.
- Variables associated with death: <10% band forms on a peripheral blood smear, persistent acidemia, bicarbonate <20 mEq/L, blood urea nitrogen >65 mg/dL.

Table 4-5 Disorders Associated With Acute Respiratory Distress Syndrome

Shock	Any cause
Sepsis	Lung infections, other bacteremic or endotoxic states
Trauma	Head injury, lung contusion, fat embolism
Aspiration	Gastric, near-drowning, tube feedings
Hematologic	Transfusions, leukoagglutinin, intravascular coagulation, thrombotic thrombocytopenic purpura
Metabolic	Pancreatitis, uremia
Drugs	Narcotics, barbiturates, aspirin
Toxic	Inhaled—O_2, smoke
	Irritant gases—NO_2, Cl_2, SO_2, NH_3
	Chemicals—paraquat
Miscellaneous	Radiation, air embolism, altitude

Therapy for ARDS

The traditional therapy for ARDS involves optimization of physiologic variables and supportive management of associated complications. Measures include optimization of gas exchange and hemodynamics, nutrition, ambulation, and control of infections. Hypoxemia typically is corrected with positive pressure ventilation with supplemental oxygen and PEEP. PEEP provides potential benefits of increased lung volume and lung compliance and improvement in ventilation-perfusion relationships. Maintaining PEEP at a level adequate to prevent repetitive opening and closing of gravitationally dependent lung units (i.e., above "closing volume") may be helpful in limiting tissue sheer forces that can potentiate capillary injury and worsen the degree of diffuse alveolar damage. Beyond an optimal level of PEEP, an increase in intrathoracic pressure may be associated with decreased venous return, increased pulmonary vascular resistance, decreased left ventricular filling, and a corresponding decrease in cardiac output.

Limiting the degree of alveolar distention during peak inflation may limit the potential for alveolar disruption and subsequent barotrauma, often referred to as "ventilator-induced lung injury." This is achieved by delivering tidal volumes of limited size, either by a volume preset or a pressure-targeted mode of ventilation. The use of PEEP levels chosen to prevent alveolar closure and tidal volumes chosen to prevent alveolar overdistention is termed the "protective ventilatory strategy" in the management of ARDS. A recent randomized study found improved survival in ARDS patients receiving a tidal volume of 6 mL/kg ideal body weight compared with a control group receiving a tidal volume of 12 mL/kg body weight. This represents the first specific therapy for ARDS that has been shown to improve survival. In many patients supported with these ventilator guidelines, the level of alveolar ventilation achieved results in an increase in arterial P_{CO_2}. This phenomenon, termed "permissive hypercapnia," does not appear to be harmful. Indeed, recent evidence indicates that mild hypercapnia and respiratory acidosis may decrease the degree of ventilator-induced lung injury.

Supportive management of associated complications includes screening for underlying infections and early antibiotic therapy. Selective bowel decontamination by oral or nasogastric administration of a combination of nonabsorbable antibiotics may decrease the colonization of the airway by gram-negative organisms (reported to decrease the incidence of pneumonia in patients receiving mechanical ventilation).

- Hypoxemia typically is corrected with positive pressure ventilation with supplemental oxygen and PEEP.
- A "protective ventilatory strategy" in ARDS is designed to limit ventilator-induced lung injury.
- A tidal volume of 6 mL/kg is the first specific intervention shown to improve survival in ARDS.

Because increased capillary permeability allows greater intravascular fluid leak at any given hydrostatic pressure, intravascular volume is usually limited to that necessary for systemic perfusion. However, associated shock states may demand volume expansion or increased inotropic support. Crystalloids can provide adequate filling pressures in patients with shock states, but large volumes may be required. Specific applications for colloids in ARDS include blood products (e.g., for coagulopathies or anemia). Supplemental nutrition typically is provided throughout the course of critical illness. Many patients with ARDS have associated multiorgan injury and may have ileus or gastrointestinal tract dysfunction that precludes enteral feeding. Enteral feeding is recommended if tolerated. The consequences of malnutrition may include impairment of respiratory muscle function, depressed ventilatory drive, and limitation of host defenses. Mobilization, ambulation, and ventilator weaning are carried out as early as practical.

- Crystalloids can provide adequate filling pressures in patients with shock states.
- Many patients with ARDS have associated multiorgan injury.

Pharmacologic therapies have been directed against proposed biochemical and cellular mechanisms of ARDS. The explanation for the presumed pathogenesis of acute lung injury is centered on the role of polymorphonuclear leukocytes. Activation of complement by many stimuli associated with lung injury may lead to recruitment and activation of neutrophils, which may injure endothelium by releasing proteolytic enzymes and liberating toxic oxygen species (e.g., hydrogen peroxide, hydroxyl radical, singlet oxygen, and superoxide). Bronchoalveolar lavage fluid from patients with established ARDS and from high-risk patients may show an increased number of cells, predominantly neutrophils. (Normal lavage fluid contains about 93% alveolar macrophages, with 5% to 7% lymphocytes and few neutrophils.) The percentage of neutrophils is correlated with the abnormalities of gas exchange and alveolar protein content. However, experimental lung injury may occur in the absence of neutrophils, and typical ARDS is seen in severely neutropenic patients, so that other mechanisms also have a role.

Arachidonic acid metabolites are implicated in many biochemical events associated with acute lung injury. Arachidonic acid is released from cell membranes by phospholipases. Arachidonate may then be metabolized via the lipoxygenase pathway to leukotriene compounds or via the cyclooxygenase pathway to prostaglandins or thromboxane. These compounds are potentially crucial in the pathogenesis of acute lung injury.

Thromboxane A_2, a potent vasoconstrictor, induces platelet aggregation. Prostacyclin, or prostaglandin (PG) I_2, has the opposite effects on smooth muscle and platelet aggregation and is a potential therapeutic agent for ARDS. PGE_1, a prostaglandin, relaxes vascular and bronchial smooth muscle and inhibits neutrophil chemotaxis.

- Acute lung injury: the pathogenesis centers on polymorphonuclear leukocytes.
- Neutrophils may injure endothelium by releasing proteolytic enzymes and liberating toxic oxygen species.
- Experimental lung injury may still occur in the absence of neutrophils.
- Arachidonic acid metabolites are implicated in many biochemical events associated with acute lung injury.
- Thromboxane A_2 is a potent vasoconstrictor that induces platelet aggregation.

- PGE_1: relaxes vascular and bronchial smooth muscle and inhibits neutrophil chemotaxis.

Potential therapeutic and prophylactic agents have been directed against steps in the arachidonate pathways. Corticosteroids decrease cell membrane disruption and have other anti-inflammatory properties, but in early-phase ARDS, corticosteroids are potentially harmful and have no proven benefit. Specifically, no differences in mortality have been observed in prospective, randomized studies of ARDS patients receiving methylprednisolone or placebo. However, limited trials have suggested that corticosteroid therapy may be of benefit in the fibroproliferative phase of ARDS, and in some instances, corticosteroids are added if no improvement has occurred after 1 to 2 weeks of conventional therapy. Trials of high-dose corticosteroids in sepsis have also shown no difference in overall mortality. High-dose corticosteroid therapy may delay the resolution of secondary infections, and an increased risk of death related to secondary infection after high-dose corticosteroid therapy has been observed. Recently, several studies have found improved survival in sepsis with use of a combination of low-dose hydrocortisone and fludrocortisone in patients with "relative adrenal insufficiency," defined as a lack of response to corticotropin stimulation. After this group was given steroid replacement for 7 days, the risk of death was reduced and no adverse effects were observed.

- Corticosteroids decrease cell membrane disruption and have other anti-inflammatory properties.
- However, in early-phase ARDS, corticosteroids are potentially harmful and have no proven benefit.
- Corticosteroids may decrease the time to resolution of fibroproliferative (late-phase) ARDS.
- In sepsis, no difference has been shown in overall mortality with short-term, high-dose corticosteroids, but low-dose corticosteroid replacement may be beneficial in patients with relative adrenal insufficiency.

Nonsteroidal anti-inflammatory drugs (NSAIDs), such as ibuprofen and indomethacin, block cyclooxygenase and thromboxane formation. In animal models of acute lung injury and septic shock, NSAIDs have beneficial effects if used prophylactically. However, no benefit is known for established ARDS. Other mediators, particularly those associated with sepsis, may be important factors in the pathogenesis of acute lung injury. Endotoxin, a complex lipopolysaccharide, may activate complement; it has been associated with neutrophilic alveolitis. Monoclonal antiendotoxin antibodies reportedly have beneficial effects in some patients with sepsis, but controlled trials have failed to show improved overall survival.

Recently, pulmonary vasodilators, of which nitric oxide has been studied most widely, have been used as adjuncts to traditional therapy. Inhaled nitric oxide, delivered by a mechanical ventilator, naturally distributes to relatively well-ventilated regions of each lung. Nitric oxide acts as a dilator of the alveolar capillary and is rapidly inactivated in the bloodstream, thereby potentially improving perfusion to ventilated areas without systemic vasodilation.

Several studies of inhaled nitric oxide have shown dramatic short-term improvement in oxygenation and pulmonary artery pressures in patients with ARDS. However, outcome studies have not shown improved survival. In a large-scale European trial, 67% of ARDS patients were identified as responders to inhaled nitric oxide, showing improvement in oxygenation and a decrease in pulmonary artery pressure. However, there was no difference in the time to reverse lung injury or in 30-day mortality. Other vasodilating agents, including prostacyclin and PGE_1, have also been tried. Currently, anti-inflammatory agents and pulmonary vasodilators should be considered investigational for the treatment of ARDS, with no documented effect on survival. The prognosis for the recovery of lung function in patients who survive ARDS is good. Studies of survivors have shown nearly normal lung volumes and airflow 6 to 12 months after the illness, with mild impairment in gas exchange—decreased diffusing capacity, desaturation with exercise, or widened A-a gradient. Therefore, the incentive is strong to continue aggressive measures in patients with otherwise reversible organ dysfunction.

- The prognosis for the recovery of lung function in patients surviving ARDS is good.
- Mild decreases in lung volumes, oxygenation, and diffusing capacity are typically observed after 6 to 12 months.

Severe Acute Respiratory Syndrome

A specific form of acute respiratory failure has been recognized recently. During 2003, a global outbreak of an acute respiratory illness was identified and was termed severe acute respiratory syndrome (SARS). Among the first 8,000 cases, approximately 800 patients died. The etiologic agent has been identified as a previously unrecognized RNA virus termed SARS-associated coronavirus (SARS-CoV). The clinical diagnosis is suspected in a patient with fever and respiratory symptoms after travel to Asia or another SARS-affected area or after exposure to someone who has traveled to a SARS-affected area. Laboratory testing may include serum antibodies to SARS-CoV, cell culture, and identification of SARS-CoV by polymerase chain reaction of secretions or blood. Transmission appears to occur by close contact, through airborne or droplet exposure. For hospitalized patients, infection precautions should include gown, gloves, eye protection, and mask with a filtering level of N-95 or higher. Various antiviral agents have been used, but no therapy is of proven benefit.

- The cause of SARS is SARS-associated coronavirus (SARS-CoV).
- Transmission is by close contact.
- In hospitals, masks with a filtering level of N-95 or higher are required.
- No therapy is of proven benefit.

Cardiopulmonary Resuscitation

General clinical algorithms for standardized responses to cardiac arrhythmias or arrest should be reviewed. Ideally, cardiorespiratory problems in ICUs should be prevented or anticipated and recognized quickly.

Airway Control

Relieve any obstruction. Remove any foreign bodies. If not dislodged or obstructing, dentures may improve the seal of a face mask. However, dentures are usually removed before endotracheal intubation.

Use suction to remove saliva, emesis, or blood. A rigid suction catheter is most useful. Use a head tilt or chin lift technique or a forward thrust of the jaw to open the posterior pharynx. The oropharyngeal or nasopharyngeal airway may help maintain patency and facilitate suctioning and mask ventilation.

Supply supplemental oxygen at a high rate of flow. Ventilation is usually begun with a bag-valve-mask technique. Because a combined respiratory and metabolic acidosis is common, hyperventilation should be carried out to the extent possible.

Endotracheal intubation provides better control of the airway for ventilation, oxygenation, and suctioning and should be performed as soon as practical during the resuscitation effort. However, the best possible ventilation and oxygenation should be provided before any attempt at intubation, and efforts should be limited to 15 to 30 seconds before mask ventilation is resumed.

For chest compressions, a 15:2 compression-to-ventilation ratio is currently recommended for one-person and two-person resuscitation. Check the femoral pulse for effectiveness of compressions. Monitoring of expired carbon dioxide (capnometry) by various devices is used to assess the adequacy of ventilation and to confirm endotracheal (versus esophageal) intubation. Under conditions of controlled ventilation and cardiac resuscitation, expired carbon dioxide may be an indicator of effective chest compressions, because carbon dioxide delivery to the lungs depends on adequate cardiac output.

- Relieve obstruction.
- Oropharyngeal or nasopharyngeal airway may help maintain patency.
- Supply a high rate of flow of supplemental oxygen.
- Endotracheal intubation: better control of the airway for ventilation.

Electrical Therapy

Ventricular fibrillation is the most common rhythm in sudden cardiac arrest. The time to defibrillation is the most important factor determining successful resuscitation. In monitored patients in ICUs, defibrillation typically should be the first treatment, with other life support efforts initiated only after immediate attempts at electrical conversion. Electrical pacing may be useful in some cases of bradycardia and heart block.

- Ventricular fibrillation is the common rhythm in sudden cardiac arrest.
- Time to defibrillation is the most important factor determining successful resuscitation.
- In monitored patients in ICUs, defibrillation typically should be the first treatment.

Drug therapy for arrhythmias is discussed in Chapter 3 (“Cardiology”).

Vascular Access and Hemodynamic Monitoring

Central Venous Catheterization

The first choice for access in stable patients requiring intravenous therapy is the peripheral veins. However, in ICUs, central venous catheterization is often necessary for the following indications: lack of adequate peripheral veins, need for hypertonic or phlebitic medications or solutions, need for long-term access, measurement of central pressures, and access for procedures (hemodialysis, cardiac pacing). Relative contraindications include inexperience of the practitioner, coagulopathy, inability to identify landmarks, infection or burn at the entry site, and thrombosis of the proposed central venous site. Central venous catheters are usually placed over a guidewire (modified Seldinger technique). Complications of central venous catheterization include infections, cardiac arrhythmias, pneumothorax, air embolism, catheter or guidewire embolism, catheter knotting, bleeding, and other potential complications of needle or catheter misplacement.

- Central venous catheterization is often necessary.
- Contraindications: inexperienced practitioner, coagulopathy, inability to identify landmarks, infection or burn at the entry site, or thrombosis of the proposed central venous site.
- Complications: infections, cardiac arrhythmias, pneumothorax, air embolism, catheter or guidewire embolism, catheter knotting, and bleeding.

Catheter-related infections are usually attributed to the migration of bacteria from the skin along the catheter tract. Catheter-related infection is usually defined by more than 15 colony-forming units (CFU)/mL on semiquantitative culture of the catheter tip. Catheter-related bacteremia is defined by similar growth and blood cultures positive for the same organism. Risk factors include infected catheter site or cutaneous breakdown, multiple manipulations, the number of catheter lumens, and the duration of use of the same site (particularly after 3 or 4 days). Treatment should include catheter removal and replacement at another site if necessary.

- Catheter-related infections usually are attributed to migration of bacteria from the skin along the catheter tract.
- Risk factors: infected catheter site or cutaneous breakdown, multiple manipulations, the number of catheter lumens, and the duration of use of the same site.

Pulmonary Artery Catheterization

Although common use (or overuse) of pulmonary artery catheterization has been criticized, data from pulmonary artery catheterization may aid diagnosis and therapy in many disorders encountered in ICUs. The physiologic data that may be obtained are listed in Table 4-6.

Clinical conditions for which hemodynamic data may be useful include shock states, pulmonary edema, oliguric renal failure, indeterminate pulmonary hypertension, and myocardial and valvular disorders. Intravascular volume may be assessed more accurately, and the effects of therapeutic interventions (volume, vasodilator therapy,

Table 4-6 Hemodynamic Data Obtained With Pulmonary Artery Catheterization

Variable	Normal values
Right atrial pressure (RAP)	2-8 mm Hg
Pulmonary arterial pressure (PAP)	16-24/5-12 mm Hg
Pulmonary capillary wedge pressure (PCWP)	5-12 mm Hg
Cardiac output (CO)	4-6 L/min
Cardiac index (CI = CO/body surface area)	2.5-3 L/min per m^2
Stroke volume (SV = CO/heart rate)	50-100 mL/beat
Stroke volume index (SVI = SV/body surface area)	35-50 mL/m^2
Systemic vascular resistance [SVR = (blood pressure – RAP)/CO]	10-15 mm Hg/L per min (×80 to convert to 800-1,200 dynes • s/cm^{-5})
Pulmonary vascular resistance [PVR = (PAP – PCWP)/CO]	1.5-2.5 mm Hg/L per min (100-200 dynes • s/cm^{-5})

or inotropes) may be evaluated. Mixed venous oxygen saturation may also be measured, as indicated above. This may be particularly useful in assessing the effects of PEEP on oxygen delivery (i.e., improving arterial saturation but potentially decreasing cardiac output).

Complications of pulmonary artery catheterization include arrhythmias, right bundle branch block, complete heart block in patients with preexisting left bundle branch block, vascular or right ventricular perforation, thrombosis and embolism, catheter knotting, infection, and pulmonary infarction or rupture due to persistent wedging or overdistention of the balloon.

Case-control studies have found that the use of a pulmonary artery catheter was associated with higher mortality than no catheter in patients who had a similar severity of illness. However, the basis of this observation is uncertain, and catheter use is still common clinical practice. Recent prospective trials of pulmonary artery catheterization in high-risk surgical and medical patients have shown no differences in outcome (i.e., no clear evidence of benefit or harm) between those who had catheterization and control groups.

- Complications of pulmonary artery catheterization: arrhythmias, right bundle branch block, complete heart block in patients with preexisting left bundle branch block, vascular or right ventricular perforation, thrombosis and embolism, catheter knotting, infection, and pulmonary infarction or rupture due to persistent wedging or overdistention of the balloon.

The use of pulmonary capillary wedge pressure (PCWP) as an indicator of left ventricular end-diastolic pressure assumes a continuous hydrostatic column extending from the pulmonary capillary to the left atrium. Although digital displays of PCWP are usually available, the pressure wave should be examined for potential artifacts and for the degree of respiratory variation. Because varying intrathoracic pressure may be sensed by the pulmonary artery catheter, recorded PCWP should be obtained at end-expiration. Even with these measures, PCWP may be influenced by airway pressure and, thus, not accurately reflect ventricular filling pressure, especially with high levels of PEEP.

- PCWP is an indicator of left ventricular end-diastolic pressure.
- PCWP may be influenced by airway pressure, especially with high levels of PEEP.

Shock States

"Shock" is defined by evidence of end-organ hypoperfusion, usually (but not necessarily) associated with hypotension. A common classification is cardiogenic (decreased cardiac output), hypovolemic (decreased blood volume), and septic (variable cardiac output, decreased systemic vascular resistance). All forms of shock may be characterized by hypotension, tachycardia, tachypnea, altered mental status, decreased urine output, and lactic acidosis. The clinical history often helps determine the diagnosis, for example, blood loss, trauma, myocardial infarction, or systemic infection. Compared with other causes, septic shock is often characterized by relatively warm extremities and normal or increased cardiac output.

- Shock is defined by evidence of end-organ hypoperfusion, usually associated with hypotension.
- Common classification: cardiogenic, hypovolemic, and septic.
- Shock is characterized by hypotension, tachycardia, tachypnea, altered mental status, decreased urine output, and lactic acidosis.
- Septic shock is often characterized by relatively warm extremities and normal or increased cardiac output.

To achieve a common terminology, the concept of systemic inflammatory response syndrome (SIRS) was introduced for findings of fever or hypothermia, tachycardia, hyperventilation, and leukocytosis or leukopenia regardless of cause. "Sepsis" is defined as SIRS in the setting of a known or presumed source of infection, and "severe sepsis" is defined as sepsis associated with organ system dysfunction and systemic effects, including hypotension, decreased urine output, or metabolic acidosis. "Septic shock" refers to persistent signs of organ hypoperfusion despite adequate fluid resuscitation.

After a rapid initial assessment, treatment of shock is directed at the presumed source, for example, volume (blood loss and

hypovolemia), vasodilator or inotropic therapy (cardiogenic), or fluids, antibiotics, and drainage of any infected space (sepsis). If the response to the initial therapy is inadequate, and especially if intravascular volume status is uncertain clinically, pulmonary artery catheterization may be useful. For example, if the wedge pressure remains less than 12 to 15 mm Hg, additional fluids should be administered. A recent prospective trial of "early goal-directed therapy" for severe sepsis stressed volume resuscitation beginning in the emergency department and showed improved hospital survival compared with standard therapy. If the wedge pressure is greater than 18 to 20 mm Hg and there is evidence of cardiac dysfunction, a vasodilator (e.g., nitroprusside) and diuretic therapy may be considered. If "hyperdynamic" indexes are observed—that is, increased cardiac output and low peripheral resistance—fluids should first be given to achieve a high-normal wedge pressure. *After* volume support has been given and if tissue perfusion remains inadequate, careful administration of vasoconstrictors (e.g., norepinephrine) may improve organ perfusion. Recently, low-dose vasopressin has been reported to be beneficial in the hemodynamic support of patients with septic shock.

Multisystem organ failure, or multiple organ dysfunction syndrome (MODS), is usually defined as acute dysfunction of two or more organ systems lasting more than 2 days. Sepsis is the most common cause. The pathogenesis is attributed to the hemodynamic and immunologic effects of endotoxin, cytokines (tumor necrosis factor [TNF]-α), interleukins (IL-1, IL-2, IL-6, and IL-8), platelet-activating factor, arachidonic acid metabolites, polymorphonuclear leukocyte-derived toxic products, and myocardial depressant factors. Corticosteroids have no known benefit and potential adverse effects in patients with sepsis syndrome, with or without ARDS. An exception is the use of relatively low doses of hydrocortisone and fludrocortisone in patients with adrenal insufficiency in the setting of severe sepsis, for which benefit has been reported.

Recently, a controlled, prospective trial of recombinant human activated protein C (drotrecogin alfa), administered intravenously over 96 hours, reported a 19% relative reduction (6% absolute decrease) in mortality among patients with severe sepsis. Activated protein C has anti-inflammatory and profibrinolytic properties that may contribute to this benefit. The main adverse effect of recombinant human activated protein C is bleeding.

- Sepsis typically is defined by a known or presumed source of infection associated with fever (or hypothermia) and leukocytosis (or leukopenia) and evidence of systemic effects (hypotension, decreased urine output, metabolic acidosis).
- Treatment is directed at the presumed source.
- Septic shock commonly is associated with multiorgan injury.
- Multisystem organ failure: acute dysfunction of two or more organ systems lasting >2 days.
- High-dose corticosteroid treatment is of no known benefit.
- Replacement therapy may be of benefit for patients with adrenal insufficiency.
- Recombinant human activated protein C is the first specific therapy to decrease mortality from severe sepsis.

Mortality of patients with sepsis and multiorgan failure may be greater than 70% to 90%. Adverse risk factors include age older than 65 years, continued systemic signs of sepsis, persistent deficit in oxygen delivery, and preexisting renal or liver failure. Physiologic scoring systems (e.g., APACHE) may predict outcome more accurately for subgroups of patients.

- Mortality of patients with sepsis and multiorgan failure may be >70% to 90%.

Disease Severity Scoring Systems

The use of a severity-of-illness scoring system is increasingly prevalent in the ICU. These systems may define quantitative overall risks for populations of patients. An accurate quantifiable description of the pretreatment status of critically ill patients can allow improved precision in the evaluation and implementation of new therapies. Furthermore, these systems can be of great use in quality improvement efforts. In most systems, however, the role in individual case management is unclear. The types of clinical scoring systems have ranged from simple counts of failing organs to sophisticated methods that incorporate (acute and chronic) clinical and physiologic parameters into proprietary logistic regression prediction equations derived from large databases.

The Glasgow Coma Scale (GCS) was developed in the early 1970s as a triage tool for patients with head injury. This scoring system assigns a weighted point score for three behavioral responses: eye opening (1 to 4 points), best verbal response (1 to 5 points), and best motor response (1 to 6 points). Thus, GCS scores range from 3 to 15 points: severe dysfunction = 3 to 8 points, moderate dysfunction = 9 to 12 points, and mild dysfunction = 13 to 14 points. The GCS system has been shown to correlate with mortality and the level of ultimate brain function in patients with traumatic brain injury. Because of its efficacy and simplicity, the GCS has been used within other scoring systems.

Several multisystem scoring systems have been developed for use in critically ill patients. Although a detailed review of these systems is beyond the scope of this text, they include the Acute Physiology and Chronic Health Evaluation (APACHE) system, Simplified Acute Physiology Score (SAPS), the Mortality Probability Model (MPM), Project IMPACT, and the Therapeutic Intervention Scoring System (TISS).

- Severity scoring systems attempt to quantify overall risk for *populations* of patients.
- Severity scoring systems can be of great use in clinical research and quality assurance functions.
- The best role for most scoring systems in the care of *individual* patients is undefined.

Ethics in the ICU

The principles listed in Table 4-7 provide a framework for assessing ethical issues in the ICU. However, the potential for conflict frequently arises because patients often are unable to participate in their

own care, many family members may be involved, and the medical staff may disagree about the prognosis and proposed interventions.

Recent legal opinions have supported the concept that a competent person may refuse life-sustaining therapy. Decision making for incompetent patients is more controversial, and living-will legislation has been designed partly to address such conflicts.

- A competent person may refuse life-sustaining therapy.
- Decision making for incompetent patients is more controversial; living-will legislation has been designed partly to address such conflicts.

"Do Not Resuscitate" orders have become increasingly common and important in recent years. The guidelines of the American Medical Association include the following:

1. Consent to cardiopulmonary resuscitation is presumed unless the patient (or patient's surrogate) has expressed in advance the wish not to be resuscitated or if, in the judgment of the treating physician, an attempt to resuscitate the patient would be futile. Resuscitation efforts should be considered futile if they cannot be expected either to restore cardiac or respiratory function or to achieve the expressed goals of the patient.
2. The appropriateness of cardiopulmonary resuscitation should be discussed with patients at risk of cardiopulmonary arrest, preferably in the outpatient setting or early during hospitalization, and the resuscitation status should be reassessed periodically.
3. The physician is ethically obligated to honor the resuscitation preferences of the patient or surrogate except when this would mandate use of futile therapeutic efforts (potential conflicts may arise in the application of this principle).
4. "Do Not Resuscitate" orders should be entered in the medical record.
5. "Do Not Resuscitate" orders affect the administration of cardiopulmonary resuscitation only; other therapeutic interventions should not be influenced by the order.

Table 4-7 Principles for Assessing Ethical Issues in Intensive Care Units

Beneficence—acting in the patient's benefit by sustaining life, treating illness, and relieving pain
Nonmaleficence—do no harm
Autonomy—fundamental right to self-determination
Informed consent—providing factual and adequate information for competent patients to make decisions about their care
Substituted judgment—ability of a family member, guardian, or other surrogate to make decisions on behalf of the patient on the basis of what he or she believes the patient would have chosen if competent
Social justice—allocation of medical resources according to need (note that this concept implies overt health care rationing and may conflict with perceived individual rights)
Advance directives—living will: designed for persons to express their wishes regarding life-sustaining treatment if they are deemed terminally ill and no longer able to participate in such decisions; typically there is provision or request for denial of specific life-support measures and designation of a surrogate decision maker

Withholding Life Support Versus Withdrawal of Existing Support

Recent deliberations and court rulings have supported the concept that withholding and withdrawing of life support are essentially equivalent. In general, an irreversible or terminal illness is considered a prerequisite for withdrawal of support, but the interpretation may vary widely.

- Withholding life support is essentially equivalent to withdrawing life support.

Critical Care Medicine Pharmacy Review

Philip J. Kuper, PharmD, Lance J. Oyen, PharmD

Review of Drugs Commonly Used in the ICU That Potentially Can Cause Delirium

Analgesics
- Opiates
- NSAIDs

Anesthetics & sedatives
- Benzodiazepines
- Bupivacaine
- Ketamine
- Lidocaine
- Propofol

Anticonvulsants
- Barbiturates
- Carbamazepine
- Phenytoin

Antifungals & antivirals
- Acyclovir
- Amphotericin
- Ketoconazole

Antihypertensives
- Captopril
- Clonidine
- Diltiazem
- Enalapril
- Hydralazine
- Methyldopa
- Nifedipine
- Nitroprusside
- Verapamil

Antimicrobials
- Aminoglycosides
- Cephalosporins
- Carbapenems
- Macrolides
- Metronidazole
- Monobactams
- Penicillins
- Quinolones
- Tetracyclines
- Trimethoprim-sulfamethoxazole (Cotrimoxazole)

Miscellaneous cardiac drugs
- Antiarrhythmics
- Atropine
- β-Blockers
- Digoxin

Miscellaneous
- Antihistamines
- Corticosteroids
- Theophylline
- Tricyclic antidepressants
- H_2 blockers

ICU, intensive care unit; NSAIDs, nonsteroidal anti-inflammatory drugs.

Critical Care Medicine Pharmacy Review (continued)

Review of Drugs Commonly Used in the ICU for Agitation With Ventilation

	Comments	
Drug	**Pros**	**Cons**
Benzodiazepines Midazolam Lorazepam Diazepam	Useful for anxiety-related agitation, inexpensive, minimal hemodynamic effects	Risk of oversedation and accumulation, especially prolonged use; depress respiratory drive; potential withdrawal reaction with long-term use
Anesthetic Propofol	Predictable, short-term sedative/hypnotic effects, no accumulation	Hypotension risk, depresses respiratory drive, high expense, deaths associated with acidosis
Neuroleptic Haloperidol	Specific for delirium, no effect on respiratory drive	Cardiac toxicity and hypotension risks, lowers seizure threshold
Sedative Dexmedetomidine	Pain and anxiolytic properties, does not depress ventilation	Short-term use only (until further research completed), potential withdrawal reaction
Opiates/analgesics Fentanyl Hydromorphone Methadone Morphine	Useful for pain-induced agitation (accurate history for pain important)	May contribute to delirium and confusion, may contribute to hypotension due to histamine release

ICU, intensive care unit.

Critical Care Medicine Pharmacy Review (continued)

Clinically Important Toxic Overdoses and Management

Drug overdose	Clinical syndrome	Basic treatment
Acetaminophen (paracetamol)	0.5-24 h: Nausea, vomiting 24-72 h: Nausea, vomiting, RUQ pain, increased LFTs and PT 72-96 h: Liver necrosis, coagulation defects, jaundice, renal failure, hepatic encephalopathy 4 d to 2 wk: Resolution of liver dysfunction	Elimination: Gastric lavage (if <1 h after ingestion), activated charcoal (if <4 h after ingestion) (both longer if sustained-release product) Treatment: *N*-acetylcysteine for toxic ingestion based on Rumack-Matthew nomogram
Amphetamines	Hypertension, tachycardia, arrhythmias, myocardial infarction, vasospasm, seizures, paranoid psychosis, diaphoresis, tachypnea	Elimination: Activated charcoal for oral ingestion Agitation/seizures: Benzodiazepines Hypertension: Control agitation, α-antagonists (phentolamine), vasodilators (nitroglycerin, nitroprusside, nifedipine) Hyperthermia: Control agitation, external cooling
Iron	0.5-6 h: Nausea, vomiting, GI discomfort, GI bleed, drowsiness, hypoglycemia, & hypotension 6-24 h: Latency/quiescence (may not occur in severe ingestions) 6-48 h: Shock, coma, seizures, coagulopathy, acidosis, cardiac failure 2-7 d: Hepatotoxicity & coagulopathy, metabolic acidosis, renal insufficiency 1-8 wk: GI disorders, achlorhydria	Elimination: Gastric lavage and/or whole bowel irrigation with polyethylene glycol–electrolyte solution, especially with tablets (radiopaque) present on KUB Shock: IV fluids and blood (if hemorrhage present); vasopressors if needed Antidote: Deferoxamine to chelate iron, when iron levels >500 μg/dL or severe ingestion suspected (will change urine to "vin rosé" color)
Salicylate	Respiratory alkalosis (initially), metabolic acidosis (after substantial absorption), pulmonary edema, platelet dysfunction, nausea, vomiting, hearing loss, agitation, delirium	Elimination: Activated charcoal, hemodialysis (for severe poisoning), alkalinization of urine Agitation/delirium: Alkalize blood (acidemia enhances transfer into tissue, especially brain) with IV bicarbonate
Tricyclic antidepressants	Wide-complex tachyarrhythmias, hypotension, seizures	Tachyarrhythmias: Alkalizing blood (pH 7.5-7.55) with IV bicarbonate reduces binding to sodium channel Seizures: Benzodiazepines Hypotension: Fluid resuscitation, vasopressors

GI, gastrointestinal; IV, intravenous; KUB, radiograph of kidneys, ureters, bladder; LFT, liver function test; PT, prothrombin time; RUQ, right upper quadrant.

Critical Care Medicine Pharmacy Review (continued)

Overview of Drotrecogin Alfa* (Activated Protein C)

Indication

Known or suspected infection that is being treated

and

Patient meets ≥3 SIRS criteria:

1) Core temperature >38°C or <36°C
2) HR >90 unless a medical condition causes tachycardia or patient is receiving treatment to prevent tachycardia (e.g., β-blocker)
3) RR >20, $PaCO_2$ <32, or the use of a mechanical ventilator
4) WBC >12,000/mL

and

APACHE II score ≥25

or

At least 1 organ or system dysfunction:

1) Cardiovascular dysfunction (shock, hypotension, or the need for vasopressor support despite adequate fluid resuscitation)
2) Respiratory dysfunction (PaO_2/FIO_2 ratio <250)
3) Renal dysfunction (oliguria despite adequate fluid resuscitation)
4) Thrombocytopenia (platelet count <80,000/μL or 50% decrease from the highest value in the past 3 d)
5) Metabolic dysfunction with elevated lactic acid concentrations

Contraindications

Clinical situations in which bleeding could be associated with increased risk of death:

1) Active internal bleeding
2) Recent (within 3 mo) hemorrhagic stroke
3) Recent (within 2 mo) intracranial or intraspinal surgery or severe head trauma
4) Trauma with an increased risk of life-threatening bleeding
5) Presence of an epidural catheter
6) Intracranial neoplasm or mass lesion or evidence of cerebral herniation
7) Known hypersensitivity to drotrecogin alfa or any of its metabolites

Warnings

Patients with single-organ dysfunction and recent surgery (within 30 d) had higher mortality, but sample was too small for statistical significance; these patients may not be at high risk of death irrespective of APACHE II score—therefore, the drug may not be indicated; carefully consider the risks and benefits

Precautions

The following conditions are likely to increase the risk of bleeding; therefore, the risks and benefits should be considered:

1) Concurrent therapeutic dosing of heparin; platelet count <30,000/μL; INR >3.0
2) Recent (within 6 wk) GI bleeding
3) Recent (within 3 d) administration of thrombolytic therapy
4) Recent (within 7 d) administration of oral anticoagulants or glycoprotein IIb/IIIa inhibitors
5) Recent (within 7 d) administration of aspirin (>650 mg/d) or other platelet inhibitors
6) Recent (within 3 mo) ischemic stroke
7) Intracranial arteriovenous malformation
8) Known bleeding diathesis
9) Chronic severe hepatic disease
10) Any other condition in which bleeding constitutes a serious hazard

Adverse reactions

Serious bleeding occurred in 3.5% of patients in the drotrecogin alfa group compared with 2% in the placebo group

Dose

24 μg/kg per h continuous infusion for 96 h

APACHE, Acute Physiology and Chronic Health Evaluation; FIO_2, fraction of inspired oxygen; GI, gastrointestinal tract; HR, heart rate; INR, international normalized ratio; RR, respiration rate; SIRS, systemic inflammatory response syndrome; WBC, white blood cell count.

*Xigris; Eli Lilly and Co., Indianapolis, Indiana.

Dermatology

Lisa A. Drage, MD
Marian T. McEvoy, MD

General Dermatology

Skin Cancer

Nonmelanoma skin cancers (basal cell, squamous cell) are the most common malignancies in the United States. There are about 1,000,000 cases annually, and the cure rate is 90% with early detection and treatment. The incidence of nonmelanoma skin cancer is increasing because of a combination of increased exposure to ultraviolet light, changes in clothing style, increased longevity, and atmospheric ozone depletion.

Both basal cell and squamous cell carcinomas occur on sun-exposed skin areas. Basal cell carcinomas are usually slow-growing and locally invasive. They may invade vital structures and can cause considerable disfigurement. Basal cell carcinomas rarely metastasize to regional lymph nodes. In contrast, squamous cell carcinomas can metastasize to regional lymph nodes, and approximately 2% of all squamous cell carcinomas lead to death.

- Basal cell carcinoma and squamous cell carcinoma occur on sun-exposed skin.
- Cure rate is 90% with early detection and treatment.

Malignant Melanoma

It is estimated that, in 2005, 59,580 people received a diagnosis of cutaneous melanomas and 7,900 died of the disease. The incidence of malignant melanoma is increasing in the United States. The estimated lifetime risk of invasive melanoma is about 1% for Americans born in the 1990s.

Risk factors for the development of malignant melanoma include fair skin, blond or red hair, freckling, intermittent sunlight exposure with blistering sunburns during childhood or adolescence, and genetic predisposition. The familial atypical mole-melanoma syndrome is transmitted by an autosomal dominant gene. Patients with either familial or nonfamilial atypical nevi have an increased risk for development of malignant melanoma. Other risk factors that have been identified include a personal or family history of melanoma or nonmelanoma skin cancer, a large number of benign pigmented nevi, giant pigmented congenital nevus, immunosuppression, human immunodeficiency virus (HIV) positivity, and the use of tanning beds. Many primary melanomas occur on non–sun-exposed sites such as the back, scalp, and subungual skin.

The key to improved survival with malignant melanoma is early detection and diagnosis. Increase in thickness of a melanoma (Table 5-1) and microscopic ulceration are both inversely correlated with survival. However, detection of intranodal deposits of melanocytes indicative of metastasis is now the most powerful staging and prognostic tool.

- The key to improved survival with malignant melanoma is early diagnosis.
- Increased tumor thickness is associated with decreased survival.
- Micrometastasis to the first draining lymph node is the most powerful staging and prognostic tool.

Stages I and II malignant melanomas consist of the cutaneous lesion without lymph node involvement. Stage III consists of the primary skin lesion plus microscopic or macroscopic lymph node involvement, and stage IV represents distant metastasis. Surgical management is recommended for treatment of the primary melanoma and consists of excision with tumor-free margins of 1 to 3 cm. Sentinel lymph node biopsy, whereby the first draining lymph node(s) is identified (by dye injection and lymphoscintigraphy) and sampled, improves prognostic accuracy in intermediate and thick melanomas

Table 5-1 **Survival in Malignant Melanoma, by Tumor Thickness***

Tumor, mm	5-y survival, %
<1.0	95.3
1.01-2.00	89.0
2.01-4.00	78.7
>4.00	67.4

*No nodal or distant metastasis.

and identifies candidates for systemic adjuvant treatment. Adjuvant high-dose interferon alfa-2b produces increase in relapse-free survival rates and may improve overall survival rates in select patients. No form of adjuvant therapy has been shown to improve overall survival in patients with advanced (distant metastasis) disease. Ongoing therapeutic studies focus on vaccine immunotherapy and targeted chemotherapy.

- Surgical management of primary melanoma consists of excision with tumor-free margins of 1 to 3 cm.
- Node status, determined by sentinel lymph node biopsy, is the most powerful predictor of recurrence and survival.

Prevention of Melanoma and Nonmelanoma Skin Cancer

Dermatologists encourage regular use of sunscreens with a sun protection factor (SPF) of at least 15 and sun-protective clothing. Sunlight exposure during the first 18 years of life accounts for up to 80% of cumulative lifetime sun exposure. Persons with light skin types and outdoor workers need to be particularly vigilant with sun protection.

Cutaneous T-Cell Lymphoma

Cutaneous T-cell lymphoma occurs as mycosis fungoides and Sézary syndrome. Mycosis fungoides generally presents with discrete or coalescing patches, plaques, or nodules on the skin. Mycosis fungoides may progress to involve lymph nodes and viscera. Once extracutaneous involvement is recognized, the median duration of survival has been estimated at 2.5 years. The course of patients with patch- or plaque-stage cutaneous lesions, without extracutaneous disease, is less predictable, but the median duration of survival is approximately 12 years. Sézary syndrome, the leukemic form of cutaneous T-cell lymphoma, is characterized by generalized erythroderma, keratoderma of the palms and soles, and a Sézary cell count of more than 1,000/mm^3 in the peripheral blood. Most patients have severe pruritus.

- Mycosis fungoides and Sézary syndrome are forms of cutaneous T-cell lymphoma.
- Mycosis fungoides may progress to involve lymph nodes and viscera.
- The median survival for patients with mycosis fungoides is 12 years, but it decreases to 2.5 years with extracutaneous involvement.

Both mycosis fungoides and Sézary syndrome are characterized by the presence of Sézary cells (lymphocytes with hyperchromatic and convoluted nuclei) involving the epidermis (epidermotrophism) and dermis. Immunohistochemical stains of cutaneous lesions demonstrate that these neoplastic T cells usually express CD3 and CD4 antigens (T-helper cell markers), and molecular genetic studies show clonal rearrangement of the T-cell receptor gene in lymphocyte populations from skin biopsy, lymph node, and peripheral blood specimens of patients with cutaneous T-cell lymphoma.

- Mycosis fungoides and Sézary syndrome are T-cell lymphomas characterized by the presence of Sézary cells in skin and peripheral blood.

Treatment of cutaneous T-cell lymphoma includes topical nitrogen mustard, psoralen with ultraviolet A (PUVA), radiotherapy (electron beam, orthovoltage), and systemic chemotherapy. Interferon, retinoids, and other agents also have been used. Most recently, extracorporeal photopheresis (ingestion of 8-methoxypsoralen, after which the patient's leukocytes are exposed to ultraviolet A and then reinfused) has been used in the treatment of cutaneous T-cell lymphoma.

Psoriasis

Psoriasis occurs in 1% to 3% of the U.S. population. Onset of lesions is most common in the third decade of life, and about a third of patients have a family history of psoriasis. Psoriasis most commonly presents with discrete papules and plaques covered with a silvery scale. Patterns of psoriasis include psoriasis vulgaris that presents with large plaquelike lesions on the trunk and limbs and classic psoriasis involving the elbows, knees, and scalp. Guttate psoriasis is an acute form of psoriasis which often follows streptococcal throat infection and presents with small lesions (5-10 mm in diameter) of psoriasis on the trunk and limbs. Other, less common forms of psoriasis include pustular psoriasis, which may be localized to the hands and feet or may be generalized. Approximately 50% of patients with psoriasis have nail abnormalities, most commonly onycholysis, pitting, and oil spots. Lesions of psoriasis may occur at previous sites of trauma (koebnerization). Medications such as lithium, β-adrenergic blockers, and antimalarials and discontinuation of the use of systemic corticosteroids can precipitate or exacerbate psoriasis. Psoriatic arthritis occurs in 5% to 8% of patients with skin psoriasis.

- The onset of psoriasis most often occurs in the third decade of life.
- One-third of patients have a family history of psoriasis.
- About 50% of patients have nail abnormalities.
- Psoriasis occurs at sites of trauma.

The treatment of psoriasis includes topical corticosteroids, topical tar preparations, and phototherapy. Newer forms of treatment of localized psoriasis include a topical synthetic vitamin D analogue, calcipotriene, and a topical retinoid, tazarotene.

Systemic agents used in the treatment of resistant psoriasis include methotrexate, acitretin, and cyclosporine.

Targeted Therapy in Psoriasis

Research into the pathogenesis of psoriasis has shown that the disease is T-cell–mediated. This knowledge has led to the development of several targeted therapies. Alefacept is a fusion protein that interferes with lymphocyte activation by binding to T cells expressing CD2. Infliximab and etanercept (anti–tumor necrosis factor-α agents) have been effective in the treatment of psoriasis.

Ultraviolet Light

Natural sunlight contains ultraviolet B (UVB, 280-320 nm), ultraviolet A (320-400 nm), and visible light. UVB radiation causes sunburn reaction. UVB has been used most commonly in combination with tar for treating inflammatory dermatoses, as in the Goeckerman

therapy of psoriasis. UVB also may benefit atopic dermatitis, lichen planus, and certain other inflammatory dermatoses.

Narrow-Band UVB
The wavelength of UVB with therapeutic effect for psoriasis has been identified in the 311-nm range. Light units producing this wavelength have been developed (narrow-band UVB) and have been shown to be more effective than traditional UVB for the treatment of psoriasis.

Psoralen and Ultraviolet A (PUVA)
PUVA consists of ingestion of psoralen followed by exposure of the skin to ultraviolet A. PUVA has been used most commonly for therapy of generalized psoriasis, but it is also effective in the treatment of lichen planus, mycosis fungoides, urticaria pigmentosa, and vitiligo. PUVA therapy is associated with minimal systemic side effects but is associated with an increased risk of cutaneous squamous cell carcinoma and melanoma in patients who have received long-term therapy.

- PUVA is commonly used for therapy of generalized psoriasis.
- PUVA is associated with minimal systemic side effects.
- PUVA is associated with an increased risk of cutaneous squamous cell carcinoma and melanoma with long-term use.

Atopic Dermatitis
Atopy is manifested by the following: atopic dermatitis, asthma, and allergic rhinitis or conjunctivitis. Atopic dermatitis often presents in the neonatal period with scaling and erythema of the scalp and face, later spreading to the trunk. The distribution is often extensor in the older infant, and by the age of approximately 3 years distribution is the more classic flexural. In adolescence, facial involvement (perioral, eyelid, and forehead) is common. Generalized flares of eczema can occur at any age.

Disturbances in cell-mediated immunity lead to an increased incidence of bacterial and viral infections. Secondary infection with *Staphylococcus aureus* presents as a weeping, crusting dermatitis (impetiginization). Eczema herpeticum is the term used to describe a secondary infection with the herpes simplex virus, which may be generalized. Infections with the human papillomavirus and molluscum contagiosum are also more common and the lesions are more numerous in patients with atopic dermatitis.

- Eczema herpeticum, a generalized herpes simplex virus infection, may occur in patients with atopic dermatitis.

For many years, emollients and topical corticosteroids have been the mainstay of treatment in atopic dermatitis.

Allergic Contact Dermatitis
Allergic contact dermatitis is a form of localized or generalized dermatitis that results from exposure to an antigen. This is a type 4 hypersensitivity reaction (delayed, cell-mediated). Recognition of antigens by T lymphocytes requires participation of Langerhans cells, which are the "antigen-presenting" cells of the epidermis. One must consider the anatomical location of the cutaneous lesions and environmental exposure to allergens, including occupational, household, and recreational contactants, to define the cause of the contact dermatitis.

- Allergic contact dermatitis is a type 4 hypersensitivity reaction (delayed, cell-mediated).
- Langerhans cells are the "antigen-presenting" cells of the epidermis.

Patch testing is performed by applying substances to the patient's back; each substance is placed under a small aluminum disk covered with adhesive tape. These are left on the patient's back for 48 hours, and the results are interpreted at 48 and 96 hours. Positive reactions occur most often to the following antigens: nickel sulfate, potassium dichromate, thimerosal, paraphenylenediamine, ethylenediamine, neomycin sulfate, benzocaine, thiuram, formaldehyde, and fragrance.

Nickel sulfate allergies are mainly associated with jewelry. Paraphenylenediamine is present in hair dyes and other cosmetics; para-aminobenzoic acid in sunscreens is immunologically related to paraphenylenediamine. Potassium dichromate sensitivity is one of the most common types of occupational allergic contact dermatitis and occurs in construction workers exposed to cement, leathers, and certain paints. Formaldehyde is a common preservative in cosmetics and shampoos. Neomycin sulfate and benzocaine are components of many topical antimicrobial and analgesic preparations. Thimerosal is a commonly used preservative in contact lens solutions and in some intramuscular injections. Thiuram is a rubber accelerator and fungicide and therefore may correlate with occupational dermatitis related to wearing shoes containing rubber or rubber gloves. Allergic contact dermatitis to thiuram and other rubber accelerators is associated with rubber glove use in health care workers.

- Nickel sulfate allergies are associated with jewelry.
- Potassium dichromate sensitivity occurs in construction workers exposed to cement, leathers, and certain paints.
- Formaldehyde is a common preservative in cosmetics and shampoos.
- Allergic contact dermatitis to thiuram and other rubber accelerators is associated with rubber glove use in health care workers.

Acne Vulgaris
Acne vulgaris is one of the most common problems addressed in clinical dermatology. Acne occurs physiologically at puberty with varying degrees of severity but may persist into the second and third decades of life. The pathogenesis of acne is multifactorial; inheritance, increase in sebaceous gland activity, hormonal influences, disturbances of keratinization, and bacterial infection have all been implicated. The primary lesions of acne are noninflammatory and include microcomedones, closed comedones (whiteheads), and open comedones (blackheads). The secondary or inflammatory lesions include papules and pustules, nodules, and cysts. Treatment options for acne are given in Table 5-2.

Table 5-2 Treatment of Acne Vulgaris

Type of acne	Treatment
Comedonal	Topical tretinoin, benzoyl peroxide
Papular or pustular	Same as above, plus topical or systemic antibiotics
Cystic	Systemic antibiotics; if severe, isotretinoin

Systemic Retinoid Use in Acne Vulgaris

Isotretinoin (13-*cis*-retinoic acid) is a synthetic vitamin A derivative used primarily for the treatment of severe nodulocystic acne vulgaris. The mechanism of action of 13-*cis*-retinoic acid in acne is probably multifactorial, including improvement in keratinization, decrease in sebum production, and decrease in inflammation. A 20-week course at a dosage of approximately 1 mg/kg per day is the standard regimen.

- Isotretinoin is used for the treatment of severe acne vulgaris.

The greatest risk associated with use of systemic retinoids is teratogenicity. Before isotretinoin is prescribed, female patients must be counseled on this side effect and use reliable contraception during therapy and for at least 1 month after use of the drug is discontinued.

- The greatest risk with the use of systemic retinoids is teratogenicity.

The systemic retinoids are associated with various side effects, including xerosis (dry skin), dermatitis, cheilitis, sticky skin, peeling skin, epistaxis, conjunctivitis, hair loss, and nail dystrophy. Symptoms of arthralgias and myalgias also may occur. Hyperlipidemia, including both hypertriglyceridemia and hypercholesterolemia, develops in most patients. Other *potential* laboratory abnormalities include increased liver enzyme values and leukopenia. Skeletal hyperostosis may occur, particularly in association with long-term use. Concerns regarding depression and suicidal ideation are being studied.

- Side effects of systemic retinoids include xerosis, dermatitis, cheilitis, sticky skin, peeling skin, epistaxis, conjunctivitis, hair loss, and nail dystrophy. Concerns regarding depression and suicidal ideation are being studied.

Autoimmune Bullous Diseases

Bullous pemphigoid (Fig. 5-1) is the most common autoimmune bullous disease. The disease predominantly occurs in elderly patients and usually presents with large, tense bullae on an erythematous base with a predilection for flexural areas. Lesions often are generalized but may be localized.

- Bullous pemphigoid is the most common autoimmune bullous disease.
- It occurs predominantly in elderly patients.
- It presents as large, tense bullae with a predilection for flexural areas.

Immunofluorescence testing is important for the diagnosis of bullous pemphigoid. Direct immunofluorescence testing of perilesional skin shows deposition of C3 in a linear pattern at the basement membrane zone in almost all cases and of IgG in more than 90%. Indirect immunofluorescence testing of serum shows IgG anti–basement-membrane zone antibodies in approximately 70% of cases.

- Immunofluorescence testing is important for the diagnosis of bullous pemphigoid.
- Almost all cases have deposition of C3 and IgG in a linear pattern at the basement membrane zone.

Treatment of bullous pemphigoid includes systemic corticosteroids, dapsone, azathioprine, cyclophosphamide, and mycophenolate mofetil. In general, bullous pemphigoid requires less immunosuppressive therapy than does pemphigus and, in contrast to pemphigus, the titer of circulating antibodies does not correlate with disease activity.

Epidermolysis bullosa acquisita is another subepidermal bullous disease. It is characterized clinically by blisters or erosions induced by trauma, which predominantly occur on distal locations. A small subset of patients have generalized lesions, which clinically may be difficult to distinguish from bullous pemphigoid.

- Epidermolysis bullosa acquisita is characterized by blisters or erosions induced by trauma.
- It occurs predominantly on distal sites.

On direct immunofluorescence testing, epidermolysis bullosa acquisita has a pattern similar to that in bullous pemphigoid, namely, deposition of IgG and C3 in a linear pattern at the basement membrane zone. In contrast to bullous pemphigoid, C3 may be absent or IgG

Fig. 5-1. Bullous pemphigoid.

may be the dominant immunoreactant. Indirect immunofluorescence testing of serum demonstrates IgG anti–basement-membrane zone antibodies in 25% to 50% of patients. Epidermolysis bullosa acquisita tends to be resistant to immunosuppressive therapy.

- On direct immunofluorescence, epidermolysis bullosa acquisita shows deposition of IgG and C3 in a linear pattern at the basement membrane zone.
- Epidermolysis bullosa acquisita tends to be resistant to immunosuppressive therapy.

Cicatricial pemphigoid is characterized by mucosal lesions, with limited or no cutaneous lesions. The disease predominantly affects oral and ocular mucous membranes, and less frequently the genital, pharyngeal, or upper respiratory mucosa. This disease is also known as benign mucous membrane pemphigoid, which is a misnomer because untreated ocular involvement may lead to blindness. Patients may present with oral erosions or diffuse gingivitis.

- Cicatricial pemphigoid affects oral and ocular mucous membranes, and less frequently genital, pharyngeal, or upper respiratory mucosa.

Treatment of cicatricial pemphigoid is similar to that of bullous pemphigoid, with systemic corticosteroids, dapsone, azathioprine, cyclophosphamide, and mycophenolate. Cyclophosphamide has been used particularly in patients with ocular involvement.

Herpes gestationis, also referred to as pemphigoid gestationis, consists of intensely pruritic urticarial papules, plaques, or blisters usually occurring in the latter half of pregnancy. The lesions are histologically characterized by a subepidermal bulla with eosinophils.

- Herpes gestationis consists of intensely pruritic urticarial papules, plaques, or blisters.

Direct immunofluorescence testing is particularly useful because the other dermatoses of pregnancy (such as pruritic urticarial papules and plaques of pregnancy) are negative by immunofluorescence testing. The serum from approximately half of patients with herpes gestationis contains the HG factor, which is a complement-fixing IgG anti–basement-membrane zone antibody. The circulating antibody crosses the placenta, and the baby born to a mother with herpes gestationis may have a transient blistering eruption develop during the neonatal period.

- In herpes gestationis, direct immunofluorescence is useful because the other dermatoses of pregnancy are negative with such testing.

Linear IgA bullous dermatosis is characterized by vesicles or blisters on an erythematous base in a generalized distribution with a high rate of mucosal involvement. Drug-induced disease has occurred with vancomycin. This disease is characterized by the direct immunofluorescence finding of IgA deposition in a linear pattern at the basement membrane zone, with or without C3 or IgG deposition.

- In linear IgA bullous dermatosis, direct immunofluorescence shows IgA deposition in a linear pattern at the basement membrane zone.

Dermatitis herpetiformis (Fig. 5-2) is characterized by extremely pruritic, grouped vesicles occurring predominantly over the elbows, knees, buttocks, back of the neck and scalp, and lower part of the back, usually beginning in the third or fourth decade of life. Virtually all patients have some degree of gluten-sensitive enteropathy (celiac sprue), although it is usually low-grade and subclinical. This association is important in terms of management of dermatitis herpetiformis. Dermatitis herpetiformis also is associated with thyroid disease.

- In dermatitis herpetiformis, virtually all patients have some degree of gluten-sensitive enteropathy (celiac sprue).

The hallmark of the diagnosis of dermatitis herpetiformis is the direct immunofluorescence finding of IgA deposits in a stippled, granular, or clumped pattern along the basement membrane zone. Skin biopsy specimens should be obtained from an area 0.5 to 1 cm from an active lesion. IgA deposits tend to persist in the skin over time. A small percentage of patients who strictly adhere to a gluten-free diet may show diminution in IgA deposits after many years, but IgA deposits in the skin are unaffected by pharmacologic therapy. Testing for endomysial antibodies and tissue transglutaminase is useful for both diagnosis and management of dermatitis herpetiformis, although

Fig. 5-2. Dermatitis herpetiformis.

these antibodies correlate with the degree of gluten-sensitive enteropathy rather than the skin lesions per se.

- In dermatitis herpetiformis, direct immunofluorescence shows IgA deposits in a stippled, granular, or clumped pattern.
- Testing for endomysial antibodies and tissue transglutaminase is useful for diagnosis and management.

The mainstay of treatment of dermatitis herpetiformis consists of dapsone and a gluten-free diet. Patients who strictly adhere to a gluten-free diet may have a decreased need for dapsone. Patients must adhere to the diet for at least 8 months before it is effective. The titer of IgA anti-endomysial antibodies decreases during strict adherence to a gluten-free diet. Patients with gluten-sensitive enteropathy have an increased risk for small bowel lymphoma. Only adherence to a gluten-free diet will affect this risk. Systemic corticosteroids are not helpful for the treatment of dermatitis herpetiformis.

- Treatment of dermatitis herpetiformis consists of dapsone and a gluten-free diet.

Bullous eruption of systemic lupus erythematosus shares clinical and histologic features with dermatitis herpetiformis. The blisters were therefore originally thought to represent the coexistence of dermatitis herpetiformis and lupus erythematosus, but they are now established as a distinct subset of lupus.

Direct immunofluorescence testing shows deposition of IgG, IgM, IgA, or C3 in a linear or granular pattern at the basement membrane zone, similar to the classic "lupus band."

- In bullous eruption of systemic lupus erythematosus, direct immunofluorescence shows deposition of IgG, IgM, IgA, or C3 in a linear or granular pattern at the basement membrane zone.

The clinical variants of *pemphigus* include pemphigus vulgaris and pemphigus foliaceus (with the subsets pemphigus erythematosus and fogo selvagem, the latter being an endemic form of pemphigus that occurs in South America). There is also a drug-induced variant of pemphigus, particularly associated with D-penicillamine, captopril, or other thiol-containing medications.

More than 50% of patients with pemphigus vulgaris present with oral lesions, and more than 90% have oral mucosal involvement at some point in the course of the disease. Pemphigus vulgaris is characterized by coalescing blisters and erosions, often with generalized involvement. In contrast, pemphigus foliaceus (Fig. 5-3), considered to represent the "superficial" variant of pemphigus, may present with superficial scaling-crusting lesions of the head and neck area (in a seborrheic dermatitis-like pattern) or generalized distribution.

- Pemphigus vulgaris is characterized by coalescing blisters and erosions.
- Pemphigus foliaceus may present with superficial scaling-crusting lesions of the head and neck.

All types of pemphigus are characterized by the deposition of IgG and C3 at the intercellular space (epidermal cell surface) on direct immunofluorescence testing (intercellular substance [ICS] antibody). On indirect immunofluorescence testing, IgG anti-ICS antibodies are found in approximately 90% of cases. The titer of IgG anti-ICS antibodies is useful in both diagnosis and management of pemphigus.

- All types of pemphigus are characterized by the direct immunofluorescence finding of IgG and C3 deposition at the epidermal cell surface.
- The titer of IgG anti-ICS antibodies is useful in diagnosis and management.

Pemphigus antibodies are pathogenic in that they have been shown to induce acantholysis in vitro and in animal models.

- Pemphigus antibodies induce acantholysis.

High-dose corticosteroids generally are required to control pemphigus. Various "steroid-sparing" immunosuppressive agents have been used, including azathioprine, mycophenolate mofetil, cyclophosphamide, gold, and dapsone.

- High-dose corticosteroids generally are required to control pemphigus, followed by institution of a steroid-sparing agent.

Erythema Multiforme

Erythema multiforme (Fig. 5-4) is an acute, usually self-limited eruption of maculopapular, urticarial, occasionally bullous lesions characterized by "iris" or "target" morphology. A subset of patients with erythema multiforme may have recurrent lesions. When erythema multiforme presents with extensive cutaneous and mucosal lesions, it is referred to as Stevens-Johnson syndrome. Various etiologic factors have been implicated in erythema multiforme. The most commonly cited precipitating factor is viral infection, particularly herpes simplex virus. This is responsible for a considerable percentage of recurrent erythema multiforme. Other infectious agents that have been noted to cause erythema multi-

Fig. 5-3. Pemphigus foliaceus.

Fig. 5-4. Erythema multiforme.

forme include *Mycoplasma pneumoniae* and *Yersinia enterocolitica*. Drugs have been reported to induce erythema multiforme, particularly sulfonamides, barbiturates, and anticonvulsants. Erythema multiforme also may be associated with underlying connective tissue disease or malignancy. A small subset of patients with erythema multiforme have disease limited to the oral mucosa. Erythema multiforme tends to involve the lips, buccal mucosa, and tongue, in contrast to pemphigus vulgaris, which typically involves the pharynx, buccal mucosa, and tongue, and pemphigoid, which most often involves gingivae. Neither pemphigus nor pemphigoid involves the lips.

- The most commonly cited precipitating factor for erythema multiforme is viral infection, particularly herpes simplex.
- Other infectious agents: *Mycoplasma pneumoniae* and *Yersinia enterocolitica*.
- Drugs also induce erythema multiforme: sulfonamides, barbiturates, anticonvulsants.

Erythema Nodosum

Erythema nodosum (Fig. 5-5) typically presents as tender, erythematous, subcutaneous nodules localized to the pretibial areas. The lesions may be acute and self-limited or chronic, lasting for months to years. The most common cause is streptococcal pharyngitis. Other infectious agents that have been implicated in the development of erythema multiforme include *Yersinia enterocolitica*, *Coccidioides*, and *Histoplasmosis*. Drug-induced erythema nodosum most often is associated with oral contraceptives and sulfonamides. Other associations with erythema nodosum include sarcoidosis, inflammatory bowel disease, and Behçet syndrome.

- The most common cause of erythema nodosum is streptococcal pharyngitis.
- Drug-induced erythema nodosum most often is associated with oral contraceptives and sulfonamides.
- Other associations: sarcoidosis, inflammatory bowel disease, Behçet syndrome.

Drug Reactions

The morphologic spectrum of reactions that may be induced by medications is broad, and hundreds of drugs may produce a given cutaneous reaction. Types of cutaneous lesions induced by drugs include maculopapular eruptions, acne-folliculitis, necrotizing vasculitis, vesiculobullous lesions, erythema multiforme, erythema nodosum, fixed drug eruptions, lichenoid reactions, photosensitivity reactions, pigmentary changes, and hair loss.

Approximately 2% of hospitalized patients have cutaneous drug reactions, and penicillin, sulfonamides, and blood products are responsible for approximately two-thirds of such reactions. The most common types of clinical presentations (in descending order of frequency) are exanthematous or morbilliform eruptions, urticaria or angioedema, fixed drug eruptions, and erythema multiforme. Stevens-Johnson syndrome, exfoliative erythroderma, and photosensitive eruptions are less common. Table 5-3 outlines the types of cutaneous reactions to drugs.

- About 2% of hospitalized patients have cutaneous drug reactions.
- Penicillin, sulfonamides, and blood products are responsible for about two-thirds of drug reactions.
- Urticarial drug reactions are most often related to aspirin, penicillin, and blood products.
- Photoallergic reactions are most often associated with sulfonamides, thiazides, griseofulvin, or phenothiazines.
- Phototoxic reactions may be induced by tetracyclines.

Exanthematous or morbilliform eruptions are the most common type of cutaneous drug reaction. This type of eruption usually begins

Fig. 5-5. Erythema nodosum.

Table 5-3 Cutaneous Reactions to Drugs

Type of skin reaction	Cause
Urticarial	Aspirin, penicillin, blood products
Photoallergic	Sulfonamides, thiazides, griseofulvin, phenothiazines
Phototoxic	Tetracyclines
Slate-gray discoloration	Chlorpromazine
Slate-blue discoloration	Amiodarone
Yellow or blue-gray pigmentation	Antimalarials

within a week of onset of therapy, but it may occur more than 2 weeks after initiation of the therapy or up to 2 weeks after use of the drug has been discontinued. Ampicillin, penicillin, and cephalosporins are commonly associated with morbilliform eruptions. A fixed drug eruption is one or several lesions that recur at the same anatomical location on rechallenge with the medication. The genital and facial areas are common sites of involvement. Phenolphthalein, barbiturates, salicylates, and oral contraceptives have been implicated in the cause of fixed drug eruptions.

- Exanthematous or morbilliform eruptions are the most common cutaneous drug reaction.
- A fixed drug eruption is one or several lesions that recur at the same location on rechallenge.
- Phenolphthalein, barbiturates, salicylates, and oral contraceptives are implicated in fixed drug eruptions.

Lichenoid drug eruptions are morphologically similar to lichen planus (with violaceous papules of the skin) and most often have been associated with gold and antimalarial drugs, although various medications may induce this type of reaction.

Cutaneous Signs of Underlying Malignancy

Cutaneous metastasis occurs in 1% to 5% of patients with metastatic neoplasms. The types of malignancy metastatic to the skin are lung, breast, kidney, gastrointestinal, melanoma, and ovary. Lesions usually present on the scalp, face, or trunk.

- Cutaneous metastasis occurs in 1%-5% of patients with metastatic neoplasms.
- Lesions usually present on the scalp, face, or trunk.

Paget disease of the nipple is an erythematous, scaly, or weeping eczematous eruption of the areola. Virtually all patients with Paget disease have an underlying ductal carcinoma of the breast. In contrast, *extramammary Paget disease*, a morphologically similar eruption that usually occurs in the anogenital region, is associated with underlying carcinoma in only about 50% of cases. Extramammary Paget disease may be associated with underlying cutaneous adnexal carcinoma or with underlying visceral carcinoma (particularly of the genitourinary or distal gastrointestinal tracts).

- Patients with Paget disease have underlying ductal carcinoma of the breast.
- Extramammary Paget disease may be associated with underlying carcinoma in only 50% of cases.

Acanthosis nigricans (Fig. 5-6) consists of velvety hyperpigmentation of the intertriginous regions, particularly the axillae and groin. It has been associated with adenocarcinoma of the gastrointestinal tract, particularly the stomach. It also occurs with insulin-resistant diabetes. Acanthosis nigricans also may be associated with obesity or certain medications (such as prednisone and nicotinic acid). There is an autosomal-dominant variant of acanthosis nigricans.

- Acanthosis nigricans is associated with adenocarcinoma of the gastrointestinal tract, particularly the stomach.
- It also may be associated with obesity, certain medications, and insulin-resistant diabetes.

Pyoderma gangrenosum (Fig. 5-7) consists of ulcers with irregular, undermined, inflammatory, violaceous borders that heal with cribriform scarring. The lesions are most commonly associated with inflammatory bowel disease or rheumatoid arthritis. Pyoderma gangrenosum may be associated with malignancy of the hematopoietic system, particularly leukemia.

- Pyoderma gangrenosum is most commonly associated with inflammatory bowel disease or rheumatoid arthritis.
- It may be associated with leukemia.

The skin lesions of *glucagonoma syndrome* (*necrolytic migratory erythema*) (Fig. 5-8) consist of erosions, crusting, and peeling involving the perineum

Fig. 5-6. Acanthosis nigricans.

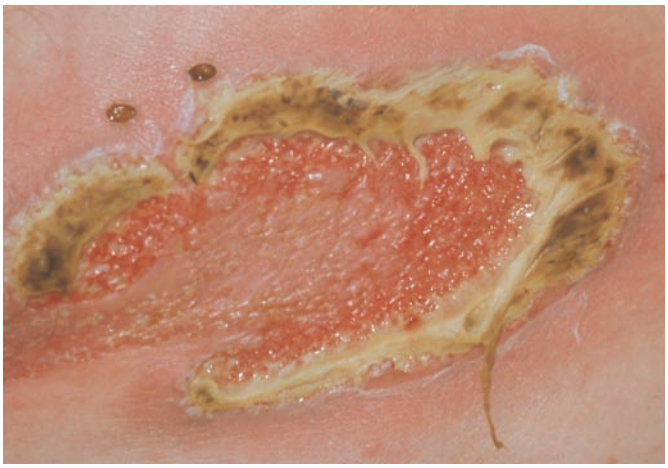

Fig. 5-7. Pyoderma gangrenosum.

and perioral areas, but they may be generalized. The syndrome also includes stomatitis, glossitis (beefy tongue), anemia, diarrhea, and weight loss. It is associated with an islet cell (α) tumor of the pancreas.

- Glucagonoma syndrome consists of erosions, crusting, and peeling involving the perineum and perioral areas.
- It is associated with an islet cell tumor of the pancreas.

Gardner syndrome is a hereditary (autosomal dominant) form of colon polyposis. Clinical features include adenomatous polyps of the colon, osteomas of the skull and face, scoliosis, soft tissue tumors (including dermoids, lipomas, and fibromas), and sebaceous (epidermal inclusion) cysts of the face and scalp. There is a high incidence of colon carcinoma. In approximately 60% of patients, adenocarcinoma of the colon develops by age 40 years. Malignancies of other sites have been associated with this syndrome, including adrenal, ovarian, and thyroid.

- Gardner syndrome is a hereditary (autosomal dominant) form of colon polyposis.
- Clinical features: soft tissue tumors, sebaceous cysts of the face.
- There is a high incidence of colon cancer.

Acquired ichthyosis most often has been associated with Hodgkin disease, but it has been reported with other types of lymphoma, multiple myeloma, and various carcinomas.

- Acquired ichthyosis is associated with Hodgkin disease.

Hirsutism may reflect androgen excess due to an adrenal or ovarian tumor.

Hypertrichosis is an increase in hair unrelated to androgen excess, such as hypertrichosis lanuginosa acquisita (growth of soft downy hair). It has been associated with carcinoid tumor, adenocarcinoma of the breast, lymphoma, gastrointestinal malignancy, and other types of neoplasms.

Sweet syndrome (*acute febrile neutrophilic dermatosis*) has skin lesions that consist of erythematous plaques and nodules, most commonly located on the proximal aspects of the extremities and face. The association is with leukemia, particularly acute myelocytic or acute myelomonocytic leukemia, although many other diseases also have been associated.

- Sweet syndrome is associated with leukemia (acute myelocytic or acute myelomonocytic).

Generalized pruritus is the presentation for many cutaneous and systemic disorders. Pruritus may be the presenting symptom in lymphoma.

- Pruritus may be the presenting symptom in lymphoma.

In *dermatomyositis*, the pathognomonic skin lesions are Gottron papules (Fig. 5-9) involving the skin over the joints of the fingers, elbows, and knees. Poikilodermatous lesions or erythematous maculopapular eruptions may diffusely involve the face, particularly the periorbital area ("heliotrope rash" [Fig. 5-10]), and the trunk and extremities. The cutaneous lesions are photosensitive and pruritic. The disease is characterized by proximal myositis. Although creatine kinase and aldolase levels usually are increased in patients with myositis, it is important to verify the diagnosis by obtaining an electromyogram and a muscle biopsy specimen. Dermatomyositis is associated with an increased incidence of underlying malignancy.

- Dermatomyositis may involve the periorbital area ("heliotrope rash") or the dorsal aspect of the hands (Gottron papules).
- The lesions are photosensitive and pruritic.
- Dermatomyositis is characterized by proximal myositis.
- Dermatomyositis is associated with an increased risk of internal malignancy.

Fig. 5-8. Glucagonoma syndrome (necrolytic migratory erythema).

Fig. 5-9. Dermatomyositis: Gottron papules.

Cutaneous amyloidosis may present clinically as macroglossia (Fig. 5-11), waxy papules on the eyelids or nasolabial folds, pinch purpura, and postproctoscopic purpura (Fig. 5-12). Multiple myeloma may be associated with amyloid.

- Amyloidosis may be associated with multiple myeloma.

Tylosis is a rare disorder characterized by palmar-plantar keratoderma associated with esophageal carcinoma. It has autosomal dominant inheritance.

- Tylosis is associated with esophageal carcinoma.

The *autoimmune bullous diseases* are a heterogeneous group of disorders characterized by antibody deposition at the basement membrane zone or epidermis. An association with malignancy has been found in several of these disorders.

- Pemphigus is associated with thymoma with or without myasthenia gravis.
- Paraneoplastic pemphigus presents with clinical and histologic features of pemphigus and erythema multiforme and is associated with lymphoma and leukemia.
- Small bowel lymphoma rarely develops in patients with dermatitis herpetiformis.
- Epidermolysis bullosa acquisita is associated with amyloidosis and multiple myeloma.
- Bullous pemphigoid has not been associated with an increased risk of underlying malignancy.

Dermatology: An Internist's Perspective

Respiratory

The skin is involved in 15% to 35% of patients with *sarcoidosis*. Lesions may present as 1) lupus pernio (erythematous swelling of the nose), 2) translucent papules around the eyes and nasolabial folds, 3) annular lesions with central atrophy, 4) nodules on the trunk and extremities, and 5) scar sarcoid.

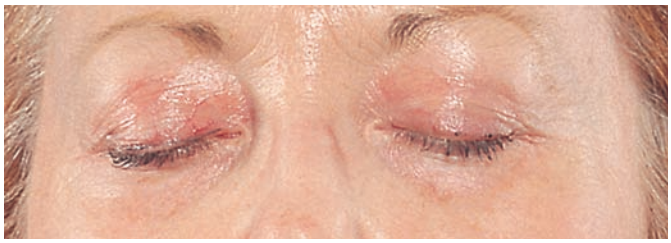

Fig. 5-10. Dermatomyositis: heliotrope discoloration.

- The skin is involved in 15%-35% of patients with sarcoidosis.
- Lesions may present as lupus pernio (erythematous swelling of the nose).

Acute sarcoidosis may present with a combination of erythema nodosum, bilateral hilar lymphadenopathy, fever, and arthralgias (Löfgren syndrome). *Erythema nodosum* (Fig. 5-5) is a reactive condition that may be associated with acute sarcoidosis. Erythema nodosum typically presents as tender, erythematous, subcutaneous nodules localized to pretibial areas.

- Erythema nodosum may be associated with acute sarcoidosis (Löfgren syndrome).

In *Wegener granulomatosis*, cutaneous involvement occurs in more than 50% of patients and is manifested by cutaneous infarction, ulceration, hemorrhagic bullae, purpuric papules, or urticaria. A skin biopsy may show hypersensitivity vasculitis or granulomatous vasculitis.

- In Wegener granulomatosis, cutaneous involvement occurs in >50% of patients.
- Manifestations: ulceration, hemorrhagic bullae, purpuric papules, urticaria.

Fig. 5-11. Amyloidosis: macroglossia.

Fig. 5-12. Amyloidosis: postproctoscopic purpura.

Churg-Strauss granulomatosis (*allergic granulomatosis*) is characterized by a combination of adult-onset asthma, peripheral eosinophilia, and pulmonary involvement with recurrent pneumonia or transient infiltrates. Skin lesions have been reported in up to 60% of patients and consist of palpable purpura, cutaneous infarcts, and subcutaneous nodules.

- Skin lesions of Churg-Strauss granulomatosis occur in up to 60% of patients.
- Skin lesions include palpable purpura, cutaneous infarcts, and subcutaneous nodules.

In *relapsing polychondritis*, there is episodic destructive inflammation of cartilage of the ears, nose, and upper airways. There may be associated arthritis and ocular involvement. In the acute stage, the ears may be red, swollen, and tender. Later, they become soft and flabby. Nasal chondritis may lead to saddle-nose deformities. Relapsing polychondritis is mediated by antibodies to type II collagen.

- Relapsing polychondritis: episodic destructive inflammation of cartilage of ears, nose, upper airways.
- Nasal chondritis may lead to saddle-nose deformities.

Cardiovascular

Pseudoxanthoma elasticum may be transmitted by autosomal dominant or autosomal recessive inheritance. Yellow xanthoma-like papules are seen on the neck (plucked-chicken skin), axillae, groin, and abdomen. Angioid streaks may be seen in the fundus. Skin biopsy shows degeneration of elastic fibers. Systemic associations include stroke, myocardial infarction, peripheral vascular disease, and gastrointestinal hemorrhage.

- Pseudoxanthoma elasticum is associated with stroke, myocardial infarction, peripheral vascular disease, and gastrointestinal hemorrhage.

Ehlers-Danlos syndrome includes 10 subgroups that vary in severity and systemic associations. Cutaneous findings are skin hyperextensibility with hypermobile joints and fish-mouth scars. Angina, peripheral vascular disease, and gastrointestinal bleeding may be associated.

- Ehlers-Danlos syndrome is associated with angina, peripheral vascular disease, and gastrointestinal bleeding.

Erythema marginatum is one of the diagnostic criteria for acute rheumatic fever. This uncommon eruption occurs on the trunk and is characterized by erythematous plaques with rapidly mobile serpiginous borders.

- Erythema marginatum is one of the diagnostic criteria for acute rheumatic fever.

Gastrointestinal

Osler-Weber-Rendu syndrome (*hereditary hemorrhagic telangiectasia*), with autosomal dominant inheritance, is manifested by cutaneous and mucosal telangiectasias. Frequent nosebleeds and gastrointestinal bleeds may be a presenting feature. Pulmonary arteriovenous malformations and central nervous system angiomas are also features of this syndrome.

- Osler-Weber-Rendu syndrome has autosomal dominant inheritance.
- Features: cutaneous and mucosal telangiectasia, nosebleeds, gastrointestinal bleeds, pulmonary arteriovenous malformations, central nervous system angiomas.

Acrodermatitis enteropathica is an inherited (autosomal recessive) or acquired disease characterized by zinc deficiency (failure of absorption or failure to supplement). The clinical features include angular cheilitis, a seborrheic dermatitis-like eruption, erosions, blisters, and pustules, with skin lesions particularly involving the face, hands, feet, and perineum. Alopecia and diarrhea are other features of this syndrome.

- Acrodermatitis enteropathica: inherited (autosomal recessive) or acquired disease.
- Characterized by zinc deficiency (failure of absorption or failure to supplement).

Peutz-Jeghers syndrome is an inherited (autosomal dominant) syndrome of intestinal polyposis. Patients have hamartomas, mostly involving the small bowel, and a slightly increased risk for carcinoma. Cutaneous lesions include macular pigmentation (freckles) of the lips, periungual skin, fingers, and toes and pigmentation of the oral mucosa.

- Peutz-Jeghers syndrome is an inherited (autosomal dominant) syndrome of intestinal polyposis.
- Patients have an increased risk for carcinoma.

Dermatitis herpetiformis (Fig. 5-2) is an immune-mediated bullous disease that presents with intensely itchy vesicles on extensor surfaces (elbows, knees, buttocks, scapulae). Gluten-sensitive enteropathy occurs in almost all patients, although it may be subclinical. Gluten-sensitive enteropathy is associated with an increased risk of small B-cell lymphoma.

- Dermatitis herpetiformis is an immune-mediated bullous disease.
- Gluten-sensitive enteropathy occurs in almost all patients.

- Gluten-sensitive enteropathy is associated with an increased risk of small B-cell lymphoma.

Extensive *aphthous ulceration* may be associated with Crohn disease or gluten-sensitive enteropathy.

- Aphthous ulceration may be associated with Crohn disease or gluten-sensitive enteropathy.

Pyoderma gangrenosum (Fig. 5-7) presents with ulceration, predominantly on the lower extremities, with inflammatory undermined borders. The lesions heal with cribriform scarring. The occurrence of the disease at sites of trauma is classic (pathergy). Systemic disease associations include inflammatory bowel disease (ulcerative colitis more commonly than Crohn disease), rheumatoid arthritis, and paraproteinemia.

- Pyoderma gangrenosum occurs at sites of trauma.
- Associated diseases are inflammatory bowel disease (ulcerative colitis more than Crohn disease), rheumatoid arthritis, and paraproteinemia.

Cutaneous Crohn disease may present as skin nodules with granulomatous histologic findings. Other manifestations include pyostomatitis vegetans (granulomatous inflammation of the gingivae), granulomatous cheilitis, oral aphthous ulceration, perianal skin tags, perianal fistulas, and peristomal pyoderma gangrenosum.

- Manifestation of Crohn disease: pyostomatitis vegetans (granulomatous inflammation of gingivae).

Bowel bypass syndrome presents with a flu-like illness with fever, malaise, arthralgias, myalgias, and inflammatory papules and pustules on the extremities and upper trunk. The disease is recurrent and episodic and occurs in up to 20% of patients after jejunoileal bypass. The condition responds to antibiotics or to reversal of the bypass procedure.

- Bowel bypass syndrome: flu-like illness, inflammatory papules and pustules.
- Occurs in up to 20% of patients after jejunoileal bypass.

Gardner syndrome and *glucagonoma syndrome* are described earlier in this chapter.

Nephrology

Partial lipodystrophy is associated with C3 deficiency and the nephrotic syndrome.

Uremic pruritus is associated with end-stage renal disease and responds to UVB therapy.

Neurocutaneous

Fabry disease is an X-linked recessive disorder due to deficiency of the enzyme α-galactosidase A. The skin changes consist of numerous vascular tumors (angiokeratomas) that develop during childhood and adolescence. Corneal opacities are present in 90% of patients. Systemic manifestations include paresthesias and pain due to involved peripheral nerves, renal insufficiency, and vascular insufficiency of the coronary and central nervous system.

- Fabry disease is a recessive disorder due to deficiency of α-galactosidase A.
- Systemic manifestations: paresthesias, renal insufficiency, vascular insufficiency.

The clinical features of *ataxia-telangiectasia* include cutaneous and ocular telangiectasia, cerebellar ataxia, choreoathetosis, IgA deficiency, and recurrent pulmonary infections.

Tuberous sclerosis may be inherited in an autosomal dominant pattern (25%) or may occur sporadically (new mutation). Predominant cutaneous lesions include hypopigmented macules, adenoma sebaceum, subungual or periungual fibromas, and shagreen patch (connective tissue nevus) (Fig. 5-13). This syndrome is associated with epilepsy (80%) and mental retardation (60%). Rhabdomyomas may occur in the heart in childhood. Angiomyolipomas occur in the kidneys in up to 80% of adults with this syndrome.

- Tuberous sclerosis may be inherited in an autosomal dominant pattern or be sporadic.
- It is associated with epilepsy (80%) and mental retardation (60%).
- Angiomyolipomas occur in the kidneys in up to 80% of affected adults.

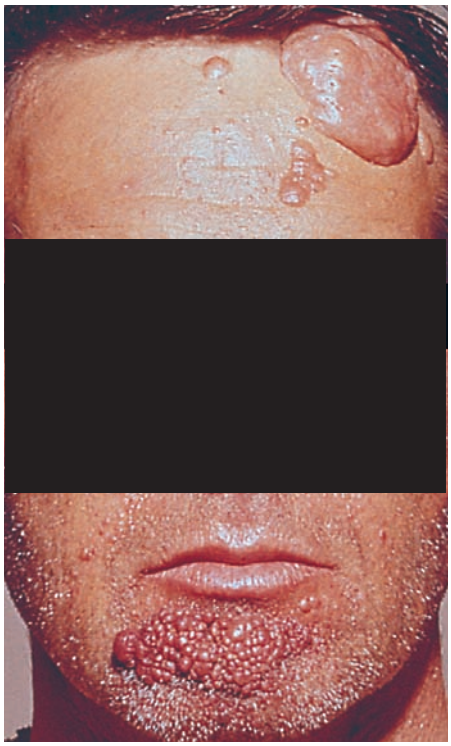

Fig. 5-13. Tuberous sclerosis: adenoma sebaceum and forehead plaque.

Neurofibromatosis (von Recklinghausen disease) (Fig. 5-14) occurs in 1 in 3,000 births. Inheritance is autosomal dominant, and approximately 50% of cases are new mutations. The major signs of the disease are café au lait spots, axillary freckling (Crowe sign), neurofibromas, and Lisch nodules of the iris.

- Neurofibromatosis is autosomal dominant.
- Major signs: café au lait spots, axillary freckling, neurofibromas.

The associated central nervous system tumors include acoustic neuromas, optic gliomas, and meningiomas. Other associated tumors include pheochromocytoma, neuroblastoma, and Wilms tumor. Café au lait spots and neurofibromas frequently occur in the absence of neurofibromatosis. The diagnostic criteria for neurofibromatosis include two or more of the following:

1. Six or more café au lait macules more than 0.5 cm in greatest diameter in prepubertal patients, or more than 1.5 cm in diameter in adults
2. Two or more neurofibromas of any type, or one plexiform neurofibroma
3. Freckling of skin in axillary or inguinal regions
4. Optic gliomas
5. Lisch nodules
6. An osseous lesion such as sphenoid dysplasia or thinning of long bone cortex with or without pseudarthrosis
7. A first-degree relative with neurofibromatosis that meets the above diagnostic criteria

Sturge-Weber-Dimitri syndrome is characterized by capillary angioma (port-wine stain) in the distribution of the upper or middle branch of the trigeminal nerve. There may be associated meningeal angioma in the same distribution. Intracranial tramline calcification, mental retardation, epilepsy, contralateral hemiparesis, and visual impairment may be associated.

Fig. 5-14. Neurofibromatosis: plexiform neurofibroma.

- Sturge-Weber-Dimitri syndrome is characterized by capillary angioma in the distribution of the upper or middle branch of the trigeminal nerve.
- Associated features: intracranial calcification, mental retardation, epilepsy, contralateral hemiparesis, visual impairment.

Rheumatology: Cutaneous Associations of Arthritis

Psoriatic arthritis occurs in 5% to 8% of patients with cutaneous psoriasis. Several different patterns of arthritis occur. An asymmetric oligoarthritis occurs in 70% of patients. This group includes patients with "sausage digits" and monoarthritis. The second most common presentation is a symmetric arthritis clinically similar to rheumatoid arthritis, which occurs in 15% of patients with psoriatic arthritis. Distal interphalangeal involvement, arthritis mutilans, and a spinal form of arthritis similar to ankylosing spondylitis each occurs in 5% of patients with psoriatic arthritis.

- Psoriatic arthritis occurs in 5%-8% of patients with psoriasis.
- Asymmetric oligoarthritis is most common.
- 5% of patients have ankylosing spondylitis.

Reiter syndrome consists of the triad of urethritis, conjunctivitis, and arthritis. The disease usually affects young men. Two-thirds of patients have skin lesions, namely, circinate balanitis, consisting of erythematous plaques of the penis, and keratoderma blennorrhagicum, a pustular psoriasiform eruption of the palms and soles. Most patients are positive for HLA-B27.

- Reiter syndrome triad: urethritis, conjunctivitis, arthritis.
- Skin signs: circinate balanitis, keratoderma blennorrhagicum.
- Most patients are positive for HLA-B27.

Erythema chronicum migrans is an annular, sometimes urticarial, erythematous lesion presenting as a manifestation of Lyme disease. The lesion develops subsequent to and surrounding the site of a tick bite. Lesions are single in 75% of patients and multiple in 25%. Other acute features of Lyme disease include fever, headaches, myalgias, arthralgias, and lymphadenopathy. The deer tick *Ixodes dammini* contains a spirochete, *Borrelia burgdorferi*, that is responsible for the syndrome. Arthritis is a late complication of Lyme disease. Weeks or months after the initial illness, meningoencephalitis, peripheral neuropathy, myocarditis, atrioventricular node block, or destructive erosive arthritis may develop.

- Erythema chronicum migrans presents as a manifestation of Lyme disease.
- The lesion develops subsequent to and surrounding the site of a tick bite.
- Lesions are single in 75% of patients and multiple in 25%.

In *rheumatoid arthritis*, nodules may occur over the extensor surfaces of joints, most commonly on the dorsal aspects of the hands and elbows. Rheumatoid vasculitis with ulceration may occur in the setting of rheumatoid arthritis with a high circulating rheumatoid factor.

During the late stages of *gout*, tophi (urate deposits with surrounding inflammation) occur in the subcutaneous tissues. Improved methods of treatment account for the decrease in the incidence of tophaceous gout in recent years.

- Gouty tophi may occur in subcutaneous tissues.

In *lupus erythematosus* (LE), cutaneous abnormalities occur in approximately 80% of patients. LE can be classified into acute cutaneous LE (malar rash, generalized maculopapular eruption, or bullous LE), subacute cutaneous LE, and chronic cutaneous LE (localized discoid LE, generalized discoid LE, and lupus panniculitis).

- In LE, cutaneous abnormalities occur in 80% of patients.

Skin lesions are present in up to 85% of patients with acute systemic LE. A butterfly rash with erythema involving the nose and cheeks is characteristic. Erythematous papules and plaques also may occur on the dorsal aspect of the hands, and the skin overlying the interphalangeal and metacarpal phalangeal joints is spared. Maculopapular erythema also may occur on sun-exposed areas.

Subacute cutaneous LE (Fig. 5-15) usually presents with generalized annular or polycyclic plaques. The lesions may appear papulosquamous or vesiculobullous. Subacute cutaneous LE is characterized by the presence of anti-Ro (anti-SSA) antibodies in serum and photosensitivity. These antibodies cross the placenta, and children born to mothers with subacute cutaneous LE may develop congenital heart block or a transient photodistributed skin eruption during the neonatal period.

- Subacute cutaneous LE presents with annular or polycyclic plaques.
- Subacute cutaneous LE is characterized by the presence of anti-Ro (anti-SSA) antibodies and photosensitivity.

Discoid LE (Fig. 5-16) is characterized by erythematous papules and plaques with follicular hyperkeratosis and scaling. Localized discoid LE is usually not associated with progression to systemic LE. Generalized discoid LE or disseminated discoid LE refers to lesions involving the head and neck area or the trunk and extremities. Discoid LE most commonly affects the face, scalp, and ears. Although most patients with discoid LE lack manifestations of systemic LE, approximately 25% of patients with systemic LE have had cutaneous lesions of discoid LE at some point during the course of their illness. Circulating antinuclear antibodies are demonstrable in most patients with systemic LE and subacute cutaneous LE, but they are present in only a small percentage of patients with discoid LE.

- Discoid LE is characterized by erythematous papules and plaques with follicular hyperkeratosis and scaling.
- Discoid LE most commonly affects the face, scalp, and ears.
- 25% of patients with systemic LE have had cutaneous manifestations of discoid LE.

The term "scleroderma" encompasses a wide spectrum of diseases ranging from generalized multisystem disease to localized cutaneous disease. The systemic end of the spectrum is represented by diffuse scleroderma and the CREST (*c*alcinosis cutis, *R*aynaud phenomenon, *e*sophageal involvement, *s*clerodactyly, and *t*elangiectasia) syndrome. The middle area of the spectrum is represented by eosinophilic fasciitis and linear scleroderma, which may have systemic involvement. Localized scleroderma (also known as morphea) may be a single plaque or may be multiple plaques in a generalized distribution.

Systemic scleroderma consists of diffuse sclerosis associated with smoothness and hardening of the skin, with masklike face and microstomia. Sclerodactyly, periungual telangiectasia, telangiectatic mats, hyperpigmentation, and cutaneous calcification may be observed. Esophageal, pulmonary, renal, and cardiac involvement may be associated with systemic scleroderma. The CREST syndrome (Fig. 5-17) is associated with circulating anticentromere antibodies.

- Systemic scleroderma may include sclerodactyly, periungual telangiectasia, telangiectatic mats, hyperpigmentation, and cutaneous calcification.

Eosinophilic fasciitis manifests as tightly bound thickening of the skin and underlying soft tissues of the extremities. Other features include arthralgias, hypergammaglobulinemia, and peripheral blood eosinophilia.

Fig. 5-15. Subacute cutaneous lupus erythematosus.

Fig. 5-16. Discoid lupus erythematosus.

Fig. 5-17. Scleroderma: CREST syndrome.

- Eosinophilic fasciitis manifests as tightly bound thickening of the skin and underlying soft tissue of the extremities.

Morphea manifests as discrete sclerotic plaques with a white, shiny center and erythematous or violaceous periphery. Localized or linear scleroderma may have various presentations depending on extent, location, and depth of sclerosis. Most lesions are characterized by sclerosis and atrophy associated with depression or "delling" of the soft tissue; underlying bone may be affected in linear scleroderma.

- Morphea manifests as discrete sclerotic plaques with a white, shiny center.
- Underlying bone may be affected in linear scleroderma.

Hematologic

Graft-versus-host disease (GVHD) most commonly occurs after bone marrow transplantation and represents the constellation of skin lesions, diarrhea, and liver enzyme abnormalities. GVHD occurs in 60% to 80% of patients who undergo allogeneic bone marrow transplantation.

- GVHD commonly occurs after bone marrow transplantation.
- GVHD includes skin lesions, diarrhea, liver enzyme abnormalities.

GVHD generally occurs in two phases. Acute GVHD begins 7 to 21 days after transplantation, and chronic GVHD begins within months to 1 year after transplantation. One or both phases may occur in the same patient. Acute GVHD results from attack of donor immunocompetent T lymphocytes and null lymphocytes against host histocompatibility antigens. Chronic GVHD results from immunocompetent lymphocytes that develop in the recipient.

The cutaneous abnormalities of acute GVHD include pruritus, numbness or pain of the palms and soles, an erythematous maculopapular eruption of the trunk, palms, and soles, and blisters that, when extensive, resemble toxic epidermal necrolysis. Acute GVHD also includes intestinal abnormalities resulting in diarrhea and liver function changes.

- Cutaneous abnormalities of GVHD: pruritus, numbness or pain of palms and soles, erythematous maculopapular eruption of trunk, palms, and soles.

Chronic GVHD mainly affects skin and liver. Early chronic GVHD is characterized by a lichenoid reaction consisting of cutaneous and oral lesions that resemble lichen planus, with coalescing violaceous papules on the skin and white reticulated patches on the buccal mucosa. Late chronic GVHD is characterized by cutaneous sclerosis, poikilodermatous-reticulated lesions, and scarring alopecia. The cutaneous infiltrate is composed predominantly of suppressor/cytotoxic T cells.

- Chronic GVHD: lichenoid reaction consisting of cutaneous and oral lesions.

Mastocytosis (mast cell disease) can be divided into four groups, depending on the age at onset and the presence or absence of systemic involvement: 1) urticaria pigmentosa arising in infancy or adolescence without substantial systemic involvement, 2) urticaria pigmentosa in adults without substantial systemic involvement, 3) systemic mast cell disease, and 4) mast cell leukemia.

The cutaneous lesions may be brown to red macules, papules, nodules, or plaques that urticate on stroking. Less commonly, the lesions may be bullous, erythrodermic, or telangiectatic. The systemic manifestations are due to histamine release and consist of flushing, tachycardia, and diarrhea.

- Cutaneous lesions of mastocytosis: brown to red macules, papules, nodules, or plaques that urticate on stroking.
- Systemic manifestations are due to histamine release.

Necrobiotic xanthogranuloma—indurated plaques with associated atrophy and telangiectasia with or without ulceration—may occur on the trunk or periorbital areas. Serum electrophoresis shows an IgG κ paraproteinemia or multiple myeloma.

Endocrine

Diabetes Mellitus

Several dermatologic disorders have been described in diabetes.

Necrobiosis lipoidica diabeticorum (Fig. 5-18) classically occurs on the shins and presents as yellow-brown atrophic telangiectatic plaques that occasionally ulcerate. Two-thirds of patients with this skin disorder have diabetes.

- Necrobiosis lipoidica diabeticorum occurs on the shins.
- Two-thirds of patients have diabetes.

Fig. 5-18. Necrobiosis lipoidica diabeticorum.

Granuloma annulare (Fig. 5-19) is an asymptomatic eruption consisting of small, firm, flesh-colored or red papules in an annular configuration (less commonly nodular or generalized). The association with diabetes is disputed.

- Granuloma annulare consists of small, firm, flesh-colored or red papules in an annular configuration.

Rarely, patients with poorly controlled diabetes present with spontaneously occurring *subepidermal blisters* (bullosa diabeticorum) on the dorsal aspects of the hands and feet.

The *stiff-hand syndrome* has been reported in juvenile-onset insulin-dependent diabetes. Patients have limited joint mobility and tight waxy skin on the hands. There is an increased risk of subsequent renal and retinal microvascular disease.

- Stiff-hand syndrome: increased risk of subsequent renal and retinal microvascular disease.

In *scleredema*, there is an insidious onset of thickening and stiffness of the skin on the upper back and posterior neck. The condition is more common in middle-aged men with diabetes. The diabetes is often long-standing and poorly controlled.

- Scleredema is more common in middle-aged men with diabetes.
- Diabetes is often long-standing and poorly controlled.

Thyroid

Pretibial myxedema and thyroid acropachy are cutaneous associations of Graves disease.

Metabolic

The *porphyrias* are a group of inherited or acquired abnormalities of heme synthesis. Each type is associated with deficient activity of a particular enzyme. The porphyrias are usually divided into three types: erythropoietic, hepatic, and mixed.

Erythropoietic porphyria is a hereditary form (autosomal recessive) characterized by marked photosensitivity, blisters, scarring alopecia, hirsutism, red-stained teeth, hemolytic anemia, and splenomegaly. The skin lesions are severely mutilating. Onset is in infancy or early childhood.

- Erythropoietic porphyria is autosomal recessive.
- Skin lesions are severely mutilating.

Erythropoietic protoporphyria is an autosomal dominant syndrome that usually begins during childhood. It is characterized by variable degrees of photosensitivity and a marked itching, burning, or stinging sensation that occurs within minutes after sun exposure. It is associated with deficiency of ferrochelatase.

- Erythropoietic protoporphyria is autosomal dominant.
- It is associated with deficiency of ferrochelatase.

Porphyria cutanea tarda (Fig. 5-20), one of the hepatic porphyrias, is an acquired or hereditary (autosomal dominant) disease associated with a defect in uroporphyrinogen decarboxylase. The disease may be precipitated by exposure to toxins (such as chlorinated phenols or hexachlorobenzene), alcohol, estrogens, iron overload, underlying hemochromatosis, and infection with hepatitis C. Porphyria cutanea tarda usually presents in the third or fourth decade of life. Clinical

Fig. 5-19. Granuloma annulare.

Fig. 5-20. Porphyria cutanea tarda.

manifestations include photosensitivity, skin fragility, erosions and blisters (particularly on dorsal surfaces of the hands), hyperpigmentation, milia, hypertrichosis, and facial suffusion. Sclerodermoid skin changes develop in some patients. The diagnosis is confirmed by the finding of increased porphyrin levels in the urine. Treatment includes phlebotomy or low-dose chloroquine.

- Porphyria cutanea tarda is acquired or inherited (autosomal dominant).
- It is associated with a defect in uroporphyrinogen decarboxylase.
- It may be precipitated by exposure to toxins, infection with hepatitis C, or underlying hemochromatosis.

Acute intermittent porphyria lacks skin lesions and is characterized by acute attacks of abdominal pain or neurologic symptoms.

- Acute intermittent porphyria lacks skin lesions.
- It involves acute attacks of abdominal pain or neurologic symptoms.

Variegate porphyria (mixed porphyria) also follows autosomal dominant inheritance. Variegate porphyria is characterized by cutaneous abnormalities that are similar to those of porphyria cutanea tarda and by acute abdominal episodes, as in acute intermittent porphyria. Variegate porphyria tends to be precipitated by drugs such as barbiturates and sulfonamides.

- Variegate porphyria is autosomal dominant.
- It tends to be precipitated by drugs such as barbiturates and sulfonamides.

Nail Clues to Systemic Disease

Onycholysis consists of distal and lateral separation of the nail plate from the nail bed. Onycholysis may be due to psoriasis, lichen planus, infection (such as *Candida* or *Pseudomonas*), a reaction to nail cosmetics, or a drug reaction. Drugs that have been noted to induce onycholysis include tetracycline and chlorpromazine. Association with thyroid disease (hyperthyroidism more than hypothyroidism) has also been observed.

- Onycholysis may be due to psoriasis, lichen planus, infection (*Candida* or *Pseudomonas*), nail cosmetics, or a drug reaction.

Pitting is a common feature of psoriatic nails. Graph-like pits have been associated with alopecia areata.

Terry nails consist of whitening of the proximal or entire nail as a result of changes in the nail bed. This abnormality is associated with cirrhosis.

- Terry nails are associated with cirrhosis.

Muehrcke lines consist of white parallel bands associated with hypoalbuminemia.

- Muehrcke lines are associated with hypoalbuminemia.

"*Half-and-half*" *nails* (*Lindsay nails*) are nails in which the proximal half is white and the distal half is red. This abnormality may be associated with renal failure.

- "Half-and-half" nails may be associated with renal failure.

Yellow nails are associated with chronic edema, pulmonary disease, pleural effusion, chronic bronchitis, bronchiectasis, and lung carcinoma.

Beau lines are transverse grooves in the nail associated with high fever, chemotherapy, systemic disease, and drugs.

Koilonychia (*spoon nails*) is associated with iron deficiency anemia, but it also may be idiopathic, familial, or related to trauma.

- Koilonychia is associated with iron deficiency anemia.

Blue-colored lunula is associated with hepatolenticular degeneration (Wilson disease) and argyria.

Mees lines are white bands associated with arsenic.

- Mees lines are associated with arsenic.

Cutaneous Manifestations of HIV Infection

Primary infection with human immunodeficiency virus (HIV) results in a flu-like illness and an exanthem in 30% to 60% of patients. The exanthem may be morbilliform or pityriasis rosea-like. Oral ulceration and erosions and erosive esophagitis also may occur at this stage. The acute exanthem and enanthem are self-limited and often go undiagnosed.

In the early stage of the disease, cutaneous manifestations include genital warts, genital herpes, psoriasis, mild seborrheic dermatitis, and pruritic papular eruption. With symptomatic HIV infection (CD4 count of 200-400/mm^3), both infections and inflammatory dermatoses occur more frequently. These include psoriasis, oral hairy

leukoplakia, candidiasis, herpes zoster, drug reactions, herpes simplex, tinea pedis, and onychomycosis. In patients with a family history of atopy, atopic dermatitis may be a manifestation at this stage.

As the CD4 count decreases to less than 200/mm^3, patients may present with a disseminated fungal infection, recurrent or severe herpes zoster, persistent herpes simplex, bacillary angiomatosis, and molluscum contagiosum. *Bacillary angiomatosis* consists of one or more vascular papules or nodules caused by the gram-negative bacteria *Bartonella quintana* and *Bartonella henselae*. Eosinophilic folliculitis, a pruritic eruption primarily involving the head, neck, trunk, and proximal extremities, is characteristic of symptomatic HIV infection.

With advanced HIV infection (CD4 counts of <50/mm^3), overwhelming infection is characteristic. Infectious agents include cytomegalovirus, *Cryptococcus*, *Acanthamoeba*, and extensive molluscum contagiosum.

Oral hairy leukoplakia is caused by Epstein-Barr virus infection of the oral mucosa and usually occurs in patients with advanced HIV infection.

Molluscum contagiosum, a common viral infection of otherwise healthy children, occurs in 10% to 20% of patients with HIV infection.

- Molluscum contagiosum occurs in 10%-20% of patients with HIV infection.

Epidemic Kaposi sarcoma usually presents as oval papules or plaques oriented along skin lines of the trunk, extremities, face, and mucosa. This presentation is in contrast to that of classic Kaposi sarcoma in elderly patients, which occurs predominantly on the distal lower extremities. Human herpesvirus 8 (HHV-8) has been identified in tissue from patients with both epidemic and classic Kaposi sarcoma.

- Epidemic Kaposi sarcoma: oval papules or plaques along skin lines of the trunk, extremities, face, mucosa.
- It is most commonly associated with HIV infection.

Dermatology Pharmacy Review

Susan V. McCluskey, RPh

Drug	Toxic/adverse effects*	Drug interactions†
Systemic antibacterials		
Cephalosporins	Nausea, vomiting, diarrhea Anaphylaxis Hemolytic anemia Nephrotoxicity Neutropenia, thrombocytopenia Pseudomembranous colitis Rash, erythema multiforme	
Clindamycin	Nausea, vomiting, diarrhea, abdominal pain Granulocytopenia, neutropenia Hypotension Pseudomembranous colitis Rash, Stevens-Johnson syndrome	
Fluoroquinolones (ciprofloxacin, gatifloxacin, levofloxacin, lomefloxacin, moxifloxacin, norfloxacin, ofloxacin, sparfloxacin, trovafloxacin)	Nausea, vomiting, diarrhea, abdominal pain Increased liver enzymes Increased serum creatinine Nephrotoxicity Phototoxicity Pseudomembranous colitis Rash, erythema multiforme, toxic epidermal necrolysis	Cardiac arrythmias: amiodarone, bepridil, bretylium, disopyramide, erythromycin, phenothiazine, procainamide, quinidine, sotalol, tricyclic antidepressants Increased cardiovascular side effects: cisapride Increased levels or effects: astemizole, terfenadine Increased toxicity: cyclosporine
Macrolides (azithromycin, clarithromycin, dirithromycin, erythromycin)	Abdominal pain, nausea, diarrhea Oral candidiasis Increased liver enzymes Pseudomembranous colitis Anaphylaxis	Cardiotoxicity: astemizole, terfenadine, cisapride, pimozide, quinolones (gatifloxacin, sparfloxacin, moxifloxacin) Increased levels or effects: warfarin, carbamazepine, digoxin, ergot alkaloids, vinblastine, cyclosporine, tacrolimus, methylprednisolone Severe myopathy, rhabdomyolysis: HMG-CoA reductase inhibitors (atorvastatin, lovastatin, simvastatin, cerivastatin)
Penicillins	Nausea, vomiting, mild diarrhea Anaphylaxis Acute interstitital nephritis Hemolytic anemia Pseudomembranous colitis	Decreased penicillin effects: tetracyclines (demeclocycline, doxycycline, minocycline, oxytetracycline, tetracycline)
Sulfonamides	Nausea, vomiting, diarrhea Hematologic reactions Hepatitis Nephrotoxicity Rash, photosensitivity, Stevens-Johnson syndrome	Increased effect: warfarin Increased nephrotoxicity and decreased effect: cyclosporine Bone marrow suppression: methotrexate
Tetracyclines (doxycycline, minocycline, tetracycline)	Photosensitivity Nausea, diarrhea Acute renal failure Exfoliative dermatitis Discoloration of teeth (young children)	Decreased effects: penicillin Increased levels: digoxin Risk of pseudotumor cerebri: isotretinoin Renal toxicity: methoxyflurane

Endocrinology

Bryan McIver, MBChB

Basic Principles of Endocrinology

Numerous chemical messages control various functions at the level of cells, organs, and organ systems. Such messages may be autocrine (the chemical message directly affects the cell producing it), paracrine (the message has local effects), or endocrine (the message has distant sites of action). Typically, endocrine effects are caused by hormones that are produced by specialized organs, although several important endocrine functions are performed by nonglandular tissues, most prominently the liver (e.g., insulin-like growth factor I [IGF-I] production and thyroid hormone activation) and the kidney (e.g., renin production and vitamin D activation).

Hormones act at the cell surface or within the cell or in both places. For example, steroid hormones and thyroid hormones exert effects on most cells in the body through nuclear receptors that regulate gene transcription and protein synthesis. In contrast, glycoprotein hormones such as corticotropin (ACTH) act through specific cell surface receptors that produce their effects through second messenger systems. Typically, hormones in the latter group exert their effects rapidly, whereas hormones that act through nuclear hormone receptors produce slower responses. Because of this lag in response, the serum concentrations of these hormones measured at any given time may not truly reflect the amount of "signal" that nuclear receptors have been exposed to over the preceding hours.

Most hormone systems are regulated by the interaction of multiple hormones secreted by different tissues. In the classic example of a negative-feedback loop, the thyroid gland produces thyroxine (T_4), which is regarded as the regulated "end product" or active hormone. The secretion of T_4 is stimulated by thyrotropin (TSH), which is produced by the pituitary gland. TSH is a trophic hormone that is required both for secretion of thyroid hormone and for maintenance of the gland itself. It is secreted in response to decreasing levels of T_4 and triiodothyronine (T_3), and its secretion is suppressed by increasing levels of T_4 and T_3. This negative-feedback control maintains a constant concentration of thyroid hormone. The process is more complex, however, because T_4 itself is a prohormone, which is converted to the active form (T_3) in the liver, kidneys, and several end organs in which it exerts its physiologic effects. The conversion of T_4 into T_3 requires the activity of microsomally located deiodinases, which may either activate (into T_3) or inactivate (into reverse T_3) the prohormone. At least some aspects of this deiodination reaction appear to be regulated, although details of the additional control mechanism remain unclear. Even the apparently straightforward negative-feedback control of thyroid hormone concentrations encompasses a complexity and subtlety that may have significant physiologic impact.

Because the design of hormone systems maintains homeostasis in response to changes in the internal and external environments, it is important to recognize that in certain situations endocrine abnormalities may be a manifestation rather than a cause of systemic illness. For example, with extreme weight loss, such as anorexia nervosa, secretion of the trophic hormones that regulate gonadal function is decreased or absent. This is not a result of a primary endocrine disease but rather represents a physiologic response to the depletion of the body's energy reserves (fat) necessary for successful reproduction. Treatment should be directed at the underlying cause. A precisely analogous situation affects TSH production in starvation or other severe illness, resulting in the euthyroid sick syndrome, which is easily mistaken for thyrotoxicosis because of the low circulating concentration of TSH.

One very important principle to remember in the evaluation of patients with suspected endocrine disease is to clearly document endocrine dysfunction before proceeding with imaging studies. Imaging studies performed in isolation may be misleading because of the propensity of modern, detailed imaging studies to detect incidental abnormalities of endocrine glands that have no functional significance and often reflect normal variation or aging.

- Hormones typically act either through nuclear receptors that regulate gene transcription mechanisms or through membrane-bound receptors that alter the concentration of intracellular second messenger systems.
- Hormone systems are finely regulated by the interaction between trophic hormones and end hormones (negative and positive feedback).
- Endocrine dysfunction may be a manifestation of systemic disease.

Hypothalamic-Pituitary Disorders

The pituitary and hypothalamus control several peripheral hormone systems. The hypothalamus contains centers vital to the regulation of sleep/wake cycles, appetite, and thirst. It is an integrator for many neural and endocrine inputs, which directly control pituitary function through a portal system running down the pituitary stalk. The pituitary can be divided, anatomically and physiologically, into anterior and posterior parts.

The anterior pituitary secretes various trophic hormones. Disease (particularly adenomas) of this region may result in syndromes of hormone excess or deficiency. The posterior pituitary is not a gland in the classic sense but instead represents the terminus of axons of neurons in the supraoptic and paraventricular nuclei of the hypothalamus. It functions as a storehouse and is the site of release for vasopressin and oxytocin. The main consequence of posterior pituitary disease is disordered water homeostasis.

In addition to their effect on systemic hormone systems, pituitary and hypothalamic lesions can cause local compressive effects on the visual pathway or the cavernous sinus (with lesions of cranial nerves II, III, IV, and VI) and on hypothalamic centers, leading to disordered appetite and sleep/wake cycles.

Hypopituitarism

Etiology

Anterior pituitary diseases can cause hypopituitarism, with deficiency of one or more (including all) of the anterior pituitary hormones. Causes of hypopituitarism include primary pituitary disease, hypothalamic disease, interruption of the pituitary stalk, and extrasellar disorders. The most common causes are pituitary tumors, pituitary operations, and radiotherapy. Hypopituitarism can also be functional, resulting from suppression of hypothalamic regulation of the anterior pituitary gland. Common causes include suppression of the hypothalamic-pituitary-adrenal axis following the use of exogenous corticosteroids; suppression of gonadotropin-releasing hormone (GnRH) related to extreme weight loss, exercise, or systemic illness; and suppression of TSH in response to severe systemic illness (the euthyroid sick syndrome). Treatment should be aimed at the underlying cause.

An extrasellar lesion, such as a craniopharyngioma (most commonly) or Rathke cleft cyst, may impinge on and impair the function of the hypothalamic-pituitary unit.

- Hypopituitarism may be functional. Treatment should be aimed at the underlying cause.
- Anterior pituitary hormone deficiency can be total, multiple, or selective.
- The most common causes of hypopituitarism are pituitary tumors, pituitary operations, and radiotherapy.
- Exogenous corticosteroid use or extreme weight loss can lead to functional suppression of hypothalamic regulation of the anterior pituitary gland.
- The commonest extrasellar cause of hypopituitarism is a craniopharyngioma.

Clinical Presentation in Adults

Adults with hypopituitarism can present with the features of deficiency of one or more anterior pituitary hormones. The clinical presentation depends on the age at onset, the hormone(s) affected, and the extent, speed of onset, and duration of the deficiency (Table 6-1). Hypopituitarism commonly occurs as a chronic process of insidious onset. With the exception of prolactin, the manifestations of hypopituitarism are not related directly to anterior pituitary hormone deficiency but to secondary deficiency of end hormones.

Gonadotropin Deficiency

In women, gonadotropin deficiency causes oligomenorrhea or amenorrhea, loss of libido, vaginal dryness and dyspareunia, and loss of secondary sex characteristics (estrogen deficiency). In men, gonadotropin deficiency leads to loss of libido, erectile dysfunction, infertility, loss of secondary sex characteristics, atrophy of the testes, and, under some circumstances, gynecomastia (testosterone deficiency).

ACTH Deficiency

In ACTH deficiency, the consequent hypocortisolism causes malaise, anorexia, weight loss, gastrointestinal tract disturbance, and hyponatremia. Because ACTH helps maintain skin pigmentation, patients often have a pale complexion and are unable to tan or maintain a tan. Patients do not have features of mineralocorticoid deficiency because aldosterone secretion is unaffected.

Patients with hypopituitarism may also present with acute symptoms and signs of cortisol deficiency, often accompanied by headache. This occurs most commonly after withdrawal of prolonged glucocorticoid therapy that has caused suppression of the hypothalamic-pituitary-adrenal axis. Patients with acute destruction of the pituitary by trauma, surgical procedure, or hemorrhage (pituitary apoplexy) can also present in this fashion. Medical or surgical illness or thyroid hormone replacement therapy in a patient with unrecognized ACTH deficiency also exacerbates cortisol deficiency.

TSH Deficiency

TSH deficiency leads to secondary hypothyroidism and an atrophic thyroid gland. Low concentrations of thyroid hormone cause the full spectrum of hypothyroid symptoms (detailed in the "Disorders of the Thyroid Gland" section), which overlap with the symptoms of steroid deficiency (which may coexist with central hypothyroidism). Treatment of steroid deficiency should precede treatment with thyroid hormone to avoid a potentially life-threatening adrenal crisis.

Prolactin Deficiency

The only clinical consequence of prolactin deficiency is the inability to lactate postpartum, which may be the first manifestation of Sheehan syndrome.

Growth Hormone Deficiency

In adults, growth hormone (GH) deficiency is often asymptomatic. However, some patients may complain of fatigue, decreased exercise tolerance, abdominal obesity, and loss of muscle mass.

- Gonadotropin deficiency manifests as hypogonadism and infertility.
- ACTH deficiency results in glucocorticoid deficiency without mineralocorticoid deficiency.
- Patients with acute hypopituitarism present with rapidly progressive features of steroid deficiency, often accompanied by headache.
- TSH deficiency leads to secondary hypothyroidism.
- Prolactin deficiency manifests as a failure of lactation in the postpartum period.
- In adults, GH deficiency leads to an ill-defined syndrome of weakness, altered body fat distribution, and malaise.
- In a typical clinical scenario for hypopituitarism, the patient has an insidious onset of numerous signs and symptoms caused by several end-hormone deficiencies. The broad spectrum and overlapping nature of the symptoms can make diagnosis more challenging.

Table 6-1 Hypothalamic-Pituitary Hormones: Functions and Clinical Syndromes

Feature	GH	PRL	LH/FSH	ACTH/LPH/END	TSH	ADH
Anterior pituitary cell type	Somatotroph	Lactotroph	Gonadotroph	Corticotroph	Thyrotroph	Supraoptic and paraventricular nuclei
Regulation *(the dominant regulators are italicized)*	*GHRH* (+) GHRIH (–)	*DA* (–) TRH, VIP (+)	*GnRH* (+) DA, opioids (–)	*CRH* (+) AVP (+)	*TRH* (+) GHRIH, DA (–)	Plasma osmolality (osmoreceptors) and blood volume (volume & baroreceptors)
Secretion	Episodic Sleep-related surge	Episodic Sleep-related surge	Phasic throughout life Episodic Cyclic in women of reproductive age	Episodic Diurnal Stress-responsive	Episodic Minimal diurnal change	Exquisitely sensitive to changes in plasma osmolality
Physiologic functions	IGF-I–mediated growth Intermediary metabolism	Lactogenesis Others (?)	Initiation & maintenance of sexual/reproductive functions	ACTH: initiation & maintenance of cortisol production by adrenal cortex LPH/END: pigmentary effects	Initiation & maintenance of T_4/T_3 secretion by thyroid	Maintenance of plasma osmolality Maintenance of blood volume & pressure
Deficiency in adult	Syndrome of GH deficiency?	Loss of postpartum lactation	Hypogonadotropism	Secondary cortisol deficiency	Secondary hypothyroidism	Central diabetes insipidus
Deficiency in child	Shortness of stature Hypoglycemia	Not recognized	Hypogonadotropism in adolescent	Secondary cortisol deficiency	Secondary hypothyroidism	Central diabetes insipidus
Hypersecretion in adult	Acromegaly	Hyperprolactinemic syndrome	No distinct syndrome	Cushing disease	TSH-induced hyperthyroidism	SIADH
Hypersecretion in child	Gigantism	Hyperprolactinemic syndrome in adolescent	Precocious puberty	Cushing disease	TSH-induced hyperthyroidism	SIADH

ACTH, corticotropin; ADH, antidiuretic hormone; AVP, arginine vasopressin; CRH, corticotropin-releasing hormone; DA, dopamine; END, β-endorphin; FSH, follicle-stimulating hormone; GH, growth hormone; GHRH, GH-releasing hormone; GHRIH, GH-releasing inhibiting hormone or somatostatin; GnRH, gonadotropin-releasing hormone; IGF-I, insulin-like growth factor I; LH, luteinizing hormone; LPH, β-lipotropin; PRL, prolactin; SIADH, syndrome of inappropriate ADH secretion; TRH, thyrotropin-releasing hormone; TSH, thyrotropin; VIP, vasoactive intestinal polypeptide.

Diagnosis

It is essential to document both the degree and the extent of endocrine dysfunction and to determine the cause of hypopituitarism. Functional causes of hypopituitarism should be considered before searching for an organic cause.

Endocrine Evaluation

Gonadotropin axis—Deficiencies in the gonadotropin axis are manifested as a low serum concentration of testosterone or estradiol, with low or inappropriately normal levels of luteinizing hormone (LH) and follicle-stimulating hormone (FSH). The menstrual cycle is a sensitive indicator of hypothalamic-pituitary-gonadal function. Thus, a woman with a normal menstrual cycle can be assumed to have normal gonadotropin secretion, and no biochemical testing is necessary. Hyperprolactinemia is a common cause of central hypogonadism.

ACTH-adrenocortical axis—A normal plasma level of cortisol does not confirm that the pituitary can secrete sufficient ACTH during conditions of stress. Morning and afternoon cortisol measurements may help to establish a normal diurnal rhythm (higher in the morning, lower in the afternoon), providing evidence of an intact hypothalamic regulatory system, but adrenal insufficiency may still be present. An ACTH stimulation test (cosyntropin test) may provide additional information. With chronic ACTH deficiency, the adrenal cortex is atrophic and typically a cortisol secretory response to exogenous ACTH is absent. However, a response may be seen if ACTH deficiency is partial or of recent onset. The cosyntropin test cannot distinguish between ACTH deficiency (secondary adrenal insufficiency) and primary adrenal insufficiency. Therefore, it is important to measure ACTH levels: a low or inappropriately normal ACTH level is consistent with pituitary dysfunction, whereas an increased ACTH level is consistent with primary adrenal disease. Assessment of renin and aldosterone may also be useful in assessment of primary adrenal insufficiency, in which aldosterone production capacity is also lost. Other provocative tests include the use of insulin-induced hypoglycemia or metyrapone to stimulate ACTH secretion, although these are used rarely. Because the most common cause of adrenal insufficiency is prior exposure to steroids, a careful drug history (including topical lotions and steroids that are inhaled or injected) and a synthetic steroid screen are crucially important to establish a diagnosis of adrenal failure.

TSH-thyroid axis—Low serum levels of free thyroxine (FT_4) and an inappropriately normal or low serum level of TSH support the diagnosis of central hypothyroidism. Consideration should be given to the effects of systemic illness and adrenal insufficiency, both of which can alter TSH secretion, giving the impression of secondary hypothyroidism.

GH—Random determinations of GH concentrations are not useful in the evaluation of GH deficiency. Low serum concentrations of IGF-I suggest the diagnosis. Provocative testing with insulin-induced hypoglycemia is the standard way to stimulate GH secretion. However, this is contraindicated for the elderly and for patients with ischemic heart disease. The stimulation test with arginine plus growth hormone–releasing hormone (GHRH) has a diagnostic accuracy similar to that of insulin-induced hypoglycemia and has become the test of choice for diagnosing GH deficiency in adults.

Prolactin—Deficiency is suggested by low serum concentrations. Note that interruption of the pituitary stalk often increases prolactin concentrations through the release of lactotrophs from tonic inhibition by dopamine ("stalk effect").

Structural Evaluation

Structural evaluation requires imaging of the hypothalamic-pituitary region, preferably with magnetic resonance imaging (MRI). If a space-occupying lesion in the region of the sella is detected, the visual fields need to be assessed. Modern high-resolution MRI scanning may be used to detect small nonfunctioning lesions of the pituitary (incidentalomas) in 5% to 10% of patients.

Therapy in Adults

Therapy includes correction, if possible, of the cause (functional or structural) and administration of the deficient hormone(s) of the target gland(s) or, in selected cases, of the pituitary hormones.

ACTH deficiency—Glucocorticoid replacement is essential. Hydrocortisone should be given twice daily. An average daily dose is 10 to 20 mg in the early morning and 5 to 10 mg in the early or mid afternoon. Alternatively, a longer acting corticosteroid such as prednisone 5 mg once daily is sufficient. Patients should double or triple the steroid dose during times of acute illness and should receive steroid parenterally when unable to take it orally. For patients with combined deficiency of ACTH and TSH, glucocorticoid replacement should be initiated before thyroid hormone replacement therapy to avoid precipitation of an acute adrenal crisis.

TSH deficiency—The drug of choice is levothyroxine sodium. Levels of serum FT_4 (rather than TSH) must be monitored to ensure the adequacy of replacement therapy.

Gonadotropin deficiency—If fertility is not desired, conjugated estrogens in combination with progesterone (on a cyclical or continuous basis) are prescribed for women with an intact uterus. Induced menopause should be considered for women at the appropriate age. In men, testosterone can be delivered intramuscularly or transdermally, using patches or gel. For the restoration of fertility, gonadotropin therapy is indicated.

GH deficiency—GH therapy may be considered for symptomatic patients with documented hypothalamic-pituitary disease and evidence of an impaired response to provocative testing. The goal of therapy is to restore serum levels of IGF-I to normal while avoiding side effects. In the short term, GH therapy may enhance the sense of well-being and increase muscle strength, exercise tolerance, and bone mineral density. Currently, the long-term effects of this therapy are not known.

- Instruct patients about glucocorticoid dose modification during acute illness.
- For the combined deficiency of ACTH and TSH, initiate glucocorticoid therapy before thyroid hormone replacement therapy.
- Use FT_4 to monitor the adequacy of therapy in secondary hypothyroidism.

Pituitary Tumors

Pituitary tumors can be sporadic or part of multiple endocrine neoplasia type 1 (MEN 1). They may be present in patients who have

the clinical features of a mass effect or endocrine dysfunction, or they may be discovered incidentally when the head is imaged for other reasons. Tumors smaller than 1 cm are *microadenomas* and those 1 cm or larger are *macroadenomas*. Evaluation of a pituitary tumor should address four questions:

1. Is the tumor causing a local mass effect? Superior extension of the tumor may compromise the optic pathways, leading to impaired visual acuity and visual field defects. Rarely, it produces a hypothalamic syndrome, with disturbed thirst, satiety, sleep, and temperature regulation. Lateral extension of the tumor may compress cranial nerves III, IV, and VI, leading to diplopia. Extension of the tumor inferiorly may lead to cerebrospinal fluid (CSF) rhinorrhea. Ophthalmologic evaluation, including assessment of visual acuity, visual fields, and optic disks, is important, particularly if there is suprasellar extension of the tumor. Headaches may accompany enlarging pituitary tumors, particularly in the presence of suprasellar extension.

2. Is hypopituitarism present? Hypopituitarism may be caused by compressive destruction of the pituitary gland or interruption of the pituitary stalk by tumor growth. Stalk compression can cause increased production of prolactin, with secondary hypogonadism. Rarely, patients with pituitary tumors present acutely with pituitary apoplexy, which may be the first clinical expression of the underlying tumor. Endocrine evaluation is essential (see "Hypopituitarism" section).

3. Is there evidence of hormone excess? Approximately 30% to 40% of pituitary tumors are nonfunctioning. The remainder are hyperfunctioning: prolactinomas (40%-50%); GH tumors causing acromegaly (10%-15%); ACTH tumors resulting in Cushing disease (10%-15%); and TSH tumors resulting in hyperthyroidism (<5%). Although the clinical history and examination findings are useful, formal biochemical evaluation is recommended in every case.

4. What is the nature of the tumor? Although the majority of intrasellar masses reflect pituitary adenomas, alternative possibilities exist, including Rathke cleft cyst, craniopharyngioma, inflammatory masses, and metastatic disease. Evaluation should be guided by the clinical setting, but on occasion a pituitary biopsy may be necessary to establish the diagnosis accurately.

- Ophthalmologic evaluation is important, particularly with suprasellar extension of a tumor.
- Endocrine evaluation should determine hormonal excess or deficiency.

Treatment

Treatment includes surgical excision, irradiation, or medical therapy. The first-line treatment for functioning pituitary tumors is surgical excision, except in the case of prolactinomas, for which dopamine agonist therapy is often effective. Large tumors that compress or threaten the optic chiasm should also be considered for resection, even in the absence of a hormonal effect. Drug therapy is available for some functional tumors (see below). Simple observation is an option if the tumor is small, does not have a local mass effect, and is nonfunctional.

- Treatment includes surgical excision, irradiation, or medical therapy.
- Observation is an option when the tumor is small and nonfunctioning or, in the case of a microprolactinoma, when it is not associated with clinical features that affect quality of life.

Surgery

Transsphenoidal surgery is the operation of choice for most pituitary tumors (except prolactinoma). Rarely, craniotomy is performed on tumors with significant suprasellar extension. Both operations require considerable neurosurgical expertise. The morbidity (bleeding, infection, transient diabetes insipidus, CSF rhinorrhea, and anterior pituitary dysfunction) associated with transsphenoidal surgery is less than 1% for microadenomas and about 5% for macroadenomas; mortality is less than 1%. Persistence or recurrence rate of the tumor is less than 20% to 30% for microadenomas but may be as high as 50% to 70% for macroadenomas.

Radiotherapy

Radiotherapy is reserved for pituitary macroadenomas after surgical or medical therapy fails or as primary therapy for patients who are poor surgical candidates or who refuse operation. Radiotherapy may be delivered by conventional external beam radiation or stereotactic gamma knife radiosurgery. The latter delivers a single highly focused beam of radiation and is reserved for the treatment of small-volume pituitary adenomas or smaller macroadenomas that may involve the cavernous sinus. Both forms of radiotherapy have a long latent period (from a few months to years) before the onset of action, and postradiation hypopituitarism may occur (30%-40% of patients receiving conventional therapy).

Drug Therapy

Dopamine agonists (bromocriptine or cabergoline) are used for the management of prolactinomas. The somatostatin analogue octreotide may be used for the management of GH- or TSH-producing tumors. GH-receptor antagonist therapy has recently been approved for the treatment of acromegaly that has failed to respond to conventional therapy.

Follow-Up

Sequential MRI scanning is used to monitor tumor size. Assessment of endocrine function is essential to assess the development of hypopituitarism, especially in patients who have undergone surgical treatment or radiotherapy.

Prolactinoma

Pituitary tumors associated with hyperprolactinemia may be prolactinomas or nonfunctioning tumors that produce a "stalk effect." In the latter situation, the impingement of the tumor on the pituitary stalk interferes with the tonic inhibition of lactotrophs by dopamine (secreted by the hypothalamus), leading to excess secretion of prolactin by normal lactotrophs. Minor increases in the concentration of prolactin may occur through several physiologic mechanisms (drugs, stress, direct nipple stimulation, or pregnancy) and may not reflect the effect of a pituitary lesion.

- Pituitary tumors associated with hyperprolactinemia are prolactinomas or any tumor or mass lesion with a suprasellar extension and stalk effect.

Clinical Features

Women typically present with galactorrhea and oligomenorrhea or amenorrhea. In men, the recognition of hyperprolactinemia is often delayed because symptoms of hypogonadism, including decreased libido and impotence, may be attributed to other factors. For this reason, men are more likely to present late, with a macroprolactinoma. Galactorrhea is unusual in men but not impossible, because of the absence of estrogen priming of the breast.

- Clinical features of prolactinoma in women: ovulatory/menstrual dysfunction and galactorrhea.
- Clinical features of prolactinoma in men: decreased libido and impotence. Galactorrhea is rare.

Diagnosis

Differential Diagnosis

Pituitary tumors are not the only cause of hyperprolactinemia. Physiologic causes of hyperprolactinemia include pregnancy, the postpartum state, and stressful conditions such as surgery or seizure. Stalk disruption may occur with infiltrative disorders, including lymphoma and hypophysitis, which lead to disinhibition of prolactin secretion by normal lactotrophs.

Drugs are a common cause of hyperprolactinemia. Neuroleptic agents, antidepressants, cimetidine, verapamil, opiates, and marijuana are all associated with hyperprolactinemia. The mechanism of action is interference with the synthesis, secretion, or action of dopamine. In primary hypothyroidism, hyperprolactinemia is often encountered because of the stimulatory effect of thyrotropin-releasing hormone (TRH) on the synthesis and secretion of prolactin. Chest wall lesions such as herpes zoster, thoracotomy, or trauma increase prolactin concentrations, possibly through stimulation of thoracic nerve terminals that eventually signal the hypothalamus. Hyperprolactinemia occurs in renal failure and cirrhosis because of slowed metabolism of the hormone. Organic hypothalamic disorders that cause hyperprolactinemia include surgery or irradiation, sarcoidosis or Langerhans cell histiocytosis, and neoplastic disorders such as craniopharyngioma and metastatic disease.

- Physiologic hyperprolactinemia occurs in pregnancy and in the postpartum period.
- Pathologic hyperprolactinemia occurs with prolactinomas or conditions that interrupt the pituitary stalk.
- Functional disorders leading to hyperprolactinemia include neuroleptics, primary hypothyroidism, chest wall lesions, and chronic renal or liver failure.

A diagnostic approach to hyperprolactinemia is outlined in the following steps:

1. Rule out pregnancy, which is the commonest cause of amenorrhea and galactorrhea in women of reproductive age.
2. Measure the TSH concentration to rule out primary hypothyroidism.
3. Review medications and drug use history.
4. Image the hypothalamus and pituitary with MRI if other causes of hyperprolactinemia have been ruled out.
5. If a tumor is present, evaluate other pituitary function and visual fields if necessary.

The main diagnostic dilemma is to differentiate a macroprolactinoma from a nonfunctioning tumor that causes a stalk effect. This distinction has therapeutic implications because medical therapy is the first-line treatment for a prolactinoma, whereas nonfunctioning tumors with suprasellar extension should be surgically resected. A serum concentration of prolactin greater than 200 ng/mL supports the diagnosis of prolactinoma; a concentration less than 75 ng/mL is more consistent with a stalk effect, particularly in the presence of a macroadenoma. If the value is between 75 and 200 ng/mL, a trial of dopamine agonist therapy is reasonable. Regression of the tumor mass and a decrease in prolactin concentrations with this therapy support the diagnosis of prolactinoma.

If, after a thorough evaluation, the cause of hyperprolactinemia is not found, follow-up is necessary because some patients may harbor a microadenoma or other hypothalamic-pituitary space-occupying lesion that is below the limit of radiographic detection, and follow-up examinations may show evidence of a mass. The serum level of prolactin should be checked every 6 to 12 months, and MRI should be repeated in 1 year, or earlier if deemed necessary by the development of new symptoms.

Therapy

Treatment is indicated for the management of infertility, hypogonadism, or galactorrhea. Medical treatment with a dopamine agonist is usually the first choice. Transsphenoidal surgery is usually reserved for patients who are intolerant or resistant to dopamine agonist therapy or who require urgent decompression of the sella for visual field defects that have not responded to a trial of dopamine agonist.

Dopamine Agonists

Dopamine agonists (bromocriptine or cabergoline) are very effective in the treatment of hyperprolactinemia caused by prolactinoma. In most cases, these agents also lead to rapid shrinkage of the tumor. Consequently, these drugs are indicated as first-line therapy even for large prolactinomas causing a visual field defect. Frequent assessment of the visual fields and tumor size is indicated in such cases. Neither tumor size nor the degree of increase in prolactin predicts tumor response. Side effects may include nausea, fatigue, nasal stuffiness, and postural hypotension. Long-term therapy with a dopamine agonist may cause tumor fibrosis and shrinkage. After 3 to 5 years of dopamine agonist therapy, withdrawal of the therapy and monitoring of prolactin levels should be considered in patients with prolactinomas because the disorder may resolve spontaneously. Intervening pregnancy may accelerate the resolution of a microprolactinoma.

Restoration of gonadal function and fertility is a major goal of drug therapy for a prolactinoma. In pregnancy, the risk of growth

for microprolactinomas is less than 5% and for macroprolactinomas, 20% to 40%. Patients should be observed closely with clinical and visual field evaluations, especially if they have a macroprolactinoma. If tumor growth is suspected, the head should be examined with MRI. Although treatment with dopamine agonists usually is discontinued during pregnancy, it is reasonable to continue maintenance therapy if the patient has a macroprolactinoma. An increase in tumor size may be an indication for surgical excision.

- The treatment of choice for prolactinomas is medical therapy with a dopamine agonist.
- During pregnancy, the risk of growth for microprolactinomas is <5% and for macroprolactinomas, 20%-40%.
- If marked tumor growth complicates pregnancy, consider surgical excision.

Surgical Treatment of Prolactinomas

For microadenomas, the surgical cure rate is 60% to 80%, and for macroadenomas, 0% to 30%.

GH Tumors: Acromegaly

GH-producing pituitary tumors account for more than 99% of acromegaly cases. Rarely, acromegaly may be caused by ectopic GH-producing tumors or hypothalamic or extra-hypothalamic GHRH-producing tumors. It is preferable to diagnose acromegaly early because the disease is associated with substantial morbidity and premature mortality.

Clinical Features

The clinical features of acromegaly are due to excess IGF-I and the mass effects of the pituitary tumor. In adults, characteristic features are prominent supraorbital ridges, macroglossia, prognathism, and an increase in hand and foot size. Patients may complain of excessive sweating, increased skin oiliness, headache, and symptoms of carpal tunnel syndrome. The prevalence of colon polyps is increased threefold among patients with acromegaly, who also are at increased risk of colon cancer. Currently, it seems prudent to perform colonoscopy on all patients when acromegaly is diagnosed. Cardiovascular disease is the most common cause of premature death. Many patients have hypertension and glucose intolerance. Sleep apnea is a common feature that may resolve or improve with successful treatment of acromegaly.

- Acromegaly is associated with an increased risk of premalignant colon polyps and colon cancer.
- Other common features include hypertension, glucose intolerance, and sleep apnea.

Diagnosis

Biochemical Diagnosis

Measuring the serum concentration of IGF-I is the best screening test for acromegaly (physiologic increases can occur in pregnancy and adolescence and with sleep apnea). If the IGF-I serum level is mildly to moderately increased, it is best to proceed with an oral glucose tolerance test to document nonsuppressible GH secretion. GH levels do not suppress to less than 1 ng/mL in active acromegaly. A random serum level of GH is not helpful because of the pulsatile secretion of GH.

Radiologic Diagnosis

After the diagnosis has been confirmed biochemically, the sella should be examined with MRI. If a pituitary tumor is not delineated (a rare event) or diffuse pituitary hypertrophy is noted, measure the serum level of GHRH to exclude a GHRH-producing tumor and search for evidence of an ectopic GH-producing tumor.

- The serum concentration of IGF-I is increased in all patients with active acromegaly.
- Failure of GH to suppress to <1 ng/mL with an oral glucose tolerance test is diagnostic of acromegaly.
- A random serum level of GH is not helpful.

Therapy

Surgical excision of the GH-secreting tumor is the usual first treatment of choice. Excision may be curative (40%-80% of cases depending on the size of the tumor and the degree of lateral extension) and facilitates adjunctive therapy. For persistent disease, treatment with octreotide or gamma knife radiosurgery (plus interim octreotide) is used to control GH secretion.

Radiotherapy has a cure rate of 70% after 10 years; hypopituitarism can occur in up to 50% of patients at 10 years, but other morbidity is rare. The major disadvantage of radiotherapy is the long latent period (months to years) before disease activity is controlled. During this wait for the full effects of radiotherapy, pharmacologic therapy is needed.

Octreotide is an effective therapeutic option. Treatment should be initiated with short-acting octreotide administered subcutaneously three times daily to assess tolerance. This can be switched quickly to the long-acting depot form of octreotide administered monthly. Octreotide can normalize GH and IGF-I levels in 80% of patients and produce shrinkage of the tumor in 30% to 50%. Side effects include nausea, flatulence, orthostatic hypotension, headache, cholelithiasis (10% of patients), and impairment of glucose tolerance. Pegvisomant (a GH-receptor antagonist) has recently become available and is indicated for patients who do not respond to, or cannot tolerate, octreotide therapy.

- Surgical excision is the treatment of choice.
- For persistent disease after excision, pharmacologic therapy or radiotherapy should be considered.
- Pharmacologic therapy is required while awaiting the full effects of adjunctive radiotherapy.

ACTH-Producing Tumors

ACTH-producing tumors are discussed below in the "Cushing Syndrome" section.

Gonadotropin-Producing Tumors

Gonadotropin-producing tumors constitute the largest fraction of "nonfunctioning" pituitary tumors, as indicated by positive

immunohistochemical staining of resected tumor specimens. Although more than 80% of these tumors are able to synthesize gonadotropins or their subunits (or both), increased serum levels of FSH, LH, or their subunits are found in less than 35% of patients. Clinically, the tumors are macroadenomas at presentation. The patients may be any age, but the tumors usually occur in middle-aged or elderly persons and predominantly in males. Mass effects dominate the clinical features, and some degree of hypopituitarism is usually present together with hyperprolactinemia caused by a stalk effect. Currently, no effective medical therapy is available. Surgical excision is required.

TSH-Producing Tumors

Primary TSH tumors are rare, and patients may present with diffuse goiter and mild hyperthyroidism. Laboratory evaluation demonstrates an increased or inappropriately normal TSH level with an increased concentration of FT_4. The α-glycoprotein subunit levels are high, and there is no TSH response to stimulation with TRH. Often such tumors cosecrete GH. Treatment options include excision, pharmacologic therapy with octreotide, and ancillary measures for the management of thyrotoxicosis.

Pituitary Incidentaloma

With advances in the resolution of imaging methods, pituitary incidentaloma is increasingly recognized. Autopsy studies suggest that approximately 10% of persons harbor small pituitary tumors, and modern MRI scanning can identify anomalies in 5% to 10% of adults. Evaluation should determine whether the tumor affects pituitary endocrine function (hypopituitarism and hyperfunction) or causes a mass effect (or both). Screening tests should include the measurement of prolactin, FT_4, testosterone (in men), and cortisol. Active intervention is dictated by the finding of a functioning pituitary tumor that can cause morbidity or mortality or an incidentaloma larger than 1 cm in diameter. Otherwise, observe the patient and repeat the imaging study in 6 to 12 months and at less frequent intervals thereafter.

Miscellaneous Pituitary Disorders

Craniopharyngioma

Craniopharyngioma is a slow-growing encapsulated benign squamous cell tumor that originates from remnants of the Rathke pouch. It is the most common tumor in the pituitary region in childhood but can occur at any age. Two-thirds of the tumors are suprasellar, and one-third originate in or extend into the sella. Most are cystic, and some have solid and cystic areas. Calcification is often present within the tumor. Mass effects and the consequences of hypopituitarism dominate the clinical presentation.

Surgical excision is possible only for small craniopharyngiomas. Treatment is often complicated by panhypopituitarism and diabetes insipidus. Larger craniopharyngiomas may be decompressed, and radiotherapy should be considered for persistent or recurrent disease.

Pituitary Apoplexy

Pituitary apoplexy is a clinical syndrome produced by sudden hemorrhage or infarction of the pituitary gland. Apoplexy usually occurs in a gland with a preexisting cyst or adenoma, but it has been described in normal pituitary glands. The onset of symptoms may be acute or subacute. The majority of patients present with headache, visual field defects, ophthalmoplegia, and, often, altered mental status. The immediate threat to the patient's life is from cortisol deficiency. Therapy includes hormonal support and neurosurgical decompression.

Lymphocytic Hypophysitis

Lymphocytic hypophysitis is presumed to be autoimmune in origin. Classically, it occurs in women during the postpartum period. The clinical presentation may be due to a mass effect (a sellar mass) but more commonly to deficiency of one or more anterior pituitary hormones (ACTH deficiency is the commonest). Corticosteroid therapy is often used in an attempt to shrink the sellar mass, but its effects are often disappointing. In many cases, the diagnosis is made only postoperatively because the process may be radiologically indistinguishable from a pituitary adenoma. Hormonal replacement therapy is given as needed.

Diabetes Insipidus

Etiology

Central diabetes insipidus may result from decreased production of ADH because of granulomatous infiltration of the posterior pituitary and the pituitary stalk (sarcoidosis, tuberculosis, or Langerhans cell histiocytosis), closed head trauma or neurosurgery, or primary neoplasms such as craniopharyngioma or metastatic neoplasms primarily from the breast or lung. Idiopathic hypothalamic diabetes insipidus is probably the commonest cause of the syndrome and may be an autoimmune disorder. Nephrogenic diabetes insipidus may be caused by chronic renal disease, electrolyte abnormalities (hypercalcemia or hypokalemia), and drugs such as lithium and demeclocycline, which antagonize the effects of antidiuretic hormone (ADH) on the renal tubules.

- Diabetes insipidus may result from decreased production of ADH or lack of renal responsiveness to the hormone.

Clinical Features

Patients typically present with polyuria and polydipsia, often with a preference for ice-cold water. Nocturia is usually present, and enuresis may be the presenting complaint of children. The absence of nocturia, intermittent symptoms, and a 24-hour urine output greater than 18 L suggest psychogenic polydipsia. It is important to remember that because patients with diabetes insipidus rely solely on their thirst mechanism to regulate water balance, lack of access to water or loss of the sensation of thirst will lead to extreme hyperosmolar dehydration.

Cortisol and, to a lesser extent, thyroid hormones are necessary for the excretion of a water load. In patients with central diabetes insipidus, the development of hypopituitarism may mask the symptoms of diabetes insipidus, which become apparent only after adequate cortisol replacement therapy.

- Diabetes insipidus is characterized by polyuria and polydipsia.

- The absence of nocturia suggests psychogenic polydipsia.
- When thirst sensation is impaired or access to water is restricted, hyperosmolar dehydration may ensue.
- Cortisol is necessary for the kidney to excrete a water load.

Diagnosis

Endocrine Diagnosis

The diagnosis of diabetes insipidus is often complicated by the disorder being partial. Also, prolonged periods of polyuria, regardless of the primary cause, may decrease the maximal urine-concentrating ability of the kidney.

In a patient with polyuria and dilute urine, a random plasma osmolality greater than 295 mOsm/kg suggests the diagnosis of diabetes insipidus. Plasma osmolality less than 280 mOsm/kg implies psychogenic polydipsia. If plasma osmolality is between 280 and 295 mOsm/kg, a water deprivation test is indicated. A random plasma osmolality greater than 295 mOsm/kg (or at the end of a water deprivation test) and urine osmolality less than 300 mOsm/kg at the end of a water deprivation test exclude primary polydipsia and confirm diabetes insipidus. To differentiate between central and nephrogenic diabetes insipidus, 1 µg desmopressin (DDAVP) is injected subcutaneously and urine osmolality is measured at 30, 60, and 120 minutes. A postinjection urine osmolality more than 150% of the preinjection osmolality is consistent with central diabetes insipidus.

A partial response to water deprivation, with urine osmolality greater than 300 mOsm/kg, can occur in partial central or nephrogenic diabetes insipidus as well as in primary polydipsia. In these circumstances, it is also necessary to collect plasma for ADH levels at the end of the water deprivation test.

- A random plasma osmolality >295 mOsm/kg suggests diabetes insipidus.
- A random plasma osmolality <280 mOsm/kg, in an untreated patient, suggests psychogenic polydipsia.
- Central diabetes insipidus can be distinguished from nephrogenic diabetes insipidus by the response to exogenous desmopressin.
- The absence of response to water deprivation (urine osmolality <300 mOsm/kg) is diagnostic of diabetes insipidus.

Etiologic Diagnosis

Imaging of the hypothalamus and neurohypophysis as well as the sella is essential. Systemic diseases involving the hypothalamus or pituitary stalk must be considered.

Therapy

The underlying cause should be treated. However, in central diabetes insipidus, treatment seldom restores ADH secretion. There is no need for intervention in patients with mild diabetes insipidus (urine output, 2-5 L daily) who have free access to water. For greater degrees of central diabetes insipidus, which interfere with the patient's sleep, desmopressin is the drug of choice. It is administered by nasal spray (5-10 µg once or twice daily) or orally (0.1-0.8 mg daily in divided doses). For patients who are unconscious or allergic to nasal desmopressin, the drug can be given parenterally (1-2 µg subcutaneously or intravenously 1 or 2 times daily). Thiazides may be useful in treating nephrogenic diabetes insipidus. Psychiatric assessment is needed for patients with psychogenic polydipsia.

Syndrome of Inappropriate Secretion of ADH

Etiology

The syndrome of inappropriate secretion of ADH (SIADH) occurs when excessive ADH is secreted in the absence of a hyperosmolar stimulus or a hypovolemic or hypotensive (or both) stimulus. SIADH may be a consequence of 1) central nervous system or hypothalamic disorders (including trauma) or inflammatory, degenerative, vascular, or neoplastic disorders; 2) the use of drugs that enhance ADH secretion or action (chlorpropamide, carbamazepine, vincristine, vinblastine, cyclophosphamide, phenothiazines, monoamine oxidase inhibitors, and tricyclic antidepressants); 3) neurogenic influences such as pain or nausea; and 4) benign and malignant pulmonary disorders (pneumonia, lung abscess, empyema, mesothelioma, and small cell lung carcinoma).

Pathophysiology

SIADH leads to hyponatremia, with low serum osmolality and inappropriately concentrated urine. The expansion of the extracellular fluid volume leads to natriuresis (from an increase in glomerular filtration rate, atrial natriuretic hormones, and suppression of the renin-angiotensin-aldosterone axis). Natriuresis exacerbates plasma hypo-osmolality, thus explaining the absence of edema despite an expanded extracellular fluid volume.

- Physiologic or appropriate ADH hypersecretion occurs in response to plasma hyperosmolality or hypovolemia or hypotension.
- SIADH is characterized by hypervolemia, hyponatremia, and hypo-osmolality of body fluids and inappropriately concentrated urine. Edema is absent.

Clinical Features

The clinical features depend on the degree and rapidity of the development of hyponatremia. Patients with SIADH may be asymptomatic if the hyponatremia develops gradually over weeks and months. Symptoms include lethargy, malaise, nausea and vomiting, and confusion. Severe or rapidly developing hyponatremia can lead to alterations in mental status or seizures.

- Clinical features depend on the degree and rapidity of the development of hyponatremia.

Diagnosis

The diagnosis of SIADH is one of exclusion. Pseudo-hyponatremia due to hyperlipidemia (normal plasma osmolality) and hyperosmolar states due to water loss, as in hyperglycemia (increased plasma osmolality), must be excluded. Exclude diseases in which increased secretion of ADH is appropriate (congestive heart failure, ascites, nephrosis, hypovolemia, hypothyroidism, and hypocortisolism).

The main diagnostic challenge is to differentiate SIADH from subclinical hypovolemia. In subclinical hypovolemia, the urinary concentration of sodium is less than 20 mEq/L (in the absence of diuretic use) and the serum levels of creatinine and uric acid are increased, as are plasma renin activity and the plasma level of aldosterone.

- The main diagnostic challenge is to differentiate SIADH from subclinical hypovolemia. Determine plasma renin activity and the concentrations of urinary sodium, serum creatinine and uric acid, and plasma aldosterone.

Therapy

Therapy for SIADH includes treating the underlying disorder. Water intake is restricted to 800 to 1,000 mL daily. If necessary, an ADH antagonist (demeclocycline, 900-1,200 mg daily) can be given. If acute neurologic sequelae are present, hypertonic saline is administered intravenously (200-300 mL of 5% NaCl over 3-4 hours) to achieve a gradual increase in serum sodium (do not exceed 0.5 mEq/h or 12 mEq/24 h). Rapid correction of hyponatremia can lead to central pontine myelinolysis.

- Identify and treat the underlying disorder.
- Therapy for hyponatremia consists of water restriction and, if needed, demeclocycline.
- In the presence of acute neurologic sequelae, administer hypertonic saline to increase serum sodium by 0.5 mEq/h.
- Rapid correction of hyponatremia can lead to potentially fatal central pontine myelinolysis.

Disorders of the Thyroid Gland

Laboratory Assessment of Thyroid Function

Several thyroid tests to determine thyroid function and structure are being used increasingly in healthy adult screening studies. However, abnormal test results can be obtained in euthyroid patients with nonthyroidal illness. Consequently, the history and physical examination are as important as laboratory investigation in the evaluation of thyroid disease.

Total T_4

Serum total T_4 concentration is a measurement of T_4 bound to thyroid hormone–binding proteins such as thyroxine-binding globulin (TBG). Therefore, conditions that affect TBG concentration affect total T_4 measurements. Androgens, anabolic steroids, glucocorticoids, chronic liver disease, niacin, and familial TBG deficiency decrease total TBG. Estrogens, pregnancy, acute hepatitis, and familial TBG excess increase TBG and total T_4 concentrations.

Total T_3

Serum total T_3 concentration is decreased in hypothyroidism, nonthyroidal illness, and caloric deprivation and by drugs such as propranolol, amiodarone, and glucocorticoids. Serum T_3 levels are increased in thyrotoxicosis and peripheral hormone resistance. Serum T_3 concentrations should be measured to establish or exclude the diagnosis of T_3 thyrotoxicosis in a patient with a suppressed TSH level and a normal serum concentration of FT_4.

FT_4

The serum concentration of FT_4 is decreased in hypothyroidism and nonthyroidal illness and increased in hyperthyroidism, nonthyroidal illness, and peripheral hormone resistance.

Thyroid Hormone-Binding Proteins

Thyroid hormone-binding proteins can be measured directly by radioimmunoassay or, more commonly, with the T_3 resin uptake test, which provides an indirect measurement of unoccupied T_4 binding sites on binding proteins. The normal range is 30% to 40%. A decrease in T_4 binding sites, and thus an increase in T_3 resin uptake, occurs in hyperthyroidism, in low TBG states, and in the presence of binding inhibitors, as in nonthyroidal illness or with the use of certain drugs (see above). An increase in T_4 binding sites, and thus a decrease in T_3 resin uptake, occurs in hypothyroidism and high TBG states.

Free Thyroxine Index

The free thyroxine index (FTI) represents the product of serum T_4 and T_3 resin uptake. It is an indirect measurement of FT_4 and correlates well with FT_4 concentrations.

Serum TSH

Current third-generation TSH assays measure TSH concentrations as low as 0.05 mU/L, allowing clinicians to differentiate low-normal values from suppressed values. TSH is increased in primary hypothyroidism, during recovery from nonthyroidal illness, and with peripheral resistance to thyroid hormones. TSH is suppressed in hyperthyroidism of any cause (except that due to TSH-producing tumors), in nonthyroidal illness, and by drugs such as somatostatin, dopamine, and glucocorticoids. Measurement of TSH is the best test of thyroid function. However, TSH levels are unreliable in cases of pituitary disease because values can be "inappropriately" normal relative to thyroid hormone concentrations. Thus, TSH levels may be normal or increased with TSH-producing tumors and normal or decreased in central hypothyroidism.

Thyroid Scanning

Thyroid scanning may be performed with technetium pertechnetate or radioactive iodine. Thyroid scanning is reserved for the documentation of toxic thyroid nodules, ectopic thyroid tissue in struma ovarii, and metastatic disease in the postoperative evaluation and follow-up of patients with differentiated thyroid cancer.

Radioactive Iodine I 131 Uptake

The normal range for 24-hour radioactive iodine I 131 uptake (RAIU) depends on the dietary iodine intake in a given population. In the U.S. population, the normal range is 10% to 25%. A 24-hour RAIU study is indicated during the evaluation of hyperthyroidism to distinguish low-uptake states from high-uptake states and to aid in dose calculations when radioactive iodine is used to treat Graves disease.

Serum Thyroglobulin

Thyroglobulin is used mainly as a tumor marker in follow-up evaluations of patients with differentiated thyroid carcinoma. It also may be useful in the differential diagnosis of suppressed TSH with low RAIU (lymphocytic thyroiditis or exogenous hyperthyroidism). Serum thyroglobulin levels are usually elevated in lymphocytic thyroiditis and low in exogenous hyperthyroidism.

TSH Receptor–Stimulating Immunoglobulins

Measurement of TSH receptor–stimulating immunoglobulins (TSIs), which are immune markers of Graves disease, is important in the differential diagnosis of hyperthyroidism in pregnant women who cannot undergo RAIU. TSI levels may help to predict the possible occurrence of neonatal thyrotoxicosis in infants born to women with active Graves disease or a history of it. TSI measurement is also helpful in the diagnosis of euthyroid Graves ophthalmopathy.

Antithyroglobulin and Antimicrosomal (Antiperoxidase) Antibodies

Antithyroglobulin and antimicrosomal antibodies are used as markers of autoimmune thyroid disease. The absence of these antibodies does not exclude the presence of autoimmune thyroid disease. Conversely, the presence of these antibodies is not diagnostic of autoimmune thyroid disease; they can be found in otherwise healthy persons. High titers occur in more than 90% of patients with Hashimoto thyroiditis, and modestly increased titers are found in primary atrophic hypothyroidism and Graves disease. Antithyroglobulin antibodies, when present, make measurement of thyroglobulin unreliable for follow-up of thyroid malignancies.

Thyroid Ultrasonography

Ultrasonography is used for the assessment of thyroid nodules, goiter, and follow-up of patients with thyroid cancer. Altered blood flow can be documented in patients with Graves disease.

Hyperthyroidism

Etiology

Primary thyroid disorders that cause hyperthyroidism can be divided into those characterized by increased production and release of T_4 (high RAIU) and those characterized by unregulated release of T_4 due to gland destruction (suppressed RAIU) (Table 6-2).

The commonest cause of hyperthyroidism in iodine-sufficient areas is Graves disease. Other frequent causes include toxic nodular goiter, lymphocytic and subacute thyroiditis, and exogenous hyperthyroidism.

Clinical Features

Typical symptoms include heat intolerance, palpitations, increased sweating, diarrhea, weight loss, menstrual irregularities, insomnia, nervousness, irritability, and emotional lability. In severe, prolonged hyperthyroidism, proximal muscle weakness may be present. Ocular manifestations include findings due to sympathetic overactivity from hyperthyroidism of any cause (retraction of the upper lid, stare, and lid lag) or findings unique to Graves disease (puffiness of the lids, conjunctival injection and chemosis, proptosis, and extraocular muscle weakness). Patients with Graves ophthalmopathy may complain of a gritty sensation in the eyes, excessive lacrimation, photophobia, and diplopia. Most patients with hyperthyroidism have a small, firm goiter, but its presence and characteristics vary according to the cause.

Atypical presentations of hyperthyroidism, particularly in the elderly, include apathy, weight loss, supraventricular tachycardia, atrial fibrillation, and congestive heart failure. Young adult males may develop gynecomastia.

- The clinical features of hyperthyroidism reflect the effects of excess thyroid hormone. However, some features, such as Graves ophthalmopathy, may be specific to the underlying cause.
- The presence of goiter and its characteristics vary according to the cause.
- Atypical presentations of hyperthyroidism in the elderly include weight loss, apathy, atrial fibrillation, and congestive heart failure.

Diagnosis of Hyperthyroidism

The biochemical diagnosis of hyperthyroidism rests on the demonstration of suppressed TSH and an increased serum level of FT_4. Normal FT_4 values should prompt the measurement of serum T_3 concentrations to determine the presence of T_3 toxicosis. An increased or inappropriately normal TSH level in the presence of an increased FT_4 level indicates hyperthyroidism due to pituitary TSH-secreting tumors or selective pituitary resistance to thyroid hormones. A low level of serum TSH by itself is not diagnostic of hyperthyroidism and can be encountered in nonthyroidal illness, glucocorticoid therapy, dopamine therapy, and secondary hypothyroidism.

Specific Causes

Graves Disease

Graves disease is characterized by the triad of hyperthyroidism, ophthalmopathy, and dermopathy, which may occur singly or in

Table 6-2 Causes of Increased and Suppressed 24-Hour Radioactive Iodine Uptake (RAIU)

High RAIU	Low RAIU
Graves disease	Lymphocytic thyroiditis (postpartum thyroiditis)
Autonomous nodular goiter	Subacute thyroiditis
HCG-dependent hyperthyroidism of trophoblastic disease	Exogenous hyperthyroidism
TSH-secreting pituitary adenoma	Recent iodine load (e.g., contrast dye)
Metastatic follicular thyroid carcinoma	Struma ovarii (if RAIU is measured over thyroid only)
Selective pituitary resistance to thyroid hormones	

HCG, human chorionic gonadotropin; TSH, thyroid-stimulating hormone.

combination. Management of hyperthyroidism does not influence the clinical course of eye or skin manifestations. The hyperthyroidism is caused by autoantibodies with TSH-like activity (i.e., TSI). Although Graves disease occurs most often in young females, it can occur at any age and in either sex. The disease tends to relapse and remit spontaneously. Usually, the thyroid is diffusely enlarged and smooth, with a firm consistency.

- Hyperthyroidism, ophthalmopathy, and dermopathy characterize Graves disease.
- Hyperthyroidism is caused by the production of TSI.

Painless Lymphocytic Thyroiditis (Postpartum Thyroiditis)
Painless lymphocytic thyroiditis is usually a self-limiting disease that occurs most commonly in the postpartum period (although it may occur in males) and tends to recur with subsequent pregnancies in two-thirds of women with the disease. Patients with a history of lymphocytic thyroiditis also have an increased incidence of chronic autoimmune thyroiditis. It classically presents with a triphasic pattern of thyroid function: an initial hyperthyroid phase (suppressed TSH, low RAIU, and increased levels of FT_4) is followed by a hypothyroid phase and subsequent recovery of normal thyroid function. However, patients may present at any stage of the disorder or may have thyroid recovery without having a hypothyroid phase.

β-Blockers may be prescribed in the hyperthyroid phase for symptomatic tachycardia or tremor. There is no indication for antithyroid medications or radioactive iodine therapy because the hyperthyroidism is due to the release of preformed thyroid hormone into the circulation and not to increased production of thyroid hormone. Temporary thyroid hormone replacement therapy may be necessary for symptomatic patients during the hypothyroid phase. In some cases, the hypothyroidism may be permanent.

- Painless lymphocytic thyroiditis may occur in both sexes, but it is more common in the postpartum period.
- Patients typically present with transient hyperthyroidism, followed by transient hypothyroidism before thyroid recovery.
- Treatment is symptomatic: β-blockers for hyperthyroid symptoms and temporary thyroid hormone replacement therapy for hypothyroidism.
- Two-thirds of women with postpartum thyroiditis have recurrence of disease with subsequent pregnancies.

Subacute Painful Thyroiditis (de Quervain Thyroiditis)
Subacute painful thyroiditis is characterized by a painful, tender goiter. Patients often complain of fever, malaise, myalgia, and a history of upper respiratory tract infection. Odynophagia may be a prominent symptom. Transient hyperthyroidism (low RAIU) is often present at diagnosis and may be followed by transient hypothyroidism. The erythrocyte sedimentation rate is invariably increased.

The differential diagnosis includes hemorrhage into a thyroid nodule. With hemorrhage, the onset of pain is similarly abrupt, but the features of a systemic illness are absent and a tender nodule can often be palpated. Thyroid function usually is unaffected, and the erythrocyte sedimentation rate is normal. Treatment options include nonsteroidal anti-inflammatory drugs (NSAIDs) for mild or moderate disease and corticosteroid therapy for severe disease. The response to corticosteroid therapy is dramatic, typically with relief of symptoms within 24 hours.

- Subacute thyroiditis is characterized by a tender thyroid gland.
- The erythrocyte sedimentation rate is markedly increased.
- Symptomatic therapy includes NSAIDs or corticosteroid therapy.

Multinodular Goiter
Toxic multinodular goiter occurs in patients with a long-standing nodular goiter in which autonomous nodules develop. The hyperthyroidism is usually mild, and cardiovascular manifestations may dominate the clinical features. The goiter is large, nodular, and asymmetrical. The thyroid may be difficult to palpate in some patients because of substernal extension or a short neck.

- Toxic multinodular goiter occurs in patients with nodular goiter.
- Hyperthyroidism may be characterized by organ-specific manifestations, particularly cardiovascular ones.
- A goiter may be difficult to palpate because of a short neck or substernal extension.

Toxic Thyroid Adenoma
A hyperfunctioning autonomous follicular adenoma ("toxic thyroid adenoma"), found most often in middle-aged women, may lead to hyperthyroidism. The solitary nodule is usually larger than 3 cm, is easy to palpate, and has a firm consistency. A radioisotope scan demonstrates intense uptake in the nodule, with suppressed uptake in the rest of the gland.

- A radioisotope scan demonstrates intense uptake in the nodule, with suppressed uptake in the rest of the gland.
- Most solitary hyperfunctioning nodules are >3 cm.

Exogenous Hyperthyroidism
Exogenous hyperthyroidism can result from the use of T_4 or T_3 (or both). Factitial thyrotoxicosis should be suspected in thyrotoxic patients who do not have a palpable goiter and do not have suppressed RAIU. Low serum levels of thyroglobulin help to differentiate this disorder from painless lymphocytic thyroiditis.

- The absence of goiter and the absence of suppressed RAIU in a thyrotoxic patient should prompt consideration of factitial thyrotoxicosis.

Therapy

Thionamides
Methimazole and propylthiouracil are used to treat the hyperthyroidism of Graves disease. They act by blocking thyroid hormone synthesis and may have immunomodulating properties that decrease the production of TSI. At very high doses, propylthiouracil decreases

the peripheral conversion of T_4 to T_3. The effect of thionamides is temporary, and hyperthyroidism often recurs after discontinuation of treatment. Therefore, these drugs are used in Graves disease to control hyperthyroidism with the hope of spontaneous remission of the disease during therapy. Treatment is given for 12 to 18 months and then discontinued. The safety of long-term antithyroid drug therapy is not well documented. In more than 50% of patients, the disease relapses within the first 3 to 6 months. Adverse effects are uncommon (<5%) but potentially serious and include agranulocytosis and hepatitis. Agranulocytosis can develop abruptly within a few hours; commonly, it initially manifests with an extreme sore throat. Thionamides can cross the placenta and, in high doses, block thyroid hormone synthesis in the fetal thyroid. For pregnant women, the lowest dose that controls symptoms is used.

- Thionamides block thyroid hormone synthesis and may decrease production of TSI.
- Agranulocytosis can develop abruptly.
- Thionamides can cross the placenta and affect the fetal thyroid.

Radioactive Iodine

Radioactive iodine therapy is effective in ablating the thyroid gland and is commonly used to treat the hyperthyroidism of Graves disease or toxic multinodular goiter. This therapy has not been associated with long-term risks, but pregnancy and breast-feeding are contraindications. Most physicians avoid administering radioactive iodine to very young patients. The goal of therapy is to render the patient hypothyroid. The maximal effect from radioactive iodine is apparent within 2 to 3 months. Treatment of toxic multinodular goiter requires higher doses of radioactive iodine and often more than one course of treatment. Painful thyroiditis may develop within a week after treatment, as can transient worsening of hyperthyroidism. Radiation-induced enlargement of the gland may worsen obstructive symptoms, particularly in patients with a substernal goiter. Currently, it is debated whether radioactive iodine therapy may worsen Graves ophthalmopathy. It has been suggested that this risk is decreased if corticosteroid treatment is given before radioactive iodine therapy to patients with symptomatic ophthalmopathy.

- Pregnancy and breast-feeding are contraindications to treatment with radioactive iodine.
- Radioactive iodine therapy may be given in Graves disease or toxic multinodular goiter.
- The dose of radioactive iodine is intended to make the patient hypothyroid.
- Radiation-induced enlargement of the gland may worsen obstructive symptoms, particularly in patients with a substernal goiter.

Surgery

Subtotal or near-total thyroidectomy is rarely performed to treat Graves disease but is indicated in certain situations, including a large obstructive gland and pregnancy. Thyrotoxic patients with thyroid nodules that look suspicious on fine-needle aspiration should be referred for surgery. To prevent a thyroid storm as well as excessive bleeding from the overactive friable gland, the patient should be rendered euthyroid with antithyroid drug therapy and then given stable iodine for 7 to 10 days preoperatively. Damage to the recurrent laryngeal nerves or parathyroid glands is not common (<1% to 2%) with experienced surgeons.

- Subtotal thyroidectomy is indicated for thyrotoxic patients with large goiters or suspicious-looking nodules and for patients with Graves disease who are young or pregnant.

Supportive Therapy

β-Blockers are used to control the adrenergic manifestations of hyperthyroidism. Propranolol (a nonselective β-blocker) is prescribed most commonly. These drugs are administered to patients with severe symptomatic hyperthyroidism while awaiting the effects of more definitive therapy. β-Blockers should not be given alone in the preoperative preparation of thyrotoxic patients because they do not prevent thyrotoxic crisis.

Thyroid Storm

Thyroid storm is a state of severe hyperthyroidism in untreated or inadequately treated hyperthyroid patients who are undergoing surgical treatment or who have acute intercurrent illness. It is characterized by delirium, fever, tachycardia, hypotension, vomiting, diarrhea, and, eventually, coma. Treatment should be initiated immediately. Together with other supportive therapy, propylthiouracil is given to block thyroid hormone synthesis, sodium iodide is given to inhibit the release of thyroid hormones, and propranolol is given to control the adrenergic manifestations.

Thyrotoxicosis in Pregnancy

Antithyroid drug therapy is the first-line treatment of thyrotoxicosis during pregnancy. Surgical excision may be an option after the first trimester. Radioactive iodine is contraindicated because of its ablative effects on the fetal thyroid. Because antithyroid drugs cross the placenta, the lowest dose necessary to control the disease should be given.

Hypothyroidism

Hypothyroidism can be primary (intrinsic thyroid disease) or secondary (hypothalamic-pituitary disease). Primary hypothyroidism accounts for more than 90% of all cases. The commonest causes of primary hypothyroidism in iodine-replete areas of the world are Hashimoto thyroiditis (goitrous hypothyroidism) and Ord disease (atrophic hypothyroidism), both caused by autoimmune thyroid disease. Hashimoto thyroiditis, which tends to cluster in families, is a common disease, particularly in middle-aged and elderly women.

Other common causes include hypothyroidism occurring after radioactive iodine treatment of hyperthyroidism, surgical thyroidectomy, and radiotherapy for neck malignancies. Hypothyroidism may be transient during the course of subacute or painless thyroiditis.

- The commonest cause of hypothyroidism is autoimmune thyroid disease (Hashimoto thyroiditis or Ord disease).

Clinical Features

The clinical presentation of hypothyroidism depends on the degree and duration of the deficiency. In current practice, many patients are asymptomatic, having received a diagnosis through routine screening. Early symptoms include leg cramps, ankle swelling, dry skin, and dry hair. Patients often complain of fatigue, achiness, and mental slowing. Cold intolerance and a mild degree of weight gain are frequently present. The thyroid gland is typically firm or rubbery, with a bosselated texture.

Uncommon manifestations include psychosis, deafness, and cerebellar ataxia. Some patients experience central hypoventilation and apnea because of respiratory depression. Macrocytic anemia, pernicious anemia (associated autoimmune disease), or microcytic anemia (iron deficiency due to menorrhagia) may be present. Patients with dramatic increases in TSH may experience galactorrhea (TRH stimulates prolactin secretion). Hyponatremia due to SIADH may be present. Associated laboratory findings include hyperlipidemia and increased aspartate aminotransferase, lactate dehydrogenase, or creatine kinase.

Autoimmune thyroiditis may be a manifestation of polyglandular autoimmunity (Addison disease, type 1 diabetes mellitus, hypoparathyroidism, or pernicious anemia). It also is associated with vitiligo and other autoimmune and connective tissue diseases.

Diagnosis

The TSH concentration is increased in primary hypothyroidism and low or inappropriately normal in secondary hypothyroidism. A low FT_4 or FTI confirms the diagnosis of hypothyroidism, provided nonthyroidal illness has been excluded. Serum measurements of T_3 are not usually helpful in the diagnosis and may be normal in hypothyroid patients, as a result of up-regulation in the conversion of T_4 to T_3.

Hashimoto thyroiditis is usually associated with a bosselated, firm goiter and a high titer of antimicrosomal antibodies. In contrast, Ord disease demonstrates an atrophic, often impalpable gland, although antibodies are typically detectable in this condition also. Hypothyroidism occurring after radioactive iodine therapy, thyroid surgery, or radiotherapy to the neck or occurring transiently during the course of subacute or silent thyroiditis is usually evident from a careful clinical evaluation. The diagnosis of central hypothyroidism should prompt imaging of the head and testing of pituitary function.

- Low FT_4 or FTI and increased TSH levels are diagnostic of primary hypothyroidism if nonthyroidal illness has been excluded.
- Low FT_4 or FTI and inappropriately normal or low TSH levels indicate central hypothyroidism. MRI of the head and pituitary function tests should be performed.
- Typical clinical scenario for Hashimoto thyroiditis: A 60-year-old woman complains of fatigue, achiness, dry skin, cold intolerance, and weight gain.

Therapy

Thyroid hormone replacement therapy is initiated with synthetic T_4. The usual daily replacement dose is 1.6 μg T_4/kg body weight. In patients with ischemic heart disease, treatment usually is initiated at a lower dose (e.g., 25 μg), with dose increments every few weeks. Care should be taken, particularly in Ord disease, in which autonomous function of the gland remnant may result in thyrotoxicosis if T_4 therapy is initiated at full replacement doses. The goals of therapy are to normalize TSH in primary hypothyroidism and to normalize FT_4 in central hypothyroidism.

Failure to normalize TSH concentrations may be indicative of poor compliance, malabsorption due to concomitant use of medications (e.g., cholestyramine, sucralfate, calcium supplements, or ferrous sulfate within 4 hours of T_4), or gastrointestinal tract disease. Other reasons include progressive thyroid disease, pregnancy, and increased hormone clearance (with use of estrogen, phenytoin, or rifampin). A suppressed TSH level in a patient treated for primary hypothyroidism may indicate reduced T_4 requirements of aging, decreased clearance, or (rarely) reactivation of the thyroid remnant with development of Graves disease. It is important to assess TSH annually or as indicated by the patient's symptoms to ensure compliance and to determine whether dose adjustment is needed.

- Monitor TSH in primary hypothyroidism.
- Monitor FT_4 in central hypothyroidism.
- Avoid medications that may interfere with intestinal absorption for at least 4 hours after ingestion.

Miscellaneous Circumstances

Thyroxine Replacement Therapy in Pregnancy

Women who are receiving T_4 replacement therapy should be counseled about the importance of ensuring adequate replacement before conception. Most patients with primary hypothyroidism who are receiving an adequate dosage before pregnancy require an increased dose as the pregnancy progresses (an average dose increase of 25% to 50%). TSH levels should be assessed periodically during pregnancy, and the T_4 dose should be adjusted as necessary to maintain a normal TSH.

Thyroxine Replacement Therapy in Patients With Angina

Hypothyroid patients with progressive, symptomatic ischemic heart disease should be evaluated by a cardiologist. Hypothyroidism does not contraindicate intervention, although there is an increased risk of hyponatremia and other perioperative complications. Replacement therapy typically is initiated with 25 μg daily, and the dose is increased gradually to the replacement dosage.

Subclinical Hypothyroidism

In subclinical hypothyroidism, serum TSH levels are increased in clinically euthyroid patients with normal FT_4 concentrations. It is a relatively common disorder and affects 5% to 15% of elderly persons. Patients are usually asymptomatic or have minimal nonspecific symptoms that may be unrelated to hypothyroidism. A trial of replacement therapy is indicated for symptomatic patients and for patients at risk of progressive disease. The risk of progression to overt hypothyroidism increases with age, the presence of thyroid antibodies, and TSH levels greater than 10 IU/mL.

Myxedema Coma

Myxedema coma occurs in patients who have severe, untreated hypothyroidism, and although it may be spontaneous, it usually is precipitated by acute illness (e.g., infection, surgery, or myocardial infarction), exposure to cold, or the use of sedatives or opiates. The mortality rate (20%-50%) is high. The onset is insidious, with progressive stupor culminating in coma. Seizures, hypothermia, hypotension, hypoventilation, hyponatremia, and hypoglycemia may be present.

Treatment should be initiated promptly with intravenous T_4. This is usually given as a single daily dose (50-100 μg). Aggressive treatment of associated conditions such as hypothermia should be initiated. The use of glucocorticoids in all cases of myxedema coma is controversial. The optimal approach is to administer corticosteroids if there is clinical and laboratory evidence of hypocortisolism. An effort should be made to conserve body heat; external warming is likely to cause cutaneous vasodilatation, with increased hypotension. Often, the prognosis is determined by the coexisting conditions.

Thyroid Nodules

Thyroid nodules are extremely common and increase in frequency with age. Nodules may be detected during a routine medical examination, noticed by the patient, or detected during neck ultrasonography performed for other reasons. With the discovery of a nodule, the primary concern is whether the underlying process is benign or malignant. In addition to considering primary thyroid malignancies, consider metastatic disease (renal cell carcinoma is the commonest malignancy metastatic to the thyroid). Patients with benign adenomas and cysts may present with thyroid nodules, and patients with a multinodular goiter may present with a dominant nodule. Occasionally, the goiter of Hashimoto thyroiditis may simulate a solitary thyroid nodule.

At least 95% of palpable thyroid nodules are benign, but the likelihood of malignancy increases with solitary nodules, older age, male gender, and a history of irradiation to the head and neck (especially during childhood). The initial step in the evaluation of a thyroid nodule is measurement of TSH to determine whether autonomy is present. Thyroid malignancy is substantially less likely if the TSH level is abnormal. If the TSH level is suppressed, a thyroid scan and an RAIU study should be performed. A thyroid scan is not helpful in the evaluation of a thyroid nodule unless the TSH is suppressed and a hyperfunctioning nodule is suspected.

Following TSH measurement, fine-needle aspiration should be performed in a palpable nodule. Fine-needle aspiration has high sensitivity and specificity for excluding malignancy if performed and interpreted by experienced personnel. If the aspirate has benign characteristics, annual follow-up with palpation and measurement of TSH is adequate, provided no change is noted in the size and characteristics of the nodule. A nondiagnostic aspirate requires repetition (under ultrasonographic guidance if needed). If the aspirate is interpreted as suspicious or compatible with malignancy, surgical intervention is required.

- Of palpable thyroid nodules, ≥95% are benign.
- TSH measurement is the first test in the evaluation of thyroid nodules.
- Fine-needle aspiration has high sensitivity and specificity for excluding malignancy if performed and interpreted by experienced personnel.
- A thyroid scan is not helpful in the evaluation of a thyroid nodule unless the TSH is suppressed and a hyperfunctioning nodule is suspected.

Thyroid Cancer

Differentiated Thyroid Cancer

Papillary thyroid carcinoma is the commonest type of thyroid cancer (70%-80% of cases). Its incidence peaks in early adulthood and again in late adulthood. Dissemination is generally via the lymphatics to lymph nodes; other sites of metastases include the lungs and bone. Typically, presentation is as a thyroid nodule, as cervical lymphadenopathy, or as an incidental finding in an excised gland.

Follicular carcinoma (20% of cases) spreads preferentially by the hematogenous route. The usual presentation is as a thyroid mass or metastatic deposits to the lungs, bones, or brain. Rarely, especially if the tumor burden is large, follicular carcinoma can cause thyrotoxicosis.

Patients with undifferentiated *anaplastic carcinoma* usually present with a rapidly progressive thyroid mass with pain and compressive local neck symptoms. It has an extremely poor prognosis, and patients have a median survival of less than 3 months after diagnosis.

Conversely, among patients with differentiated cancer, the 20-year cause-specific mortality rate varies from less than 5% to 15%, with papillary cancer having the best prognosis. Factors associated with a poorer prognosis include age older than 45 at diagnosis, incomplete resection, extensive local invasion, large size of primary tumor, and the presence of distant metastases (metastases to the cervical lymph nodes do not affect prognosis).

Surgical excision is the therapy of choice for differentiated thyroid cancer. For anaplastic cancer, excision is sometimes undertaken to palliate compression of the trachea and to prevent or delay asphyxiation. The extent of surgical excision in differentiated thyroid cancer is a subject of debate, but near-total thyroidectomy is usually performed. The affected lymph nodes are selectively excised.

Patients at low risk of recurrent disease are treated with a dose of T_4 to maintain TSH between 0.1 and 0.4 mIU/L. Those at higher risk undergo radioactive iodine imaging at 4 to 8 weeks postoperatively, after thyroid hormone withdrawal. If necessary, a sufficient dose of radioactive iodine is administered to ablate the thyroid remnant. Suppressive therapy is initiated, with the target TSH level being less than 0.1 mIU/L.

Reevaluation in 3 to 6 months and annually thereafter is required. Chest radiography, determination of serum levels of TSH and thyroglobulin, and neck ultrasonography are performed at each visit. Whole body iodine scanning is also in widespread use in the routine follow-up of patients with thyroid cancer. Most differentiated thyroid malignancies synthesize and secrete thyroglobulin, which can be used as a marker of recurrent or persistent disease. If a patient has little or no thyroid tissue and is receiving suppressive T_4 therapy, the

serum thyroglobulin level should be less than 5 ng/mL; a higher (or increasing) level implies persistent or recurrent disease.

- Papillary cancer spreads via the lymphatics to the lymph nodes and has the best prognosis. Presentation is as a thyroid mass or cervical lymphadenopathy or as an incidental finding.
- Follicular carcinoma spreads preferentially by the hematogenous route. Presentation is as a thyroid mass or distant metastatic deposits.
- Anaplastic carcinoma presents with rapidly progressive local symptoms.
- Surgical excision is the definitive therapy for differentiated thyroid cancer.
- Follow-up evaluation requires determination of TSH and thyroglobulin levels, neck ultrasonography, and chest radiography. Radioactive iodine imaging is performed if there is evidence of recurrent or persistent disease.
- Recurrences are treated, depending on location, with excision or radioactive iodine.

Miscellaneous Thyroid Disorders

Sick Euthyroid Syndrome

Patients who require hospitalization for a systemic illness, psychiatric disorder, or trauma frequently have abnormal thyroid function test results without identifiable intrinsic thyroid disease. The abnormalities resolve with recovery from the associated illness. Specific therapy is not required. During the acute illness, the TSH level may be normal or low (approximately 0.01 μU/mL) because of the central effects of the illness. TSH levels may be increased during recovery.

The main challenge in sick hospitalized patients is to distinguish between nonthyroidal illness and intrinsic thyroid or pituitary disease. Helpful features in the differential diagnosis include the presence of goiter, extrathyroidal manifestations of Graves disease, hypothalamic-pituitary mass effects, or hypopituitarism. A high serum level of T_3 suggests hyperthyroidism, whereas a TSH level greater than 20 μU/mL supports the diagnosis of primary hypothyroidism.

Amiodarone and the Thyroid

Amiodarone is a class III antiarrhythmic agent. Iodine comprises 40% of the drug by weight. This drug can affect thyroid function in several ways, including causing a drug-induced thyroiditis. In persons with impaired thyroid autoregulation (underlying autoimmune thyroid disease or nodular goiter), iodide excess can lead to hyperthyroidism or hypothyroidism. When using amiodarone, it is important to monitor thyroid function, particularly in the elderly (consider the high prevalence of Hashimoto thyroiditis and nodular goiter and the difficulty with detecting thyroid dysfunction in this age group).

Lithium and the Thyroid

Lithium decreases the synthesis and secretion of thyroid hormones. Its use has been associated with the development of goiter and hypothyroidism, especially in patients who have underlying autoimmune thyroid disease.

Disorders of Calcium and Bone Metabolism

Hypercalcemia

Clinically, the causes of hypercalcemia are best categorized as either parathyroid-dependent or parathyroid-independent.

Parathyroid-Dependent Hypercalcemia

Primary Hyperparathyroidism

Etiology—Primary hyperparathyroidism is the commonest cause of hypercalcemia in ambulatory patients. It is more common in females. A single parathyroid adenoma is the cause in 80% of patients, multiple adenomas are the cause in 5% of patients, and hyperplasia of all four glands is the cause in 15%. Rarely, patients with parathyroid carcinoma present with a neck mass and hypercalcemia. In 6% to 10% of patients with hyperparathyroidism, the adenoma may be found in the thyroid, thymus, or mediastinum. The disease may be sporadic or familial. Familial hyperparathyroidism may be a manifestation of MEN 1 or MEN 2A. Parathyroid hyperplasia is usually present in familial hyperparathyroidism.

- Primary hyperparathyroidism is a common disorder that may be sporadic or familial.
- Parathyroid adenoma is the usual cause.
- Hyperplasia is common in the familial forms of hyperparathyroidism. It may be an isolated feature or occur in association with MEN 1 or MEN 2A.

Clinical features—Most patients with primary hyperparathyroidism are asymptomatic, and the hyperparathyroidism is identified by routine laboratory testing. Symptomatic hypercalcemia may be manifested as polyuria and polydipsia. Hypercalciuria can cause nephrolithiasis. Nephrocalcinosis and band keratopathy may occur in severe disease. Nonspecific symptoms of fatigue, weakness, myopathy, and depression may be present. Skeletal manifestations include osteopenia or osteoporosis and, in severe disease, bone pain and pathologic fractures.

- Primary hyperparathyroidism is commonly asymptomatic.
- When the disease is symptomatic, symptoms may involve several organ systems, including the kidneys, skeleton, and nervous and cardiovascular systems.

Laboratory features—Hypercalcemia is usually mild and often has existed for several years before diagnosis. In most cases, serum phosphate concentrations are normal, but with prolonged hyperparathyroidism, they may be low. The serum level of parathyroid hormone (PTH) is usually increased or it may be inappropriately normal for the degree of hypercalcemia. Urinary calcium excretion is often increased or at the upper limits of normal. Its measurement is important not only to assess the risk of nephrolithiasis but also to exclude disorders characterized by low rates of calcium excretion (familial hypocalciuric hypercalcemia and thiazide use).

Radiographic features—Primary hyperparathyroidism is associated with loss of cortical bone. Characteristic radiographic skeletal

changes include subperiosteal bone resorption (visible on the radial borders of the phalanges), a "salt-and-pepper" appearance of the skull, and osteitis fibrosa cystica (fibrous replacement of the resorbed bone, with bone pain, tenderness, deformity, or fracture). Brown tumors are collections of osteoclasts intermixed with poorly mineralized woven bone. Renal stones or nephrocalcinosis may be visible on abdominal radiographs.

- The principal laboratory findings are hypercalcemia and increased PTH or inappropriately normal PTH for the degree of hypercalcemia.
- Urinary calcium measurement is important in the differential diagnosis and helps guide management.
- Characteristic skeletal findings in severe disease are subperiosteal bone resorption and cortical bone loss. A "salt-and-pepper" appearance of the skull and osteitis fibrosa cystica may be present.

Therapy—Parathyroidectomy is the treatment of choice for primary hyperparathyroidism. All parathyroids should be inspected at the time of the operation. An isolated parathyroid adenoma requires resection. In patients with parathyroid hyperplasia, subtotal parathyroidectomy is performed, leaving about 50 mg of parathyroid tissue intact. Later, it may be necessary to remove this tissue if hypercalcemia persists or recurs. Reversible, mild, asymptomatic hypocalcemia is common in the early postoperative period. However, in patients with severe preexisting parathyroid-induced bone disease, correction of hyperparathyroidism may lead to marked and prolonged hypocalcemia.

Conservative therapy may be indicated for mild uncomplicated disease, especially in the elderly. Indications for excision include serum calcium level greater than 1 unit above the upper limit of normal, nephrolithiasis or pronounced hypercalciuria, osteopenia or osteoporosis, and symptomatic hypercalcemia. Imaging studies to localize the parathyroid neoplasm usually are reserved for patients with persistent or recurrent hyperparathyroidism. However, with the advent of minimally invasive parathyroid surgery, preoperative localization with sestamibi scanning is increasingly being used.

- Parathyroidectomy is the treatment of choice.
- Indications for parathyroidectomy include serum calcium >1 unit above the upper limit of normal, nephrolithiasis, marked hypercalciuria, osteopenia, osteoporosis, and symptomatic hypercalcemia.

Familial Hypocalciuric Hypercalcemia

Familial hypocalciuric hypercalcemia, an autosomal dominant disorder, results from an altered set point of the calcium-sensing receptor in the parathyroid glands and renal tubules. Characteristically, it is an uncomplicated, asymptomatic, mild hypercalcemia in a patient with a normal or slightly increased level of PTH, low urinary calcium, and a positive family history. The diagnosis is strongly supported by a calcium–creatinine clearance ratio less than 0.01. Parathyroid surgery is not indicated because the complications of hyperparathyroidism do not develop.

- Familial hypocalciuric hypercalcemia is not associated with symptoms and does not require treatment.

Thiazide-Induced Hypercalcemia

Mild hypercalcemia may occur in patients taking thiazide diuretics. The hypercalcemia is multifactorial (dehydration, decreased renal calcium clearance, and possibly increased PTH secretion). PTH levels are inappropriately normal or mildly increased. The hypercalcemia usually resolves within a few weeks after the discontinuation of drug therapy. Thiazide-induced hypercalcemia is more likely to occur in patients with underlying mild primary hyperparathyroidism.

Lithium

Lithium raises the threshold of inhibition of PTH secretion by serum calcium. PTH levels are inappropriately normal or mildly increased. The hypercalcemia resolves after discontinuation of lithium.

Parathyroid-Independent Hypercalcemia

Hypercalcemia of Malignancy

Hypercalcemia of malignancy often develops acutely and may be severe and life-threatening. It is the commonest cause of hypercalcemia in hospitalized patients and may be due to the destructive effects of skeletal metastases or the paraneoplastic effect of a discrete neoplasm. Patients in the latter group have few or no skeletal metastases, and the hypercalcemia resolves after treatment of the malignancy. Most of these tumors secrete parathyroid hormone–related peptide (PTHrp), which mediates this humoral hypercalcemia of malignancy. Serum PTH is suppressed in all cases of hypercalcemia due to malignancy.

Vitamin D Intoxication

Hypercalcemia, hypercalciuria, renal insufficiency, and soft tissue calcification follow prolonged ingestion of toxic doses of vitamin D or its metabolites. Because vitamin D is stored in fat, the condition may persist for months after treatment has been discontinued. Hypercalcemia also occurs in vitamin A intoxication.

Sarcoidosis, Other Granulomatous Disorders, and Some Lymphomas

The hypercalcemia and hypercalciuria in these disorders are due to the presence of vitamin D–dependent granulomas and some lymphomas that express high concentrations of the 1α-hydroxylase enzyme and thus can autonomously generate 1,25-dihydroxyvitamin D from circulating 25-hydroxyvitamin D. The serum levels of 25-hydroxyvitamin D are normal, and those of 1,25-dihydroxyvitamin D are increased. The hypercalcemia is responsive to glucocorticoid therapy.

Miscellaneous Causes

Hyperthyroidism enhances bone turnover and may lead to net bone loss. Hypercalcemia and, more frequently, hypercalciuria may be present. The hypercalcemia resolves with the treatment of thyrotoxicosis. In an addisonian crisis, hypercalcemia is often present and may be symptomatic. It is related to dehydration and increased albumin concentration and is reversible with glucocorticoid therapy.

Immobilization may result in hypercalcemia in patients with rapid bone turnover, as in Paget disease of bone.

- Hypercalcemia of malignancy may be due to skeletal metastases, the secretion of a humoral factor such as PTHrp, or to the production of 1,25-dihydroxyvitamin D (typically by lymphomas).

Management of Hypercalcemia

When feasible, treatment of the primary cause may be the most important intervention. Glucocorticoids are the drugs of choice for the hypercalcemia of granulomatous disorders. Humoral hypercalcemia of malignancy may be treated by complete resection of the tumor.

In severe hypercalcemia or hypercalcemia in which the primary cause is not immediately treatable, calcium concentrations should be decreased. Aggressive rehydration with volume expansion promotes calciuresis (saline diuresis) and has a transient hypocalcemic effect. Loop (but not thiazide) diuretics help promote renal calcium excretion but should only be given after volume expansion. Pamidronate (a bisphosphonate) given as a single intravenous dose of 30 to 90 mg inhibits bone resorption and mobilization of calcium from bone and has a marked and prolonged effect on calcium concentrations. Calcitonin is used rarely because of its modest effects and the rapid onset of tachyphylaxis. Dialysis is reserved for patients with renal failure.

- Volume expansion and calciuresis (saline diuresis) form the cornerstone of therapy. Loop diuretics are useful adjuncts after rehydration.
- Pamidronate decreases calcium concentrations by inhibiting bone resorption and has a marked and prolonged effect on calcium concentrations.
- Dialysis is reserved for patients with renal failure.

Hypoparathyroidism

Etiology

Hypoparathyroidism may be due to decreased PTH production by the parathyroid glands or to resistance of the target tissue to the actions of PTH. The parathyroid glands may be damaged during thyroidectomy or radical neck dissection, or they may be excised completely for the treatment of primary hyperparathyroidism due to parathyroid hyperplasia. Hypoparathyroidism may be transient or permanent, and it may appear within hours after the operation. Hypocalcemia after neck surgery often is manifested by symptoms of neuromuscular excitability, for example, Chvostek and Tinel signs.

Hypoparathyroidism also may result from an autoimmune or infiltrative process (hemochromatosis or Wilson disease) or from defective formation of the branchial arches associated with thymic aplasia (DiGeorge syndrome). Hypomagnesemia (from use of diuretics, malabsorption, or malnutrition) impairs the secretion and action of PTH.

Pseudohypoparathyroidism is characterized by end-organ resistance to the actions of PTH because of a receptor or postreceptor defect. Patients often have a characteristic appearance: short stature, round face, short metacarpals and metatarsals, calcification of the basal ganglia, and mild mental retardation. A defect in the Gs subunit of the receptor is commonly identified. Pseudopseudohypoparathyroidism is a variant of the disorder, and the patients have the same characteristic physical features but not the biochemical abnormalities.

- Hypoparathyroidism may result from surgical damage to the parathyroids or from an autoimmune, infiltrative, or congenital process.
- Hypomagnesemia is a cause of functional hypoparathyroidism.

Clinical Features

Hypoparathyroidism leads to decreased mobilization of calcium from bone, decreased renal distal tubular calcium reabsorption, decreased proximal renal tubular phosphate excretion, and decreased renal production of 1,25-dihydroxyvitamin D. This leads to hypocalcemia and hyperphosphatemia. In hypoparathyroidism, PTH is low or inappropriately normal in the presence of hypocalcemia. In contrast, PTH is increased in pseudohypoparathyroidism.

Symptoms reflect the degree as well as the rate of development of hypocalcemia and include paresthesias, carpopedal spasm, laryngeal stridor, and convulsions. Apathy and depression may occur. Calcification of the basal ganglia and benign intracranial hypertension also occur. Gastrointestinal tract manifestations include abdominal pain, nausea, vomiting, and malabsorption. A prolonged QT interval may be present. Hypoparathyroidism is also associated with the development of cataracts and alopecia. Mucocutaneous candidiasis may be a manifestation of DiGeorge syndrome.

- Symptoms of hypocalcemia reflect its degree and the rate of its development.
- Hypoparathyroidism is characterized by hypocalcemia and hyperphosphatemia in the presence of normal renal function.
- PTH is low in hypoparathyroidism and increased in pseudohypoparathyroidism.

Diagnosis

Differential Diagnosis

Hypoparathyroidism with resultant hypocalcemia must be differentiated from other causes of hypocalcemia. Hypocalcemia may result from decreased secretion of PTH, PTH resistance, decreased production of vitamin D, vitamin D resistance, and disorders associated with decreased mobilization of calcium from bone or increased calcium deposition in tissues. Vitamin D deficiency may be caused by malnutrition, malabsorption, or liver or kidney disease. In vitamin D deficiency, hypocalcemia triggers secondary hyperparathyroidism with renal phosphate wasting. In acute or chronic renal failure, the pathogenesis of hypocalcemia is multifactorial, resulting from hyperphosphatemia and decreased production of 1,25-dihydroxyvitamin D.

Hypocalcemia may occur in osteoblastic metastases (e.g., prostate cancer) and in the hungry bone syndrome seen after parathyroidectomy for hyperparathyroidism with severe bone disease. Hypocalcemia and soft tissue calcification may occur in acute pancreatitis. Hypocalcemia is also associated with the use of loop diuretics.

Diagnostic Approach

When evaluating hypocalcemia, it is important to correct the total calcium value for the prevailing albumin levels or to determine the level of ionized calcium. The next step is to measure the serum level of PTH. In a hypocalcemic patient, a low serum level of PTH is diagnostic of hypoparathyroidism. A high serum level of PTH suggests vitamin D deficiency or pseudohypoparathyroidism. Low plasma levels of 25-hydroxyvitamin D occur from poor nutrition, malabsorption, or liver disease. Low plasma levels of 1,25-dihydroxyvitamin D occur in renal failure. The measurement of serum concentrations of creatinine and magnesium will identify renal failure and magnesium deficiency states.

Therapy

For acute, severe hypocalcemia, urgent treatment with intravenous calcium is indicated to prevent tetany, laryngeal stridor, or convulsions. Calcium gluconate, 10 to 20 mL of a 10% solution (90 mg elemental calcium per 10 mL), is infused over 5 to 10 minutes. The serum calcium level is maintained between 7.0 and 8.5 mg/dL by a subsequent infusion of calcium (10-15 mg/kg infused over 4-6 hours). Continuous electrocardiographic monitoring is essential.

For chronic hypocalcemia, treatment is oral calcium supplements (2.0-3.0 g daily). Ergocalciferol is given as 50,000 to 100,000 IU daily. It has a slow onset and offset of action. An alternative is calcitriol (1,25-dihydroxyvitamin D). Thiazide diuretics may be given to decrease the risk of marked hypercalciuria, and oral phosphate binders may be given to control hyperphosphatemia.

It is critical to monitor therapy closely because patients are at risk of hypercalciuria, nephrolithiasis, and nephrocalcinosis. Therapeutic doses are adjusted to keep the serum level of calcium just below the lower limits of normal, around 8.5 mg/dL, and the urinary level of calcium at less than 300 mg/24 h.

- Severe, acute hypocalcemia requires treatment with intravenous calcium.
- Chronic hypocalcemia requires treatment with oral calcium and vitamin D.

Osteoporosis

Osteoporosis is the commonest skeletal disorder encountered in clinical practice. It is characterized by decreased bone mass, with thinning of the cortices and loss of trabeculae, leading to increased bone fragility and risk of fracture. Bone density (and bone loss) can be quantified with dual energy X-ray absorptiometry. Osteopenia is defined as a bone mass 1.0 to 2.5 standard deviations below the mean peak bone mass of a sex- and height-matched control population. Osteoporosis is defined as a bone mass value more than 2.5 standard deviations below the peak bone mass of a sex- and height-matched control population.

Etiology

The commonest types of osteoporosis are postmenopausal osteoporosis, characterized by high turnover of bone, and senile osteoporosis, which occurs in older men and women. Osteoporosis may be secondary to hypogonadism, hyperparathyroidism, hyperthyroidism, or hypercortisolism. It is associated with malnutrition (calcium deficiency, protein malnutrition, vitamin C deficiency, and alcoholism), malabsorption, neoplastic disorders (multiple myeloma, leukemia, lymphoma, and systemic mastocytosis), and abnormalities of bone collagen (osteogenesis imperfecta). Drugs such as corticosteroids, heparin, methotrexate, and GnRH analogues all increase bone loss. Immobilization also promotes bone loss.

- Osteoporosis may be primary or secondary.
- Osteoporosis may be secondary to endocrine, nutritional, intestinal, neoplastic, or genetic disorders. It also may be induced by drugs or immobilization.

Clinical Features

Fractures can occur with minor trauma and be axial or appendicular. Osteoporotic fractures heal normally. Vertebral fractures lead to loss of height and spinal deformity (kyphoscoliosis and dowager hump). Other osteoporotic fractures include those of the hip and distal radius (Colles fracture).

The serum levels of calcium, phosphate, and alkaline phosphatase are normal in osteoporosis. The serum level of alkaline phosphatase may be increased slightly during fracture healing.

Lateral spine radiographs show a loss of horizontal trabeculae and an apparent prominence of the vertical trabeculae, biconcave vertebrae, and a decrease in vertebral height. Bone mineral density can be assessed by dual energy x-ray absorptiometry of the lumbar vertebrae (although vessel wall calcification and vertebral deformity with advancing age can make this measurement unreliable) or the hip. A decrease of 1 standard deviation from peak bone density of a control population leads to a doubling of the fracture risk.

- Osteoporosis is characterized by the occurrence of fracture with minimal trauma and normal serum levels of calcium, phosphate, and alkaline phosphatase.

Diagnosis

The diagnosis of osteoporosis is based on the finding of low bone mass with or without fractures and the exclusion of other causes of osteopenia, such as osteomalacia, multiple myeloma, and metastatic disease. Bone densitometry should be used as a screening study for patients at risk of osteoporosis (e.g., postmenopausal women not taking preventive measures). Whether routine screening for baseline values should be performed for asymptomatic postmenopausal women who receive estrogen replacement therapy is debated. Bone densitometry is indicated for patients who have radiologic evidence of previous vertebral fracture. It also is helpful in determining the need for surgery in hyperparathyroidism.

During the evaluation of a patient who has a fracture, it is important to remember that osteomalacia may coexist with osteoporosis. Myeloma or metastatic disease should be excluded as a cause of pathologic fracture. Secondary causes of osteoporosis should be actively excluded during history taking and the physical examination as well as by appropriate laboratory and radiographic investigations. The evaluation should include serum levels of calcium (and,

if necessary, PTH), 25-hydroxyvitamin D, and TSH. If indicated, the patient should undergo screening for Cushing syndrome with a 1-mg overnight dexamethasone suppression test or 24-hour urinary free cortisol measurement. Measurement of testosterone is indicated for males.

- The diagnosis of osteoporosis requires the exclusion of other causes of low bone mineral density. Osteomalacia, malignancy, and other secondary causes of osteoporosis should be actively excluded by the judicious use of history taking, physical examination, and laboratory evaluation.

Prevention and Treatment of Osteoporosis

To a certain extent, bone loss can be prevented by timely estrogen replacement in women at and beyond menopause and by the provision of adequate calcium and vitamin D intake in all adults (in premenopausal women and men younger than 65 years, 1,000 mg daily of elemental calcium; in postmenopausal women and men older than 65 years, 1,500 mg daily). Other measures to ensure attainment (and maintenance) of adequate bone mass include regular weight-bearing exercise and avoidance of alcohol and tobacco abuse.

Estrogen replacement is considered the therapy of choice for the prevention and treatment of osteoporosis in women who do not have contraindications to it. It decreases bone resorption and has been shown in epidemiologic and retrospective studies to decrease the incidence of osteoporotic fractures. Estrogen can be given orally or transdermally. Women receiving estrogen replacement therapy require a breast examination and mammography annually. To decrease the risk of endometrial hyperplasia, progesterone is also administered in a cyclical or continuous fashion if the patient has an intact uterus.

Alendronate and risedronate are oral bisphosphonates that have potent antiresorptive effects; they prevent bone loss and increase bone density. They have been shown to reduce fracture risk and to be effective in preventing steroid-induced bone loss. Bisphosphonates should be prescribed for patients who cannot or do not wish to take estrogen. Side effects include dyspeptic symptoms and esophagitis, particularly if the medication is taken incorrectly. Oral bisphosphonates should be taken in the morning with a glass of water and on an empty stomach (any food or other drink may interfere with intestinal absorption), and the patient should not lie down for 30 to 60 minutes after the dose. These medications are available as a once-weekly dose, which increases tolerability and compliance. Preliminary studies have shown that combination therapy with estrogen and alendronate may increase bone density more effectively than single-agent therapy. No decrease in fracture risk has been demonstrated.

Calcitonin is a weak antiresorptive agent and is administered by nasal spray. The advent of alternative medications with greater efficacy means that calcitonin is rarely indicated. The exception is for the management of painful vertebral fractures.

- Estrogen replacement is the therapy of choice for the prevention and treatment of osteoporosis in women who do not have a contraindication to it.
- Women receiving estrogen replacement therapy require a breast examination and mammography annually.
- Nasal calcitonin is a weak antiresorptive agent.
- Bisphosphonates are potent antiresorptive agents that decrease the incidence of fractures. Severe esophagitis is a potential side effect.

Recombinant PTH has recently become available for treatment of osteoporosis after clinical trials demonstrated the ability of this agent to increase bone formation and bone mass when given by daily subcutaneous injection. There is little experience with recombinant PTH outside clinical trials, and whether it is best given in conjuction with a bisphosphonate is not clear. Similarly, the optimal schedule and duration of treatment is not known.

Osteomalacia

In adults, osteomalacia is characterized by defective mineralization of newly formed bone matrix, with the accumulation of unmineralized osteoid. Normal mineralization of bone requires adequate calcium and phosphate concentrations in the extracellular fluid, functional osteoblasts, and optimal conditions for the mineralization of mature osteoid. Osteomalacia results when any or a combination of these prerequisites is not met.

Vitamin D deficiency is the commonest cause of osteomalacia and results from poor intake (chronic alcoholism and institutionalized patients), malabsorption (celiac disease), and decreased exposure to the sun. Other causes include decreased liver production of 25-hydroxyvitamin D due to liver disease or increased metabolism to inactive compounds (phenytoin or rifampin). Renal disease and vitamin D–dependent rickets type I lead to decreased production of 1,25-dihydroxyvitamin D.

Phosphate deficiency may result from malnutrition or increased renal losses. This is seen in hereditary X-linked hypophosphatemia, acquired tubular phosphate leak due to production of a phosphaturic substance from an occult mesenchymal tumor (oncogenic osteomalacia), and a generalized tubular defect (Fanconi syndrome) that may be hereditary or acquired.

- Osteomalacia is characterized by defective mineralization and accumulation of unmineralized osteoid.
- The common causes of vitamin D deficiency are malnutrition, malabsorption, and liver disease.

Clinical Features

In addition to fractures or pseudofractures, typical symptoms of osteomalacia include diffuse bone pain and tenderness, muscle weakness, and a waddling gait. The serum level of alkaline phosphatase is usually increased in all cases of osteomalacia except for cases due to hypophosphatasia. In vitamin D deficiency, secondary hyperparathyroidism is usually present and the level of 25-hydroxyvitamin D is decreased. The serum level of calcium is low or normal.

Radiography may not be helpful, although radiographic features of secondary hyperparathyroidism may be apparent. In later stages, there may be radiographic evidence of pseudofractures (Looser zones). These are narrow lines of radiolucency that are perpendicular to the cortical bone surface and are typically bilateral and symmetrical.

They are found most commonly in the pubic rami, the medial aspect of the femur near the femoral head, the scapulae, and the metatarsals.

Therapy

Effective therapy is based on identifying and treating the underlying disorder as well as providing adequate calcium and phosphate at the areas of mineralization. This usually is achieved with calcium, vitamin D, and, when indicated, phosphate supplementation. Calcium supplementation should provide 1,000 to 2,000 mg of elemental calcium daily, whereas the degree of vitamin D supplementation varies according to the underlying diagnosis. In nutritional deficiency, 2,000 to 4,000 IU daily of vitamin D_2 is given until healing occurs, and then 400 IU daily is given for maintenance. Higher doses (25,000-50,000 IU daily) are used to treat vitamin D deficiency caused by malabsorption.

The goals of therapy are to achieve bone healing and to normalize the serum concentrations of calcium, phosphate, and alkaline phosphatase. Complications of treatment include hypercalciuria, hypercalcemia, and renal impairment. Hypercalciuria is the first sign of overdosage.

- Diffuse bone pain, tenderness, and muscle weakness are typical symptoms of osteomalacia.
- Serum alkaline phosphatase is increased in all cases of osteomalacia except for cases due to hypophosphatasia.
- Vitamin D deficiency is characterized by a low or normal serum level of calcium and secondary hyperparathyroidism.
- Treatment is directed at the underlying cause and at providing adequate mineral and vitamin D supplementation.
- Complications of treatment include hypercalciuria, hypercalcemia, and renal impairment.

Paget Disease

Paget disease affects 3% of the population older than 45 years. It is a monostotic or polyostotic bone disorder characterized by the presence of abnormal osteoclasts, which lead to an increased rate of bone resorption and, subsequently, disorganized bone remodeling. This results in decreased tensile strength, skeletal pain, and bone deformities. Commonly affected sites include the sacrum, spine, femur, tibia, skull, and pelvis. Its pathogenesis is not fully understood.

Clinical Features

Most patients present with increased serum levels of alkaline phosphatase or a radiographic abnormality. The two main clinical features are pain and deformity. The pain may be related to pagetoid involvement, fracture, degenerative changes in adjoining joints, or, rarely, the development of osteosarcoma. Deformity may affect the long bones, skull, or spine. The serum level of alkaline phosphatase is the most useful marker of disease activity and its response to therapy.

Neurologic complications are caused by nerve entrapment or hydrocephalus due to the development of platybasia. High-output cardiac failure is rare but can occur when more than 20% of the skeleton is affected, because of the increased vascularity of affected bone. Hypercalciuria and hypercalcemia can occur in an immobilized patient.

Diagnosis

Paget disease should be suspected if serum alkaline phosphatase concentrations are increased and serum calcium, phosphate, and 25-hydroxyvitamin D levels are normal. A bone scan is the most sensitive test for identifying pagetic bone lesions. Typical radiographic findings demonstrate the characteristic bone expansion, deformity, trabecular expansion, sclerosis, and pseudofractures.

Therapy

Many patients require only monitoring of alkaline phosphatase levels. Indications for active therapy include the presence of pain, disease involving weight-bearing bones, disease in proximity to joints, neurologic complications, or marked increase in alkaline phosphatase level (>1,000 U/L). Medical therapy consists of bisphosphonates administered intravenously or orally. Alkaline phosphatase levels are used to monitor therapy. Orthopedic surgery may be needed to treat deformity, fracture, or degenerative joint disease. Pretreatment with an antiresorptive agent reduces bleeding and postoperative hypercalcemia. Neurosurgical intervention may be required for nerve entrapment syndromes.

- Typical findings in Paget disease include normal serum levels of calcium, phosphate, and 25-hydroxyvitamin D and increased serum levels of alkaline phosphatase.
- Pseudofractures are characteristic radiographic findings.
- Indications for active therapy include the presence of pain, disease involving weight-bearing bones, disease in proximity to joints, neurologic complications, or a marked increase in the alkaline phosphatase level (>1,000 U/L).

Disorders of the Adrenal Glands

Adrenal Failure

Etiology

Primary Adrenal Failure

Primary adrenal failure is manifested clinically by glucocorticoid and mineralocorticoid deficiency. It may result from autoimmune adrenalitis (Addison disease), the commonest cause in the United States; destruction of the adrenals by a granulomatous process such as tuberculosis; bilateral adrenal hemorrhage related to sepsis, anticoagulation therapy or a lupus anticoagulant; congenital adrenal enzyme deficiency; or the use of drugs such as aminoglutethimide or ketoconazole that inhibit steroidogenesis. Adrenal metastases are common in metastatic malignancies such as lung cancer. However, clinically pronounced adrenocortical failure is uncommon in this setting.

Secondary Adrenal Failure

Secondary adrenal failure is due to ACTH deficiency. Mineralocorticoid deficiency is not present. ACTH deficiency may occur alone (exogenous steroid use or lymphocytic hypophysitis) or, more often, in association with other features of hypopituitarism. Functional ACTH deficiency is the most common cause of secondary adrenal failure and is a consequence of the suppression of the

hypothalamic-pituitary-adrenal axis by the prolonged use of pharmacologic doses of glucocorticoids.

- In the United States, the commonest cause of primary adrenocortical failure is autoimmune adrenalitis (Addison disease).
- Primary adrenal failure: deficiencies of cortisol, adrenal sex steroids, and aldosterone.
- Secondary adrenal failure: deficiencies of cortisol and adrenal sex steroids. Aldosterone secretion is intact.

Clinical Features

Patients with adrenal failure usually have an insidious presentation, with fatigue, muscle weakness, anorexia, weight loss, nausea, vomiting, and diarrhea. Hyponatremia, lymphocytosis, and eosinophilia may be present. Aldosterone deficiency leads to hypovolemia, orthostatic hypotension, hyperkalemia, and a hyperchloremic acidosis. In females, the loss of adrenal androgens leads to decreased pubic hair. Because ACTH levels are increased (lack of negative feedback by cortisol), patients with primary adrenal failure become hyperpigmented, particularly on the elbows, knees, and buccal mucosa and on surgical scars. In contrast, patients with secondary adrenal failure are pale (low ACTH levels). Because aldosterone secretion is unaffected, hyperkalemia does not occur.

Acute Adrenocortical Failure or Adrenal Crisis

Adrenal crisis usually occurs in patients with unrecognized adrenal failure who develop an intercurrent illness such as pneumonia. They experience dehydration and hypotension out of proportion to the severity of the current illness. Abdominal pain in combination with nausea and vomiting may mimic an acute abdomen. Unexplained fever, hyponatremia, hyperkalemia, azotemia, hypercalcemia, and eosinophilia may all be present. Adrenal crisis may occur with inadequate cortisol replacement or it may be the first manifestation of bilateral adrenal hemorrhage.

- Addison disease develops insidiously with both glucocorticoid and mineralocorticoid deficiency.
- Adrenal crisis may develop during intercurrent illness in a patient with unrecognized adrenal failure, with inadequate cortisol replacement, or after bilateral adrenal hemorrhage.

Diagnosis

Endocrine Diagnosis

The diagnosis of adrenal failure is confirmed with the cosyntropin test, which assesses the cortisol response to synthetic ACTH (1 μg or 250 μg). An appropriate response to cosyntropin is an increase in plasma cortisol by more than 7 μg/dL from the baseline value (this may not be achieved in healthy patients with a high basal level of cortisol) or to an absolute value greater than 18 μg/dL.

A high ACTH level suggests primary adrenal insufficiency, whereas a low or "inappropriately normal" level indicates secondary failure. A normal response to cosyntropin rules out Addison disease but does not completely exclude ACTH deficiency (although the 1-μg test is more sensitive in this regard) that is partial or of recent onset. If the diagnosis is still suspected, an insulin-hypoglycemia or metyrapone test may be performed; these test the ACTH response to hypoglycemia (insulin) or to inhibition of adrenal steroidogenesis (metyrapone).

- An abnormal cosyntropin test establishes the diagnosis of adrenal failure but cannot differentiate primary from secondary adrenal failure.
- A normal cortisol response excludes primary adrenal failure but does not completely exclude secondary adrenal failure that is partial or of recent onset.

Therapy

Primary adrenal failure requires glucocorticoid and mineralocorticoid replacement, whereas secondary adrenal failure requires only glucocorticoid replacement. Patients should be educated about the need to increase their steroid dosage during acute illness and the use of injectable glucocorticoid when oral replacement therapy is not possible. Patients should always wear a MedicAlert bracelet or necklace. Usually, glucocorticoid replacement is with hydrocortisone or prednisone. The adequacy of therapy can be assessed only by the patient's sense of well-being and the absence of manifestations of glucocorticoid excess. Mineralocorticoid replacement is provided by fludrocortisone. Dose adjustment is guided by the presence of orthostatic hypotension, edema, hyperkalemia or hypokalemia, and, if needed, plasma renin activity.

In mild or moderate acute illness, the glucocorticoid dosage is doubled or tripled for the duration of the illness. Dexamethasone (4 mg intramuscularly) is given when the patient cannot take oral medications (nausea or vomiting). Intravenous hydrocortisone is given in stress doses before and during recovery from surgery. The management of an adrenal crisis requires intravenous rehydration, electrolyte replacement, and hydrocortisone (usually 100 mg every 6 hours). The cortisol and serum ACTH levels should be checked, but management should not be delayed while awaiting results. A search should be undertaken for a precipitating illness.

- Primary adrenal failure requires both glucocorticoid and mineralocorticoid replacement, whereas secondary failure requires only glucocorticoid replacement.
- Patient education is a critical component of effective management.
- Glucocorticoid replacement needs to be modified in acute illness.

Cushing Syndrome

Etiology

The commonest cause of Cushing syndrome is the prolonged use of supraphysiologic doses of glucocorticoids. Endogenous Cushing syndrome is caused by overproduction of cortisol by the adrenal cortex (Cushing disease in 60% of cases, adrenal tumors in 25%, and ectopic ACTH-producing tumors in 15%). This may be the result of adrenal autonomy (ACTH-independent) or unregulated, excessive secretion of ACTH (ACTH-dependent). ACTH-independent disorders include autonomous adrenal adenomas, adrenal carcinoma

(which also usually produces adrenal androgens), or, rarely, macronodular or micronodular adrenal hyperplasia. ACTH-dependent Cushing syndrome may be caused by a small pituitary corticotroph adenoma (Cushing disease) or ectopic secretion of ACTH. Ectopic ACTH-secreting tumors can be aggressive and malignant (e.g., squamous cell carcinoma of the lung) or indolent (e.g., pheochromocytoma, medullary carcinoma of the thyroid, or bronchial carcinoid). Very rarely, corticotropin-releasing hormone (CRH)-producing tumors, such as a bronchial carcinoid, cause pituitary hyperplasia and excess ACTH secretion.

- Exogenous glucocorticoid therapy is the most common cause of Cushing syndrome.
- Endogenous Cushing syndrome comprises ACTH-independent and ACTH-dependent disorders.
- The most common causes of endogenous Cushing syndrome are Cushing disease (60% of cases), adrenal tumors (25%), and ectopic ACTH-producing tumors (15%).

Clinical Features

Many of the clinical features of Cushing syndrome are nonspecific and include weight gain, diabetes mellitus, hypertension, and changes in mood and affect. Symptoms and signs that appear to be more specific for the disorder include central obesity, supraclavicular fat pads, thin skin, easy bruising, wide (>1 cm) purple striae, and proximal muscle weakness. In severe and rapidly progressive disease (usually ectopic ACTH production by a malignant tumor), the presentation is dominated by weight loss, weakness, secondary diabetes, and mineralocorticoid excess (hypertension, edema, and hypokalemia). Often, there is not sufficient time for the development of the classic features of cortisol excess.

Adrenal androgen excess may produce acne, hirsutism, and menstrual irregularities. However, in adrenal carcinoma, the overproduction of androgens may be more extreme and lead to virilization. When ACTH is produced in marked quantities, as in the syndrome of ectopic ACTH, hyperpigmentation may occur.

- The clinical picture of cortisol excess varies according to the rapidity of onset and the underlying disorder.
- Central obesity, supraclavicular fat pads, thin skin, easy bruising, wide purple striae, and proximal muscle weakness are the more specific features of the disease.

Diagnosis

Confirmation of Cushing Syndrome

The diagnosis of Cushing syndrome involves a two-step approach: biochemical confirmation of the disorder and determination of the underlying cause. The best screening test for Cushing syndrome is measurement of 24-hour urinary free cortisol excretion. An increase in urinary free cortisol suggests but does not confirm the diagnosis of Cushing syndrome (levels increased more than threefold the upper limit of normal in a 24-hour collection are considered diagnostic if the clinical suspicion for the disorder is high). The differential diagnosis includes pseudo-Cushing states (depression, alcohol use, and acute illness). If the clinical suspicion of Cushing syndrome is high, a normal urinary free cortisol excretion does not rule out the disorder (of the 24-hour urinary cortisol collections from 10% of patients with established Cushing syndrome, 1 in 4 are normal). In this situation, it is best to repeat the test in 1 month. The 1-mg dexamethasone suppression test is best reserved for screening for subclinical Cushing syndrome in a patient with an adrenal incidentaloma (see below). The 2-day low-dose dexamethasone suppression test (0.5 mg every 6 hours for 2 days) has limited usefulness in the diagnosis of Cushing syndrome (except for cases in which the clinical suspicion for the disorder is low). False-positive results may be obtained in patients with pseudo-Cushing states or those taking estrogen-containing medications that increase cortisol-binding globulin. False-negative results may also occur, particularly in the case of ACTH-producing pituitary adenomas, some of which show unusual suppressibility to dexamethasone. Therefore, the 2-day low-dose dexamethasone suppression test has been replaced by the dexamethasone-CRH test.

- The best screening test for Cushing syndrome is measurement of the 24-hour urinary free cortisol level. A level increased more than threefold in 24 hours is considered diagnostic, particularly if the clinical features of the disorder are prominent.
- The 24-hour urinary free cortisol level may be intermittently normal in some patients with Cushing syndrome. If clinical suspicion is high but the 24-hour urinary free cortisol level is normal, the test should be repeated.
- The 24-hour urinary free cortisol level may be increased in pseudo-Cushing states, including psychiatric disorders and acute illness. In these conditions, false-positive results may be obtained on a low-dose dexamethasone suppression test.
- The 2-day low-dose dexamethasone suppression test has limited usefulness in the diagnosis of Cushing syndrome and has been largely replaced by the dexamethasone-CRH test.

Cause of Cushing Syndrome

After the diagnosis of Cushing syndrome has been confirmed biochemically, the next step is to determine whether the disease is ACTH-dependent or ACTH-independent. A suppressed ACTH (<5 pg/mL) implies adrenal autonomy, and computed tomography (CT) of the abdomen should be performed. A normal (10-80 pg/mL) or modestly increased (<200 pg/mL) concentration is observed in an ACTH-dependent process. Extreme increases in ACTH (>200 pg/mL) suggest—but do not confirm—ectopic ACTH secretion.

The differentiation of pituitary-dependent disease from ectopic ACTH production can be one of the most difficult evaluations in endocrinology. Most causes of ACTH-dependent disease are due to pituitary disease; thus, if the clinical features are consistent with pituitary disease (middle-aged woman, slow onset, progression of disease), magnetic resonance imaging (MRI) of the pituitary gland should be considered. A pituitary lesion larger than 4 mm is suggestive of an ACTH-producing pituitary tumor, and the patient may proceed directly to transsphenoidal exploration. The absence of a pituitary lesion on MRI does not rule out Cushing disease because 50% of the tumors are not visible on MRI. If no abnormality is

found on imaging of the sella, sampling of the inferior petrosal sinuses (together with CRH provocative testing) should be performed. Documentation of a central-to-peripheral ACTH concentration gradient confirms that the source of excess ACTH is from a pituitary tumor. The 2-day high-dose dexamethasone suppression test was used to distinguish between pituitary-dependent disease and ectopic ACTH secretion. However, this test is considered obsolete when traditional criteria are used for interpretation because one-third of bronchial carcinoid tumors respond like pituitary adenomas. Also, the clinical presentation of bronchial carcinoids may be indistinguishable from that of pituitary-dependent disease.

- After biochemical confirmation of Cushing syndrome, the next step is to measure ACTH levels.
- If the ACTH level is <5 pg/mL, proceed to CT of the adrenal glands.
- If the ACTH level is >10 pg/mL, distinguish between a pituitary-dependent tumor and ectopic ACTH production.
- Clinically, bronchial carcinoid tumors may be indistinguishable from pituitary disease.
- Inferior petrosal sinus sampling is the gold standard test for distinguishing between pituitary disease and ectopic disease.
- The 2-day high-dose dexamethasone suppression test is considered obsolete in the differential diagnosis of ACTH-dependent Cushing syndrome.

Therapy

Removal of the source of ACTH secretion is the treatment of choice in ACTH-dependent Cushing syndrome. However, this is not always possible; transsphenoidal surgery has about a 30% failure rate, and an ectopic source of ACTH may not be resectable or detectable. In these cases, bilateral adrenalectomy is the treatment of choice.

In ACTH-independent Cushing syndrome, resection of the adrenal adenoma or carcinoma is indicated. In adrenal carcinoma, complete resection may not be possible and adjuvant treatment with inhibitors of steroidogenesis, such as ketoconazole, may be indicated.

In all cases, surgical excision of the causative tumor is followed by a period of cortisol deficiency because of suppression of the hypothalamic-pituitary-adrenal axis. This may take 1 year to recover, and glucocorticoid replacement is required during this time. Lifelong replacement of glucocorticoid and mineralocorticoid is necessary after bilateral adrenalectomy.

- A period of suppression of the normal axis occurs after removal of the causative tumor and may last up to 1 year.

Primary Aldosteronism

Etiology

Primary aldosteronism results from autonomous (renin-independent) aldosterone production by the zona glomerulosa. It may be due to an aldosteronoma, idiopathic bilateral hyperplasia, adrenocortical carcinoma, or, rarely, familial glucocorticoid-remediable aldosteronism.

Clinical Features

Most patients present with hypertension and hypokalemia. The hypertension can be of variable severity. The hypokalemia is often mild and may be absent (30% of patients are normokalemic). However, it may be exacerbated by diuretic therapy. Most patients are asymptomatic, but a few experience myopathic symptoms and paresthesias due to hypokalemia and alkalosis. Edema is usually absent.

Diagnosis

The diagnosis of primary aldosteronism requires documentation of autonomous aldosterone secretion and, subsequently, definition of the underlying cause. Although hypokalemia is often present in primary aldosteronism, it is a nonspecific finding and may not occur in patients treated with angiotensin-converting enzyme inhibitors or potassium-sparing diuretics such as spironolactone. A urinary potassium concentration greater than 30 mEq/L in a patient with hypokalemia suggests renal wasting of potassium and increases suspicion for mineralocorticoid excess.

The measurement of the ratio of plasma aldosterone (PA in ng/dL) to plasma renin activity (PRA in ng/mL per hour) is used to screen for primary aldosteronism. It is important to measure PA after correction of hypokalemia because the latter decreases aldosterone secretion. Increased PA and suppressed PRA, with a PA/PRA ratio greater than 20, is suggestive of primary aldosteronism. The diagnosis is confirmed by the demonstration of a nonsuppressed 24-hour urinary aldosterone in the salt-replete state (instruct patients to add salt to their food during the collection).

Hypertension caused by excess of a mineralocorticoid other than aldosterone is seen in deoxycorticosterone-producing tumors, congenital adrenal hyperplasia due to 11- or 17-hydroxylase deficiency, Cushing syndrome, and genetic or acquired (use of licorice or chewing tobacco) deficiency of 11β-hydroxysteroid dehydrogenase. This enzyme is present in the distal renal tubule and catalyzes the inactivation of cortisol. Inactivation of this enzyme potentiates the mineralocorticoid effect of cortisol.

- It is estimated that 30% of patients with primary aldosteronism have normokalemia.
- If hypokalemia occurs with the use of diuretics, suspect primary aldosteronism.
- Urinary potassium concentration >30 mEq/L in a patient with hypokalemia suggests renal wasting of potassium and increases suspicion for primary aldosteronism.
- A PA/PRA ratio >20 suggests primary aldosteronism.

The major challenge is to distinguish between an aldosterone-secreting adenoma and bilateral adrenal hyperplasia. This is important because an aldosterone-secreting adenoma can be treated surgically. However, bilateral hyperplasia can be treated only medically. CT of the adrenals may be misleading if the functional tumor is small and not visualized. Furthermore, a visible adrenal mass may be an incidental finding or the mass may be a hyperplastic nodule superimposed on a background of bilateral adrenal hyperplasia. Selective adrenal venous sampling is the most useful localizing procedure; a unilateral aldosterone gradient helps direct surgical excision.

- An adrenal mass seen on CT may not be an aldosteronoma.
- The most reliable localizing test is selective adrenal venous sampling.

Therapy

Unilateral adrenalectomy is indicated for aldosteronoma unless the patient is a poor surgical risk. Surgical resection corrects the hypokalemia (100%) and normalizes or markedly improves the hypertension in about 70% of patients. Persistent postoperative hypertension should be treated with standard antihypertensive therapy.

Medical treatment is indicated for the management of bilateral adrenal hyperplasia and for patients with aldosteronoma who are not candidates for surgery. Spironolactone, an aldosterone antagonist, restores potassium concentrations and normalizes blood pressure in most patients. Adverse effects include gastrointestinal upset, menstrual irregularity, and, in men, gynecomastia, decreased libido, and impotence. Women of childbearing age who take spironolactone should use effective contraception because the drug may cause feminization of the male fetus through its androgen-blocking effects. Alternative treatment includes amiloride or triamterene.

Pheochromocytoma

Etiology

Pheochromocytomas arise in chromaffin cells of neural crest origin in the adrenal medulla or, less frequently, along the sympathetic chain and rarely in sympathetic tissue in the walls of the urinary bladder. Of these tumors, 10% are malignant and 10% are familial. Familial pheochromocytomas are more likely to be intra-adrenal, bilateral, and malignant. Pheochromocytomas can secrete catecholamines continuously or episodically.

Clinical Features

Pheochromocytomas may present as an incidental finding on abdominal imaging performed for other reasons. More commonly, they are suspected because of the presence of hypertension that is paroxysmal, refractory to treatment, or associated with paroxysmal symptoms of headache, palpitations, sweating, anxiety, and pallor. Some patients present with hypermetabolism that is manifested as heat intolerance, sweating, and weight loss. The tumor may be part of MEN 2A or 2B, von Hippel-Lindau disease, or neurofibromatosis. In most patients, the paroxysmal symptoms are stereotyped and vary only in severity or frequency.

- Pheochromocytomas can be asymptomatic and discovered incidentally.
- Common symptoms include headache, palpitations, and sweating. The symptoms may be paroxysmal.
- Some patients may have a family history of pheochromocytoma. The tumor may be a manifestation of MEN 2A or 2B.

Diagnosis

The diagnosis of pheochromocytoma requires documentation of increased urinary excretion of free catecholamines and metanephrines. Catecholamine-containing drugs, alpha-methyldopa, labetalol, and monoamine oxidase inhibitors cause falsely elevated concentrations. Severe stress, intercurrent illness, acute myocardial ischemia, drug and food interaction with monoamine oxidase inhibitors, abrupt withdrawal of clonidine, or excessive use of sympathomimetic amines also causes increased excretion of urinary catecholamines. Normal values in a hypertensive or otherwise symptomatic patient are sufficient to exclude the diagnosis. In patients with paroxysmal symptoms, the diagnostic yield is increased by collecting urine during or shortly after a paroxysm.

For screening purposes, 24-hour urinary metanephrines are preferred over plasma metanephrine levels because the latter is a less specific test. Plasma catecholamines have limited usefulness in the diagnosis of pheochromocytoma.

- Normal urinary catecholamine values in a hypertensive patient exclude the diagnosis. In patients with paroxysmal symptoms, the diagnostic yield is increased substantially by initiating collection during or shortly after a paroxysm.
- Increased values in hypertensive patients establish the diagnosis only if other disorders associated with hypertension and catecholamine excess are excluded (severe stress, intercurrent illness, acute myocardial ischemia, certain medications, or abrupt withdrawal of clonidine).

CT or MRI of the abdomen (and, if indicated, the pelvis, thorax, and neck) is used to localize a pheochromocytoma. On MRI, pheochromocytomas have a high-intensity signal on T2-weighted images. ^{123}I-metaiodobenzylguanidine (^{123}I-MIBG) is taken up by pheochromocytomas and is used as an adjunct to CT or MRI if metastatic disease is suspected.

- Radiographic localization of the pheochromocytoma is attempted only if the biochemical diagnosis is firm.
- Pheochromocytomas appear as a high-intensity signal on T2-weighted MRI.
- ^{123}I-MIBG is used as an adjunct to CT or MRI if metastatic disease is suspected.

Therapy

Complete excision of a pheochromocytoma is curative. Medical treatment is used preoperatively to diminish perioperative morbidity and mortality. Ongoing treatment is required if resection is incomplete and if recurrent or metastatic disease is present. α-Adrenergic blockade should be instituted with phenoxybenzamine, starting with 10 mg twice daily. β-Adrenergic blockers may be necessary to control reflex tachycardia after maximal α-blockade has been achieved. If cure is achieved, urinary catecholamine concentrations return to normal within 2 weeks. Long-term follow-up is important to assess for persistent or recurrent disease.

- Surgical excision of the tumor is curative.
- α-Adrenergic blockade should be initiated when the diagnosis is made.
- β-Blockade may be necessary to control reflex tachycardia after effective α-blockade.

Adrenal Incidentaloma

Etiology

Small (1-6 cm) adrenal masses are found in about 10% of autopsies and increasingly are being detected on abdominal CT performed for other reasons. Although most of them are nonfunctioning adenomas, a few are functioning adenomas or carcinomas of the adrenal gland. Also, metastatic disease to the adrenals may present in this way.

Evaluation

Evaluation should address the following two questions:

1. Is the lesion benign or malignant?
2. Is the lesion hyperfunctioning?

The size of the adrenal mass can help to distinguish between a benign tumor and a malignant tumor. Most adenomas are smaller than 4 cm in diameter. The incidence of carcinoma exceeds 35% in masses larger than 6 cm. Needle biopsy cannot distinguish between a benign and a malignant adrenal neoplasm and should not be attempted if pheochromocytoma is suspected. Needle biopsy is useful to confirm a suspicion of disease metastatic to the adrenals.

For all patients, screen for pheochromocytoma (24-hour urinary metanephrines) and subclinical Cushing syndrome (1-mg overnight dexamethasone suppression test). It is important to ascertain the functional status of the adrenal mass before surgical management. An unsuspected pheochromocytoma may provoke a hypertensive crisis. Similarly, removal of the cortisol-producing tumor may be followed by an adrenal crisis. Such patients need perioperative and postoperative cortisol replacement until the ACTH-adrenal axis recovers, and this may take up to 1 year. Also, screen for primary aldosteronism (PA/PRA ratio) if the patient has hypertension. An androgen-producing or a feminizing adrenal tumor needs to be considered only when clinical findings suggest overproduction of sex steroids.

Therapy

A functioning tumor should be excised. Patients with nonfunctioning tumors smaller than 4 cm should have CT repeated in 3 months to assess for growth. If the size is stable after 3 months, additional scans are performed 1 year after the diagnosis. An adrenal mass larger than 4 cm in diameter or a mass that is increasing in size on serial observation should be excised.

- Laboratory investigation of an adrenal incidentaloma should include measurement of 24-hour urinary catecholamines, a |1-mg overnight dexamethasone suppression test, and, if the patient is hypertensive, determination of the PA/PRA ratio.
- Pheochromocytoma or subclinical cortisol production should be excluded before surgical excision.
- Needle biopsy of an adrenal incidentaloma is not indicated unless metastatic disease is suspected (first, rule out pheochromocytoma).
- Excision is indicated for a functioning tumor, a mass >4 cm, and a mass that is increasing in size on serial observation.

The Testis

Male Hypogonadism

Etiology

Decreased testosterone production may be a result of testicular failure (hypergonadotropic hypogonadism or primary hypogonadism) or LH deficiency due to a hypothalamic or pituitary disorder (hypogonadotropic hypogonadism or secondary hypogonadism). Hypergonadotropic hypogonadism may result from Klinefelter syndrome, testicular trauma, radiotherapy or chemotherapy, autoimmune or infectious (mumps) disorders, or orchitis and degenerative disorders such as dystrophia myotonica. Hypogonadotropic hypogonadism may be due to a functional hypothalamic disorder (e.g., constitutional delay in puberty, use of neuroleptic drugs, nutritional disorders, severe systemic illness, hyperprolactinemia, or thyroid or adrenal disorders). Organic disorders of the hypothalamus and pituitary can also lead to hypogonadism (e.g., a pituitary tumor).

Androgen resistance may be genetic or acquired. Genetic androgen resistance includes testicular feminization and 5α-reductase deficiency. Acquired androgen resistance may occur with the use of the androgen receptor blockers spironolactone or flutamide.

- Decreased testosterone production may result from primary testicular failure or from a central hypothalamic or pituitary disorder.
- Central hypogonadotropism may result from functional or organic hypothalamic disorders or from organic diseases of the anterior pituitary gland.

Clinical Features

Adult males with hypogonadism present with decreased libido and potency, decreased ejaculate volume, infertility, decreased stamina, decreased sexual hair growth, and gynecomastia. Hot flashes may occur if testosterone deficiency is rapid in onset. In men with chronic and severe testosterone deficiency, physical findings may include pallor, a female pattern of fat distribution, testicular atrophy, and gynecomastia.

Adolescents with hypogonadism present with delayed puberty and growth. Sexual infantilism is associated with the absence of a pubertal growth spurt, eunuchoid habitus (ratio of arm span to height is >1), high-pitched voice, poor muscle development, and a female pattern of fat distribution. The testes usually are small and soft. Small, firm testes in a hypogonadal male suggest Klinefelter syndrome, and the presence of midline defects or anosmia in an adolescent with sexual infantilism suggests Kallmann syndrome.

Diagnosis

The diagnosis is confirmed by documenting low serum levels of testosterone. Measurement of LH and FSH helps to differentiate primary from secondary hypogonadism. Gonadotropin concentrations are increased in primary testicular failure, but they are decreased or inappropriately normal in secondary hypogonadism. Additional tests that may be indicated include karyotyping to confirm Klinefelter syndrome. Secondary hypogonadism requires exclusion of Kallmann

syndrome, measurement of the serum concentration of prolactin, pituitary function testing, and MRI of the head to exclude organic hypothalamic-pituitary disease.

- Serum levels of LH and FSH help to differentiate primary from secondary hypogonadism.
- Hypogonadotropic hypogonadism mandates assessment of pituitary function and MRI of the head. Evaluate for the presence of midline defects or anosmia in adults (Kallmann syndrome).

Therapy

Androgen Therapy

In adults, androgen therapy is aimed at the restoration and maintenance of secondary sex characteristics. Testosterone replacement cannot stimulate spermatogenesis. In secondary hypogonadism, gonadotropins can be used to induce spermatogenesis and to restore fertility.

Androgens can be replaced by 17-hydroxyl esters of testosterone (e.g., testosterone enanthate) administered intramuscularly every 2 weeks. However, this mode of delivery produces a supraphysiologic level of testosterone shortly after the injection, and the level gradually decreases to a low level before the next injection. A more favorable mode of delivery is transdermal testosterone by means of a patch or gel applied to the skin. Also, 17α-alkylated derivatives of testosterone can be administered orally; however, they are associated with substantial hepatotoxicity and should not be used.

Testosterone replacement therapy is contraindicated in the presence of prostate cancer (the prostate-specific antigen [PSA] level should be checked before treatment is initiated) or psychosis, and it may worsen the symptoms of prostatism. Side effects include acne, edema, erythrocytosis, and exacerbation of obstructive sleep apnea. Patients receiving testosterone replacement therapy should have a prostate examination and a PSA test annually.

- In adults, androgen therapy restores and maintains secondary sex characteristics.
- An annual prostate examination and serum PSA level are recommended for patients receiving testosterone replacement therapy.

Selected Disorders of Male Hypogonadism

Klinefelter Syndrome

Klinefelter syndrome is common (1:400 to 1:500) and arises because of the presence of one or more extra X chromosomes. The classic karyotype is 47,XXY. The disorder is characterized by hyalinization of the seminiferous tubules and dysfunction of the Leydig cells, which is manifested at puberty. The testes are small and firm, gynecomastia is present, FSH levels are increased, and testosterone levels are decreased. If more than one X chromosome is present, the incidence of mental retardation and somatic abnormalities is increased. In mosaicism, the clinical manifestations are less severe and if an XY line is present, fertility may be possible.

Patients with Klinefelter syndrome have a slightly increased incidence of diabetes mellitus, chronic obstructive pulmonary disease, autoimmune disorders, varicose veins, malignancy of the breast, lymphoma, and germ cell neoplasm. Therapy includes testosterone replacement. Breast reduction surgery is indicated if the patient's gynecomastia is a source of emotional distress.

- Klinefelter syndrome is due to one or more extra X chromosomes; the classic karyotype is 47,XXY.
- Characteristic findings include small, firm testes, gynecomastia, increased FSH levels, and various degrees of testosterone deficiency.

Kallmann Syndrome

This syndrome is characterized by secondary hypogonadism and anosmia. It is a congenital disorder, often familial, that is due to defective migration of GnRH-producing neurons during embryogenesis. Patients present with delayed puberty. Anosmia is present in 80% of patients. Other midline defects such as a cleft lip or palate, color blindness, cryptorchidism, and skeletal abnormalities may occur. Laboratory evaluation shows isolated hypogonadotropic hypogonadism. On MRI, the olfactory bulbs may be abnormal or absent, but the hypothalamic-pituitary region is normal. Therapy for Kallmann syndrome consists of testosterone replacement to allow for the development of secondary sex characteristics. The administration of gonadotropin is required for fertility.

- Kallmann syndrome is characterized by hypogonadotropic hypogonadism and anosmia.

Gynecomastia

Etiology

Gynecomastia, the most common disorder of the male breast, is caused by some degree of estradiol excess that can be 1) a relative estrogen excess due to decreased testosterone production or the use of an androgen receptor blocker (spironolactone, cimetidine, or flutamide) or 2) an absolute increase in estradiol production because of adrenal cancer, a Leydig cell tumor, or a human chorionic gonadotropin (HCG)-producing tumor. Androgen-secreting tumors or exogenous androgen use can produce gynecomastia through the peripheral conversion of testosterone to estrogen.

In young, healthy, pubertal males, gynecomastia is physiologic and tends to be transient. The use of anabolic steroids or Klinefelter syndrome may account for a small number of cases. All other causes are rare in this age group. In adults, the two common causes are drugs and alcohol-related liver disease. Ectopic HCG-producing tumors, feminizing adrenal and testicular tumors, and pituitary tumors are rare causes of gynecomastia. In about 10% of cases, the cause of gynecomastia is indeterminate.

- The basic mechanism underlying the development of gynecomastia is an increase in the estrogen-androgen ratio.
- In adults, the two most common causes of gynecomastia are drugs and alcoholic liver disease.
- In about 10% of cases, the cause of gynecomastia is indeterminate.

Clinical Features

Patients usually present with breast enlargement or tenderness (or both) that may be unilateral or bilateral. Rarely, a patient may complain of galactorrhea. Gynecomastia is firm, with a fine nodularity, and spreads radially with a well-defined outer border.

Diagnosis

The differential diagnosis includes pseudogynecomastia (bilateral fatty enlargement) and malignancy (if unilateral gynecomastia). A history of alcohol consumption and medications should be part of the initial evaluation. Endocrine tests should include measurement of testosterone, estradiol, LH and FSH, β-HCG, TSH, and prolactin levels. If indicated, karyotyping should be performed.

An increase in β-HCG implies the presence of an HCG-secreting tumor. A high level of estradiol should prompt evaluation for feminizing adrenal or testicular tumors. If LH, FSH, and sex steroid concentrations are normal, an underlying endocrine disorder is unlikely.

- If the gynecomastia is bilateral, consider pseudogynecomastia. If unilateral, consider malignancy.
- Evaluation includes measurement of testosterone, LH, FSH, β-HCG, TSH, estradiol, and prolactin levels.

The Ovary

Amenorrhea

Primary amenorrhea is present when menarche has not occurred by age 16 years in a young female who has normal secondary sex characteristics or by age 14 in the absence of secondary sex characteristics. Secondary amenorrhea is present when a woman with previously established menstrual function does not menstruate for a period longer than three of her previous cycle intervals or for 6 months.

Etiology

Amenorrhea may be physiologic, as in pregnancy or after menopause. Pathologic amenorrhea may result from a hypothalamic disorder that leads to the loss of cyclical GnRH production, a pituitary disorder resulting in hypogonadotropic hypogonadism, an ovarian disorder, or a uterine disorder or genital tract disorder that prevents the egress of shed endometrium. The common causes of primary amenorrhea are gonadal dysgenesis (45% of cases), constitutional delay of puberty (20%), and müllerian agenesis (15%). The common causes of secondary amenorrhea are hypothalamic dysfunction (40% of cases), polycystic ovarian syndrome (30%), pituitary disease (20%), and ovarian failure (10%).

- Amenorrhea can result from impaired function of any component of the hypothalamic-pituitary-gonadal axis or from an anatomical abnormality of the genital tract.
- The common causes of amenorrhea are physiologic, for example, pregnancy.

Primary Amenorrhea

Developmental anomalies in patients who present with primary amenorrhea include imperforate hymen, isolated absence of the uterus, and vaginal atresia. Ovarian disorders account for most of the causes of primary amenorrhea. Functional suppression of the hypothalamic GnRH cell population by a nutritional or psychiatric disorder, prolonged heavy exercise, systemic illness, hyperprolactinemia, or thyroid or adrenal disorders also cause amenorrhea. Organic hypothalamic-pituitary disease is an uncommon cause of primary amenorrhea; in young adults, craniopharyngioma is more common than prolactinoma.

- Outflow tract disorders are uncommon causes of primary amenorrhea.
- Ovarian disorders are the most common cause of primary amenorrhea.
- Hypothalamic-pituitary disease may be functional or organic.

Secondary Amenorrhea

Patients who have polycystic ovary syndrome, autoimmune oophoritis, abdominal radiotherapy, chemotherapy with cyclophosphamide or vincristine, or ovarian tumors that secrete excessive androgen can present with secondary amenorrhea.

Functional hypogonadotropism may be triggered by situational stress, weight loss, or systemic illness (e.g., hyperthyroidism). In organic hypothalamic-pituitary disorders, secondary hypogonadism occurs alone or in association with other pituitary function abnormalities. The incidence of postpartum pituitary necrosis (Sheehan syndrome), previously a common cause, has decreased with improved obstetric care.

Acquired outflow tract abnormalities are rare causes of secondary amenorrhea. Such disorders may be the result of postpartum endometritis or destruction of the basal layer of the endometrium by overzealous dilatation and curettage, with subsequent obliteration of the endometrial cavity (Asherman syndrome).

- Functional or organic hypothalamic-pituitary disorders are the common causes of secondary amenorrhea.
- Ovarian causes of secondary amenorrhea include polycystic ovary syndrome and autoimmune oophoritis.
- Acquired outflow tract abnormalities are uncommon causes of secondary amenorrhea.
- Patients with hyperthyroidism may present with amenorrhea.

Clinical Features

In addition to amenorrhea, patients may experience symptoms of estrogen deficiency. These include vaginal dryness, hot flashes, and loss of secondary sex characteristics. Other findings are those related to the etiologic disorder, such as galactorrhea, hirsutism, shortness of stature, or features of Turner syndrome.

Diagnosis

Secondary Amenorrhea

The first step in the work-up of amenorrhea is to exclude pregnancy (measure HCG level) regardless of the patient's history of sexual activity or contraceptive use. The serum levels of prolactin and TSH should be measured to exclude hyperprolactinemia and thyroid

dysfunction, respectively. Serum levels of estradiol, LH, and particularly FSH help to differentiate ovarian from hypothalamic-pituitary disorders. An increase in FSH in a patient with low estradiol levels confirms primary ovarian failure. If ovarian failure (chemotherapy or radiotherapy) has no readily apparent cause, autoimmune oophoritis is likely, and appropriate tests to exclude other autoimmune endocrine disorders are indicated. A low estradiol level and inappropriately low levels of FSH and LH indicate a hypothalamic-pituitary disorder, and pituitary function testing and appropriate imaging should be performed. Hirsutism and acne suggest hyperandrogenism and should be investigated by measuring the serum concentration of testosterone and dehydroepiandrosterone sulfate (DHEAS).

- The evaluation of secondary amenorrhea should include measurement of HCG, prolactin, TSH, estradiol, FSH, LH, and, if indicated, testosterone and DHEAS.
- Low estradiol and increased FSH levels indicate primary ovarian failure.
- Low estradiol and inappropriately low FSH and LH levels indicate a hypothalamic-pituitary disorder: rule out functional and organic disease.

Primary Amenorrhea

If the appearance is that of an adult female and there is no evidence of pregnancy, consider outflow tract obstruction or androgen insensitivity (e.g., testicular feminization). A pelvic examination is an important part of the evaluation. Normal findings on pelvic examination should prompt an evaluation similar to that for secondary amenorrhea. The absence of a uterus should prompt measurement of testosterone; a normal female testosterone concentration supports the diagnosis of müllerian agenesis, whereas a high serum level of testosterone suggests androgen insensitivity.

If sexual infantilism is present, gonadotropins should be measured. An increase in FSH suggests primary gonadal failure and dictates karyotyping. Normal or low FSH levels suggest hypogonadotropic hypogonadism or delayed puberty.

- Adult female sex characteristics and a negative pregnancy test should lead to a consideration of genital tract anomalies or androgen insensitivity.
- The presence of sexual infantilism suggests a disorder of the hypothalamic-pituitary-gonadal axis or delayed puberty.

Therapy

Management is directed at the underlying disorder and restoration of normal gonadal function. However, if successful treatment of the underlying disorder is not possible, estrogen replacement therapy and, when feasible, restoration of fertility are indicated.

Estrogen Replacement Therapy

Estrogen replacement therapy is undertaken to help control hot flashes, prevent atrophic vaginitis, preserve secondary sex characteristics, and prevent osteoporosis. Estrogen therapy is contraindicated if the patient has an estrogen-dependent neoplasm, cholestatic liver disease, or a history of venous thrombosis. Progesterone replacement therapy is indicated only for women with an intact uterus. Estrogen and progesterone replacement therapy can be administered sequentially or in combination. Sequential therapy usually results in predictable cyclic withdrawal bleeding. The goal of combination therapy is to induce endometrial atrophy and amenorrhea and is preferred by patients who find cyclic withdrawal bleeding inconvenient.

Estrogen replacement therapy increases the risk of endometrial cancer (but this is prevented by progesterone), and it is associated with a slight increase in the risk of breast cancer.

Ovulation Induction

Hypogonadal women who desire fertility can be given clomiphene citrate, exogenous gonadotropin, or GnRH therapy. The treatment of choice for hyperprolactinemia is bromocriptine or cabergoline.

Selected Disorders Associated With Amenorrhea

Turner 45/XO Gonadal Dysgenesis

Turner syndrome is the most common cause of primary amenorrhea and affects 1 in 3,000 newborn females. It is characterized by a missing X chromosome, which leads to the development of streak gonads, primary ovarian failure, and sexual infantilism. Physical abnormalities associated with Turner syndrome include a webbed neck, low-set ears, micrognathia, a shield-like chest, short metacarpals and metatarsals, an increased carrying angle at the elbows, renal developmental abnormalities, and cardiovascular anomalies (including coarctation and aortic stenosis). Mosaics tend to have less severe manifestations of the syndrome, and the degree of ovarian dysgenesis varies depending on the ratio of XO to XX germ cells.

Anorexia Nervosa

This syndrome occurs almost exclusively in females younger than 25 years. It is characterized by a distorted perception of weight and body image that leads to poor nutrition. Patients deny the nature of the problem. Amenorrhea occurs in most females with anorexia nervosa and often precedes the weight loss. Other features of the disorder include bradycardia, hypotension, constipation, growth of lanugo hair, and, in severe cases, dependent edema. Endocrine findings include secondary hypogonadism, low IGF-I levels, increased reverse T_3 levels, and increased serum cortisol concentrations that are suppressed in response to exogenous dexamethasone.

Androgens in Healthy Females

Circulating androgens in adult females originate from the ovaries and adrenal cortex. Testosterone is synthesized by the ovaries and adrenals and from conversion of androstenedione in the peripheral tissues. Dehydroepiandrosterone (DHEA) is produced mainly by the adrenals and, to a lesser extent, the ovaries. DHEAS is derived almost exclusively from the adrenal cortex. Ovarian androgens are synthesized by thecal cells in an LH-dependent fashion. Adrenal androgens are synthesized in the zona fasciculata and zona reticularis in an ACTH-dependent manner. These androgens are metabolized to testosterone or dihydrotestosterone at their target tissues. In females,

androgens mediate increased hair growth and maintain libido and muscle mass.

- Testosterone originates from the ovaries and adrenals, but DHEAS is produced almost exclusively by the adrenal cortex.
- Ovarian androgen production is LH-dependent. Adrenal androgen production is ACTH-dependent.

Hirsutism and Virilization

Hirsutism refers to excessive androgen-induced hair growth in the androgen-sensitive areas of the female body. *Virilization* refers to the masculinization of secondary sex characteristics and the sex organs and is the result of pronounced androgen stimulation. Although virilization always is associated with hirsutism, hirsutism frequently occurs without virilization.

Etiology

Androgen excess may result from increased production of androgens by the ovaries or adrenal cortex (or both). Ovarian (LH-dependent) disorders include polycystic ovarian syndrome. Adrenocortical (ACTH-dependent) disorders include congenital adrenal hyperplasia and ACTH-dependent Cushing disease. Hirsutism also can occur because of increased sensitivity of the hair follicles to androgen. Hirsutism and virilization may be the consequence of exposure to exogenous androgens, anabolic steroids, or some progestational agents derived from testosterone.

Clinical Features

The clinical features depend on the severity of the hyperandrogenism. Manifestations include acne, hirsutism of androgen-sensitive areas (including the upper lip, chin, chest, and lower abdomen), menstrual abnormalities, and masculinization (temporal hair recession, deepening voice, increased muscle mass, and clitorimegaly).

Diagnosis

A benign cause is suggested by onset at puberty with an indolent, slowly progressive course. In contrast, rapid onset with a severe, progressive course suggests a malignant disorder.

A positive family history is often elicited in facial hirsutism, polycystic ovarian syndrome, and late-onset congenital adrenal hyperplasia. Generally, a young woman who has mild hirsutism of pubertal onset and normal menstrual function and who does not have any major disorder does not need to undergo detailed endocrine testing. Hirsutism of pubertal onset associated with menstrual irregularity but no virilization may be due to polycystic ovaries or late-onset congenital adrenal hyperplasia.

Diagnostic testing should include determination of serum levels of testosterone, DHEAS, and prolactin as well as screening for Cushing syndrome (overnight 1-mg dexamethasone suppression test or 24-hour urinary free cortisol). If a neoplastic disorder is suspected (serum testosterone >200 ng/dL or plasma DHEAS >7 ng/dL), pelvic ultrasonography and abdominal CT are indicated. In selected patients, determination of the serum level of 17-hydroxyprogesterone, with or without ACTH stimulation, to confirm congenital adrenal hyperplasia may be necessary.

- The most important diagnostic clues are the time of onset, tempo of progression, and severity of hyperandrogenic state.
- DHEAS >7 ng/dL suggests an adrenal tumor.
- Serum testosterone >200 ng/dL suggests an ovarian neoplasm. Serum testosterone <200 ng/dL suggests polycystic ovarian syndrome (see "Polycystic Ovarian Syndrome" section).

Selected Hyperandrogenic States

Idiopathic Hirsutism

Idiopathic hirsutism is usually due to a modest increase in ovarian androgen production, with increased peripheral androgen production and increased sensitivity of hair follicles to androgens. The hyperandrogenicity is usually mild and LH-dependent. Onset occurs at puberty and progresses slowly. Menstrual cycles are regular and findings on pelvic examination are unremarkable. The serum levels of testosterone and DHEAS are normal.

Polycystic Ovarian Syndrome

Polycystic ovarian syndrome is the commonest cause of hyperandrogenism. The diagnosis is made when the following criteria are present: 1) oligomenorrhea or amenorrhea, 2) clinical or biochemical hyperandrogenism, and 3) exclusion of other causes of hyperandrogenism (e.g., Cushing syndrome or congenital adrenal hyperplasia). The onset of the disorder is at puberty, and progression is slow. Most patients experience some degree of infertility. The serum levels of testosterone are usually at the upper limits of normal or modestly increased (usually <200 ng/dL). DHEAS levels are normal or mildly increased in 25% of patients. Serum levels of estradiol are normal. Gonadotropin secretion is abnormal, and approximately 60% of patients have an increased LH/FSH ratio. In most patients, the ovaries have a characteristic appearance on ultrasonography, with multiple peripherally located cysts. This radiologic finding, however, is not specific for polycystic ovarian syndrome; it is seen also in women with other causes of hyperandrogenism and in nonhirsute women with normal menses.

Polycystic ovarian syndrome is also considered a metabolic disorder: most patients are obese and have insulin resistance. Patients are at increased risk of glucose intolerance or type 2 diabetes mellitus. Treatment with metformin may be considered for patients with established glucose intolerance. Currently, the use of this agent or insulin-sensitizing agents is not routinely recommended for treatment of hirsutism in women with polycystic ovarian syndrome who have normal glucose levels. Studies have shown that these agents may result in resumption of ovulation; thus, the patient should be counseled about contraception.

- Hirsutism, menstrual abnormality, infertility, and anovulation characterize polycystic ovarian syndrome.
- Serum concentrations of testosterone are normal or modestly increased but usually <200 ng/dL.
- Ultrasonographic findings of polycystic-appearing ovaries are not sufficient to make the diagnosis.
- Patients are usually obese, have insulin resistance, and are at increased risk of glucose intolerance or type 2 diabetes mellitus.

Late-Onset Congenital Adrenal Hyperplasia

Congenital adrenal hyperplasia (CAH) is due to an inherited (autosomal recessive) deficiency of one of the steroidogenic enzymes necessary for the synthesis of corticosteroid hormones by the adrenal gland. Patients may present in a classic fashion in the neonatal or postnatal period. This usually occurs with severe enzyme deficiency. However, patients with mild enzyme deficiency can present after puberty. The commonest cause is 21-hydroxylase deficiency (90%), but deficiency of 11β-hydroxylase or 3β-hydroxysteroid dehydrogenase also leads to CAH. Such blocks in the steroidogenic pathway result in the accumulation of precursor molecules proximal to the site of block. These precursors are shunted into pathways that lead to the synthesis of androgens. The process is ACTH-dependent and, thus, can be suppressed by dexamethasone. In 21-hydroxylase deficiency, the concentration of 17-hydroxyprogesterone is usually increased (>300 ng/dL), and if it is normal, an ACTH stimulation test is indicated. A concentration of 17-hydroxyprogesterone greater than 1,200 ng/dL 30 minutes after stimulation is diagnostic.

Virilizing Tumors of the Ovary and Adrenal Gland

Virilizing tumors of the ovary and adrenal gland can occur at any age; they produce severe hyperandrogenism, with a rapid onset and progression. Adrenal tumors characteristically are associated with high levels of DHEAS, whereas ovarian tumors produce high levels of testosterone. Diagnosis requires appropriate imaging. Rarely, selective venous sampling is required to localize the source of androgen excess.

Therapy of Hirsutism

Oral contraceptives are used in the management of idiopathic hirsutism and polycystic ovarian syndrome. They suppress LH production, which in turn decreases ovarian testosterone production. It is important to avoid agents with androgenic progestins. Spironolactone is an androgen receptor blocker. Because it causes menstrual dysfunction, it often is combined with an oral contraceptive agent (some form of contraception is required because spironolactone may cause abnormal development of genitalia in a male fetus). A patient who receives medical therapy should be counseled that an effect may not be seen for 6 months. Also, because treatment is not effective against established hair, some form of mechanical hair removal is desirable early during therapy.

- In hirsutism, medical therapy is used to decrease androgen production or to inhibit the effect of androgens on hair follicles.

Hyperlipidemias

Disorders of lipoprotein metabolism predispose to premature ischemic heart disease and vascular disease. In some patients, an extreme increase in triglyceride concentrations can lead to acute pancreatitis.

Etiology

Increases in total cholesterol and triglyceride concentrations may be caused by a coexisting disorder (e.g., poorly controlled diabetes mellitus) or the use of drugs (e.g., corticosteroids). In the absence of precipitating factors, an increase in lipoprotein concentration is termed *primary hyperlipidemia*. It is the result of genetic defects (e.g., absence of the low-density lipoprotein [LDL] receptor) or acquired defects (due to an interaction of aging, weight gain, poor diet, sedentary lifestyle, and genetic predisposition).

- Hyperlipidemias: genetic or acquired disorders that can result from increased production or reduced clearance (or both).

Some of the primary hyperlipidemias are outlined in Table 6-3, and the causes of secondary hyperlipidemia are outlined in Table 6-4.

Clinical Features

Most patients with hyperlipidemia have no physical findings attributable directly to increased concentrations of lipoprotein. Some patients have a corneal arcus (arcus senilis), but the significance of this finding decreases with increasing age. Patients with an extreme increase in LDL may exhibit tendon xanthomas or thickening of the Achilles tendon. Other patients with an increase in intermediate-density lipoprotein (IDL) may have palmar tuboeruptive xanthomas. In hyperchylomicronemia, eruptive xanthomas may develop on the buttocks.

Increased LDL, increased IDL, increased Lp(a) lipoprotein, and decreased high-density lipoprotein (HDL) all confer an increased risk of atherosclerotic vascular disease. Increased HDL is associated with decreased atherogenic risk. Hypertriglyceridemia may be atherogenic by inducing alterations in other lipoproteins (e.g., it may decrease HDL and increase small-density LDL, very-low-density lipoprotein [VLDL] remnants, and IDL) and, in addition, may have an unidentified direct atherogenic action. Pancreatitis may develop with increases in triglyceride-rich lipoproteins (>1,000 mg/dL).

- Clinical presentations: ischemic vascular disease, pancreatitis, or xanthomas.

Diagnosis

The Adult Treatment Panel of the National Cholesterol Education Program has recommended that all adults older than 20 be evaluated for hypercholesterolemia to identify those at risk of coronary artery disease. Lipid screening tests should not be performed during an acute illness or hospitalization. Plasma triglyceride concentrations vary considerably after meals and must be measured in the fasting state. Provided plasma triglyceride concentrations are less than 400 mg/dL, LDL cholesterol (LDL-C) concentrations can be reliably estimated by use of the Friedewald equation:

$$\text{LDL-C} = \text{total cholesterol} - \text{HDL cholesterol} - \frac{\text{triglycerides}}{5}$$

Lp(a) lipoprotein is believed to be an independent risk factor for vascular disease. It should be measured only in patients with a strong family history of premature ischemic heart disease who do not have conventional risk factors or in patients with established

coronary artery disease who have progressive disease despite control of conventional risk factors.

- Lipid screening tests should not be conducted during an acute illness or hospitalization.

Nonmodifiable risk factors for cardiovascular disease include age older than 45 for men and 55 for women. Note that a woman with premature menopause who is not receiving estrogen replacement therapy is at increased risk of premature cardiovascular disease. A family history of premature coronary artery disease (a parent or sibling with myocardial infarction or sudden death before age 55) confers increased risk. Modifiable risk factors include smoking, hypertension, diabetes mellitus, and an HDL less than 35 mg/dL. An HDL greater than 60 mg/dL confers protection against cardiovascular disease.

- Assessment of other coronary risk factors is important for evaluating the overall atherogenic risk and planning effective management.

Table 6-3 Features of Primary Hyperlipidemias

Feature	Familial hypercholesterolemia	Familial combined hyperlipidemia	Familial dysbetalipoproteinemia	Familial hypertriglyceridemia	Severe hypertriglyceridemia	
					Early onset	Adult onset
Pathophysiology	Defective LDL receptor or defective apo B-100; impaired catabolism of LDL	Overproduction of hepatic VLDL-apo B-100 but not of VLDL-Tg	Defective or absent apo E; excess of CM remnants and VLDL in fasting state	Overproduction of hepatic VLDL-Tg but not of apo B-100	Lipoprotein lipase deficiency Apo C-II deficiency; defect in CM & VLDL catabolism	Overproduction of VLDL triglyceride Delayed catabolism of CM & VLDL
Mode of inheritance	Autosomal codominant	Autosomal dominant	Autosomal recessive	Autosomal dominant	Autosomal recessive	Autosomal recessive
Estimated population frequency	1:500	1:50	1:5,000	1:50	<1:10,000	Rare
Risk of CAD	+++	++	+	+ In families in which HDL-C is deficient	–	+
Physical findings	Arcus senilis Tendinous xanthomas	Arcus senilis	Arcus senilis Tuberoeruptive & palmar xanthomas	None	Lipemia retinalis Eruptive xanthomas	Milky plasma Lipemia retinalis Eruptive xanthomas Pancreatitis
Associated findings		Obesity Glucose intolerance Hyperuricemia HDL deficiency	Obesity Glucose intolerance Hyperuricemia	Obesity Glucose intolerance Hyperuricemia HDL deficiency	HDL deficiency Recurrent abdominal pain Pancreatitis Hepatosplenomegaly	Obesity Glucose intolerance Hyperuricemia HDL deficiency Pancreatitis
Treatment	Diet Niacin & resin Statin & resin Probucol & resin	Diet Drugs singly or in combination with niacin, statin, gemfibrozil, resin	Diet Niacin Gemfibrozil Statin	Diet Niacin Gemfibrozil Abstain from alcohol, estrogen	Diet Fish oil	Diet Control diabetes when present Avoid alcohol, estrogen Gemfibrozil Fish oil

C, cholesterol; CAD, coronary artery disease; CM, chylomicrons; HDL, high-density lipoprotein; LDL, low-density lipoprotein; Tg, triglyceride; VLDL, very-low-density lipoprotein; +++, very high; ++, high; +, moderate; –, no increased risk.

Table 6-4 Causes of Secondary Hyperlipidemia

Increased LDL cholesterol	Increased triglycerides	Decreased HDL cholesterol
Hypothyroidism	Obesity	Hypertriglyceridemia
Dysglobulinemia	Diabetes mellitus	Obesity
Nephrotic syndrome	Hypothyroidism	Diabetes mellitus
Obstructive liver disease	Sedentary life	Cigarette smoking
Progestins	Alcohol	Sedentary life
Anabolic steroids, glucocorticoid therapy	Renal insufficieny	β-Blockers
Anorexia nervosa	Estrogens	Progestins
Acute intermittent porphyria	β-Blockers	Anabolic steroids
	Thiazides, steroids	
	Dysglobulinemias	
	Systemic lupus erythematosus	

Therapy

The National Cholesterol Education Program Guidelines are used to guide therapy (Table 6-5). The target LDL level depends on the presence of ischemic heart disease (secondary prevention) or risk factors for ischemic heart disease (primary prevention). High-risk patients have two or more risk factors.

Treatment requires dietary and lifestyle modification and correction of secondary causes when feasible (e.g., treatment of hypothyroidism or diabetes mellitus) in conjunction with the appropriate use of lipid-lowering agents.

Diet Therapy

Dietary therapy is used to achieve and maintain a normal body weight. A typical healthy diet can be provided by following the American Heart Association step I diet, which provides for 30% or fewer calories from fat and 10% or fewer calories from saturated fat. Alcohol restriction often decreases triglyceride concentrations.

Behavior Modification

Weight reduction enhances the cholesterol-lowering effect of an appropriate diet, decreases triglycerides, increases HDL, decreases blood pressure, and improves glucose tolerance. Smoking cessation and regular exercise also increase HDL.

Drug Therapy

After drug therapy for hyperlipidemia has been instituted, it is likely to be lifelong. Therefore, drug therapy should be embarked upon only after vigorous efforts at dietary and lifestyle modification. Both the physician and the patient should be made aware of the potential risks associated with lipid-lowering agents. The teratogenic potential of most of these drugs should also be borne in mind when prescribing them for females of childbearing age. Patients should be monitored for potential side effects as well as for the efficacy of the medication in reaching the predetermined goals. Lipid concentrations should be checked approximately 3 months after therapy has been instituted. If the lipid goals are not achieved, the dose may need to be increased. However, combination therapy may need to be considered for some patients. Because of the increased risk of myositis or hepatitis (or both), combination therapy should be reserved for secondary prevention in established cardiovascular disease.

Treatment of Increased LDL

In most instances, a statin is the drug of choice for the treatment of increased concentration of LDL. In estrogen-deficient women, estrogen replacement therapy is effective in decreasing LDL and increasing HDL. However, oral estrogens should not be given to patients with hypertriglyceridemia; for these patients, a transdermal estrogen patch may be considered. It must be noted that recent studies of long-term estrogen use do not provide evidence of dramatic benefit in cardiovascular outcomes. Patients who do not reach their therapeutic goals will benefit from the addition of a resin (colesevelam or cholestyramine) to the statin. Niacin can also be used for the treatment of increased LDL. However, few patients are able to tolerate this medication long-term because of its side effects, most notably facial flushing and worsening of glucose tolerance.

Treatment of Hypertriglyceridemia

Extreme hypertriglyceridemia (>1,000 mg/dL) requires timely treatment to reduce the risk of pancreatitis. This includes cessation of oral estrogen or alcohol use, better control of diabetes, and restriction of caloric intake. Fibrates such as gemfibrozil or fenofibrate are the drugs of choice. Most patients with hypertriglyceridemia have glucose intolerance or diabetes. These disorders are a relative contraindication to niacin, which increases insulin resistance and may worsen glycemic control. Fish oil capsules (1 g) at a dosage of 8 to 10 capsules daily may also be effective.

Treatment of Low HDL

In the absence of heart disease, lifestyle modification is the intervention of choice in conjunction with an attempt to discontinue drugs that can lower HDL (e.g., androgens). In the presence of ischemic heart disease, lowering LDL to less than 100 mg/dL is

Table 6-5 Overview of Therapy for Hyperlipidemia

Clinical risk assessment	Initiate diet	Initiate drug therapy	Goal of therapy
No CAD; <2 risk factors	>160 mg/dL	>190 mg/dL	<160 mg/dL
No CAD; ≥2 risk factors	>130 mg/dL	>160 mg/dL	<130 mg/dL
CAD; step II AHA diet	>100 mg/dL	>130 mg/dL	<100 mg/dL

AHA, American Heart Association; CAD, coronary artery disease.

indicated. Drugs that can increase HDL include niacin, statins, and, to a lesser extent, fibrates. In postmenopausal women, estrogen replacement therapy can increase HDL concentrations.

Treatment of Increased Lp(a) Lipoprotein

There is no effective treatment for increased concentrations of Lp(a) lipoprotein. Niacin may produce some modest decrease. Some authorities advocate intervention to lower LDL to less than 100 mg/dL in patients with increased Lp(a) lipoprotein. Estrogen replacement therapy may be effective in postmenopausal women.

Diabetes Mellitus

Etiology and Classification

Diabetes mellitus is a metabolic disorder characterized by increased fasting and postprandial concentrations of glucose. It is the commonest metabolic disorder and affects about 10% of the U.S. population. The classification of this disorder into two broad categories is somewhat artificial and the reader should recognize that a degree of overlap exists. Type 1 diabetes mellitus (T1D) is characterized by immune destruction of the insulin-producing beta cells in the islets of Langerhans. It affects 10% to 20% of the diabetic population and usually appears at a younger age. Most patients eventually lose all endogenous insulin secretion and are prone to the development of ketoacidosis.

A complex interaction between genes and the environment leads to the development of T1D. This is illustrated by the 50% concordance for the disease seen in monozygotic twins when one of the twins has T1D. This disease is associated frequently with certain histocompatibility antigen (HLA) types, with polymorphisms of the insulin gene and other variants in immune response genes having weak contributions to the pathogenesis of this disorder. Antibodies to islets or some constituent of the islets are frequently present, at least in the early stages of the disease (islet-cell antibodies and glutamic acid decarboxylase [GAD] antibodies) and help to differentiate T1D from type 2 diabetes mellitus (T2D). Often, a "honeymoon" period occurs, during which insulin requirements decrease dramatically after restoration of euglycemia. The duration of this phase is highly variable.

- Type 1 diabetes is characterized by immune destruction of the islets, which leads to insulin deficiency.
- Concordance is seen in 50% of monozygotic twins.

The pathogenesis of T2D is more complex. It is characterized by abnormalities of insulin secretion and insulin action in target tissues such as the liver, muscle, and adipose tissue. The ability of glucose to stimulate its own uptake and to suppress its own release is also defective. Impaired suppression of glucagon secretion after the ingestion of a meal also contributes to postprandial hyperglycemia in these patients. Although T2D usually appears in older, obese patients, it increasingly has been described in obese, sedentary children and adolescents. T2D is more common among certain ethnic groups. Monozygotic twins exhibit almost 100% concordance if one of the twins is affected. The overall genetic contribution to the pathogenesis of T2D is greater than in T1D. However, individual genes have a weaker contribution than in T1D, for example, HLA polymorphisms in T1D. Environmental factors such as obesity also have a definite role in the development of the disease.

- Type 2 diabetes is characterized by defective insulin secretion and action.
- Environmental factors such as obesity have an important role in the development of T2D.
- T2D can occur at any age.

Maturity-onset diabetes of the young (MODY) describes a group of single-gene disorders in patients who present with diabetes at a young age. MODY is usually inherited as an autosomal dominant trait. Various mutations are responsible for this disorder, and the clinical expression is variable.

Clinical Features

The onset of T1D is usually quite dramatic, with weight loss, polyuria, and polydipsia. Often, it is precipitated by an infection or other severe physical stress because patients lack the reserve of endogenous insulin secretion to overcome the effects of counter-regulatory hormones (glucagon, cortisol, growth hormone, and epinephrine) on glucose metabolism. Severe dehydration and ketoacidosis may be present. In very young children, nocturnal enuresis may signal the onset of disease.

T2D usually has an insidious onset. Often, the disease is diagnosed during routine laboratory testing by the presence of glycosuria or fasting hyperglycemia. Patients may complain of blurring of vision, myopia, episodes of recurrent skin infections, or monilial vaginitis (females) or balanitis (males). Occasionally, patients may present with evidence of chronic diabetic complications (neuropathy, nephropathy, or retinopathy) but without symptoms related to

glucose intolerance. Symptoms such as polyuria, polydipsia, and polyphagia may only develop in situations of increased insulin resistance such as pregnancy, infection, or steroid use. Also, patients occasionally present with hyperosmolar nonketotic coma.

- T1D has a dramatic onset related to abrupt, severe insulin deficiency, with polyuria, polydipsia, weight loss despite polyphagia, severe dehydration, and ketoacidosis.
- T2D has an insidious onset, and patients may present with complications. Under certain conditions, polyuria, polydipsia, and polyphagia may develop.

Diagnosis

The normal fasting plasma glucose concentration is less than 105 mg/dL. In adults (but not pregnant women), fasting values of 126 mg/dL or greater on two or more occasions confirm the diagnosis of diabetes mellitus. Fasting values between 110 mg/dL and 125 mg/dL encompass the class of impaired fasting glucose. In July 1997, the American Diabetes Association recommended lowering the level for diagnosis from 140 mg/dL to 126 mg/dL because epidemiologic data demonstrated a progressive increase in microvascular complications with progressive impairment in fasting glucose concentrations greater than 105 mg/dL.

- In adults (but not pregnant women), fasting plasma glucose values ≥126 mg/dL on two or more occasions confirm the diagnosis of diabetes mellitus.

Oral Glucose Tolerance Test

Currently, the main utility of glucose tolerance testing is during pregnancy, when it is used to screen for gestational diabetes mellitus. Epidemiologic data have demonstrated that impaired glucose tolerance is a marker for increased cardiovascular morbidity (in some cohorts) and mortality. However, the clinical application of glucose tolerance testing in this situation is unknown. Current therapy does not adequately treat postprandial hyperglycemia without causing fasting hypoglycemia.

Therapy for T1D

Insulin replacement is the cornerstone of therapy for T1D. The optimal regimen allows the patient to maintain a healthy, active lifestyle, with optimal glycemic control and minimal hypoglycemia. This can be achieved with intensive insulin therapy, but it requires considerable commitment from the patient to self-monitor plasma glucose concentrations and to adjust the insulin dosage accordingly. The Diabetes Control and Complications Trial has demonstrated conclusively that intensive therapy with tight glycemic control prevents or markedly decreases the risks of chronic microvascular complications of diabetes.

Nutrition

Intake should allow for maintenance of a reasonable weight and for growth in children and adolescents. Protein should account for 10% to 20% of the total calories; total fat, less than 30% (saturated fat, <10%); and complex carbohydrates, the rest.

Exercise

The glycemic response to exercise varies depending on the duration and type of exercise, the fitness of the person, and the relationship of exercise to meals and insulin injections. Blood glucose levels should be monitored before and after exercise to determine the response to exercise and to prevent hypoglycemia. Patients should always carry appropriate identification and have access to glucose or glucagon (or both).

Insulin Therapy

Intensive insulin therapy allows the use of insulin in a fashion that mimics insulin secretion by the healthy pancreas. Short-acting insulin (regular or lispro) is injected at mealtimes to facilitate disposal of the meal, and a once-daily long-acting insulin (Ultralente or glargine insulin) is taken to replace basal insulin secretion.

An insulin pump provides a continuous subcutaneous infusion of insulin in a programmed fashion. It also is used to provide meal-stimulated insulin secretion, and it allows the patient to change the infusion rate of "basal" insulin (during exercise or at night).

The insulin dosage required for a typical patient with T1D who is within 20% of ideal body weight and does not have intercurrent illness is approximately 0.5 to 1.0 U/kg daily. The insulin requirements may increase markedly during intercurrent illness.

The glycemic goals are individualized according to the presence of intercurrent disease (ischemic heart disease or cerebrovascular disease), diabetic complications, and the ability to perceive hypoglycemia. If a female who has T1D is considering pregnancy or is pregnant, tighter control is important to decrease the risk of birth defects or macrosomia.

- Intensive insulin therapy attempts to simulate normal insulin secretion, with a combination of short-acting and long-acting insulin.
- An insulin pump allows the patient to adjust basal insulin levels as needed.

Glycemic Goals of Optimal Therapy

Blood glucose targets are as follows: fasting, 70 to 130 mg/dL; bedtime, 100 to 140 mg/dL. Hemoglobin A_{1c} should be less than 7%. Higher target levels are required for patients at risk of hypoglycemia because of their inability to recognize hypoglycemic symptoms.

Monitoring

On most days, the blood glucose concentration should be self-monitored 4 times daily—before meals and at bedtime. If the patient has unexplained morning hypoglycemia or hyperglycemia, blood glucose should be measured at 2 AM to 4 AM. Hemoglobin A_{1c} should be measured every 2 to 3 months.

- Hemoglobin A_{1c} should be monitored every 2 to 3 months; the goal is <7%.
- The patient should self-monitor blood glucose at least 4 times daily. The goal is 70-130 mg/dL fasting and 100-140 mg/dL at bedtime.

Therapy for T2D

Most patients with T2D are obese and lead sedentary lifestyles. Often, they have multiple cardiovascular risk factors such as hypertension and dyslipidemia. Therapy should include appropriate modification of these risk factors, appropriate exercise and nutrition, and achievement of appropriate glycemic control with a near-normal hemoglobin A_{1c}.

Calorie restriction while consuming a healthy, balanced diet is appropriate to promote weight reduction. Exercise improves insulin action, facilitates weight loss, reduces cardiovascular risks (increases HDL and decreases VLDL-triglycerides), and increases a patient's sense of well-being. If the patient has preexisting coronary or peripheral vascular disease, exercise recommendations should be modified appropriately.

- The treatment goals for T2D include appropriate lifestyle modification, modification of cardiovascular risk factors, and optimal glycemic control.
- Calorie restriction is appropriate to promote weight reduction.
- A prudent exercise program facilitates weight reduction and improves insulin action, cardiovascular fitness, and the sense of well-being.

Drug Therapy for T2D

Sulfonylureas are insulin secretagogues. These agents bind to the sulfonylurea receptor on beta cells, causing closure of potassium channels, with the subsequent influx of calcium and exocytosis of insulin. The efficacy of these medications depends on the presence of endogenous insulin secretion. Primary failure occurs in the absence of endogenous insulin secretion. Secondary failure occurs with progression of disease, when sulfonylureas are no longer effective in achieving glycemic control.

Repaglinide and *nateglinide* belong to a new class of oral hypoglycemic agents that have an extremely short half-life and act in a fashion similar to sulfonylureas. These agents are taken before each meal (the dose is skipped if the meal is missed).

Metformin is a biguanide, a class of drugs that improves the liver action of insulin. Lactic acidosis is extremely rare if the specific exclusion criteria for the use of metformin are followed: 1) renal impairment—plasma creatinine value of 1.5 mg/dL or greater for men and 1.4 mg/dL or greater for women, 2) cardiac or respiratory insufficiency that is likely to cause central hypoxia or reduced peripheral perfusion, 3) history of lactic acidosis, 4) severe infection that could lead to reduced tissue perfusion, 5) liver disease, 6) alcohol abuse with binge drinking, and 7) use of intravenous radiographic contrast agents. For hospitalized patients, it is prudent to withhold metformin therapy.

Thiazolidinediones chiefly improve peripheral insulin action. Troglitazone, the first member of the class to be used clinically, has been discontinued because of its association with severe hepatotoxicity. The newer members of the group, rosiglitazone and pioglitazone, do not contain a vitamin E moiety, which is thought to account for the hepatotoxicity associated with troglitazone. Nevertheless, it is recommended that liver function be monitored closely during treatment with these drugs. Thiazolidinediones can cause marked fluid retention and should not be prescribed if the patient has congestive heart failure.

- Sulfonylureas are insulin secretagogues. Their efficacy depends on the presence of some degree of endogenous insulin secretion.
- Metformin improves the action of insulin in the liver. Its use should be avoided in certain circumstances because of the risk of lactic acidosis.
- Thiazolidinediones improve peripheral insulin action but are associated with fluid retention.
- Repaglinide and nateglinide are short-acting agents that increase insulin secretion; they are taken before meals.

Insulin is reserved for patients with T2D in whom diet and oral agents (monotherapy and combination therapy) have not provided adequate glycemic control. It is the preferred therapy when patients are pregnant, are undergoing surgical treatment, or are severely ill. Patients with T2D often have some degree of meal-stimulated endogenous insulin secretion, which allows treatment with simpler insulin regimens than for T1D. Once-daily injections of intermediate-acting insulin in combination with an oral agent or twice-daily injections of intermediate-acting insulin are commonly used to manage T2D. Insulin therapy is associated with some degree of weight gain in most patients. For this reason, insulin sometimes is given in combination with metformin to help limit weight gain. In patients who have a more severe insulin deficiency, an intensive insulin program or a split-mix program may be used (e.g., NR-0-NR-0).

- Simple insulin regimens are useful for patients with T2D who have experienced secondary treatment failure (e.g., intermediate insulin once or twice daily; supplement once-daily dosing with an oral agent if necessary).
- Prescribe an intensive insulin program or split-mix program (e.g., NR-0-NR-0) for patients with severe insulin deficiency.

Combination Therapy

Combination therapy is frequently prescribed for patients with T2D if maximal therapy with a single agent fails to achieve adequate glycemic control. This takes advantage of the different mechanisms of action of oral agents. A commonly used regimen is the combination of a sulfonylurea with metformin.

- Combination therapy with metformin and a sulfonylurea significantly improves control when therapy with one agent fails.

Hypoglycemia in Diabetes

Hypoglycemia occurs when there is a mismatch between glucose availability and glucose requirements. This may be due to unplanned exercise, inappropriate dosing of insulin, or inadequate caloric intake. Patients with T1D are prone to hypoglycemia unawareness, which develops after repeated neuroglycopenia. This may require appropriate adjustment of glycemic goals because the prevention of hypoglycemia has been shown to reverse or ameliorate hypoglycemia

unawareness. Many episodes of severe hypoglycemia occur at night and may not be apparent if glucose is checked at bedtime and at breakfast. Occasionally, patients report symptoms such as nightmares, morning headache, or night sweats. It is important to emphasize the need for periodic self-monitoring of blood glucose between 1 AM and 3 AM. Preventive strategies for nocturnal hypoglycemia include increasing the bedtime snack or modifying the insulin regimen.

Patients with long-standing T1D also have defective counterregulation because they are unable to secrete glucagon and become dependent on the autonomic nervous system to respond to hypoglycemia. The use of β-blockers in these situations can abolish all acute responses to hypoglycemia.

Insulin clearance is delayed by renal impairment and by circulating insulin antibodies. Alcohol may interfere with gluconeogenesis and with the perception of hypoglycemic symptoms. Hypoglycemia may be a manifestation of cortisol deficiency (patients with T1D are at increased risk of other autoimmune endocrinopathies).

- Patients with T1D are especially prone to hypoglycemia.
- Episodes of severe hypoglycemia may occur during the night—check the blood glucose level between 1 AM and 3 AM.
- Hypoglycemia may be precipitated by exercise, decreased caloric intake, renal insufficiency, and cortisol deficiency.

Acute Complications of Diabetes Mellitus

Diabetic Ketoacidosis

Diabetic ketoacidosis occurs in patients with T1D and may be the initial presentation of diabetes. It is characterized by polyuria, polydipsia, dehydration, anorexia, nausea and vomiting, abdominal pain, tachypnea, obtundation, and coma. The physical findings include clinical evidence of dehydration, decreased mentation, deep and rapid Kussmaul respiration, and a characteristic breath odor (acetone). Often, diabetic ketoacidosis is precipitated by a failure to take insulin or to increase insulin and consume extra fluids during acute illness, infection, or other intercurrent illness such as myocardial infarction, pancreatitis, stroke, or trauma.

The diagnosis is based on the demonstration of moderate or severe hyperglycemia, ketonemia, and metabolic acidosis. Associated biochemical abnormalities include hyponatremia, azotemia, and hyperamylasemia. Serum levels of potassium, phosphate, and magnesium (despite large body losses) may be normal. However, concentrations of these ions often decrease precipitously after the acidosis has been corrected.

- Diabetic ketoacidosis occurs with severe insulin deficiency and is often precipitated by intercurrent illness.
- It may be the initial manifestation of T1D.
- Diagnosis requires the presence of pronounced hyperglycemia, ketonemia, and metabolic acidosis.
- Serum levels of potassium may be normal despite large body losses.
- A thorough search for precipitating factors should be undertaken in all cases.

Treatment

Treatment of diabetic ketoacidosis requires correction of the metabolic state and electrolyte depletion. These goals are achieved by the administration of insulin, the replacement of fluid and electrolytes, and treatment of precipitating factors.

Insulin—Insulin infusion is preferred over subcutaneous or intramuscular injection. A priming dose of 10 to 20 units intravenously is followed by insulin infusion (5-10 U/h). This allows suppression of lipolysis and ketogenesis and stimulates glucose uptake.

Fluids—Fluids are given intravenously to restore volume and to correct electrolyte and fluid losses. The average fluid deficit in adults is 5 to 8 L. Approximately 4 L should be replaced in the first few hours. As plasma glucose values approach 250 mg/dL, change to 0.45% saline in 5% dextrose in water. This allows maintenance of intravenous insulin while keeping the plasma glucose at about 200 mg/dL during the first 12 hours, permitting correction of ketosis and avoiding a rapid decrease in osmolarity with its risk of cerebral edema.

Electrolytes—The potassium deficit is about 300 to 500 mEq. Regardless of the initial serum level of potassium, the total body stores of potassium are low. With correction of the acidosis, the serum level of potassium decreases. Potassium should be added to the intravenous fluids as soon as renal perfusion and urine flow are assured. Add 40 mEq of potassium, as potassium chloride, to each liter of intravenous fluid. Phosphate repletion is indicated by phosphate levels less than 1 mg/dL. Give phosphate in a dose of 0.08 mM/kg intravenously over 6 hours. (Neutral potassium phosphate: 1 ampule contains 3 mM phosphate and 15 mEq of potassium.) Monitor the serum level of phosphate carefully because of the risk of hypocalcemia, seizures, and death.

Prognosis

The mortality rate of diabetic ketoacidosis is 5% to 15% and, in most patients, is due to an associated precipitating illness such as myocardial infarction, stroke, or sepsis. After successful therapy, the goal is to avoid recurrence by educating the patient.

- Prognosis: 5%-15% mortality, usually from associated illness.
- After successful therapy, the goal is to avoid recurrence.

Hyperglycemic Hyperosmolar Nonketotic Coma

Hyperglycemic hyperosmolar nonketotic coma is characterized by hyperglycemia, hyperosmolar dehydration, and the absence of ketoacidosis. It usually occurs in poorly treated T2D when there is sufficient insulin to inhibit excess lipolysis and ketogenesis but not enough to suppress hepatic glucose production or to stimulate peripheral glucose uptake. High concentrations of urinary glucose provoke an osmotic diuresis, with marked dehydration and subsequently decreased renal function. It often is precipitated by acute illness such as myocardial infarction, pancreatitis, pneumonia, or surgery.

Diagnosis

Hyperglycemic hyperosmolar nonketotic coma should be suspected in any patient with diabetes who presents with an altered level of consciousness and severe dehydration. Laboratory abnormalities

include marked hyperglycemia (often >600 mg/dL), absence of ketones, and increased plasma osmolarity (>320 mOsm/L). A search for an underlying disorder is an integral part of the evaluation.

- Hyperglycemic hyperosmolar nonketotic coma is characterized by hyperglycemia and dehydration without ketoacidosis.
- The disorder should be suspected in any patient with diabetes who has altered sensorium and severe dehydration.
- Laboratory evaluation demonstrates marked hyperglycemia (>600 mg/dL), no significant ketosis, and plasma hyperosmolarity (>320 mOsm/L).
- Always search for a precipitating disorder.

Therapy

The objectives of treatment are to restore volume and osmolarity and to control the hyperglycemia. Fluid resuscitation with normal saline should be followed by 0.45% saline to correct the hyperosmolarity. Insulin is administered intravenously, but it is important to decrease the plasma glucose level gradually to a level between 200 and 300 mg/dL to avoid cerebral edema. At this stage, the infusion of insulin should be discontinued, and it should be given subcutaneously. Electrolyte replacement as outlined above for diabetic ketoacidosis is also important. Repeated neurologic evaluation is essential because focal deficits or seizures may become apparent during therapy. Complications include vascular events such as myocardial infarction or stroke, cerebral edema, and hypokalemia. The mortality rate is 50%.

- Treatment: fluid and electrolyte replacement and management of hyperglycemia.
- Hyperglycemic hyperosmolar nonketotic coma has a mortality rate of 50%.

Chronic Complications of Diabetes Mellitus

Microvascular Disease in Diabetes

Chronic hyperglycemia and other metabolic abnormalities associated with diabetes lead to damage of the microcirculation. This is manifested clinically as diabetic retinopathy, nephropathy, and neuropathy. Some degree of diabetic retinopathy occurs in 50% to 70% of patients with T1D within 10 years after diagnosis and reaches a prevalence of 95% by 15 to 20 years; it is rare in those who have had T1D for less than 5 years. Diabetic retinopathy is present in 15% to 20% of patients at the time of diagnosis of T2D and reaches 50% by 15 years. Background diabetic retinopathy is characterized by microaneurysms, hard exudates, hemorrhages, and macular edema. Proliferative retinopathy occurs when areas of the retina are ischemic; this provides a stimulus to the growth of new vessels. These vessels are fragile and prone to hemorrhage, which can lead to loss of vision. Panretinal photocoagulation is used to treat proliferative retinopathy. The destruction of ischemic areas of the retina decreases the stimulus for neovascularization and progression of proliferative retinopathy. The treatment of hypertension, hyperglycemia, glaucoma, and dyslipidemia is also important in these circumstances. Patients should have an annual dilated ophthalmic examination by an experienced ophthalmologist to identify those at risk.

Infections and Diabetes

Cutaneous skin infections are often a presenting feature of poorly controlled T2D. Typical infections include candidiasis as well as furuncles and carbuncles (caused by *Staphylococcus aureus* infection). Malignant external otitis due to infection with *Pseudomonas* is peculiar to diabetes and is life-threatening.

Ischemic Heart Disease in Diabetes

Ischemic cardiovascular disease appears earlier and is more extensive in persons with diabetes than in the general population. Coronary artery disease accounts for about 70% of deaths among those with diabetes, and patients may present with sudden cardiac death. Epidemiologic studies have shown that persons with T2D have the same risk of myocardial infarction as patients who have already had a myocardial infarction. For this reason, treatment of dyslipidemia is considered to be secondary prevention in diabetes. Patients with ischemic heart disease may present in an atypical manner; patients with angina may present with epigastric distress, heartburn, and neck or jaw pain; myocardial infarction may be silent (in 15% of patients) and patients may present with sudden onset of left ventricular failure.

Hyperlipidemia in Diabetes

In poorly controlled T2D, the concentrations of triglyceride-rich lipoproteins are increased because of an overproduction of VLDL together with decreased lipoprotein lipase activity. HDL levels are low, and levels do improve but usually do not normalize with control of glucose and triglyceride levels. Compositional changes in LDL (small, dense LDL) that increase the atherogenicity of these particles are more likely to occur in patients with T2D.

Diabetes and Pregnancy

Both fasting and postprandial glucose concentrations decrease in normal pregnancy. Because of an increase in the concentration of circulating hormones such as human placental lactogen, estrogen, progesterone, and cortisol (which increase insulin resistance), insulin secretion also increases. Glucose is a major metabolic substrate for the fetus and traverses the placenta by facilitated diffusion.

Pregnancy is a diabetogenic state and may worsen glucose control in women with established diabetes. Inadequate glycemic control early in pregnancy increases the risk of congenital malformations, whereas poor control in late pregnancy increases the risk of macrosomia, neonatal hypoglycemia, hypocalcemia, polycythemia, hyperbilirubinemia, and respiratory distress. Pregnancy may exacerbate diabetic retinopathy, and nephropathy may lead to pregnancy-induced hypertension and toxemia.

Gestational diabetes complicates 2% to 3% of all pregnancies. All pregnant women older than 25 years should be evaluated at 24 to 28 weeks with a 50-g oral glucose tolerance test. Plasma glucose levels higher than 140 mg/dL 1 hour after ingestion of the glucose drink require formal testing with a 100-g glucose drink. Gestational diabetes is diagnosed if glucose values exceed 105 mg/dL (fasting), 190 mg/dL (1 hour), 165 mg/dL (2 hours), and 145 mg/dL (3 hours).

- Early detection and optimal management of diabetes during pregnancy can prevent congenital malformations and decrease neonatal morbidity and mortality.
- Gestational diabetes complicates 2%-3% of all pregnancies.
- Screen all pregnant women older than 25 years at 24-28 weeks.

Treatment

Tight glycemic control is essential in pregnancy and before conception to decrease the risk of fetal malformations. The goals of therapy are to ensure tight control of diabetes (while avoiding hypoglycemia and fasting ketonemia) and adequate nutrition and optimal weight gain. Home monitoring for blood glucose and urine ketones is important. Because postprandial glucose concentrations are closely associated with malformations and macrosomia, they are often used to guide therapy. The blood glucose concentration should be between 60 and 90 mg/dL while fasting and 70 to 140 mg/dL 1 hour after a meal.

Women with gestational diabetes who become euglycemic in the postpartum state should be followed up periodically. They are at high risk of T2D (60% develop the disease within 15 years after the diagnosis of gestational diabetes) and should be encouraged to exercise, consume an appropriate diet, and make an effort to lose weight.

- Periodic follow-up of patients with gestational diabetes is necessary because 60% develop T2D within 15 years.

Hypoglycemia in Nondiabetic Patients

Etiology

Hypoglycemic disorders may be classified into *insulin-mediated* (insulin levels not appropriately suppressed) and *noninsulin-mediated* (insulin levels suppressed). Causes of insulin-mediated hypoglycemia include insulinoma, use of sulfonylurea or exogenous insulin, and autoimmune hypoglycemia mediated by insulin antibodies that bind insulin and prevent its degradation. Noninsulin-mediated hypoglycemia may be related to alcohol use, cortisol insufficiency, or GH deficiency in children. Renal failure, liver failure, and sepsis are the common causes of noninsulin-mediated hypoglycemia in hospitalized patients. Mesenchymal or epithelial tumors may cause hypoglycemia through production of an insulin-like growth factor such as IGF-II.

- Insulin-mediated causes of hypoglycemia include insulinoma, exogenous insulin use, sulfonylurea use, and autoimmune hypoglycemia.
- Noninsulin-mediated causes of hypoglycemia include alcohol use, cortisol deficiency, childhood GH deficiency, renal failure, liver failure, sepsis, and tumors secreting IGF-II.

Clinical Features

Hypoglycemia may result in hyperadrenergic and neuroglycopenic symptoms. Hyperadrenergic symptoms include palpitations, sweating, tremor, and nervousness. Neuroglycopenic symptoms include confusion, inappropriate affect, blurred vision, diplopia, seizures, and loss of consciousness. Often, confusion or inappropriate affect are recognized by the patient's family or work colleagues. Symptoms are relieved promptly after oral nutrient intake. Patients with fasting hypoglycemia often learn to reduce symptoms by increasing the frequency of their meals; they may gain weight.

- Hypoglycemia may cause symptoms related to activation of the sympathoadrenal system and neuroglycopenia.

Diagnosis

The first essential step in the evaluation of a patient with a history suggestive of hypoglycemia is to document a low level of plasma glucose (<50 mg/dL) in the presence of symptoms and the prompt resolution of symptoms when the plasma glucose level is increased to the normal range (the Whipple triad). This can be achieved during a spontaneous episode or after provocation of symptoms by fasting. Capillary blood glucose monitoring devices are inaccurate and unreliable when used to record low blood glucose levels and should not be used to confirm hypoglycemia or the Whipple triad.

After hypoglycemia has been confirmed, the next step is to establish its mechanism (insulin-mediated vs. noninsulin-mediated). This is achieved by simultaneously measuring the beta-cell polypeptides, insulin, and C peptide during a hypoglycemic episode (spontaneous or provoked). In insulin-mediated hypoglycemia, insulin levels do not suppress appropriately (insulin = 6 mU/mL). In patients with hyperinsulinemia, C peptide is measured to determine whether the source of insulin is endogenous or exogenous. Endogenous insulin is secreted from the pancreas with equimolar concentrations of C peptide, whereas exogenous insulin does not contain C peptide. Thus, C peptide is not suppressed (C peptide = 200 pmol/L) in endogenous hyperinsulinemia and is undetectable in exogenous hyperinsulinemia. It is essential to measure plasma sulfonylurea levels when the person is hypoglycemic because beta-cell polypeptide levels in a patient taking sulfonylureas are indistinguishable from those associated with insulinoma. The use of sulfonylureas is not always surreptitious: it may also be the result of pharmacy error or the patient mixing up his or her medications with those belonging to a family member.

- It is essential to document the Whipple triad in all patients with suspected hypoglycemic disorder: low plasma glucose at the time of symptoms and prompt resolution of symptoms following normalization of plasma glucose level.
- Capillary blood glucose monitors should not be used to confirm hypoglycemia or the Whipple triad.
- Plasma insulin levels should be measured to determine the mechanism of hypoglycemia: insulin is not appropriately suppressed in insulin-mediated causes of hypoglycemia.
- C-peptide levels distinguish between exogenous and endogenous insulin: if the patient is injecting insulin, C-peptide levels are undetectable.
- Endogenous hyperinsulinemic hypoglycemia caused by insulinoma is indistinguishable from sulfonylurea use: plasma sulfonylurea levels should be measured in all cases of insulin-mediated hypoglycemia (while the patient is hypoglycemic).

Insulinoma

The diagnosis of insulinoma is confirmed with the demonstration of endogenous hyperinsulinemic hypoglycemia in the absence of

detectable sulfonylurea in the blood. Diagnostic criteria for insulinoma include plasma concentration of insulin 6 mU/mL or greater (radioimmunoassay) and C peptide of 200 pmol/L or greater when the plasma glucose level is less than 50 mg/dL. The next step in the evaluation is an attempt at preoperative localization of the insulinoma with ultrasonography and spiral CT of the pancreas. This is not always successful because ultrasonography and CT have a detection rate for insulinoma of only 60%. The key to successful removal of an insulinoma in patients with both positive and negative preoperative localization studies is surgical exploration of the pancreas by an experienced surgeon in combination with intraoperative ultrasonography. Almost all insulinomas can be identified and excised in this manner. Patients with insulinoma who refuse surgical excision or who have persistent or recurrent malignant insulinoma may be treated with diazoxide, which inhibits insulin secretion.

- Diagnostic criteria for insulinoma are plasma insulin ≥6 mU/mL and C peptide ≥200 pmol/L when plasma glucose is <50 mg/dL and plasma sulfonylurea is undetectable.
- Preoperative abdominal ultrasonography and spiral CT of the pancreas localize approximately 60% of insulinomas.
- Intraoperative ultrasonography of the pancreas is a useful localization tool.

Postprandial Hypoglycemia

Postprandial hypoglycemia is defined as symptomatic hypoglycemia occurring 1 to 5 hours after a meal. It can occur in patients who have had gastrectomy or who have rapid gastric emptying of unknown cause. The mechanism is believed to be due to the rapid entry of glucose into the small bowel, causing a rapid increase in the plasma level of glucose and dramatic secretion of insulin. So-called reactive hypoglycemia is most likely not a true clinical entity. This disorder has been diagnosed in many patients on the basis of the results of an oral glucose tolerance test. However, this test is not reliable: normal subjects may demonstrate low plasma levels of glucose after an oral glucose load and remain asymptomatic, symptomatic patients often do not have associated low plasma levels of glucose, and patients who have "hypoglycemia" after oral glucose frequently have normal glucose levels after a mixed meal test.

- The oral glucose tolerance test is not useful in the evaluation and diagnosis of postprandial hypoglycemia.

Therapy

Treatment is directed at the hypoglycemia and underlying cause. For patients unable to eat or drink, 1 mg of glucagon can be administered subcutaneously or intramuscularly to stimulate endogenous glucose production. Alternatively, in the appropriate setting, 25 to 50 mL of 50% dextrose may be given intravenously and repeated in 15 minutes if necessary, although this may be associated with superficial phlebitis and pain.

- Glucagon injected subcutaneously or intramuscularly may be used to treat hypoglycemia if the oral route is not available.

Multiple Endocrine Neoplasia

MEN 1

MEN 1 is a syndrome characterized by neoplasms of the parathyroid, endocrine pancreas, and anterior pituitary. It is familial and inherited as an autosomal dominant trait with high penetrance. The gene for MEN 1 belongs to the family of tumor suppressor genes and is located on chromosome 11.

Primary Hyperparathyroidism

Primary hyperparathyroidism is the most common manifestation of MEN 1, exhibiting almost 100% penetrance by middle age. Parathyroid hyperplasia is usually the underlying cause. The differential diagnosis includes familial hyperparathyroidism (positive family history with no other features of MEN 1) and familial hypocalciuric hypercalcemia. Treatment requires removal of most parathyroid tissue. Half of one gland may be left in situ or transplanted to the forearm to facilitate reexploration if hypercalcemia recurs.

Islet Cell Neoplasia

Islet cell neoplasia is the second most common neoplasm in MEN 1. Tumors may secrete pancreatic polypeptide (75%-85% of tumors), gastrin (60%), insulin (25%-35%), vasoactive intestinal peptide (VIP) (3%-5%), glucagon (5%-10%), and somatostatin (1%-5%). Islet cell tumors may also secrete other peptide hormones, including ACTH, CRH, and GHRH. One-third of these tumors are malignant and many are metastatic by the time of diagnosis. Malignant islet cell tumors are the leading cause of death in patients with MEN 1. Diagnosis depends on the clinical recognition and appropriate investigation of the characteristic syndromes.

Pituitary Tumors

More than 10% to 50% of patients with MEN 1 have pituitary tumors. The most common tumor is a prolactinoma. Acromegaly in MEN 1 may be due to a pituitary tumor that secretes GH or to ectopic secretion of GHRH. Similarly, Cushing syndrome in MEN 1 may be caused by an ACTH-secreting pituitary tumor or ectopic secretion of ACTH or CRH.

Other Manifestations of MEN 1

Other manifestations of MEN 1 include carcinoid tumors (secretion of serotonin, calcitonin, or CRH), thyroid or adrenal adenomas, and subcutaneous or visceral lipomas.

Screening for MEN 1

Family screening is best undertaken with use of genetic screening if the causative mutation can be identified in the proband. Alternatively, measurement of serum calcium and PTH will identify hyperparathyroidism, the most likely initial presenting feature of MEN 1. Laboratory evaluation or imaging studies (or both) for pancreatic or pituitary tumors may be indicated in the presence of relevant symptoms. Currently, there is only scanty evidence that aggressive screening decreases the morbidity and mortality of MEN 1.

MEN 2

MEN 2 is subdivided into MEN 2A (medullary carcinoma of the thyroid [MTC], pheochromocytoma, and primary hyperparathyroidism) and MEN 2B (MTC, pheochromocytoma, mucosal neuromas, and marfanoid habitus). These two familial syndromes are inherited in an autosomal dominant pattern with a high degree of penetrance.

MEN 2A

MTC is the most common manifestation (>90% of cases) and is preceded by C-cell hyperplasia. Pheochromocytomas occur in about 50% of patients, and one-half are bilateral. These tumors have an increased incidence of malignancy (20%-40%). Hyperparathyroidism develops in 15% to 20% of patients.

MEN 2B

MEN 2B, unlike MEN 2A, is characterized by the absence of hyperparathyroidism and the presence of mucosal neuromas. The MTC of MEN 2B develops earlier in life and is more aggressive. Hypercalcemia may indicate bone metastases. Mucosal neuromas are the most distinctive feature of MEN 2B and may occur on the tongue, eyelids, or lips and along the gastrointestinal tract. Intestinal neuromas may cause intermittent obstruction or diarrhea.

Genetics of MEN 2

MEN 2 is caused by mutations in the *RET* proto-oncogene, which is present in 95% to 98% of affected persons. Screening for *RET* mutations allows early identification of patients at risk of MTC. This should be undertaken as early as possible in childhood. The presence of an *RET* mutation in a family member of a proband with MEN 2 is an indication for thyroidectomy.

Endocrinology Pharmacy Review

Lisa K. Buss, PharmD

Drug	Toxic/adverse effects	Drug interactions
Hypoglycemic agents		
Insulin	Hypoglycemia, localized reaction at injection site	See following table
Sulfonylureas Glipizide Glyburide Glimepiride	Hypoglycemia, GI effects (nausea, diarrhea), dermatologic effects (pruritus, erythema, urticaria, photosensitivity)	See following table
Biguanides Metformin	GI effects (diarrhea, nausea, vomiting, abdominal cramping, flatulence), metallic/abnormal taste, lactic acidosis, decreased vitamin B_{12} levels	Cimetidine, ethanol, iodinated contrast media, cationic drugs (amiloride, digoxin, morphine, quinine, procainamide, quinidine, ranitidine, vancomycin, trimethoprim)
α-Glucosidase inhibitors Acarbose Miglitol	Flatulence, abdominal bloating & pain, diarrhea	Digoxin, sulfonylurea, digestive enzymes, intestinal absorbents
Thiazolidinediones Pioglitazone Rosiglitazone	Myalgias, respiratory effects (URI, pharyngitis, sinusitis), headache, edema	Oral contraceptives
Repaglinide	Hypoglycemia, GI effects (nausea, diarrhea), musculoskeletal effects (arthralgia, back pain), respiratory effects (URI, sinusitis), headache	See following table
Nateglinide	Respiratory effects (URI, flu-like symptoms), back pain, dizziness	None reported
Pramlintide	Nausea, vomiting, abdominal pain, anorexia, headache, hypoglycemia	Avoid with medications that alter GI motility (e.g., anticholinergics), administer oral medications 1 h before or 2 h after pramlintide
Osteoporosis		
Calcium	Constipation	Decreased calcium absorption with iron, fiber laxatives, fluoride, quinolones, phenytoin, tetracyclines
Vitamin D	None unless dose exceeds physiologic requirements	Decreased vitamin D absorption with mineral oil and cholestyramine
Calcitonin—salmon	Nasal symptoms (irritation, redness, sores), taste disorders, rhinitis	
Bisphosphonates Alendronate Ibandronate Risedronate	Nausea, diarrhea, abdominal pain, esophagitis, constipation	Antacids, calcium, salicylates (increased risk of GI effects)
Raloxifene	Hot flashes, GI effects (nausea, dyspepsia), respiratory effects (sinusitis, pharyngitis, flu-like symptoms), musculoskeletal effects (arthralgia, myalgia), weight gain, depression, insomnia	Cholestyramine, warfarin, estrogen
Teriparatide	Arthralgia, asthenia, leg cramps, constipation, diarrhea, dizziness, syncope, increased cough, rhinitis, nausea, hyperuricemia, hypercalcemia	None identified

Drug	Toxic/adverse effects	Drug interactions
Thyroid agents		
Thyroid replacement	Unusual if dose is appropriate	Antacids, iron, colestipol, antidiabetic agents, cholestyramine, oral anticoagulants
Levothyroxine	If overdosed, weight loss, increased appetite, palpitations, tachycardia, increased pulse rate & blood pressure may result	
Liothyronine		
Liotrix		
Thyroid, desiccated		
Antithyroid agents	Dermatologic effects (pruritus, rash, arthralgia), GI effects (nausea, vomiting), loss of taste, headache	Warfarin
Methimazole		
Propylthiouracil		
Male reproductive drugs		
Androgenic agents	Females: amenorrhea or oligomenorrhea, virilism	Anticoagulants, tricyclic antidepressants
Danazol		
Fluoxymesterone	Males: gynecomastia, changes in libido, headache, depression, sleep apnea, acne, hirsutism, male pattern baldness	
Methyltestosterone		
Testosterone		
Erectile dysfunction agents		
Sildenafil	Headache, flushing, dyspepsia, dizziness, priapism	Nitrates, α_1-adrenergic blockers, erythromycin, antifungals, protease inhibitors
Tadalafil		
Vardenafil		
Papaverine	Priapism, penile fibrosis, pain at injection site	
Phentolamine		
Alprostadil	Penile pain, penile fibrosis, priaprism, warmth/burning in urethra	None identified
Contraception	Thrombosis, hypertension, increased risk of cervical cancer	Antibiotics, anticoagulants, anticonvulsants, antifungals, corticosteroids, tricyclic antidepressants
Estrogens	Estrogen-related: nausea, bloating, migraine headache, breast tenderness, edema, cervical discharge, melasma	
Ethinyl estradiol		
Mestranol		
Progestins	Progestin-related: increased appetite, weight gain, fatigue, acne, hair loss, hirsutism, depression, breast regression, hypomenorrhea	
Ethynodiol diacetate		
Desogestrel		
Gestodene		
Levonorgestrel		
Norethindrone		
Norethindrone acetate		
Norgestimate		
Norgestrel		
Norelgestromin		
Etonogestrel		
Drospirenone		

Endocrinology Pharmacy Review (continued)

Drug	Toxic/adverse effects	Drug interactions
Hormone replacement therapy	Breast tenderness, breast enlargement, increased risk of ovarian cancer, possible increased risk of breast cancer	No significant interactions have been reported
Estrogens	Estrogen-related: breakthrough bleeding, spotting, thromboembolism, increased risk of endometrial cancer if estrogen therapy is unopposed, increased risk of gallbladder disease	
Conjugated estrogens		
Esterified estrogens		
Estradiol		
Estropipate		
Progestins	Progestin-related: menstrual periods may resume, breast tumors, abdominal cramping	
Medroxyprogesterone		
Micronized progesterone		
Antihyperlipidemic agents		
Bile acid sequestrants		
Cholestyramine	GI effects (bloating, constipation, flatulence)	Administer at least 4 h before or 2 h after other drugs
Colestipol	Same as above	Same as above
Colesevelam	Dyspepsia, constipation	
HMG-CoA reductase inhibitors		
Lovastatin	Headache, myalgia, increased liver enzymes, diarrhea, rhabdomyolysis	CYP3A4 inhibitors,* fibrates
Pravastatin	Same as lovastatin	Cholestyramine, colestipol, fibrates, cyclosporine
Simvastatin	Same as lovastatin	Same as lovastatin
Atorvastatin	Same as lovastatin	Same as lovastatin
Fluvastatin	Same as lovastatin	Potent CYP2C9 inhibitor, warfarin
Fibric acid derivatives		
Gemfibrozil	Dyspepsia, diarrhea, myopathy, hepatotoxicity, cholelithiasis	Warfarin, statins, sulfonylureas
Fenofibrate		
Nicotinic acid	GI distress, skin flushing, tingling & warmth, headache, hypotension, hyperglycemia, hyperuricemia, hepatotoxicity (>2 g/d, increased risk with extended-release form)	Statins, colestipol, cholestyramine
Immediate-release		
Extended-release		
Selective cholesterol absorption inhibitor		
Ezetimibe	Diarrhea, arthralgia, abdominal pain, headache, fatigue	Cyclosporine, fibric acid derivatives

GI, gastrointestinal tract; URI, upper respiratory tract infection.
*CYP3A4 inhibitors include azole antifungals, macrolide antibiotics, diltiazem, verapamil, cyclosporine, nefazodone, fluvoxamine, ritonavir, nelfinavir, indinavir, and grapefruit juice.

Esophagus

Esophageal Function

The upper esophageal sphincter (or cricopharyngeal muscle) and the muscle of the proximal one-third of the esophagus are striated muscle under voluntary control. A transition from skeletal to smooth muscle occurs in the midesophagus. In the distal one-third of the esophagus, the muscle is smooth muscle that is under involuntary control. The lower esophageal sphincter is a zone of circular muscle located in the distal 2 to 3 cm of the esophagus. To transport food from the mouth through the negative pressure of the chest into the positive pressure of the abdomen, the esophagus must transport food against a pressure gradient. To prevent reflux of gastric contents, the lower esophagus has a sphincter for unidirectional flow. Normal esophageal motility accomplishes both transport of food and prevention of reflux.

- The esophagus must transport food against a pressure gradient and prevent reflux of gastric contents.

Normal Motility

After a person swallows, the upper esophageal sphincter relaxes within 0.5 second. A primary peristaltic wave then passes through the body of the esophagus at a rate of 1 to 5 cm/s, generating an intraluminal pressure of 40 to 100 mm Hg. Within 2 seconds after the swallow, the lower esophageal sphincter relaxes and stays relaxed until the wave of peristalsis passes through it. Next, the lower esophageal sphincter contracts again to maintain its resting tone. Two major symptom complexes result if the esophagus is unable to perform its two major functions: dysphagia (transport dysfunction) and reflux (lower esophageal sphincter dysfunction).

- Dysphagia: transport dysfunction.
- Reflux: lower esophageal sphincter dysfunction.

Dysphagia

Dysphagia is the defective transport of food and is usually described as "sticking." Odynophagia is pain on swallowing. The three causes of dysphagia must be distinguished: mechanical (obstructed lumen), functional (motility disorder), and oropharyngeal (faulty transfer of a food bolus to the esophagus). Answers to three questions frequently suggest the diagnosis (Fig. 7-1): 1) What type of food produces the dysphagia? 2) What is the course of the dysphagia? 3) Is there heartburn? Dysphagia with an intermittent course is caused by a ring, a web, or a motility disorder.

- Mechanical dysphagia must be distinguished from functional dysphagia.
- Intermittent dysphagia is caused by a ring, a web, or a motility disorder.

Mechanical Cause

Mechanical obstruction occurs if the lumen diameter is less than 12 mm. The course is progressive, dysphagia with solids is greater than with liquids, and there is associated weight loss.

- Mechanical obstruction: progressive course, weight loss, and dysphagia with solids is greater than with liquids.

Peptic stricture results from prolonged reflux and is usually a short (<2-3 cm long) narrowing in the distal esophagus.

- Peptic stricture results from prolonged reflux, usually in the distal esophagus.

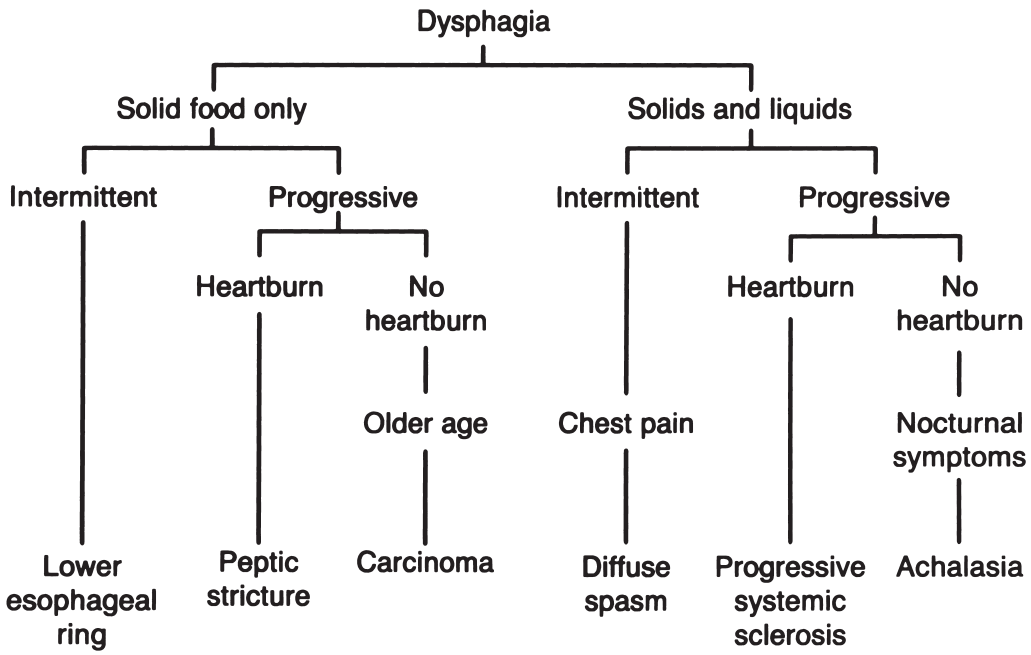

Fig. 7-1. Diagnostic scheme for dysphagia. Obtaining answers to three questions (see text) often yields the most likely diagnosis. (From MKSAP VI: part 1:44, 1982. American College of Physicians. Used with permission.)

Barrett esophagus is characterized by abnormal columnar epithelium that replaces the normal squamous mucosa in the distal esophagus. It can occur with an ulcer as a stricture in the midesophagus; it increases the risk of adenocarcinoma. Barrett esophagus is a complication of reflux and, thus, is acquired and not congenital.

- Barrett esophagus: a complication of chronic reflux, characterized by abnormal columnar epithelium in the distal esophagus; predisposes to adenocarcinoma.

Alkali is more injurious to the esophagus than acid and can produce a lye stricture (in postgastrectomy patients, alkaline reflux can produce severe esophagitis). Do not induce vomiting after the ingestion of lye. Stricture tends to occur at the three physiologic narrowings where the initial passage of the corrosive may have been delayed. Bougienage after 3 or 4 weeks may prevent occurrence of stricture. There is an increased incidence of squamous cell cancer.

- Postgastrectomy alkaline reflux can produce severe esophagitis.
- Do not induce vomiting after the ingestion of lye.
- Lye stricture is associated with an increased incidence of squamous cell cancer.

Leiomyoma is the most common benign tumor. It is usually asymptomatic. Radiographically, a leiomyoma appears as a smooth filling defect with normal mucosa. It arises from the esophagus at a 90° angle, and its border is distinct from the esophageal wall. Perform endoscopy even if classic changes are seen on barium swallow.

The conditions that predispose to esophageal squamous cell carcinoma include achalasia, lye stricture, Plummer-Vinson syndrome, human papillomavirus, tylosis, smoking, and alcohol. In the United States, 20% of malignant tumors are squamous cell carcinoma and 80% are adenocarcinoma. Progressive dysphagia with weight loss is typical. The diagnosis is established by endoscopy with biopsy and cytology. The 5-year survival rate is only 7% to 15%; 28% of patients have lung metastases, and 25% have liver metastases. The prognosis is poor in the United States because of late detection of the tumor. In China, the prognosis is excellent because of screening programs and early detection.

Squamous cell carcinoma is more radiosensitive than adenocarcinoma. Surgery is difficult for proximal lesions. Surgery and preoperative irradiation are used for lesions in the distal one-third of the esophagus. Palliation strategies include laser endoscopy, bougienage, and stent placement. No chemotherapeutic agents are known to be beneficial. Squamous cell carcinoma can produce ectopic parathyroid hormone; therefore, hypercalcemia does not mean the tumor is unresectable.

- Conditions that predispose to esophageal squamous cell cancer: achalasia, lye stricture, Plummer-Vinson syndrome, human papillomavirus, tylosis, smoking, and alcohol. Barrett esophagus predisposes to adenocarcinoma.
- Esophageal malignancies are usually unresectable; palliative treatment.
- The 5-year survival of U.S. patients is only 7%-15%.

A lower esophageal ring (Schatzki ring) is a mucosal membrane that marks the junction of the esophageal and gastric mucosa. Muscular rings are rare. Patients present with intermittent dysphagia with solids or with a sudden obstruction from a food bolus ("steak house

syndrome"). On radiographs, a lower esophageal ring is a thin annulus at the junction of the esophagogastric mucosa. Treatment is dilatation.

- Esophageal ring: intermittent dysphagia and food bolus impaction.
- Treatment is dilatation.

A web is a membrane of squamous mucosa that occurs anywhere in the esophagus. Patients present with intermittent dysphagia. Plummer-Vinson syndrome is a cervical esophageal web and iron deficiency anemia. It is associated with a 15% chance of oropharyngeal or esophageal squamous cell cancer.

- Esophageal web: intermittent dysphagia.
- Plummer-Vinson syndrome: cervical esophageal web and iron deficiency anemia, with a 15% chance of oropharyngeal or esophageal squamous cell cancer.

Functional Cause

Functional obstruction (motility disorders) is characterized by dysphagia with solids and liquids and an intermittent course; weight loss may or may not occur. The three important motor abnormalities of the esophagus are achalasia, diffuse esophageal spasm, and scleroderma.

- Functional obstruction: intermittent dysphagia with solids and liquids, with or without weight loss.

Achalasia results from esophageal denervation, specifically the degeneration of Auerbach ganglion cells. Chest radiography shows an air-fluid level. Barium swallow fluoroscopy shows a dilated esophagus with a beak-like tapering. The motility pattern is characterized by incomplete relaxation of the lower esophageal sphincter, hypertensive lower esophageal sphincter (usually does not have reflux), and aperistalsis in the body (most important). Patients with achalasia should be examined endoscopically because cancer of the esophagogastric junction may have the radiographic appearance and motility pattern of achalasia (pseudoachalasia). A clue would be an older patient with dysphagia and heartburn. This is detected by endoscopy. Treatment is pneumatic dilatation rather than bougienage. Pneumatic dilatation is as effective as Heller myotomy. Botulinum toxin blocks the release of acetylcholine from presynaptic cholinergic neurons and decreases lower esophageal pressure for 3 to 12 months. Botulinum toxin provides short-term relief of symptoms, is safe, and has few side effects. Currently, it is given to elderly patients and to patients who have a high surgical risk.

In Brazil, the parasite *Trypanosoma cruzi* (Chagas disease) produces a neurotoxin that destroys the myenteric plexus. Esophageal dilatation identical to that of achalasia, megacolon, and megaureter occurs in Chagas disease.

- Achalasia: a chest radiograph shows air-fluid level.
- Dilated esophagus with beak-like tapering on barium swallow fluoroscopy.
- Most important motility pattern in achalasia: aperistalsis.
- Endoscopically examine patients who have achalasia.
- Treat achalasia with pneumatic dilatation and not with bougienage.
- Chagas disease has esophageal dysfunction identical to that of achalasia.

Patients with diffuse esophageal spasm usually present with chest pain but may have intermittent dysphagia, which is aggravated by stress and hot or cold liquids. Barium swallow fluoroscopy demonstrates a corkscrew esophagus. Motility studies demonstrate simultaneous contractions of high amplitude in the body of the esophagus. If the patient is asymptomatic during the test, motility may be normal. The lower esophageal sphincter is hypertensive or has defective relaxation in one-third of patients. Medical treatment (nitrates, anticholinergic agents, and nifedipine) has unpredictable results. Surgical treatment is long myotomy.

- Diffuse esophageal spasm usually causes chest pain.
- It is aggravated by stress and hot or cold liquids.
- Barium swallow fluoroscopy shows a corkscrew esophagus.
- Medical treatment has unpredictable results.

Esophageal involvement with scleroderma is associated with Raynaud phenomenon. Barium swallow fluoroscopy shows a common esophagogastric tube. Aperistalsis in the body of the esophagus and incompetence of the lower esophageal sphincter, which causes severe reflux, is demonstrated with motility studies.

- Scleroderma: Raynaud phenomenon, aperistalsis, and reflux.

Oropharyngeal Dysphagia

Oropharyngeal dysphagia is the result of faulty transfer of a food bolus from the oropharynx to the esophagus caused by structural abnormalities or disorders of either neural regulation or skeletal muscle (Table 7-1). Patients with oropharyngeal dysphagia present with high esophageal dysphagia associated with coughing, choking, or nasal regurgitation. After the presence of oropharyngeal dysphagia is recognized, other associated symptoms may lead to the diagnosis of the underlying illness (e.g., a young person with oropharyngeal dysphagia, central scotoma, and neurologic symptoms has multiple sclerosis).

- Oropharyngeal dysphagia is the result of faulty transfer of a food bolus from the oropharynx to the esophagus caused by structural or neuromuscular disorders.
- Patients present with cervical esophageal dysphagia associated with coughing, choking, or nasal regurgitation.

Gastroesophageal Reflux Disease

Reflux

The lower esophageal sphincter is the major barrier to reflux. This sphincter is a 2- to 4-cm–long specialized segment of circular smooth muscle in the terminal esophagus. The pressure of this sphincter varies markedly during the day, but the normal resting pressure is

Table 7-1 Causes of Oropharyngeal Dysphagia

Muscular disorders	Neurologic disorders	Structural causes
Amyloidosis	Amyotrophic lateral sclerosis	Cervical osteophytes
Dermatomyositis	Cerebrovascular accident	Cricopharyngeal dysfunction
Hyperthyroidism	Diphtheria	Goiter
Hypothyroidism	Huntington disease	Lymphadenopathy
Myasthenia gravis	Multiple sclerosis	Zenker diverticulum
Myotonia dystrophica	Parkinson disease	
Oculopharyngeal myopathy	Polio	
Stiff-man syndrome	Tabes dorsalis	
	Tetanus	

15 to 30 mm Hg. Swallowing causes the pressure to decrease promptly (within 1-2 seconds after the onset of swallowing) and for the sphincter to remain relaxed until the peristaltic wave passes over it. The sphincter then contracts to maintain the increased resting pressure that prevents reflux. The pressure of the lower esophageal sphincter decreases markedly for 2 hours after a meal. Transient relaxations of the lower esophageal sphincter cause some gastroesophageal reflux to occur in everyone during the day but do not cause symptoms or esophagitis. Patients with clinically symptomatic reflux or inflammation show more frequent transient lower esophageal sphincter relaxations of unknown cause and have more frequent and longer lasting episodes of reflux.

- Lower esophageal sphincter pressure decreases for 2 hours after a meal.
- Patients with clinically symptomatic reflux show relatively frequent, transient lower esophageal sphincter relaxations.

The degree of tissue damage is the real concern in gastroesophageal reflux disease (GERD). Factors that determine whether reflux esophagitis occurs include the frequency of transient relaxations of the lower esophageal sphincter, the volume of gastric contents, the rate of gastric emptying (if delayed, reflux may develop), the potency of the refluxate (acid, pepsin, and bile), the efficiency of esophageal clearance (motility and salivary bicarbonate), and the resistance of esophageal tissue to injury and ability to repair.

The evaluation of esophagitis is designed to answer four important questions (Table 7-2): 1) Does the patient have reflux and, if so, how severe? 2) Does the patient have esophagitis and, if so, to what extent? 3) Are the patient's symptoms due to reflux? 4) What is the mechanism of reflux?

For most patients, the medical history is sufficiently typical to warrant a trial of therapy without expensive tests being conducted. Testing should be performed in patients who have an atypical medical history, refractory symptoms, long-standing reflux, dysphagia, iron deficiency anemia, weight loss, or possible complications of esophagitis. Test elderly patients who have onset of reflux.

Atypical symptoms of GERD include noncardiac chest pain, asthma, chronic cough, and hoarseness. Reflux is the most common cause of noncardiac chest pain. Asthmatic patients with coexisting reflux should receive treatment for reflux because it may improve control of respiratory symptoms. Reflux should be considered in asthmatic patients who have postprandial or nocturnal wheezing. Complications of reflux include ulceration, bleeding, stricture, aspiration, Barrett esophagus, and adenocarcinoma of the esophagus.

- For most patients, the medical history is sufficiently typical to warrant a trial of therapy without tests.
- Testing should be performed in patients who have an atypical medical history, refractory symptoms, long-standing reflux, dysphagia, iron deficiency anemia, weight loss, or possible complications of esophagitis. Test elderly patients who have onset of reflux.
- Atypical symptoms of GERD: noncardiac chest pain, asthma, chronic cough, and hoarseness.
- Complications of gastroesophageal reflux: ulceration, bleeding, stricture, aspiration, Barrett esophagus, and adenocarcinoma of the esophagus.

Barrett Esophagus

Barrett esophagus is a complication of chronic gastroesophageal reflux in which the normal esophageal squamous mucosa is replaced by columnar epithelium. Patients with Barrett esophagus are at increased risk of adenocarcinoma developing in this columnar epithelium. Patients with Barrett esophagus should have aggressive

Table 7-2 Evaluation of Esophagitis

Question	Tests for reflux (the more sensitive one is listed first)
Is reflux present?	pH probe, isotope scan
Is esophagitis present?	Biopsy, endoscopy
Are symptoms due to reflux?	Acid perfusion (Bernstein test)
What is the mechanism of reflux?	Motility

antireflux treatment. Although the matter is controversial, most experts recommend a screening endoscopy in high-risk patients (older than 50 years, Caucasian, and male) with chronic reflux for more than 5 to 7 years. If the mucosal characteristics are seen endoscopically, biopsies are needed to confirm the diagnosis as well as to look for dysplasia. There is some debate on surveillance frequency after the diagnosis is made, but in general, after dysplasia has been excluded on two endoscopies 1 year apart, the screening interval can be increased to every 3 years. If low-grade dysplasia is identified at any time, the screening frequency should be increased to every year. If high-grade dysplasia is identified (and confirmed by two pathologists), the patient should be referred for an esophagectomy. Photodynamic therapy could also be considered for these patients who are not surgical candidates.

- Esophagogastroduodenoscopy should be performed to screen for Barrett esophagus in high-risk patients (older than 50 years, Caucasian, and male) with chronic reflux for more than 5-7 years.

Tests for Reflux

During barium swallow fluoroscopy, reflux of barium occurs in 60% of patients with esophagitis but also in 25% of control subjects. It is a qualitative test and does not distinguish between "normal" and abnormal reflux. Upper gastrointestinal radiography is used primarily as a screening test to exclude other diagnoses (e.g., ulcer) and to identify complications of reflux (e.g., strictures, ulcers, and cancer or mass). Radiography may not detect Barrett esophagus.

- Reflux of barium is found in 60% of patients with esophagitis but also in 25% of control subjects.

Esophagoscopy is the definitive test if gross inflammation is present. However, 40% of patients may have symptomatic reflux with no gross inflammation. This is the preferred first test for long-standing cases of reflux to rule out Barrett esophagus. It is also the first test for patients with reflux without dysphagia.

- Esophagoscopy is the test preferred first for long-standing cases of reflux to rule out Barrett esophagus.
- It is the first test for patients with reflux without dysphagia.

Esophageal biopsy findings in patients with reflux but without gross esophagitis include elongation of the basal cell layer and papillae. Esophagoscopy and distal esophageal biopsies are about 60% sensitive for detecting reflux. Eosinophilia in the biopsy specimen is 100% sensitive for the diagnosis of esophagitis. If Barrett esophagus is found, biopsy specimens should be obtained from along the length of Barrett epithelium as surveillance for dysplasia (premalignant changes) or malignancy.

- Biopsy may detect esophagitis when gross inflammation is not present.
- With Barrett esophagus, it is important to obtain biopsy specimens from along the length of the mucosa as surveillance for dysplasia (premalignant changes) or malignancy.

Monitoring of the pH in the distal esophagus of patients during a 24-hour period of normal routine allows a more physiologic evaluation of reflux during daily activities. This test is valuable for patients with atypical symptoms, reflux symptoms refractory to therapy, a nondiagnostic evaluation, or pulmonary symptoms.

- With 24-hour pH monitoring, a more physiologic evaluation of reflux during daily activities is possible.
- This test is valuable for patients with atypical symptoms.

The acid perfusion test (Bernstein test) involves saline perfusion for 10 minutes, which should not cause symptoms; next, switch to 0.1N HCl to determine whether the pain is reproduced. If heartburn and chest pain occur with acid instillation, treat for reflux.

- If heartburn and chest pain are reproduced with acid instillation, treat for reflux.

Esophageal manometry is reserved for patients with suspected esophageal motility disorders or for preoperative evaluation of surgical candidates.

- Esophageal manometry is reserved for suspected esophageal motility disorders.

Treatment of Reflux

The treatment of GERD is divided into three phases:

Phase 1 therapy includes lifestyle modifications. The patient should elevate the head of the bed 6 inches, modify the diet so it contains less fat and more protein, eat three meals a day, not eat for 3 hours before reclining, lose weight if overweight, and avoid specific foods (fatty foods, chocolate, alcohol, citrus juices, tomato products, coffee, and carminatives). The patient should stop smoking and avoid alcohol. Avoid drugs that decrease lower esophageal sphincter pressure: anticholinergic agents, sedatives, tranquilizers, theophylline, progesterone or progesterone-containing birth control pills, nitrates, β-adrenergic agonists, and calcium channel blockers. Therapy is with antacids or alginic acid 30 minutes after meals and at bedtime.

Phase 2 therapy includes drugs that decrease gastric acid output. All histamine (H_2) receptor antagonists are equally effective, and a twice-daily dose is preferable for treating gastroesophageal reflux. Proton pump inhibitors (e.g., omeprazole) are the most effective agents to relieve symptoms and to promote mucosal healing. It is best to treat gross esophagitis for 6 weeks. Long-term use of these agents is safe. Drugs that increase lower esophageal sphincter pressure and esophageal clearance, metoclopramide and bethanechol, have a limited role in treating reflux and often cause side effects.

Phase 3 therapy includes antireflux surgery, which is reserved for younger patients who want to avoid lifelong medical treatment and for patients who have reflux that is refractory to medical therapy or who develop complications. Nissen fundoplication is the preferred operation; fundoplication increases lower esophageal sphincter pressure. Although a new endoscopic suturing procedure has been developed, its long-term results are not available.

- Phase 1 therapy: modify lifestyle, avoid drugs that decrease lower esophageal sphincter pressure, and use antacids as the first line of treatment.
- Phase 2 therapy: H_2-blockers or omeprazole.
- Phase 3 therapy: antireflux surgery is reserved for younger patients who want to avoid lifelong medical treatment and for patients who have reflux that is refractory to medical therapy or who develop complications.

Noncardiac Chest Pain

Chest pain is a frightening symptom, and patients are often referred to internists and gastroenterologists when the findings of a cardiac evaluation are negative for cardiac disease. Internists must understand the limitations of the diagnostic studies used to evaluate noncardiac chest pain. First, important cardiac disease must be ruled out. GERD is the most common cause of noncardiac chest pain, but esophageal pain may be due to a motor disorder (e.g., spasm) or esophageal inflammation (e.g., infection or injury). Esophageal spasm can closely mimic angina. Esophagogastroduodenoscopy rules out mucosal disease, that is, inflammation, neoplasms, and chemical injury. An esophageal motility study is performed to look for motor disorders (e.g., esophageal spasm and "nutcracker esophagus"), and 24-hour pH monitoring can be used to document the presence of reflux and its correlation with episodes of chest pain. Therapy for noncardiac chest pain includes avoidance of precipitants. Antacids, H_2 receptor antagonists, and proton pump inhibitors may be beneficial for patients with reflux. Sublingual nitroglycerin or calcium channel blockers are sometimes helpful in motor disorders, but their efficacy is unproven. If appropriate, reassure the patient that cardiac disease is not present.

- For noncardiac chest pain, rule out important cardiac disease.
- GERD is the commonest cause of noncardiac chest pain.
- Esophageal spasm can closely mimic angina.
- Esophagogastroduodenoscopy detects mucosal disease.
- Motility studies detect motility disorders.
- Use of 24-hour pH monitoring documents episodic reflux and correlation with symptoms.
- Sublingual nitroglycerin or calcium channel blockers are sometimes helpful.

Infections of the Esophagus

Patients with immunodeficiency disorders (acquired immunodeficiency syndrome [AIDS]), diabetes mellitus, malignancies (especially lymphoma and leukemia), or esophageal motility disorders are susceptible to opportunistic infections of the esophagus. Patients with these infections present with odynophagia. The most important infections to recognize are those caused by *Candida*, herpesvirus, or cytomegalovirus. In candidal infection, barium radiography shows small nodules in the upper one-third of the esophagus, and endoscopy shows cottage cheese–like plaques. Diagnosis is made by demonstrating pseudohyphae on potassium hydroxide preparations. Treatment is with nystatin or clotrimazole for colonization and ketoconazole or fluconazole for esophagitis. Rarely, amphotericin B is used. In herpesviral infection, barium radiography and endoscopy show small discrete ulcers without plaques. Diagnosis is based on finding intranuclear inclusions (Cowdry type A bodies) in biopsy specimens from one of the ulcer edges. Treatment is with acyclovir. In cytomegaloviral infection, radiography and endoscopy show severe inflammation with large ulcers. Intranuclear inclusions may be seen in biopsy specimens from the ulcer base, but viral cultures are unreliable. Treatment is with ganciclovir or foscarnet (if resistant to ganciclovir).

- Immunosuppressed patients with opportunistic infections present with odynophagia.

Other Esophageal Problems

Medication-Induced Esophagitis

Patients with medication-induced esophagitis present with odynophagia (or, less frequently, dysphagia). Esophagitis is more likely to occur if there is abnormal motility, stricture, or compression (left atrial enlargement). It is more common in the elderly and is recognized as inflammation in the midesophagus, with sparing of the distal esophagus. Medications commonly associated with esophagitis include tetracycline, doxycycline, quinidine, potassium supplements, bisphosphonates (alendronate and risedronate), ferrous sulfate, and ascorbic acid.

- Midesophageal inflammation is associated with abnormal motility, stricture, or compression and is more common in the elderly.
- Medicines responsible for esophagitis: tetracycline, doxycycline, quinidine, potassium supplements, bisphosphonates (alendronate and risedronate), ferrous sulfate, and ascorbic acid.

Mallory-Weiss Syndrome

Mallory-Weiss syndrome is mucosal laceration at the gastric side of the esophagogastric junction. It accounts for about 10% of cases of upper gastrointestinal tract bleeding: 75% of patients have a history of retching or vomiting before bleeding and 72% have diaphragmatic hernias. In 90% of patients, the bleeding stops spontaneously. Vasopressin, endoscopic injection, or electrocautery may control bleeding. Surgical treatment for persistent bleeding is rarely necessary. Angiography with intra-arterial infusion of vasopressin is successful in 70% of patients with continued bleeding.

- Mallory-Weiss syndrome: mucosal laceration at the esophagogastric junction.
- Accounts for about 10% of cases of upper gastrointestinal tract bleeding. Bleeding stops spontaneously in 90%.
- Among patients with Mallory-Weiss syndrome, 75% have a history of retching and vomiting before bleeding.

Esophageal Perforation

Esophageal perforation commonly occurs after dilatation in an area of stricture. Spontaneous perforation of the esophagus (Boerhaave syndrome) follows violent retching, often after an alcoholic binge. It also occurs after heavy lifting, defecation, seizures, and forceful labor (childbirth). The most common site of perforation is the left posterior

part of the distal esophagus. If pleural fluid is present, it may have an increased concentration of amylase. Zenker diverticulum, cervical osteophytes (difficult intubations), and endoscopy (intubation) are causes of perforation of the cervical esophagus.

- Esophageal perforation commonly occurs after dilatation.
- Boerhaave syndrome follows violent retching, often after an alcoholic binge.

Stomach and Duodenum

Peptic ulcers are defects in the gastric or duodenal mucosa which result from an imbalance between the digestive activity of acid and pepsin in the gastric juice and the host's protective mechanisms to resist mucosal injury. Recent advances in understanding the pathogenesis of peptic ulcer have resulted in modification of the presumption that idiopathic acid hypersecretion is a major etiologic factor. Newer classifications of peptic ulcers categorize ulcers as being associated with three possible etiologic factors: 1) *Helicobacter pylori*; 2) nonsteroidal anti-inflammatory drugs (NSAIDs), including aspirin; or 3) miscellaneous causes. Miscellaneous causes include ulcers due to hypersecretion from gastrinomas (Zollinger-Ellison syndrome), idiopathic hypersecretion, and duodenogastric reflux of gastric mucosal barrier–breaking agents such as bile salts or lysolecithin. Recent reports estimate that less than 5% of ulcers have a miscellaneous cause. Thus, at least 95% of peptic ulcers are due to either *Helicobacter pylori* or NSAIDs.

Helicobacter pylori

The Organism

H. pylori is a gram-negative, spiral-shaped microaerophilic bacillus that contains four to six unipolar, sheathed flagella. This fastidious organism resides beneath and within the mucous layer of the gastric mucosa and produces several enzymes, such as urease and mucolytic proteases, that are important for its survival and pathogenic effect. After it has been ingested, the organism moves into and through the mucous layer of the stomach. It has been postulated that several virulent factors are needed for successful colonization of the gastric mucosa, including the organism's motility, adhesins, proteases, phospholipases, cytokines, cytotoxins, and urease. Urease is thought to protect the organism from the acidic environment. After colonization, the organism multiplies in the gastric mucous layer. Defense mechanisms may help control the infection, but unless treated, the organism remains in the gastric mucous layer for life.

H. pylori causes persistent gastric infection and chronic inflammation. Ingestion of *H. pylori* can cause acute symptoms, but within weeks to months after infection, a chronic superficial gastritis develops, and after years to decades, chronic atrophic gastritis or gastric malignancy may develop.

Epidemiology

In the United States, *H. pylori* has an age-related prevalence, occurring in 10% of the general population younger than 30 and in 60% of those older than 60. *H. pylori* is present in 40% to 50% of the general population overall; it is more prevalent among blacks and Hispanics, poorer socioeconomic groups, and institutionalized persons. In developing countries such as India and Saudi Arabia, 50% of the population is infected by age 10 and 70% by age 20, and 85% to 95% of the population overall is infected. Evidence of person-to-person transmission includes clustering within families, higher than expected prevalence among institutionalized persons, transmission by endoscopy and biopsy, and a higher prevalence of infection among gastroenterologists. The fecal-oral route of transmission has been postulated, and indeed, *H. pylori* has been isolated from human feces.

Associated Diseases

Active Chronic Gastritis

H. pylori infection (type B gastritis) is found universally in patients with active chronic gastritis that is not associated with autoimmunologic mechanisms (type A gastritis—pernicious anemia) or chemical injury (alcohol, NSAIDs, and bile salts). *H. pylori*–induced active chronic gastritis is the most common type of chronic gastritis, and in some patients, it may progress to chronic atrophic gastritis. An important concept is that *H. pylori*–induced gastritis is the basic disease, and the development of duodenal or gastric ulcers or malignancy is a complication of the gastritis.

Duodenal Ulcer

H. pylori is found in 60% to 95% of patients with duodenal ulcers. The most important link between *H. pylori*–induced gastritis and the development of duodenal ulcers is the presence of gastric metaplasia in the duodenal bulb. Some data suggest that the metaplastic cells must be infected by *H. pylori* to permit the development of duodenitis or duodenal ulcer. Among *H. pylori*–positive patients with duodenal ulcer who do not receive treatment, most have disease relapse within 1 year. However, if the infection is eradicated, the rate of relapse approaches zero. *H. pylori* infection causes an increase in basal and meal-stimulated gastrin release. Asymptomatic carriers of the bacillus may have a protective mechanism that prevents the hypersecretion of gastric acid. Enhanced gastric acid secretion occurs only in ulcer patients.

Gastric Ulcer

H. pylori is found in about 80% of patients with gastric ulcer. Eradication of the bacteria decreases the relapse rate of gastric ulcers.

Gastric Tumors

Studies from the United States and Great Britain have established a strong association between *H. pylori* infection (diagnosed through serum samples) and the emergence of noncardiac gastric adenocarcinoma. It has been postulated that *H. pylori* gastritis progresses to atrophic gastritis, and, in the presence of other risk factors, gastric adenocarcinoma eventually develops. This appears to be a rare occurrence. A cause-and-effect relationship has not been established, and further studies are needed to determine the exact role of *H. pylori* in the development of gastric adenocarcinoma.

H. pylori has also been associated with MALT lymphoma of the stomach. Of 450 patients with *H. pylori*–positive gastritis, 125 (28%) had mucosal lymphoid follicles and 8 (1.8%) had B lymphocytes

infiltrating the epithelium, consistent with the development of early lymphoma. Simple eradication of the *H. pylori* infection can induce regression or even complete remission in a significant percentage of these early lymphomas.

Nonulcer Dyspepsia
Nonulcer dyspepsia is common, affecting about 20% of the U.S. population. Of those with functional dyspepsia, approximately 50% are infected with *H. pylori*, which is similar to the prevalence of *H. pylori* in asymptomatic persons. There is no convincing evidence that treatment of *H. pylori*–positive patients with nonulcer dyspepsia results in marked clinical improvement.

Diagnostic Tests for H. pylori *Infection*
Various diagnostic tests are available for determining whether *H. pylori* infection is present. The choice of which test to use is determined by the clinical setting and the cost.

Serology
H. pylori produces not only a local immune response but also a systemic immune response. Current detection methods exist for antibodies of the IgG, IgA, and IgM classes. Serologic testing is the most cost-effective, noninvasive way to diagnose primary *H. pylori* infection, but serologic results remain positive over time, which limits the usefulness of this test in follow-up evaluation. The sensitivity is 95%, the specificity is 90% to 95%, and the cost is $40 to $100.

Breath Test
A radiolabeled dose of urea is given orally to the patient. If *H. pylori* is present, the urease splits the urea and radiolabeled carbon dioxide is exhaled. The advantage of this test is that it is quick, easy to perform, and does not require endoscopy. As the breath test becomes more widely available, it will be the test of choice for follow-up evaluation. The sensitivity is 95% to 98%, the specificity is 95% to 98%, and the cost is $100 to $200.

Biopsy Urease Tests
A biopsy specimen is impregnated into agar that contains urea and a pH indicator. As the urea is split by *H. pylori*–produced urease, the pH of the medium changes the color of the agar from yellow to red. This test depends on bacterial urease: the more organisms present, the more rapidly the test becomes positive. The sensitivity is 95%, the specificity is 98%, and the cost is $20 (plus the cost of endoscopy to obtain tissue).

Stool Antigen Test
The *H. pylori* stool antigen test is simple and noninvasive and can be used to assess the success of eradication efforts. The sensitivity is 94%, and the specificity is 92%.

Histology
An advantage of histology is being able to examine the underlying inflammatory reaction. *H. pylori* can be demonstrated with the following stains: Gram, hematoxylin-eosin, Giemsa, and Warthin-Starry silver. The sensitivity is 98%, the specificity is 98%, and the cost is $250.

Culture
Culturing *H. pylori* is tedious and expensive and should be reserved for special circumstances, for example, if an antibiotic-resistant organism is suspected or if virulence testing is being done. The sensitivity is 90% to 95%, the specificity is 100%, and the cost is $150.

Currently, because many symptomatic patients undergo endoscopy, histologic examination and biopsy urease tests are used most commonly in the initial evaluation. Newer, inexpensive serologic tests that can be performed in minutes are being investigated.

Treatment
With an *H. pylori*–positive duodenal or gastric ulcer, the treatment goal is to heal the ulcer and eradicate (not suppress) the bacteria. Combination therapy with antisecretory agents and antimicrobial therapy for *H. pylori* is most effective. The two most widely used therapies are summarized in the Gastroenterology Pharmacy Review at the end of this chapter (Review of *Helicobacter pylori* Treatment Regimens). Both of these therapies are equally effective for eradication of *H. pylori* (95%) and for preventing recurrence (80%). Patients with severe symptoms should continue to receive a standard dose of proton pump inhibitor for 3 additional weeks at the end of the combination drug treatment. There is extensive research to determine the simplest and most efficacious agents for combination therapy, and specific recommendations for treatment regimens are constantly changing. The following general principles should guide treatment:

1. All patients with gastric or duodenal ulcer who are infected with *H. pylori* should receive combination therapy.
2. Patients with a well-documented ulcer who are infected with *H. pylori* but whose disease is in remission with maintenance antisecretory therapy should receive combination therapy; then maintenance antisecretory therapy will not be necessary.
3. Maintenance antisecretory therapy is unnecessary except for patients with recurrent *H. pylori*–negative ulcers and for some patients with a previous history of bleeding from an ulcer.
4. Currently, treatment is not recommended for nonulcer dyspepsia and asymptomatic *H. pylori*–infected patients.

NSAID-Induced Ulcers
NSAIDs inhibit gastroduodenal prostaglandin synthesis, which results in decreased secretion of mucus and bicarbonate and reduced mucosal blood flow. NSAID-induced ulcers occur more commonly in the stomach than in the duodenum. They are located typically in the prepyloric area or antrum of the stomach.

The risk of peptic ulcer disease with NSAIDs is dose-dependent. It is important for physicians to understand that the anti-inflammatory properties of NSAIDs predispose patients to ulceration (prostaglandin inhibition) and that there are different dose-response relationships for the analgesic and anti-inflammatory properties of NSAIDs. The maximal analgesic effect plateaus well below the effective anti-inflammatory dose. Low doses of aspirin or NSAIDs give pain relief but have little anti-inflammatory activity. The newer NSAIDs have been marketed with more convenient (less frequent) dosing intervals and in dosages that have marked anti-inflammatory activity. Thus, the use of newer NSAIDs may subject the patient to an increased risk of ulcer without providing increased analgesia.

Selective cyclooxygenase (COX)-2 inhibitors have been shown to decrease the rate of ulcer formation as well as ulcer complications such as bleeding, perforation, and pain. However, data suggest that even low-dose aspirin may reduce or eliminate any protective benefit of COX-2 drugs. In many instances, the use of NSAIDs can be discontinued and simple analgesic therapy with acetaminophen substituted. For patients who require NSAIDs, an attempt should be made to use the lowest possible dose. It also is important for physicians to know that the risk of peptic ulcer disease with NSAID use is maximal in the first month of treatment (ulcers may occur shortly after treatment is begun), and elderly patients and patients with a previous history of peptic ulcer disease are at highest risk.

The first step in the treatment of an NSAID-induced ulcer is to discontinue use of the drug. H_2-receptor antagonists and sucralfate are ineffective in preventing gastric ulcers and in decreasing the frequency of NSAID-induced mucosal erosions. Prostaglandin replacement with the synthetic prostaglandin misoprostol decreases the incidence of NSAID-induced gastric ulcers. However, diarrhea develops in many patients, thus limiting the usefulness of misoprostol. Proton pump inhibitors are effective in healing and preventing ulcers and have few side effects.

Duodenal Ulcer

H. pylori infection and associated antral gastritis occur in approximately 95% of patients with duodenal ulcer. However, only 10% to 20% of all patients who are infected with *H. pylori* ever develop an ulcer; therefore, other risk factors must be involved. Other risk factors that contribute to duodenal ulceration include use of NSAIDs, acid hypersecretion, cigarette smoking, cirrhosis, chronic pulmonary disease, and chronic renal disease. The use of NSAIDs is the second most common cause of duodenal ulcer. There is no evidence that diet, alcohol, corticosteroids, caffeine, or stress increases the risk of duodenal ulceration.

- *H. pylori* or NSAIDs, including aspirin, cause 95% of duodenal ulcers.
- Risk factors for duodenal ulcers: *H. pylori*, NSAIDs, acid hypersecretion, cigarette smoking, cirrhosis, chronic pulmonary disease, and chronic renal disease.

Gastric Ulcer

H. pylori infection and associated antral gastritis are present in 80% of patients with gastric ulcer. Most gastric ulcers occur in areas of gastritis on the lesser curvature of the stomach near the junction of the body and antrum. Because acid secretion is normal or low in patients with gastric ulcer, gastric ulceration is believed to occur when the gastric mucosal barrier of mucus and bicarbonate is damaged. The risk factors other than *H. pylori* that contribute to gastric ulceration include NSAIDs, bile reflux, and cigarette smoking. Bile reflux may occur from previous gastroduodenal surgery or from abnormal antral motility or pyloric sphincter function. Alcohol can cause gastritis, but there is no evidence that alcohol predisposes to gastric ulceration.

- Risk factors for gastric ulcers are *H. pylori*, NSAIDs, bile reflux, and cigarette smoking.

Zollinger-Ellison Syndrome

Zollinger-Ellison syndrome is characterized by the triad of peptic ulceration, acid hypersecretion, and diarrhea caused by a gastrin-producing tumor. The tumor usually is located in the pancreas, but it can occur in the wall of the duodenum. Two-thirds of gastrinomas are malignant and can metastasize to regional lymph nodes and the liver. One-fourth of gastrinomas are related to a multiple endocrine neoplasia type 1 (MEN 1) syndrome and are associated with pituitary adenoma and hyperparathyroidism.

The most common clinical presentation is duodenal bulb ulceration, although multiple postbulbar ulcers or the coexistence of a duodenal ulcer with diarrhea or a duodenal ulcer with hypercalcemia increases the likelihood of Zollinger-Ellison syndrome. A duodenal ulcer that is not related to *H. pylori* infection or to NSAID use should also increase the likelihood of Zollinger-Ellison syndrome. Gastrinoma also should be considered in patients with recurrent ulcers, intractable ulcers, a family history of ulcer disease or MEN 1 syndrome, or evidence of gastric acid hypersecretion (enlarged rugal folds, dilated duodenum, and increased acid output).

The serum level of gastrin should be determined if Zollinger-Ellison syndrome is suspected. Serum levels of gastrin greater than 1,000 pg/mL in patients who produce gastric acid are essentially diagnostic of gastrinoma. Increased serum levels of gastrin may also be present in atrophic gastritis, pernicious anemia, postvagotomy states, proton pump inhibitor therapy, and renal failure because gastric acid output is low in these conditions. Basal and stimulated gastric acid secretory studies should be performed in all patients who have increased levels of gastrin. The basal acid output is more than 10 mEq per hour. When the laboratory results are equivocal, a secretin test should be performed. An intravenous bolus of secretin produces a paradoxical increase in the serum level of gastrin in patients with gastrinoma.

The test of choice to localize a gastrinoma is an octreotide scan. Almost all gastrinomas have somatostatin receptors, and radiolabeled octreotide, a somatostatin analogue, produces a positive scan in approximately 80% of cases. Endoscopic ultrasonography has been reported to localize approximately 70% of gastrinomas. Computed tomography (CT) of the abdomen localizes 50% of gastrinomas, and selective arteriography localizes 33%. In combination, these studies localize 80% to 85% of gastrinomas. If a tumor cannot be localized, surgical exploration is indicated in patients who do not have evidence of metastases or MEN 1.

Approximately 20% to 25% of gastrinomas can be completely removed surgically. If the tumor cannot be removed, a parietal cell vagotomy may help control acid secretion. Patients who are not candidates for surgery or who have an unresectable tumor can be managed medically with acid suppression and chemotherapy. High-dose, long-term treatment with proton pump inhibitors is safe and effective. Chemotherapy with streptozocin and 5-fluorouracil is effective in 50% of patients with metastatic disease.

- Zollinger-Ellison syndrome: peptic ulceration, acid hypersecretion, and diarrhea caused by a gastrin-secreting tumor.
- Rule out Zollinger-Ellison syndrome in patients with duodenal ulcers not related to *H. pylori* or NSAID use or with duodenal ulcers with diarrhea, multiple postbulbar ulcers, or hypercalcemia.

- Do not explore surgically if metastatic disease or MEN 1 is present.

Stress Ulcers

Stress ulceration is caused by gastric mucosal ischemia due to an underlying illness. *H. pylori* is not an important pathogenic factor. The underlying conditions for stress ulcers are trauma, sepsis, and serious illness. Most of the hemorrhages occur 3 to 7 days after the traumatic event. Burns, especially those involving more than 35% of the body, may cause ulcers. Central nervous system trauma produces Cushing ulcer, which occurs in 50% to 75% of patients with head injury. This ulcer tends to be deep and perforate more often than other ulcers.

- Underlying conditions for stress ulcers: trauma, sepsis, and serious illness.
- Hemorrhaging occurs 3-7 days after the traumatic event.
- Burns involving >35% of the body may produce ulcers.
- Stress ulcers occur in 50%-75% of patients with head injury (Cushing ulcers).

Prophylaxis against bleeding is to maintain intragastric pH greater than 4.0. Antacids clearly decrease the incidence of bleeding compared with placebo. H_2 receptor antagonists are as effective as antacids and sometimes easier to use. Sucralfate is as effective as antacids and H_2-blockers, according to some studies. Also, sucralfate may decrease nosocomial pneumonia in ventilator-dependent patients because gastric pH is not decreased (decreased bacterial overgrowth). Prostaglandins may have a role in prophylaxis. Enteral feedings can maintain intragastric pH greater than 3.5. If antacids cannot be used, give H_2-blockers or sucralfate; combination treatment may be helpful.

- Prophylaxis: maintain intragastric pH >4.0.
- Antacids, H_2 receptor antagonists, and sucralfate decrease the incidence of bleeding.
- Sucralfate may decrease nosocomial pneumonia in ventilator-dependent patients.

The medical therapy for bleeding, acute gastric mucosal ulcers is to correct the underlying predisposing condition. Generally, upper gastrointestinal tract bleeding stops spontaneously about 85% of the time. Angiographic therapeutic techniques include intra-arterial vasopressin and transcatheter embolization. Endoscopic techniques include epinephrine injection and cautery (BiCap/heater probe) or laser photocoagulation. Surgical therapy for bleeding, acute gastric mucosal ulcers must be considered when the blood requirement is more than 4 to 6 units per 24 to 48 hours. The mortality rate with all forms of surgical therapy is 30% to 40%.

Nonerosive Nonspecific Chronic Gastritis

Chronic gastritis is divided into type A and type B. Type A, or autoimmune, gastritis involves the body and fundus of the stomach. A subset of patients develops atrophic gastritis (inflammation of the gland zone with variable gland loss). Pernicious anemia with hypochlorhydria or achlorhydria and megaloblastic anemia may result. Antiparietal cell antibodies are found in 90% of patients. Intrinsic factor antibodies are detected less commonly. Other autoimmune diseases, such as Addison disease and Hashimoto thyroiditis, are often present. The serum levels of gastrin are increased, which may give rise to gastric carcinoid tumors. Gastric polyps occur, and intestinal metaplasia may be a precursor to gastric adenocarcinoma.

- Type A gastritis is associated with three *A*'s: *a*utoimmune, *a*trophic gastritis, and pernicious *a*nemia.
- The serum levels of gastrin are increased.
- Type A gastritis is associated with gastric carcinoids, polyps, and adenocarcinoma.

Type B gastritis involves the antrum and is associated with *H. pylori* infection. Serum levels of gastrin are normal or increased. Gastric ulcers and duodenal ulcers occur commonly, and the incidence of gastric adenocarcinoma is increased.

- Type B gastritis is associated with *H. pylori* infection.
- The serum levels of gastrin are normal or increased.
- Type B gastritis is associated with gastric and duodenal ulcers and with adenocarcinoma.

Gastric Cancer

In the 1940s, gastric cancer was the most common malignant disease in the United States. Since then, the decrease in incidence has been dramatic. Japan has the highest mortality rate from gastric cancer. Migration studies show a decrease in incidence among persons who move from high-risk areas to low-risk areas and a suggestion of increased risk among persons who move from low-risk areas to high-risk areas. Environmental factors include diet: there is an increased association with increased consumption of starch, pickled vegetables, salted fish and meat, smoked foods, nitrate and nitrite, and salt. The population at risk is persons older than 50. The male-to-female ratio is as high as 2:1. Also, gastric cancer is more common in lower socioeconomic groups. There is a twofold to threefold greater incidence among relatives.

- The incidence of gastric cancer has decreased dramatically in the United States since the 1940s.
- The incidence decreases among persons who move from high-risk areas.
- Increased association with increased consumption of starch, pickled vegetables, salted fish and meat, smoked foods, nitrate and nitrite, and salt.
- A twofold to threefold greater incidence among relatives.

Possible Precancerous Lesions or Situations

H. pylori infection, chronic atrophic gastritis, and intestinal metaplasia are frequently found in patients with gastric cancer; however, all three conditions are found frequently in older persons without gastric carcinoma. Chronic benign gastric ulcer rarely progresses to cancer. Previous autopsy studies showed that the prevalence of

pernicious anemia was 10%. An endoscopic screening study of 123 patients with pernicious anemia showed a prevalence of gastric neoplastic lesions of 8.1%. The risk is minimally increased after gastrectomy, but surveillance endoscopy is not necessary.

- *H. pylori*–positive chronic atrophic gastritis is found frequently in patients with gastric cancer.
- Chronic benign gastric ulcer rarely progresses to cancer.
- Pernicious anemia: prevalence of 10%.
- Postgastrectomy: minimal increased risk, but endoscopy screening is not necessary.

Clinical Aspects

Gastric cancer is often asymptomatic, but abdominal discomfort and weight loss are the common presenting complaints. Physical examination is often unrevealing, but up to 30% of patients have an epigastric mass. Endoscopy, with multiple (seven or eight) biopsies, and CT of the abdomen (to identify extragastric extension) are indicated.

- Abdominal discomfort and weight loss are common presenting complaints.
- Up to 30% of patients have an epigastric mass.
- Perform endoscopy, with multiple (7-8) biopsies.

Treatment and Prognosis

For local disease, resection often requires total gastrectomy for tumor-free margins. The omentum and spleen (splenic hilar nodes) are often removed in curative resection.

For disseminated disease, surgical treatment is necessary only for palliation. Response to chemotherapy is generally poor. The only consistent factor is extent of disease. Five-year survival is 90% if the tumor is confined to the mucosa and submucosa, 50% if the tumor is through the serosa, and 10% if the tumor involves lymph nodes.

Gastric Polyps

Gastric polyps are rare; a 0.5% prevalence has been reported in an autopsy series. The two types of polyps are hyperplastic and adenomatous. Hyperplastic polyps are more common and not premalignant. No therapy is needed. Adenomatous polyps are premalignant, especially if larger than 2 cm. They occur most often in achlorhydric stomachs, that is, in patients with pernicious anemia, and are usually localized to the antrum. If pedunculated, the polyp can be removed endoscopically.

- Hyperplastic polyps are more common and not premalignant.
- Adenomatous polyps are premalignant, especially if >2 cm.

Gastroduodenal Dysmotility Syndromes

Symptoms of abnormal gastric motility may include nausea, vomiting, bloating, early satiety, dyspepsia, heartburn, anorexia, weight loss, and food avoidance. The specific cause of abnormal gastric motor function is unknown but is believed to be related to autonomic neuropathy. Diabetes mellitus is probably the most common medical cause of symptomatic gastric motor dysfunction. Causes of gastroparesis are listed in Table 7-3.

- Nausea, vomiting, bloating, early satiety, dyspepsia, heartburn, anorexia, weight loss, and food avoidance may suggest abnormal gastric motility.
- Abnormal gastric motor function is believed to be related to autonomic neuropathy.
- Diabetes mellitus: the most common medical cause of symptomatic gastric motor dysfunction.

Treatment

Currently, several prokinetic drugs are available in the United States. These drugs augment motility, thus enhancing the movement of luminal contents. Metoclopramide is a dopamine antagonist and a cholinergic agonist that increases the rate and amplitude of antral contractions. It crosses the blood-brain barrier and frequently causes such side effects as drowsiness, athetosis, and the release of prolactin. Domperidone is a selective dopamine antagonist that works only on peripheral receptors in the gut. It has no cholinergic effects and fewer side effects than metoclopramide. Bethanechol is a systemic cholinergic agonist with side effects. It may be useful in low dosage in combination with other agents. Erythromycin stimulates both cholinergic and motilin receptors.

- Metoclopramide is a dopamine antagonist and a cholinergic agonist.
- Domperidone is a selective dopamine antagonist.
- Erythromycin stimulates both cholinergic and motilin receptors.

Small Intestine

Diarrhea

Patients use the term "diarrhea" to refer to any increase in the frequency, fluidity, or volume of the stool or to any change in its consistency. Normally, stools are generally solid and brown, but these features vary with diet. The frequency of stools varies among persons, from one to three daily to two or three stools weekly. Blood, pus (leukocytes), and oil are not present in normal stools (Table 7-4).

Diarrhea is defined as an increase in stool weight or volume. Because a stool is 65% to 80% water, stool weight is proportional to stool water. Because dietary fiber content influences the water content of the stool, stool weight can vary according to the diet of a culture. In the United States, normal daily stool weight is less than 200 g per

Table 7-3 Conditions Causing Gastroparesis

Acute conditions	Chronic conditions
Anticholinergic drug use	Amyloidosis
Hyperglycemia	Diabetes mellitus
Hypokalemia	Gastric dysrhythmias
Morphine use	Pseudo-obstruction
Pancreatitis	Scleroderma
Surgical procedure	Vagotomy
Trauma	

day and normal stool volume is less than 200 mL per day (compared with <400 g/d and 400 mL/d in rural Africa).

Normal daily intestinal fluid balance is important to understand. Each day, 9 to 10 L of isotonic fluid is presented to the proximal small intestine (2 L from diet; 8 L from endogenous secretions). The small bowel absorbs most of the fluid (7-9 L), and the colon absorbs all the 1 to 2 L presented to it each day (except for <200 mL) and forms a soft, solid stool. There is considerable reserve because the maximal absorptive capacity is 12 L per day for the small bowel and 4 to 6 L per day for the colon.

Mechanisms of Diarrhea

Osmotic diarrhea occurs when water-soluble molecules are poorly absorbed, remain in the intestinal lumen, and retain water in the intestine. Osmotic diarrhea follows ingestion of an osmotically active substance and stops with fasting. Stool volume is less than 1 L per day, and the stool has an osmolar gap—stool osmolality is greater than the sum of the electrolyte concentrations.

$$\text{Stool osmolar gap} = 290 - 2\,(\text{stool Na} + \text{K})$$

A normal stool osmolar gap is less than 50. Often, stool pH is less than 6.0 in carbohydrate malabsorption (lactase deficiency) owing to colonic fermentation of the undigested sugars. Clinical causes of osmotic diarrhea that produce an osmolar gap greater than 50 include lactase deficiency, sorbitol foods, saline cathartics, and antacids.

- In osmotic diarrhea, stool volume is <1 L/d.
- Diarrhea stops with fasting.
- Stool has an osmolar gap.
- Causes of osmotic diarrhea: lactase deficiency, sorbitol foods, and antacids.

In secretory diarrhea, fluid and electrolyte transport is abnormal, that is, the intestine secretes rather than absorbs fluid. Stool volume is greater than 1 L per day, and its composition is similar to that of extracellular fluid, so there is no osmolar gap. The diarrhea persists despite fasting, and hypokalemia is often present. Causes of secretory diarrhea include bacterial toxins, hormone-secreting tumors, surreptitious ingestion of laxative, bile acid diarrhea, and fatty acid diarrhea.

- In secretory diarrhea, stool volume is >1 L/d.
- There is no osmolar gap.
- Diarrhea persists despite fasting.
- Causes of secretory diarrhea: bacterial toxins, hormone-secreting tumors, surreptitious ingestion of laxative, bile acid diarrhea, and fatty acid diarrhea.

In exudative diarrhea, membrane permeability is abnormal and serum proteins, blood, or mucus is exuded into the bowel from sites of inflammation, ulceration, or infiltration. The volume of feces is small and the stools may be bloody. Examples include invasive bacterial pathogens (e.g., *Shigella* and *Salmonella*) and inflammatory bowel disease.

Table 7-4 Normal Stool Composition

Feature	Value
Weight, g	<200
Water, %	65-80
Fat, g	<7
Nitrogen, g	<2.5
Electrolytes, mEq/L	
Na^+	40
K^+	90
Cl^-	15
HCO_3^-	30

- Exudative diarrhea: abnormal membrane permeability.
- Volume of feces is small.
- Causes: invasive bacterial pathogens (*Shigella* and *Salmonella*) and inflammatory bowel disease.

In motility disorders, both rapid transit (inadequate time for chyme to contact the absorbing surface) and delayed transit (bacterial overgrowth) can cause diarrhea. Rapid transit occurs after gastrectomy or intestinal resection and with hyperthyroidism or carcinoid syndrome. Delayed transit occurs with structural defects (strictures, blind loops, and small-bowel diverticula) or with underlying illnesses that cause visceral neuropathy (diabetes) or myopathy (scleroderma), that is, pseudo-obstruction.

- Rapid transit: diarrhea results from malabsorption.
- Delayed transit: diarrhea results from bacterial overgrowth.

Many disease processes may have more than one mechanism for causing diarrhea (mixed mechanisms). For example, generalized malabsorption has osmotic and secretory components (fatty acids cause secretion in the colon).

Clinical Approach

It is useful to differentiate small-bowel ("right-sided") diarrhea from colonic ("left-sided") diarrhea (Table 7-5). Right-sided diarrhea is characterized by large-volume stools, and the increase in the number of stools is modest. Symptoms attributed to inflammation of the rectosigmoid are absent, and proctoscopic examination findings are normal. Left-sided diarrhea is characterized by frequent, small-volume stools with obvious evidence of inflammation, and proctosigmoidoscopic examination usually confirms inflammation. Left-sided diarrhea usually suggests an exudative mechanism, whereas the mechanism for right-sided diarrhea is nonspecific.

Acute Diarrhea

Acute diarrhea is abrupt in onset and usually resolves in several days (3-10 days). It is self-limited, and the cause (possibly viral) usually is

not found. No evaluation is necessary unless the stools are bloody and fever or infection is suspected (e.g., from travel history or a common source outbreak). If these conditions exist, do not treat with antimotility agents. Begin the evaluation with stool studies for bacterial pathogens, ova, and parasites and proctosigmoidoscopy. Recognize the common situations that predispose to specific infections (see "Infectious Diarrheas" subsection).

- For acute diarrhea, no evaluation is necessary unless the stools are bloody and fever or infection is suspected.
- Do not administer antimotility agents if the stools are bloody and fever or infection is suspected.

Chronic Diarrhea

Chronic diarrhea is an initial episode lasting longer than 4 weeks or diarrhea that recurs after the initial episode. The most common cause of chronic diarrhea is irritable bowel syndrome, but lactase deficiency should always be considered. Several features are used to differentiate organic diarrhea from functional diarrhea (Table 7-6).

- The most common cause of chronic diarrhea is irritable bowel syndrome.
- Always consider lactase deficiency in suspected irritable bowel syndrome.
- Differentiate organic diarrhea from functional diarrhea.

Chronic Watery Diarrhea

The evaluation of chronic watery diarrhea usually requires distinguishing between secretory diarrhea and osmotic diarrhea (Table 7-7). This can be done by collecting stools and measuring volume, osmolality, and electrolyte content and observing the patient's response to fasting.

- Evaluation of chronic watery diarrhea requires distinguishing between secretory diarrhea and osmotic diarrhea.

Physiology of Nutrient Absorption

The sites of nutrient, vitamin, and mineral absorption are the following: The duodenum absorbs iron, calcium, magnesium, folate, water-soluble vitamins, and monosaccharides. The jejunum absorbs fatty acids, amino acids, monosaccharides, and water-soluble vitamins. The ileum absorbs monosaccharides, fatty acids, amino acids, fat-soluble vitamins (A, D, E, and K), vitamin B_{12}, and conjugated bile salts. The distal small bowel can adapt to absorb nutrients. The proximal small bowel cannot adapt to absorb vitamin B_{12} or bile salts.

- The distal small bowel can adapt to absorb nutrients.
- The proximal small bowel cannot adapt to absorb vitamin B_{12} or bile salts.

Fat absorption is the most complex process. Dietary fat consists mostly of triglycerides that must be digested by pancreatic lipase to fatty acids and glycerol, which are solubilized by micelles for absorption. The fatty acids and monoglycerides are reesterified by intestinal epithelial cells into chylomicrons that are absorbed into the circulation by lymphatic vessels. Medium-chain triglycerides are absorbed directly into the portal vein and do not require micellar solubilization.

Mechanisms of fat malabsorption are summarized in Table 7-8. Suspect malabsorption if the medical history suggests steatorrhea or

Table 7-5 Right-Sided and Left-Sided Diarrhea: Contrasts in Clinical Presentation

Feature	Right-sided, or small-bowel, diarrhea	Left-sided, or colonic, diarrhea
Reservoir capacity	Intact	Decreased
Stool volume	Large	Small
Increase in number of stools	Modest	Large
Urgency	Absent	Present
Tenesmus	Absent	Present
Mucus	Absent	Present
Blood	Absent	Present

Table 7-6 Features Differentiating Organic Diarrhea From Functional Diarrhea

Feature	Organic diarrhea	Functional diarrhea
Weight loss	Often present	Absent
Duration of illness	Variable (weeks to years)	Usually long (>6 mo)
Quantity of stool	Variable but usually large (>200 g/24 h)	Usually small (<200 g/24 h)
Presence of blood in stool	May be present	Absent (unless from hemorrhoids)
Timing when diarrhea occurs	No special pattern	Usually in the morning but rarely wakes patient
Fever, arthritis, skin lesions	May be present	Absent
Emotional stress	No relation to symptoms	Usually precedes or coincides with symptoms
Cramping abdominal pain	Often present	May be present

Table 7-7 Features Differentiating Osmotic Diarrhea From Secretory Diarrhea

Feature	Osmotic diarrhea	Secretory diarrhea
Daily stool volume, L	<1	>1
Effect of 48-hour fasting	Diarrhea stops	Diarrhea continues
Fecal fluid analysis		
Osmolality, mOsm	400	290
([Na] + [K]) × 2,* mEq/L	120	280
Solute gap†	>100	<50

*Multiplied by 2 to account for anions.
†Calculated by subtracting ([Na] + [K]) × 2 from osmolality.
From Krejs GJ, Hendler RS, Fordtran JS. Diagnostic and pathophysiologic studies in patients with chronic diarrhea. In Field M, Fordtran JS, Schultz SG, editors. Secretory diarrhea. Bethesda (MD): American Physiological Society; 1980. p. 141-51. Used with permission.

if there is diarrhea with weight loss (especially if intake is adequate), chronic diarrhea of indeterminate nature, or nutritional deficiency. The causes of symptoms in malabsorption are summarized in Table 7-9.

Various features suggest specific conditions, as follows:

1. Diarrhea with iron deficiency anemia (evaluation for blood loss is negative)—proximal small-bowel malabsorption, e.g., sprue
2. Diarrhea with metabolic bone disease—decreased calcium and protein; thus, proximal small-bowel malabsorption
3. Hypoproteinemia with normal fat absorption—protein-losing enteropathy (with eosinophilia, eosinophilic gastroenteritis; with lymphopenia, intestinal lymphangiectasia)
4. Oil droplets (neutral fat) or muscle fibers (undigested protein) present in stool—pancreatic insufficiency (maldigestion)
5. Normal (usually) serum levels of calcium, magnesium, and iron—pancreatic insufficiency (serum levels of albumin may also be normal)
6. Howell-Jolly bodies (if there is no history of splenectomy) or dermatitis herpetiformis—celiac sprue (small-bowel biopsy is not diagnostic for sprue, but the response to a gluten-free diet is)
7. Fever, arthralgias, and neurologic symptoms—Whipple disease

Helpful hints in the medical history, physical examination, or laboratory results may suggest the possibility of diarrhea or malabsorption (Table 7-10). For example, the medical history may include previous surgery (resulting in short-bowel syndrome, dumping syndrome, blind loop syndrome, postvagotomy diarrhea, or ileal resection), irradiation, or systemic disease. Other hints in the history might include any of the following:

1. Age—youth suggests lactase deficiency, inflammatory bowel disease, or sprue
2. Travel—parasites or toxicogenic agents (exposure to contaminated food or water)
3. Drugs—laxatives, antacids, antibiotics, colchicine, or lactulose
4. Family history—celiac sprue, inflammatory bowel disease, polyposis coli, or lactase deficiency

- Medical history: previous surgery (short-bowel syndrome, dumping syndrome, blind loop syndrome, postvagotomy diarrhea, and ileal resection), irradiation, or systemic disease.

Diseases Causing Diarrhea

Osmotic Diarrhea

Lactose is normally split by lactase into glucose and galactose, which are absorbed in the small bowel. In lactase deficiency, lactose is not

Table 7-8 Mechanisms of Fat Malabsorption

Alteration	Mechanism	Disease state
Defective digestion	Inadequate lipase	Pancreatic insufficiency
Impaired micelle formation	Duodenal bile salt concentration	Common duct obstruction or cholestasis
Impaired absorption	Small-bowel disease	Sprue and Whipple disease
Impaired chylomicron formation	Impaired β-globulin synthesis	Abetalipoproteinemia
Impaired lymphatic circulation	Lymphatic obstruction	Intestinal lymphangiectasia and lymphoma

Table 7-9 Causes of Symptoms in Malabsorption

Extragastrointestinal symptom	Cause
Muscle wasting, edema	Decreased protein absorption
Paresthesias, tetany	Decreased vitamin D and calcium absorption
Bone pain	Decreased calcium absorption
Muscle cramps	Weakness, excess potassium loss
Easy bruisability, petechiae	Decreased vitamin K absorption
Hyperkeratosis, night blindness	Decreased vitamin A absorption
Pallor	Decreased vitamin B_{12}, folate, or iron absorption
Glossitis, stomatitis, cheilosis	Decreased vitamin B_{12} or iron absorption
Acrodermatitis	Zinc deficiency

split in the small intestine but enters the colon, where it is fermented in the lumen by bacteria, forming lactic acid and liberating hydrogen. The result is diarrhea of low pH and increased intestinal motility. The most common disaccharidase deficiency is lactase deficiency. "Acquired" lactase deficiency (possibly genetic) is common in Orientals, blacks, Eskimos, and people from the Middle East. Diarrhea, abdominal cramps, and flatulence occur after ingestion of dairy products. There is improvement with dietary changes. The pH of the stool is less than 6.0. In the lactose tolerance test, blood glucose levels increase less than 20 mg/100 mL after ingestion of lactose. Results of the hydrogen breath test may be abnormal. Jejunal biopsy results are normal (disaccharidase levels are decreased). Lactose intolerance can occur in any clinical setting in which the intestinal mucosa is damaged. In patients on a weight reduction diet who drink diet soda or chew sugarless gum, osmotic diarrhea may develop from artificial sweeteners.

- Lactase deficiency: lactose is not split in the small intestine.
- Diarrhea is of low pH and increased intestinal motility.
- The most common disaccharidase deficiency is lactase deficiency.
- Diarrhea, abdominal cramps, and flatulence occur after ingestion of dairy products.
- Results of the hydrogen breath test may be abnormal.
- In patients on a weight reduction diet who drink diet soda or chew sugarless gum, osmotic diarrhea may develop from artificial sweeteners.

Secretory Diarrhea

Watery diarrhea, hypokalemia, achlorhydria (WDHA) syndrome, also called Verner-Morrison syndrome or "pancreatic cholera," is a massive diarrhea (5 L daily) with dehydration and hypokalemia. (The patient may have numerous other endocrine tumors [hypercalcemia or hyperglycemia].) This diarrhea is associated with a non–beta islet cell tumor of the pancreas. Vasoactive intestinal peptide is the most common mediator, followed by prostaglandin, secretin, and calcitonin. It is diagnosed with pancreatic scan or angiography and measurement of hormone levels. Treatment is with somatostatin or surgery.

- Pancreatic cholera: massive diarrhea, dehydration, and hypokalemia.
- Patients may have multiple endocrine tumors.
- It is associated with a non–beta islet cell tumor of the pancreas.

Carcinoid Syndrome

Carcinoid tumors arise from enterochromaffin cells of neural crest origin. About 90% of the tumors are in the terminal ileum. There is episodic facial flushing (lasting up to 10 minutes), watery diarrhea, wheezing, right-sided valvular disease (endocardial fibrosis), and hepatomegaly. If the gut is normal, look for bronchial tumors or

Table 7-10 Associated Signs and Symptoms of Systemic Illnesses Causing Diarrhea

Sign or symptom	Diagnosis to be considered
Arthritis	Ulcerative colitis, Crohn disease, Whipple disease, *Yersinia* infection
Marked weight loss	Malabsorption, inflammatory bowel disease, cancer, thyrotoxicosis
Eosinophilia	Eosinophilic gastroenteritis, parasitic disease
Lymphadenopathy	Lymphoma, Whipple disease
Neuropathy	Diabetic diarrhea, amyloidosis
Postural hypotension	Diabetic diarrhea, Addison disease, idiopathic orthostatic hypotension
Flushing	Malignant carcinoid syndrome
Proteinuria	Amyloidosis
Peptic ulcers	Zollinger-Ellison syndrome
Hyperpigmentation	Whipple disease, celiac disease, Addison disease, pancreatic cholera, eosinophilic gastroenteritis

From Fine KD, Krejs GJ, Fordtran JS. Diarrhea. In Sleisenger MH, Fordtran JS, editors. Gastrointestinal disease: pathophysiology, diagnosis, management. 4th ed. Philadelphia: WB Saunders Company; 1989. p. 290-316. Used with permission.

gonadal tumors. Dietary tryptophan is converted into serotonin (which causes diarrhea, abdominal cramps [intestinal hypermotility], nausea, and vomiting), histamine (responsible for flushing), and other chemicals (bradykinin and corticotropin). Intestinal tumors are usually asymptomatic because of the high hepatic first-pass clearance of these mediators. Carcinoid syndrome arises when these mediators are released into the systemic bloodstream; this suggests that liver metastases or bronchial tumors are present. The diagnosis of carcinoid syndrome is made by finding increased urinary levels of 5-hydroxyindoleacetic acid (5-HIAA) and by liver biopsy. This syndrome is not associated with hypertension, as in pheochromocytoma. Treatment is with octreotide.

Laxative Abuse

Of the population older than 60 years, 15% to 30% take laxatives regularly. This is laxative abuse. With the surreptitious ingestion of laxatives, patients complain of diarrhea but do not admit taking laxatives. In referral centers, this is the commonest cause of watery diarrhea. Proctoscopy shows melanosis coli. Barium enema demonstrates "cathartic colon," that is, the colon is dilated, hypomotile, and lacking haustra. Laxatives that cause melanosis coli include anthracene derivatives (senna, cascara, and aloe). Stool phenolphthalein is the diagnostic test. Underlying emotional problems should be addressed.

- Proctoscopy demonstrates melanosis coli.
- Barium enema shows "cathartic colon" (i.e., dilated, hypomotile, and lacking haustra).
- Address underlying emotional problems.

Bile Acid Malabsorption

Bile acid malabsorption is caused by ileal resection or disease. Diarrhea due to bile acid malabsorption may produce two different clinical syndromes, each requiring a different treatment. In a limited resection (<100 cm), malabsorbed bile acids enter the colon and stimulate secretion. Liver synthesis can compensate, so bile acid concentration in the upper small bowel is sufficient to achieve the critical micelle concentration and allow for normal fat absorption. There is no steatorrhea. Fecal fat is less than 20 g/24 h. The treatment is cholestyramine, which binds excess bile acids.

In an extensive resection (>100 cm), bile acids are severely malabsorbed, and enterohepatic circulation is interrupted. This limits synthesis, and the liver cannot compensate. Bile acid concentration is decreased in the upper small bowel, micelles cannot be formed, and fat malabsorption results. The malabsorbed fatty acids themselves stimulate secretion in the colon. Fat-soluble vitamins (A, D, E, and K) may be malabsorbed. Additionally, excess fatty acids bind intestinal calcium; this allows an increase in oxylate absorption, which increases the risk of oxylate renal stones. The treatment of this bile acid malabsorption is a low-fat diet (<50 g daily) rich in medium-chain triglycerides. Cholestyramine would further decrease bile acid concentration and increase steatorrhea.

- Limited resection: treat with cholestyramine.
- Extensive resection: treat with a low-fat diet rich in medium-chain triglycerides.

Bacterial Overgrowth

The proximal small intestine is usually sterile, and its major defense mechanisms are gastric acid, normal peristalsis (the most important defense), and intestinal IgA. When defenses are altered, bacterial overgrowth results. The mechanism of steatorrhea is deconjugation of bile acids by bacteria that normally do not occur in the proximal intestine. Deconjugation of the bile acids changes the ionization coefficient, and the deconjugated bile acids can be passively absorbed in the proximal small bowel. Normally, conjugated bile acids are actively absorbed distally in the ileum. As a result, the critical micellar concentration is not reached, and mild steatorrhea results from the intraluminal deficiency of bile acids.

- Normal peristalsis is the most important defense in the proximal small bowel.
- Deconjugated bile acids can be absorbed passively.
- Mild steatorrhea results from the intraluminal deficiency of bile acids.

Clinical features of bacterial overgrowth are steatorrhea (10-20 g daily), vitamin B_{12} malabsorption (macrocytic anemia), positive jejunal cultures (>10^5 organisms), increased folate levels from bacterial production, and abnormal bile acid breath test results. In the bile acid breath test, ^{14}C-labeled bile acids release $^{14}CO_2$ when deconjugated by bacteria in the gut. This test has low sensitivity (a 20%-30% false-negative rate).

Associated conditions include postoperative conditions (blind loops, enteroenterostomy, or gastrojejunocolic fistula), structural conditions (diverticula, strictures, or fistulas), motility disorders (scleroderma or pseudo-obstruction), achlorhydria (atrophic gastritis or gastric resections; achlorhydria is corrected with antibiotics), and impaired immunity. Two types of impaired immunity are hypogammaglobulinemic sprue (in small-bowel biopsy specimens, no plasma cells are seen in the lamina propria and the villi are flat) and nodular lymphoid hyperplasia associated with IgA deficiency, which predisposes to *Giardia lamblia* infection.

- Diarrhea, vitamin B_{12} deficiency, and the above conditions suggest bacterial overgrowth.

Infectious Diarrheas

The toxicogenic and invasive causes of bacterial diarrhea and the associated features are outlined in Tables 7-11 and 7-12.

Noninvasive Bacterial Diarrhea (Toxicogenic)

Toxicogenic bacterial diarrhea, characterized by watery stools without fecal leukocytes, is caused by several organisms, including the following:

Staphylococcus aureus—The diarrhea is of rapid onset and lasts for 24 hours. There is no fever, vomiting, or cramps. The toxin is ingested in egg products, cream, and mayonnaise. Treatment is supportive.

Clostridium perfringens ("church picnic diarrhea")—The toxin is ingested in precooked foods, usually beef and turkey. Heat-stable spores produce toxins. Although the bacteria are killed and the toxin

is destroyed, the spores survive. When food is rewarmed, the spores germinate, producing toxin. The diarrhea is worse than the vomiting and is later in onset. It lasts 24 hours. Treatment is supportive.

Escherichia coli ("traveler's diarrhea")—The toxin is ingested in water and salads. It is a plasmid-mediated enterotoxin. Treatment is rehydration with correction of electrolytes and ciprofloxacin, norfloxacin, or trimethoprim-sulfamethoxazole. *E. coli* may be important in nursery epidemic diarrhea.

Vibrio cholerae—The toxin is ingested in water. It is the only toxicogenic bacterial diarrhea in which antibiotics clearly shorten the duration of the disease. Treatment is with tetracycline.

Bacillus cereus—The source of the toxin is fried rice in Oriental restaurants. One type has rapid onset and resembles *S. aureus* infection; the other type has a slower onset and resembles *C. perfringens* infection. The diagnosis is made by isolating the organism from contaminated food and by the medical history. Treatment is supportive.

Other toxicogenic bacteria—*Clostridium botulinum* produces a neurotoxin that is ingested in improperly home-processed vegetables, fruits, and meats. It interferes with the release of acetylcholine from peripheral nerve endings. *Clostridiuim difficile*—See "Antibiotic Colitis" subsection.

- Toxicogenic bacterial diarrhea: watery, no fecal leukocytes.
- *S. aureus*: rapid onset.
- *C. perfringens*: "church picnic diarrhea" from precooked foods; delayed onset of diarrhea is the predominant symptom.
- *E. coli*: "traveler's diarrhea."
- *V. cholerae*: the only toxicogenic diarrhea in which antibiotics shorten the duration of the disease. Tetracycline is the treatment of choice.
- *B. cereus*: fried rice in Oriental restaurants.

Invasive Bacterial Diarrhea

Invasive bacterial diarrhea, characterized by fever, bloody stools, and fecal leukocytes, is caused by several organisms, including the following:

Shigella—It is often acquired outside the United States. Bloody diarrhea is characteristic, and fever and bacteremia occur. Diagnosis is based on positive stool and blood cultures. Treatment is with ampicillin. Resistant strains are emerging for which chloramphenicol is an alternative. (Plasmids are responsible for antibiotic deactivation resistance.)

Salmonella (non-*typhi*)—In the United States, *Salmonella typhimurium* is the most common agent. The toxin is ingested with poultry. Fever is present. The absence of bloody diarrhea is the main characteristic that distinguishes it from *Shigella* infection. Diagnosis is based on positive stool culture. Treatment is supportive. Treat only severe symptoms with ciprofloxacin. Treating mild symptoms with other antibiotics may result in a prolonged carrier state.

Vibrio parahaemolyticus—The toxin is ingested with undercooked shellfish. This infection is increasing in frequency in the

Table 7-11 Causes of Bacterial Diarrhea: Toxicogenic

Organism	Onset, h	Mediated by cyclic AMP	Fever	Intestinal secretion
Staphylococcus aureus	1-6	+	–	+
Clostridium perfringens	8-12	–	±	+
Escherichia coli	12	+	+	+
Vibrio cholerae	12	+	Due to dehydration	++++
Bacillus cereus	1-6	+	–	+

AMP, adenosine monophosphate.

Table 7-12 Causes of Bacterial Diarrhea: Invasive

Organism	Fever	Bloody diarrhea	Bacteremia	Antibiotic effectiveness
Shigella	+	+	+	+
Salmonella	+	–	–	–
Vibrio parahaemolyticus	+	+	–	+(?)
Escherichia coli	+	+	–	–
Staphylococcus aureus (enterocolitis)	+	+	±	+
Yersinia enterocolitica	+	+	+	+
Campylobacter jejuni	+	+	±	+
Vibrio vulnificus	+	+	+	+

United States (it is common in Japan). Fever and bloody diarrhea are the chief characteristics. Diagnosis is based on positive stool culture. Antibiotics are of questionable value in treating this infection, but erythromycin may be most effective.

E. coli—In the United States, enteroinvasive *E. coli* is a rare cause of diarrhea. Enteroinvasive *E. coli* involves the colon and causes fever, bloody diarrhea, and profound toxicity (similar to *Shigella* infection). Enterohemorrhagic *E. coli* (serotype O157:H7) produces a cytotoxin that damages vascular endothelial cells. *E. coli* O157:H7 can cause sporadic or epidemic illness from contaminated meat and raw milk. Enterohemorrhagic *E. coli* infection should be suspected when bloody diarrhea occurs after eating hamburger and when bloody diarrhea is complicated by hemolytic uremic syndrome or thrombotic thrombocytopenic purpura. Antibiotic treatment has not been effective and is not recommended because it may increase the risk of development of hemolytic uremic syndrome or thrombotic thrombocytopenic purpura from the rapid release of toxin during bacterial death.

S. aureus (enterocolitis)—Diagnosis is based on positive stool culture or Gram stain, which shows a predominance of gram-positive cocci and a paucity of other organisms.

- Invasive bacterial diarrhea: fever, bloody stools, and fecal leukocytes.
- *Shigella*: bloody diarrhea.
- *S. typhimurium*: no bloody diarrhea, treat with antibiotics only if blood cultures are positive.
- *V. parahaemolyticus*: undercooked shellfish, bloody diarrhea.
- *E. coli*: bloody stools, abdominal pain with fever. Occurs after eating hamburgers; may cause hemolytic uremic syndrome and thrombotic thrombocytopenic purpura.

"Newer" Pathogens That Cause Invasive Bacterial Diarrhea

Yersinia enterocolitica—The spectrum of disease includes acute enteritis and chronic enteritis. Acute enteritis is similar to shigellosis and usually lasts 1 to 3 weeks. It is characterized by fever, diarrhea, leukocytosis, and fecal leukocytes. Chronic enteritis occurs especially in children, with diarrhea, failure to thrive, hypoalbuminemia, and hypokalemia. Other features are acute abdominal pain (mesenteric adenitis), right lower quadrant pain, tenderness, nausea, and vomiting. It mimics appendicitis or Crohn disease. This gram-negative rod is hardy and can survive in cold temperatures. It grows on special medium (cold enriched). It is an invasive pathogen, with fecal-oral transmission in water and milk.

Extraintestinal manifestations are nonsuppurative arthritis and ankylosing spondylitis (in HLA-B27). Skin manifestations are erythema nodosum and erythema multiforme. Thyroid manifestations are Graves disease and Hashimoto disease. Multiple liver abscesses and granulomata are present.

Treatment is with aminoglycosides or trimethoprim-sulfamethoxazole (Bactrim). The bacteria are variably sensitive to tetracycline and chloramphenicol. β-Lactamases are frequently produced, making penicillin resistance common.

- *Y. enterocolitica* infection: acute abdominal pain (differential diagnosis includes appendicitis and Crohn disease).
- Fecal-oral transmission in water and milk.
- Manifestations include nonsuppurative arthritis and ankylosing spondylitis (in HLA-B27).

Campylobacter jejuni—*C. jejuni* are comma-shaped, motile, microaerophilic gram-negative bacilli. Transmission is linked to infected water, unpasteurized milk, poultry, sick dogs, and infected children. The incubation period is 2 to 4 days before invasion of the small bowel. Infection results in the presence of blood and leukocytes in the stool. It may mimic granulomatous or idiopathic ulcerative colitis. It also may mimic small-bowel secretory diarrhea, with explosive, frequent watery diarrhea due to many species that produce a cholera-type toxin. The diarrhea usually lasts 3 to 5 days but may recur. Antibiotic treatment is with erythromycin when severe, but treatment often is not needed. Postdiarrheal illnesses are hemolytic uremic syndrome and postinfectious arthritis.

- *Campylobacter jejuni*: transmission is linked to infected water, unpasteurized milk, poultry, sick dogs, and infected children.
- It may mimic granulomatous or idiopathic ulcerative colitis.
- Diarrhea usually lasts 3-5 days but may recur.

Vibrio vulnificus (noncholera)—The organisms are extremely invasive and produce necrotizing vasculitis, gangrene, and shock. They are routinely isolated from seawater, zooplankton, and shellfish along the Gulf of Mexico and both coasts of the United States, especially in the summer. The two clinical syndromes are wound infection, cellulitis, fasciitis, or myositis after exposure to seawater or cleaning shellfish and septicemia after the ingestion of raw shellfish (oysters). Patients at high risk of septicemia include those with liver disease, congestive heart failure, diabetes mellitus, renal failure, an immunosuppressive state, or hemochromatosis. Treatment is with tetracycline.

- *V. vulnificus* is extremely invasive, producing necrotizing vasculitis, gangrene, and shock.
- Wound infection, cellulitis, fasciitis, or myositis occurs after exposure to seawater or cleaning shellfish.
- Septicemia occurs after the ingestion of raw shellfish (oysters).

Aeromonas hydrophila—Previously, the pathogenicity of *A. hydrophila* was questioned. Although the infection is often mistaken for that of *E. coli*, *A. hydrophila* is now recognized as an increasingly frequent cause of diarrhea after a person has been swimming in fresh or salt water. The organism produces several toxins. Treatment is with trimethoprim-sulfamethoxazole and tetracycline.

Malabsorption Due to Diseases of the Small Intestine

Celiac Sprue

Celiac sprue is a gluten-sensitive enteropathy characterized in children as growth retardation and in adults as an iron deficiency that is unresponsive to iron taken orally. Osteomalacia can be present without steatorrhea if the proximal small bowel is involved. Splenic atrophy and an abnormal blood smear with Howell-Jolly bodies may be clues to the diagnosis in 10% to 15% of patients. The skin manifestation

is dermatitis herpetiformis. The measurement of circulating antigliadin and endomysial and tissue transglutaminase antibodies is useful for noninvasive screening. If the results are positive, a small-bowel biopsy should be performed. If the result of the endomysial antibody test is negative, another diagnosis should be considered. Small-bowel biopsy findings are not diagnostic, but response to a gluten-free diet is diagnostic. If the patient is unresponsive to the diet, review the diet for inadvertent gluten ingestion. If symptoms recur after 10 to 15 years of successful dietary management, consider small-bowel lymphoma (especially if there is also abdominal pain).

- Celiac sprue: iron deficiency that is unresponsive to iron taken orally; osteomalacia with or without steatorrhea.
- Splenic atrophy and abnormal blood smear with Howell-Jolly bodies may be clues to the diagnosis in 10%-15% of patients.
- Lymphoma is a late complication.

Tropical Sprue

In tropical sprue, diarrhea occurs 2 to 3 months after travel to the tropics. After 6 months, megaloblastic anemia develops because of folate deficiency and possible coexisting vitamin B_{12} deficiency. Although the cause is somewhat controversial, the infectious agents are most likely *Klebsiella* and *E. coli*. Small-bowel biopsy specimens show blunted villi similar to those in celiac sprue. Treatment is with tetracycline (250 mg four times daily) and folate with or without vitamin B_{12}.

- Tropical sprue: diarrhea and megaloblastic anemia after travel to the tropics.
- Cause: controversial; coliform bacteria (*Klebsiella* more than *E. coli*).
- Treatment: tetracycline (250 mg four times daily) and folate with or without vitamin B_{12}.

Whipple Disease

Whipple disease is a systemic infectious disease involving the central nervous system (CNS), heart, kidneys, and small bowel. It is caused by gram-positive bacilli. Small-bowel biopsy specimens show periodic acid-Schiff (PAS)–positive granules in the macrophages. Suspect Whipple disease in patients who have recurrent arthritis, pigmentation, adenopathy, or CNS symptoms (dementia, myoclonus, ophthalmoplegia, visual disturbances, coma, or seizures). Treatment is with trimethoprim-sulfamethoxazole or tetracycline for 1 year.

- Suspect Whipple disease in patients who have recurrent arthritis, pigmentation, adenopathy, or CNS symptoms.
- Small-bowel biopsy specimens show PAS-positive granules in the macrophages.
- Treatment: trimethoprim-sulfamethoxazole or tetracycline for 1 year.

Eosinophilic Gastroenteritis

Patients with eosinophilic gastroenteritis have a history of allergies (e.g., asthma) and food intolerances and episodic symptoms of nausea, vomiting, abdominal pain, and diarrhea. Laboratory findings include eosinophilia, iron deficiency anemia, and steatorrhea or protein-losing enteropathy. Small-bowel radiographs show coarse folds and filling defects, and biopsy specimens show infiltration of the mucosa by eosinophils and, occasionally, absence of villi. Rule out parasitic infection. Treatment with corticosteroids produces a rapid response.

- Mucosal eosinophilic gastroenteritis: allergies, food intolerances, eosinophilia, and episodic intestinal symptoms.
- Rule out parasitic infection.
- Corticosteroids produce a rapid response.

Systemic Mastocytosis

Systemic mastocytosis is a proliferation of mast cells in the skin (urticaria pigmentosa), bones, lymph nodes, and parenchymal organs. Histamine is released, and 50% of patients have gastrointestinal symptoms, that is, diarrhea and peptic ulcer. "Bath pruritus" (itching after a hot bath) is a clue to the diagnosis.

- Systemic mastocytosis causes urticaria pigmentosa.
- Gastrointestinal symptoms occur in 50% of patients.
- "Bath pruritus" is a clue to the diagnosis.

Intestinal Lymphangiectasia

Intestinal lymphangiectasia is a disorder caused by lymphatic obstruction. Hypoplastic lymphatics cause lymph to leak into the intestine. The clinical features are edema (often unilateral leg edema), chylous peritoneal or pleural effusions, and steatorrhea or protein-losing enteropathy. Laboratory findings include lymphocytopenia (average, 0.6×10^9/L) due to enteric loss. All serum proteins are decreased, including immunoglobulins. Small-bowel radiographs show edematous folds, and small-bowel biopsy specimens show dilated lacteals and lymphatics in the lamina propria that may contain lipid-laden macrophages. The same biopsy findings are seen in obstruction of mesenteric nodes (lymphoma, Whipple disease, and Crohn disease) and obstruction of venous inflow to the heart (constrictive pericarditis and severe right heart failure). Diagnosis is based on abnormal small-bowel biopsy findings and documented enteric protein loss by increased α_1-antitrypsin levels in the stool. Treatment is with a low-fat diet and medium-chain triglycerides (they enter the portal blood rather than the lymphatics). Occasionally, surgical excision of the involved segment is useful if the lesion is localized.

- Intestinal lymphangiectasia: unilateral lymphedema of the leg and chylous peritoneal or pleural effusions.
- Lymphocytopenia is universal.
- Decreased serum proteins.
- Small-bowel biopsy specimens show dilated lacteals and lymphatics.
- Treatment: low-fat diet and medium-chain triglycerides.

Amyloidosis

Systemic amyloidosis is characterized by a diffuse deposition of an amorphous eosinophilic extracellular protein polysaccharide complex in the tissue. The main sites of amyloid deposition are the walls of

blood vessels and the mucous membranes and muscle layers of the intestine. Any portion of the gut may be involved. Amyloid damages tissues by infiltration (muscle and nerve infiltration causes motility disorders and malabsorption) and ischemia (obliteration of vessels causes ulceration and bleeding). Intestinal dysmotility can produce diarrhea, constipation, pseudo-obstruction, megacolon, and fecal incontinence. Clinical findings in amyloidosis include macroglossia, hepatomegaly, cardiomegaly, proteinuria, and peripheral neuropathy. Pinch (posttraumatic) purpura or periorbital purpura after proctoscopic examination may occur. Small-bowel radiography shows symmetrical, sharply demarcated thickening of the valvulae conniventes. Fat aspirate confirms the diagnosis in 80% of patients and rectal biopsy stained with Congo red in 70%.

Miscellaneous Small-Bowel Disorders

Meckel Diverticulum

Meckel diverticulum, the persistence of the vitelline duct, is the most frequent developmental abnormality of the gut. It usually occurs within 100 cm of the ileocecal valve on the antimesenteric border of the ileum. It contains all layers of the intestinal wall and so is a true diverticulum. The mucosa is usually ileal but may be gastric (pancreatic or intestinal). Complications include obstruction due to intussusception and volvulus around the band that fixes the diverticulum to the bowel wall. Benign (leiomyomas) and malignant (carcinoids or leiomyosarcoma) tumors have been found in diverticula. Diverticulitis is uncommon. Incarceration in an indirect inguinal hernia (Littre hernia) and perforation that causes peritonitis may occur. Hemorrhage is the common complication and results from ulceration of the ileal mucosa adjacent to the gastric mucosa. This accounts for 50% of the cases of lower gastrointestinal tract bleeding in children and young adults. Radiography usually is not helpful in making the diagnosis. A nuclear scan (parietal cells concentrate technetium) may show the diverticulum, but false-positive and false-negative results can occur.

- Meckel diverticulum is the most frequent developmental abnormality of the gut.
- It accounts for 50% of the cases of lower gastrointestinal tract bleeding in children and young adults.

Aortoenteric Fistula

A history of gastrointestinal tract bleeding in a patient who has had a previous aortic graft demands immediate evaluation to rule out an aortoenteric fistula. If the patient presents with massive bleeding, do not attempt endoscopy or arteriography. Emergency surgery is indicated.

Management of a smaller bleeding episode is more controversial, and urgent CT or endoscopy has been suggested as a possible alternative to surgical exploration. If the presence of a graft fistula is confirmed (by air in the vessel wall on CT or erosion of a graft into the intestinal lumen on endoscopy), emergent surgery is indicated.

- If a patient presents with massive bleeding, do not attempt endoscopy or arteriography. Emergency surgery is indicated.

Chronic Intestinal Pseudo-Obstruction

Pseudo-obstruction is a syndrome characterized by the clinical findings of mechanical bowel obstruction but without occlusion of the lumen. The two types are primary and secondary.

The primary type, also called idiopathic pseudo-obstruction, is a visceral myopathy or neuropathy. It is associated with recurrent attacks of nausea, vomiting, cramping abdominal pain, distention, and constipation, which are of variable intensity and duration. If the cause is familial, the patient will have a positive family history and the condition will be present at a young age. Esophageal motility is abnormal (achalasia) in most patients. Occasionally, urinary tract motility is abnormal, and diarrhea or steatorrhea results from bacterial overgrowth. Upper gastrointestinal tract and small-bowel radiographs show dilatation of the bowel and slow transit (not mechanical obstruction).

- Idiopathic pseudo-obstruction is due to a familial cause or to a sporadic visceral myopathy or neuropathy.
- Recurrent attacks have variable frequency and duration.
- Abnormal esophageal motility occurs in most patients.
- Steatorrhea is caused by bacterial overgrowth.

Secondary pseudo-obstruction is due to underlying systemic disease or precipitating causes. These causes include the following (the most important causes are in italics):

1. Diseases involving the intestinal smooth muscle: *amyloidosis*, scleroderma, systemic lupus erythematosus, myotonic dystrophy, and muscular dystrophy
2. Neurologic diseases: *Parkinson disease*, Hirschsprung disease, Chagas disease, and familial autonomic dysfunction
3. Endocrine disorders: *myxedema* and hypoparathyroidism
4. Drugs: *antiparkinsonian medications* (*L-dopa*), phenothiazines, tricyclic antidepressants, ganglionic blockers, clonidine, and narcotics

Approach to the Patient With Chronic Intestinal Pseudo-Obstruction

First, rule out a mechanical cause for the obstruction. Second, look for an underlying precipitating cause such as metabolic abnormalities, medications, or an underlying associated disease. If a familial idiopathic cause is suspected, assess esophageal motility. Suspect scleroderma if intestinal radiography shows large-mouth diverticula of the small intestine. Suspect amyloidosis if the skin shows palpable purpura and if proteinuria and neuropathy are present.

- Secondary pseudo-obstruction is due to an underlying systemic disease or precipitating cause.
- Patients with scleroderma present with large-mouth diverticula of the intestine.
- Patients with amyloidosis present with palpable purpura, proteinuria, and neuropathy.

Inflammatory Bowel Disease

"Idiopathic inflammatory bowel disease" refers to two disorders of unknown cause: chronic ulcerative colitis and Crohn disease. Other

possible causes of inflammation, especially infection, should be excluded before making the diagnosis of idiopathic inflammatory bowel disease.

Ulcerative colitis is a mucosal inflammation involving only the colon. Crohn disease is a transmural inflammation that can involve the gastrointestinal tract anywhere from the esophagus through the anus. The rectum is involved in about 95% of patients with ulcerative colitis and in only 50% of patients with Crohn disease. Ulcerative colitis is a continuous inflammatory process that extends from the anal verge to the more proximal colon (depending on the extent of the inflammation). Crohn disease is a segmental inflammation in which inflamed areas alternate with virtually normal areas. Patients with ulcerative colitis usually present with frequent bloody bowel movements with minimal abdominal pain, whereas patients with Crohn disease present with fewer bowel movements, less bleeding, and, more commonly, abdominal pain. Crohn disease is associated with intestinal fistula, fistula from the intestine to other organs, and perianal disease. Ulcerative colitis does not form fistulas, and perianal disease is uncommon. Strictures of the intestine are common with Crohn disease but rare in ulcerative colitis (when they are present, they suggest cancer).

- Ulcerative colitis involves only the colon.
- Crohn disease can involve the gastrointestinal tract anywhere from the esophagus through the anus.
- Ulcerative colitis is a continuous process.
- Crohn disease is a segmental inflammation.
- Ulcerative colitis is characterized by frequent, bloody bowel movements.
- Crohn disease is characterized by fewer bowel movements, less bleeding, and more abdominal pain.
- Crohn disease is associated with intestinal fistula, strictures, and perianal disease.

Extraintestinal Manifestations of Inflammatory Bowel Disease

Arthritis occurs in 10% to 20% of patients, usually monarticular or pauciarticular involvement of large joints. Peripheral joint symptoms mirror bowel activity: joint symptoms flare when colitis flares and joint symptoms improve as colitis improves. Also, axial joint symptoms such as ankylosing spondylitis (relationship with HLA-B27) and sacroiliitis—which are usually progressive and do not improve when colitis improves—can develop.

- The peripheral joint symptoms mirror bowel activity.
- Axial joint symptoms such as ankylosing spondylitis and sacroiliitis can develop and have a progressive course independent of bowel activity.

Skin lesions occur in 10% of patients. The three types of lesions are erythema nodosum, pyoderma gangrenosum, and aphthous ulcers of the mouth. Erythema nodosum and aphthous ulcers usually improve with treatment of colitis, whereas pyoderma gangrenosum has an independent course. Severe, refractory skin disease is an indication for surgical treatment.

- The skin lesions are erythema nodosum, pyoderma gangrenosum, and aphthous ulcers of the mouth.

Eye lesions occur in 5% of patients. The lesion is usually episcleritis or uveitis (or both). Episcleritis usually mirrors inflammatory bowel disease activity, but uveitis does not.

Liver disease also occurs in 5% of patients. Primary sclerosing cholangitis is more common in chronic ulcerative colitis than in Crohn disease. If the alkaline phosphatase level is increased in a patient with inflammatory bowel disease, the work-up for primary sclerosing cholangitis includes ultrasonography, endoscopic retrograde cholangiopancreatography, and liver biopsy.

- If a patient's alkaline phosphatase level increases with inflammatory bowel disease, evaluate for primary sclerosing cholangitis.
- Central (axial) arthritis, pyoderma gangrenosum, primary sclerosing cholangitis, and uveitis usually follow a course independent of bowel disease activity.

Renal lithiasis occurs in 5% to 15% of patients. In Crohn disease with malabsorption, calcium oxalate stones occur. In chronic ulcerative colitis, uric acid stones are due to dehydration and loss of bicarbonate in the stool, leading to acidic urine.

Indications for Colonoscopy

Colonoscopy is indicated for evaluating the extent of the disease and for stricture (biopsy) and filling defect (biopsy). It is also indicated for differentiating Crohn disease from ulcerative colitis when the two are otherwise indistinguishable. Another indication is for monitoring by random mucosal biopsy the development of dysplasia or cancer in patients who have had ulcerative colitis or Crohn disease for more than 8 years.

- Colonoscopy and random mucosal biopsy are recommended for patients who have had ulcerative colitis or Crohn disease for more than 8 years.

Toxic Megacolon

In patients with active inflammation, avoid the causes of toxic megacolon, including aerophagia, opiates, anticholinergic agents, hypokalemia, and barium enema.

- In patients with active inflammation, avoid the causes of toxic megacolon.

Treatment of Ulcerative Colitis

Sulfasalazine and other aminosalicylates can induce remission in 80% of patients with mild or moderate ulcerative colitis and are effective maintenance therapy for 50% to 75% of patients with ulcerative colitis. The active agent of sulfasalazine, 5-aminosalicylic acid (5-ASA), is bound to sulfapyridine (the vehicle). Colonic bacteria break the bond and release 5-ASA, which is not absorbed but stays in contact with the mucosa and exerts its anti-inflammatory action. The efficacy of 5-ASA may be related to its ability to inhibit the lipoxygenase pathway of arachidonic acid metabolism or to

function as an oxygen free radical scavenger (further studies are needed). It is effective in acute disease and in maintaining remission. The side effects (male infertility, malaise, nausea, pancreatitis, rashes, headaches, hemolysis, impaired folate absorption, hepatitis, aplastic anemia, and exacerbation of colitis) are related to the sulfapyridine moiety and occur in 30% of patients who take sulfasalazine.

The 5-ASAs are a group of new drugs that deliver 5-ASA to the intestine in various ways. They eliminate sulfa toxicity but are more expensive than sulfasalazine. Two of these drugs are mesalamine and olsalazine. Mesalamine can be given topically (Rowasa suppositories and Rowasa enema) or orally (Asacol, which is 5-ASA coated with an acrylic polymer that releases 5-ASA in the terminal ileum, and Pentasa, which has an ethyl cellulose coating that releases 50% of the 5-ASA in the small bowel). Olsalazine consists of two 5-ASA molecules conjugated with each other. Bacteria break the bond, releasing 5-ASA into the colon.

Aminosalicylates are used for mild to moderately active ulcerative colitis and for Crohn disease. Topical forms are useful for proctitis or left-sided colitis; systemic forms are used for pancolitis. Of the patients who do not tolerate sulfasalazine, 80% to 90% tolerate oral 5-ASA preparations. Side effects include hair loss, pancreatitis (often in patients who developed pancreatitis while taking sulfasalazine), reversible worsening of underlying renal disease, and exacerbation of colitis.

- Sulfasalazine and other aminosalicylates can induce remission in 80% of patients with mild or moderate ulcerative colitis and are effective maintenance therapy for 50%-75% of patients with ulcerative colitis.
- Sulfasalazine: side effects occur in 30% of patients.
- Other aminosalicylates are equally effective but more expensive; they are useful in 80%-90% of patients intolerant of sulfasalazine.

Topical corticosteroid preparations should be used twice daily by patients with active disease that is mild or moderate and is limited to the distal colon. Oral corticosteroids should be added to the regimen of patients with more proximal disease if sulfasalazine does not control the attacks. Up to 50% of the dose can be absorbed (depending on the preparation used and its vehicle). Oral preparations are indicated in active pancolonic disease of moderate severity in doses of 40 to 60 mg once daily or 20 to 40 mg daily in cases of mild disease that are unresponsive to topical corticosteroids and sulfasalazine. Prednisolone, the active metabolite, is the preferred form of drug for patients with cirrhosis (these patients may not be able to convert inactive prednisone to prednisolone). For patients who have a prompt response to oral corticosteroids, the dose may be tapered gradually at a rate not to exceed a 5-mg decrease in the total dose every 3 to 7 days. In severely ill patients, intravenous preparations should be given in large doses (prednisolone, 100 mg in divided doses) for up to 10 to 14 days. If improvement occurs at that time, therapy should be converted to oral corticosteroids (60-100 mg daily). If there is no improvement, surgical intervention (colectomy) is required. Because corticosteroids are not believed to prevent relapse, they should not be prescribed after the patient has complete remission and is symptom-free.

- Prescribe topical preparations twice daily for patients with active mild or moderate disease that is limited to the distal colon.
- Oral corticosteroids should be added to the regimen of patients with more proximal disease if topical steroids and sulfasalazine have not controlled the attacks.
- Oral preparations are useful in active pancolonic disease of moderate severity.
- Intravenous preparations are given to severely ill patients.
- Corticosteroids are useful in remission induction for ulcerative colitis but are not effective in maintenance of remission.

Total parenteral nutrition does not alter the clinical course of an ongoing attack. Indications for its use include severe dehydration and cachexia with marked fluid and nutrient deficits, excessive diarrhea that has not responded to standard therapy for chronic ulcerative colitis, and debilitated patients undergoing colectomy. Opiates (or their synthetic derivatives) and anticholinergic agents are contraindicated in chronic ulcerative colitis because they are ineffective and can contribute to the development of toxic megacolon.

- Total parenteral nutrition does not alter the clinical course of the ongoing attack.
- Use of opiates and anticholinergic agents is contraindicated in chronic ulcerative colitis.

Surgical treatment is curative in chronic ulcerative colitis. Indications for colectomy include severe intractable disease, acute life-threatening complications (perforation, hemorrhage, or toxic megacolon unresponsive to treatment), symptomatic colonic stricture, and suspected or documented colon cancer. Other indications are intractable moderate or severe colitis, refractory uveitis or pyoderma gangrenosum, growth retardation in pediatric patients, cancer prophylaxis, or inability to taper a regimen to low doses of corticosteroid (i.e., <15 mg daily) over a period of 2 to 3 months. Procedures include proctocolectomy with ileoanal anastomosis, Kock pouch, and conventional Brooke ileostomy.

- Surgical treatment is curative in chronic ulcerative colitis.

Treatment of Crohn Disease

The use of sulfasalazine is discussed above (see "Treatment of Ulcerative Colitis" section). This drug is more effective for colonic disease than for small-bowel disease, although 5-ASA products designed to be released and activated in the small bowel may prove to be effective in the colon. Sulfasalazine does not have an additive effect or a steroid-sparing effect when given with corticosteroids, nor does it maintain remission in Crohn disease as it does in ulcerative colitis. None of the aminosalicylates are effective for the prophylaxis of Crohn disease.

- Sulfasalazine is more effective for colonic disease than for small-bowel disease.
- It does not have an additive effect or a sparing effect when given with corticosteroids.

- It does not maintain remission in Crohn disease.

The use of corticosteroids is discussed above (see "Treatment of Ulcerative Colitis" section). Corticosteroids are the agents that most quickly control an acute exacerbation of Crohn disease. They are the most useful drugs for treating acute small-bowel Crohn disease and for achieving rapid remission.

Azathioprine and 6-mercaptopurine (the active metabolite of azathioprine) have steroid-sparing effects. Their use should be reserved for patients with active disease who are taking steroids and whose corticosteroid dose needs to be reduced (or a given dose needs to be maintained in the face of worsening disease activity).

- 6-Mercaptopurine is the active metabolite of azathioprine.
- Azathioprine and 6-mercaptopurine are effective as maintenance therapy for Crohn disease.
- Both agents have a steroid-sparing effect.

Metronidazole (at a dose of 20 mg/kg) is effective for treating perianal disease. Six weeks may be needed for the therapeutic effect to become manifest. Recurrences are frequent when the drug dose is tapered or discontinued, leading to chronic therapy. It is as effective as sulfasalazine for treating disease of the colon. If the disease is unresponsive to sulfasalazine, it is worthwhile switching to metronidazole, but not vice versa. It is less effective for small-bowel disease. Side effects include glossitis, metallic taste, vaginal and urethral burning sensation, neutropenia, dark urine, urticaria, disulfiram (Antabuse) effect, and paresthesias.

- Metronidazole is effective for treating perianal disease.
- Recurrences are frequent when the drug dose is tapered or discontinued.
- It is as effective as sulfasalazine for disease of the colon.

Infliximab (Remicade) is a chimeric monoclonal antibody directed against tumor necrosis factor α. This intravenously administered anti-inflammatory agent is effective in treating moderately or severely active Crohn disease that is refractory to conventional therapy and in treating fistulizing Crohn disease. Infliximab is a steroid-sparing agent that is effective in maintaining remission of Crohn disease. Infusion reactions consisting of pruritus, dyspnea, or chest pain may occur. The drug is associated with an increased risk of infection, including perianal abscesses, tuberculosis, and other respiratory infections. Rarely, subsequent infusions of infliximab may be associated with delayed hypersensitivity reactions.

- Infliximab is effective in treating moderately or severely active Crohn disease that is refractory to conventional therapy and in treating fistulizing Crohn disease.
- Infliximab is associated with acute infusion reactions, delayed hypersensitivity reactions, and an increased risk of infections.

Bowel rest per se does not have any role in achieving remission in Crohn disease. However, providing adequate nutritional support does help facilitate remission; any form of nutritional support is acceptable as long as the amount is adequate. Adequate nutrition can be essential in maintaining growth in children who have severe Crohn disease.

If Crohn disease is present during exploration for presumed appendicitis, the acute ileitis should be left alone (many of these patients do not develop chronic Crohn disease). Appendectomy can be performed if the cecum and appendix are free of disease. Of the patients with Crohn disease who have surgical treatment, 70% to 90% require reoperation within 15 years (many within the first 5 years after the initial operation). The anastomotic site is the most likely site for recurrence of disease. Indications for surgical treatment include intractable symptoms, acute life-threatening complications, obstruction, unhealed fistulas that cause complications, abscess formation, and malignancy.

- Of the patients with Crohn disease who are operated on, 70%-90% require reoperation within 15 years.
- The anastomotic site is the most likely site for disease recurrence.

Gastrointestinal Manifestations of AIDS

Gastrointestinal tract symptoms occur in 30% to 50% of North American and European patients with AIDS and in nearly 90% of patients in developing countries. The gastrointestinal tract in patients with AIDS is predisposed to a spectrum of viral, bacterial, fungal, and protozoan pathogens. The most frequent gastrointestinal tract symptom is diarrhea, which is often chronic, associated with weight loss, and usually caused by one or more identifiable pathogens. Dysphagia, odynophagia, abdominal pain, and jaundice are less frequent, and gastrointestinal tract bleeding is rare. The goal of evaluation is to identify treatable causes of infection or symptoms. When no cause is identified, the condition may be idiopathic AIDS enteropathy or it may be caused by as yet unidentified pathogens.

- The majority of AIDS patients with diarrhea have one or more identifiable pathogens.
- Some have no identifiable cause despite extensive evaluation. This may represent idiopathic AIDS enteropathy or as yet unidentified pathogens.

Viral

Cytomegalovirus

Cytomegalovirus is one of the most common and potentially serious opportunistic pathogens. It most commonly affects the colon and esophagus, although the entire gut, liver, biliary tract, and pancreas are susceptible. A patchy or diffuse colitis may progress to ischemic necrosis and perforation. Symptoms include watery diarrhea and fever and, less commonly, hematochezia and abdominal pain. Odynophagia may be present if the esophagus is involved. Diagnosis is based on biopsy specimens that show cytomegalic inclusion cells with surrounding inflammation ("owl's eye"). Treatment is ganciclovir, 5 mg/kg twice daily for 14 to 21 days. If the virus is resistant to ganciclovir, use foscarnet.

Herpes Simplex Virus

The three gastrointestinal tract manifestations of herpes simplex virus infection in patients with AIDS are perianal lesions (chronic cutaneous ulcers), proctitis, and esophagitis. The organs affected are the colon and esophagus. Symptoms include perianal lesions that are painful; proctitis that causes tenesmus, constipation, and inguinal lymphadenopathy; and esophagitis that causes odynophagia, with or without dysphagia. Diagnosis is based on the cytologic identification of intranuclear (Cowdry type A) inclusions in multinucleated cells and is confirmed with viral cultures. Treatment is acyclovir given orally or intravenously.

Adenovirus

Adenovirus reportedly causes diarrhea. The organ affected is the colon. The main symptom is watery, nonbloody diarrhea. Diagnosis is based on culture and biopsy. There is no treatment.

Bacteria

Mycobacterium avium-intracellulare

Mycobacterium avium-intracellulare causes infection of the gut in patients with disseminated disease. The small intestine is affected more commonly than the colon. Symptoms include fever, weight loss, diarrhea, abdominal pain, and malabsorption. Diagnosis is based on finding acid-fast organisms in the stool and tissue, with confirmation from culture of stool and biopsy specimens. Treatment is multiple drug therapy with ethambutol, rifampin, ciprofloxacin, and clarithromycin.

Other Bacteria

Other important bacteria include the following:

Salmonella typhimurium and *Salmonella enteritidis*—Treatment is with amoxicillin, trimethoprim-sulfamethoxazole, or ciprofloxacin.

Shigella flexneri—Treatment is with trimethoprim-sulfamethoxazole, ampicillin, or ciprofloxacin.

Campylobacter jejuni—Treatment is with erythromycin or ciprofloxacin.

In patients with AIDS, *Salmonella*, *S. flexneri*, and *C. jejuni* have a substantially higher incidence of intestinal infection, bacteremia, and prolonged or recurrent infections because of antibiotic resistance or compromised immune function, or both.

Fungi

Candida albicans

In patients with AIDS, *Candida* causes locally invasive mucosal disease in the mouth and esophagus. Disseminated candidiasis is rare because neutrophil function remains relatively intact. The presence of oral candidiasis in persons at risk of AIDS should alert the physician to possible human immunodeficiency virus (HIV) infection. If oral candidiasis is present, endoscopy is required to confirm esophageal involvement. The symptoms of odynophagia suggest esophageal involvement. Diagnosis is based on histologic examination showing hyphae, pseudohyphae, or yeast forms. Treatment is with nystatin, ketoconazole, fluconazole, or amphotericin.

Histoplasma capsulatum

H. capsulatum causes an important opportunistic infection in AIDS patients who reside in endemic areas. Colonic involvement is more common than small-bowel involvement. Symptoms include diarrhea, weight loss, fever, and abdominal pain. Diagnosis is established by culture. Colonoscopy may show inflammation and ulcerations, and histologic examination with Giemsa stain shows intracellular yeast-like *H. capsulatum* within lamina propria macrophages. Treatment is with amphotericin or itraconazole.

Protozoa

Cryptosporidium

Cryptosporidium is among the commonest enteric pathogens, occurring in 10% to 20% of patients with AIDS and diarrhea in the United States and in 50% of those in developing countries. The organs affected are the small and large intestines and the biliary tree. Symptoms include voluminous watery diarrhea, severe abdominal cramps, weight loss, anorexia, malaise, and low-grade fever. Biliary tract obstruction has been reported. Diagnosis is based on microscopic identification of organisms in stool specimens with modified acid-fast staining or stains specific for *Cryptosporidium*. Organisms may also be identified in biopsy specimens or in duodenal fluid aspirates. Treatment is with paromomycin, which reduces the diarrhea.

Isospora belli

Isospora belli is the more common cause of diarrhea in developing countries. The small intestine is primarily affected, but the organisms can be identified throughout the gut and in other organs. Symptoms include watery diarrhea, cramping abdominal pain, weight loss, anorexia, malaise, and fever. Diagnosis is based on identifying oval oocysts in stool with a modified Kinyoun carbolfuchsin stain. Biopsy specimens from the small intestine may show organisms in the lumen or within cytoplasmic vacuoles in enterocytes. Although *I. belli* oocysts resemble *Cryptosporidium* oocysts, *I. belli* oocysts contain two sporoblasts. *Cryptosporidium* oocysts are small and round and contain four sporozoites. Treatment is with trimethoprim-sulfamethoxazole.

Microsporida (Enterocytozoon bieneusi)

Organisms in the order Microsporida are emerging as important pathogens; they have been identified in up to 33% of AIDS patients who have diarrhea. The organ affected is the small intestine, and symptoms include watery diarrhea with gradual weight loss but no fever or anorexia. Diagnosis is based on electron microscopic identification of round or oval meront (proliferative) and sporont (spore-forming) stages of Microsporida in the villous but not crypt epithelial cells of the duodenum and jejunum. There are reports of positive stool specimens with Giemsa staining. There is no known treatment.

Other Protozoa

Entamoeba histolytica—Treatment is with metronidazole.

Giardia lamblia—Treatment is with metronidazole.

Blastocystis hominis—Because there is no evidence that *B. hominis* is pathogenic, it does not need to be treated.

The rates of symptomatic infection with *E. histolytica*, *G. lamblia*, or *B. hominis* are not markedly higher than in patients who do not have AIDS. *E. histolytica* is a nonpathogenic commensal in most patients with AIDS. Giardiasis may require prolonged treatment, as in other immunocompetent persons.

Diagnostic Evaluation of Patients With AIDS Who Have Diarrhea

When patients with AIDS have diarrhea, initial studies include examination for stool leukocytes; stool cultures for *Salmonella* species, *Shigella flexneri*, and *Campylobacter jejuni* (at least three specimens); stool examination for ova and parasites (using saline, iodine, trichrome, and acid-fast preparations); and stool assay for *Clostridium difficile* toxin. Additional studies include gastroscopy to inspect tissue, to aspirate luminal material, and to obtain biopsy specimens; examination of duodenal aspirate for parasites and culture; culture of duodenal biopsy specimens for cytomegalovirus and mycobacteria; colonoscopy to inspect tissue and to obtain biopsy specimens; culture of biopsy specimens for cytomegalovirus, adenovirus, mycobacteria, and herpes simplex virus; and staining biopsy specimens with hematoxylin-eosin for protozoa and viral inclusion cells, with methenamine silver or Giemsa stain for fungi, and with Fite method for mycobacteria.

Whether further evaluation is needed if the studies listed above do not yield a diagnosis is a matter of controversy. Most experts advocate empirical treatment with loperamide (Imodium). Others recommend that biopsy specimens from the duodenum be examined with electron microscopy for Microsporida or from the colon for adenovirus. Empirical treatment with loperamide is favored because there is no treatment for either Microsporida or adenovirus.

Colon

Pseudomembranous Enterocolitis

Pseudomembranous enterocolitis is a necrotizing inflammatory disease of the intestines characterized by the formation of a membrane-like collection of exudate overlying a degenerating mucosa. Precipitating factors include colon obstruction, uremia, ischemia, intestinal surgery, and all antibiotics (except vancomycin).

Antibiotic Colitis

The symptoms of antibiotic colitis are fever, abdominal pain, and diarrhea (mucus and blood), which usually occur 1 to 6 weeks after antibiotic therapy. Sigmoidoscopy shows pseudomembranes and friability. Biopsy specimens show inflammation and microulceration with exudation. The condition usually remits, but it recurs in 15% of patients. Complications include perforation and megacolon. The pathogenesis begins with the antibiotic altering the colonic flora, resulting in an overgrowth of *Clostridium difficile*. The toxin produced by *C. difficile* is cytotoxic, causing necrosis of the epithelium and exudation (pseudomembranes). Diagnosis is based on a toxin assay, which is positive in 98% of patients, and on cultures, which are positive in about 75%. Radiography shows pseudomembranes. Proctoscopic findings may be normal or show classic pseudomembranes. The treatment is to discontinue the use of antibiotics and provide general supportive care (e.g., fluids). Avoid use of antimotility agents. If there is no response, metronidazole (250 mg three times daily) is 80% effective and inexpensive. Vancomycin (125 mg four times daily) is also 80% effective but expensive. If the patient is very ill, cholestyramine binds toxin. For a first recurrence, the same antibiotic can be used or the drug can be switched. For multiple recurrences, add cholestyramine and prolong the course of treatment with antibiotics.

- Antibiotic colitis: symptoms include fever, abdominal pain, and diarrhea 1-6 weeks after antibiotic therapy.
- A toxin assay is positive in 98% of patients.
- Culture is positive in 75%.
- Metronidazole is the initial treatment.
- It recurs in 15% of patients.

Radiation Colitis

Irradiation injury usually affects both the colon and the small bowel. Endothelial cells of small submucosal arterioles are very radiosensitive and respond to large doses of irradiation by swelling, proliferating, and undergoing fibrinoid degeneration. The result is obliterative endarteritis. *Acute disease* occurs during or immediately after irradiation; the mucosa fails to regenerate, and there is friability, hyperemia, and edema. *Subacute disease* occurs 2 to 12 months after irradiation. Obliterative endarteritis produces progressive inflammation and ulceration. *Chronic disease* consists of fistulas, abscesses, strictures, and bleeding from intestinal mucosal vessels. Predisposing factors include other diseases that produce microvascular insufficiency (e.g., hypertension, diabetes mellitus, atherosclerosis, and heart failure) because they accelerate the development of vascular occlusion, total irradiation dose of 40 to 50 Gy, previous chemotherapy, adhesions, previous surgical procedure and pelvic inflammatory disease, and age (the elderly are more susceptible). Radiography of acute disease shows fine serrations of the bowel, and radiography of chronic disease shows stricture of the rectum, which is involved most commonly. Endoscopy shows atrophic mucosa with telangiectatic vessels. Endoscopic coagulation is effective treatment for bleeding, but surgery may be required for fistulas, strictures, or abscesses.

- Radiation colitis involves both the colon and the small bowel.
- The endothelial cells of the small submucosal arterioles are very radiosensitive.
- The result is obliterative endarteritis.
- Predisposing factors: hypertension, diabetes mellitus, atherosclerosis, chemotherapy, and >40 Gy of irradiation.
- The rectum is involved most commonly.

Ischemia

Review of Vascular Anatomy

The celiac trunk supplies the stomach and duodenum. The superior mesenteric artery supplies the jejunum, ileum, and right colon. The inferior mesenteric artery supplies the left colon and rectum.

Acute Ischemia

The symptoms of acute ischemia are sudden severe abdominal pain, vomiting, and diarrhea (with or without blood). Early in the course of

ischemia, physical examination findings are normal despite complaints of severe abdominal pain, but later findings indicate peritonitis. Risk factors include severe atherosclerosis, congestive heart failure, atrial fibrillation (source of emboli), hypotension, and oral contraceptives.

There are several syndromes. *Acute mesenteric ischemia* is due to embolic obstruction of the superior mesenteric artery in 80% of patients. Most (95%) emboli lodge in this artery because of laminar flow, vessel caliber, and the angle it takes off from the aorta. The clue to search for emboli is atrial fibrillation. This syndrome results in a loss of small bowel and produces short-bowel syndrome. Radiography shows ileus, small-bowel obstruction, and, later, gas in the portal vein. The treatment is embolectomy. *Ischemic colitis* is due to a transient decrease in perfusion pressure in a setting of chronic, diffuse mesenteric vascular disease. This decrease occurs in severe dehydration or shock and results in ischemia of the gastrointestinal tract. It commonly involves areas of the colon between adjacent arteries, that is, "watershed areas," such as the splenic flexure and rectosigmoid. Patients with this syndrome present with abdominal pain and rectal bleeding. The characteristic radiographic feature is thumbprinting of watershed areas. The treatment is supportive and, if the condition deteriorates, surgical resection. *Nonocclusive ischemia* is due to poor tissue perfusion caused by inadequate cardiac output. It can involve both the small and large bowels. Its distribution does not conform to an area supplied by a major vessel. It occurs in patients with cardiac failure or anoxia or in patients who are in shock. It is questioned whether digitalis causes mesenteric vasoconstriction.

- Acute mesenteric ischemia is usually due to emboli.
- Ischemic colitis: diagnosis is based on the radiographic finding of thumbprinting of watershed areas.

Chronic Ischemic Colitis (Intestinal Angina)

Chronic ischemic colitis is uncommon. Symptoms include postprandial pain and fear of eating (weight loss). At least two of three major splanchnic vessels must be occluded. It is associated with hypertension, diabetes mellitus, and atherosclerosis. An abdominal bruit is a clue to the diagnosis. Angiography is diagnostic in about 50% of cases and shows a stenotic area in two of three major vessels. The treatment is surgical revascularization.

Occlusion of the superior mesenteric vein accounts for approximately 10% of cases of bowel ischemia. Risk factors include hypercoagulable states such as polycythemia vera, liver disease, pancreatic cancer, intra-abdominal abscess, and portal hypertension. Patients present with abdominal pain that gradually becomes severe. Diagnosis is based on angiographic findings. The treatment is surgical.

- Chronic ischemic colitis is associated with hypertension, diabetes mellitus, and atherosclerosis.
- Mesenteric venous thrombosis occurs with hypercoagulable states.

Amebic Colitis

The colon is the usual initial site of amebic colitis. Symptoms vary from none to explosive bloody diarrhea with fever, tenesmus, and abdominal cramps. Proctoscopy shows discrete ulcers with undermined edges and normal adjacent mucosa. If an exudate is present, swab and make wet mount preparations for trophozoites. Indirect hemagglutination is useful for invasive disease. Radiography shows concentric narrowing of the cecum in 90% of cases. Treat with metronidazole. *Entamoeba histolytica* is the only pathogenic ameba in humans.

- The colon is the initial site of disease.
- Proctoscopy shows discrete ulcers with undermined edges.
- Radiography shows concentric narrowing of the cecum in 90% of cases.
- *E. histolytica* is the only pathogenic ameba in humans.

Tuberculosis

Patients with tuberculosis present with diarrhea, a change in bowel habits, and rectal bleeding. The ileocecal area is the most commonly involved site. Radiography shows a contracted cecum and ascending colon and ulceration. Proctoscopy demonstrates deep and superficial ulcers. The rectum may be spared. A hypertrophic ulcerating mass may be seen. Biopsy samples stained with Ziehl-Neelsen stain are positive for acid-fast bacilli. All cases are associated with pulmonary or miliary tuberculosis.

- Tuberculosis is associated with diarrhea, change in bowel habits, and rectal bleeding.
- The ileocecal area is commonly involved.
- Deep and superficial ulcers are characteristic findings.
- All cases are associated with pulmonary or miliary tuberculosis.

Streptococcus bovis Endocarditis

Streptococcus bovis endocarditis is associated with colon disease (diverticulosis or cancer). The colon should be evaluated.

Irritable Bowel Syndrome

The term "irritable bowel syndrome" is used for symptoms that are presumed to arise from the small and large intestines. It refers to a well-recognized complex of symptoms arising from interactions of the intestine, the psyche, and, possibly, luminal factors. Most patients have abdominal pain that is relieved with defecation or associated with a change in the frequency or consistency of the stool. Other associated symptoms include abdominal bloating and passage of excessive mucus with the stool.

Patients with irritable bowel syndrome usually have a long duration of symptoms, symptoms associated with situations of stress, and no weight loss, no intestinal bleeding, and no associated organic symptoms (e.g., arthritis or fever). Irritable bowel syndrome is a diagnosis of exclusion: the diagnosis is confirmed by an appropriate medical evaluation that does not reveal any organic illness. Always ask whether the patient's symptoms are related to ingestion of dairy foods because lactase deficiency must be ruled out. Patients who have upper abdominal discomfort and bloating may require an ultrasonographic examination of the abdomen and esophagogastroduodenoscopy. Patients with lower abdominal discomfort or with a change in bowel habits may require stool studies, proctoscopic examination, and colon radiography or colonoscopy.

The treatment of irritable bowel syndrome is reassurance, stress reduction, high-fiber diet, or the use of fiber supplements. The use of antispasmodics to control abdominal pain or antimotility agents to control diarrhea should be reserved for patients who do not have a response to a high-fiber diet.

Nontoxic Megacolon (Pseudo-Obstruction)

Acute pseudo-obstruction of the colon occurs postoperatively (nonabdominal operations) and with spinal cord injury, sepsis, uremia, electrolyte imbalance, and drugs (narcotics, anticholinergics, and psychotropic agents). When the cecum is more than 13 or 14 cm in diameter, the risk of perforation increases. Obstruction should be ruled out with a Hypaque enema. Treatment includes placement of a nasogastric tube, discontinuation of drug therapy, correction of metabolic abnormalities, and, if needed, colonoscopic decompression or cecostomy.

Chronic pseudo-obstruction of the colon occurs with disorders that cause generalized intestinal pseudo-obstruction.

Congenital Megacolon

Congenital megacolon (Hirschsprung disease) occurs in 1 in 5,000 births. The incidence is increased with Down syndrome. Congenital megacolon usually becomes manifest in infancy; however, it can occur in adulthood. There is a variable length of aganglionic segment from the rectum to the proximal colon (usually confined to the rectum or rectosigmoid). The diagnosis is usually made at birth because of meconium ileus or obstipation. If the diagnosis is made in an adult, the patient has a history of chronic constipation. Colon radiography shows a characteristically narrowed distal segment and a dilated proximal colon. Rectal biopsy shows aganglionosis. Anorectal manometry shows loss of the anorectal inhibitory reflex. Treatment is with sphincter-saving operations.

- Congenital megacolon: increased incidence with Down syndrome.
- If the diagnosis is made in an adult, there is a history of chronic constipation.
- Colon radiography shows a characteristically narrowed distal segment and a dilated proximal colon.
- Rectal biopsy shows aganglionosis.
- Motility: absence of anorectal inhibitory reflex.

Lower Gastrointestinal Tract Bleeding

The evaluation of rectal bleeding should begin with a digital examination, anoscopy, and proctosigmoidoscopy. If a definitive diagnosis cannot be made, perform a barium enema or arteriography, depending on the nature of the bleeding. The inability to cleanse the colon appropriately during active bleeding makes the barium enema difficult to perform and interpret. Some advocate the use of nuclear scanning if the activity of the bleeding is uncertain. With active bleeding, angiography is the diagnostic procedure of choice. It is also indicated for patients with recurrent episodes of rectal bleeding who have had normal results on previous standard tests, that is, barium enema or colonoscopy. Colonoscopy is not useful if bleeding in the lower gastrointestinal tract is torrential, but it may be of some benefit if there is a slower rate of bleeding. Colonoscopy is valuable for evaluating patients who have unexplained rectal bleeding and persistently positive findings on tests for occult blood in the stool.

- Initial evaluation of rectal bleeding: digital examination, anoscopy, and proctosigmoidoscopy.
- If activity of bleeding is uncertain, a nuclear scan may be the next best test.
- Colonoscopy is not useful if there is torrential bleeding in the lower gastrointestinal tract.
- Angiography is the procedure of choice for active bleeding.

The important causes of lower gastrointestinal tract bleeding are the following:

1. Angiodysplasia—usually involves the right colon and small bowel and may respond to endoscopic treatment
2. Diverticular disease—usually bleeding without other symptoms
3. Inflammatory bowel disease (colitis)—5% of patients present with it
4. Ischemic colitis—painful and bloody diarrhea
5. Cancer—rarely causes marked bleeding
6. Meckel diverticulum—the commonest cause of lower gastrointestinal tract bleeding in young patients; it is usually painless
7. Hemorrhoids—usually are present with rectal outlet bleeding

In the evaluation of lower gastrointestinal tract bleeding, stabilize the patient, perform proctoscopy to rule out rectal outlet bleeding, and obtain a nasogastric tube aspirate or use esophagogastroduodenoscopy to rule out upper gastrointestinal tract bleeding. A radionuclide-tagged red blood cell scan may help determine whether bleeding is occurring, but it may not localize precisely the bleeding site. If there is active bleeding, perform angiography. If bleeding stops or occurs at a slow rate, perform colonoscopy. If the patient is young, perform a Meckel scan.

If angiography localizes the bleeding site, infusion of vasopressin or embolization may be useful. If colonoscopy demonstrates bleeding, injection of epinephrine, electrocoagulation, or laser coagulation may be useful. If bleeding is massive or if marked bleeding continues, surgical management is needed.

Diverticular Disease of the Colon

Definitions

Diverticula are acquired herniations of the mucosa and submucosa through the muscular layers of the colonic wall. *Diverticulosis* is the mere presence of uninflamed diverticula of the colon. *Diverticulitis* is the inflammation of one or more diverticula. The diagnosis and management of the complications of diverticular disease are outlined in Table 7-13.

Diverticulitis

Microperforation or macroperforation of the diverticulum with subsequent peridiverticular inflammation is necessary to produce diverticulitis. The severity of the clinical symptoms depends on the

extent of the inflammation. Free perforation is infrequent (diverticula are invested by longitudinal muscle and mesentery). Local perforations may dissect along the colon wall and form intramural fistulas. The clinical presentation is left lower quadrant pain, fever, abdominal distention, constipation, and, occasionally, a palpable tender mass. Treatment includes resting the bowel or using a low-fiber diet and antibiotics and obtaining an early surgical consultation. Indications for surgical treatment during the acute phase include the development of generalized peritonitis, an enlarging inflammatory mass, fistula formation, colonic obstruction, inability to rule out carcinoma in an area of stricture, or recurrent episodes of diverticulitis.

- Diverticulitis: the clinical symptoms depend on the extent of inflammation.
- Free perforation is infrequent.
- Clinical presentation: left lower quadrant pain, fever, abdominal distention, constipation, and, occasionally, a palpable tender mass.
- Treatment: bowel rest and antibiotics; obtain a surgical consultation.

Angiodysplasia

Angiodysplasia is a common and increasingly recognized cause of lower gastrointestinal tract bleeding in elderly patients. Acquired vascular ectasias are believed to be associated with aging. Angiodysplasia is associated with cardiac disease, especially aortic stenosis. It usually involves the cecum and ascending colon. There are no associated skin or visceral lesions. The ectasias appear to be due to the chronic, partial, intermittent, and low-grade obstruction of submucosal veins where they penetrate the colon. Obstruction is from muscle contraction and distention of the cecum. Colon radiography is of no diagnostic value. Angiography localizes the extent of involvement. Colonoscopy may show lesions. Cautery application may be effective.

- Acquired vascular ectasias are associated with aging.
- Angiodysplasia is associated with cardiac disease, especially aortic stenosis.
- It usually involves the cecum and ascending colon.
- Colonoscopy may show lesions. Apply cautery.

Colon Polyps

Three types of epithelial polyps are benign: hyperplastic, hamartomatous, and inflammatory polyps. *Hyperplastic polyps* are metaplastic, completely differentiated glandular elements. *Hamartomatous polyps* are a mixture of normal tissues. *Inflammatory polyps* are an epithelial inflammatory reaction.

The fourth type of epithelial polyp is *adenomatous polyps*, which represent a failure of differentiation of glandular elements. They are the only neoplastic (premalignant) polyp. The three types of adenomatous polyps are tubular adenoma, mixed (tubulovillous) adenoma, and villous adenoma (syndrome of hypokalemia and profuse mucus). The risk of cancer with any adenomatous polyp depends on two features: size larger than 1

Table 7-13 **Diagnosis and Management of Complications of Diverticular Disease**

Complication	Signs and symptoms	Findings	Treatment
Diverticulitis	Pain, fever, and constipation or diarrhea (or both)	Palpable tender colon, leukocytosis	Liquid diet, with or without antibiotics, or elective surgery
Pericolic abscess	Pain, fever (with or without tenderness), or pus in stools	Tender mass, guarding, leukocytosis, soft tissue mass on abdominal films or ultrasonograms	Nothing by mouth, intravenous fluids, antibiotics, early surgical treatment with colostomy
Fistula	Depends on site: dysuria, pneumaturia, fecal discharge on skin or vagina	Depends on site: fistulogram, methylene blue	Antibiotics, clear liquids, colostomy, and, later, resection
Perforation	Sudden severe pain, fever	Sepsis, leukocytosis, free air	Antibiotics, nothing by mouth, intravenous fluids, immediate surgical treatment
Liver abscess	Right upper quadrant pain, fever, weight loss	Tender liver, tender bowel or mass, leukocytosis, increased serum alkaline phosphatase, lumbosacral scan (filling defect)	Antibiotics, surgical drainage, operation for bowel disease
Bleeding	Bright red or maroon blood or clots	Blood on rectal exam, sigmoidoscopy, colonoscopy, angiography	Conservative: blood transfusion if needed, with or without operation

cm and the presence of villous elements. If a polyp is found on flexible sigmoidoscopy and biopsy shows a hyperplastic polyp, no further work-up is needed. If biopsy shows an adenomatous polyp, perform colonoscopy to look for additional polyps and to perform polypectomy.

- Adenomatous polyps are the only neoplastic (premalignant) polyp.
- The risk of cancer with any adenomatous polyp depends on size >1 cm and the presence of villous elements.
- If biopsy shows an adenomatous polyp, perform colonoscopy.

Hereditary Polyposis Syndromes Associated With Risk of Cancer

Only the polyposis syndromes associated with adenomatous polyps have a risk of cancer.

Familial Adenomatous Polyposis

Familial adenomatous polyposis (FAP) is characterized by adenomatous polyps of the colon. Colorectal carcinoma develops in more than 95% of patients. There are no extra-abdominal manifestations except for bilateral congenital hypertrophy of the retinal pigment epithelium. Diagnosis is based on family history and documentation of adenomatous polyps. Screening is indicated for all family members, and colectomy is indicated before malignancy develops. The inheritance is autosomal dominant; however, the phenotypic expression may vary considerably.

- Colorectal carcinoma develops in more than 95% of patients with FAP.
- There are no extra-abdominal manifestations except for bilateral congenital hypertrophy of the retinal pigment epithelium.
- Colectomy is indicated before malignancy develops.

Gardner Syndrome

In Gardner syndrome, adenomatous polyps involve the colon, although rarely the terminal ileum and proximal small bowel are involved. Colorectal cancer develops in more than 95% of patients. Extraintestinal manifestations include congenital hypertrophy of the retinal pigment epithelium; osteomas of the mandible, skull, and long bones; supernumerary teeth; soft tissue tumors; thyroid and adrenal tumors; and epidermoid and sebaceous cysts. Screening is indicated for family members, and colectomy should be performed before malignancy develops. The inheritance is autosomal dominant.

- Colorectal cancer develops in more than 95% of patients with Gardner syndrome.
- There are extraintestinal manifestations.
- Screening is indicated for family members.

Turcot Syndrome

In Turcot syndrome, adenomatous polyps of the colon are associated with malignant gliomas and other brain tumors. The inheritance is likely autosomal dominant but with variable penetrance.

Hereditary Polyposis Syndromes Not Associated With Risk of Cancer

Peutz-Jeghers Syndrome

In Peutz-Jeghers syndrome, hamartomas occur in the small intestine and, less commonly, in the stomach and colon. Pigmented lesions of the mouth, hands, and feet are associated with ovarian sex cord tumors and tumors of the proximal small bowel. The inheritance is autosomal dominant.

- Peutz-Jeghers syndrome: hamartomas of the small intestine.
- Pigmented lesions of the mouth, hands, and feet are associated with ovarian sex cord and proximal small bowel tumors.

Juvenile Polyposis

In juvenile polyposis, hyperplastic polyps involve the colon and, less commonly, the small intestine and stomach. Patients present with gastrointestinal tract bleeding or intussusception with obstruction.

- Only the polyposis syndromes associated with adenomatous polyps carry a risk of cancer.
- Perform colectomy for diffuse polyposis only if the polyps are adenomatous.
- Screening is indicated for patients with heritable polyposis syndromes only if the polyps are adenomatous.
- Polyposis syndromes are autosomal dominant.

Colorectal Cancer

Epidemiology

Epidemiology is important in etiologic theories. Colorectal carcinoma is the second most common cancer in the United States, with 100,000 new cases and 60,000 deaths annually. Colon cancer eventually develops in 6% of Americans, and the mortality rate has not decreased since the 1930s. The incidence, which varies widely among different populations, is highest in "westernized" countries. Compared with past rates, rates for cancer of the right colon and sigmoid colon have increased, but rates for cancer of the rectum have decreased: cecum/ascending colon, 25%; sigmoid, 25%; rectum, 20%; transverse colon, 12%; rectosigmoid, 10%; and descending colon, 6%.

- Colorectal cancer is the second most common cancer in the United States.
- Rates for cancer of the right colon and sigmoid colon have increased.

Etiology

The role of the environment as a cause of colorectal cancer is supported by regional differences and migrant studies of incidence. A high-fat diet increases the risk and may enhance the cholesterol and bile acid content of bile, which is converted by colonic bacteria to compounds that may promote tumors. A high-fiber diet is protective. Increased stool bulk may dilute carcinogens and promoters and decrease exposure by decreasing transit time. Fiber components may bind carcinogens or decrease bacterial enzymes that form toxic compounds. Charbroiled

meat or fish and fried foods contain possible mutagens. Antioxidants (vitamins A and C), selenium, vitamin E, yellow-green vegetables, and calcium may protect against cancer.

- A high-fat diet increases the risk of colorectal cancer.
- A high-fiber diet has a protective effect.
- Charbroiled meat or fish and fried foods contain possible mutagens.

Genetic Factors

Certain oncogenes amplify or alter gene products in colon cancer cells. Aneuploidy is characteristic of more aggressive tumors. The carbohydrate structure of colonic mucus is altered in colon cancer. Cell-cell interaction possibly has a role in cancer development. Also, genetic predisposition has a role in many patients with colon cancer. FAP syndromes are autosomal dominant. Most colon cancer arises in adenomatous polyps. Hereditary nonpolyposis colon cancer (Lynch syndrome) is an autosomal dominant disease that may account for up to 5% of cases of colon cancer. Genetic susceptibility in the general population also has a role; for example, there is a threefold increased risk of colorectal cancer in first-degree relatives of patients with sporadic colorectal cancer.

- Aneuploidy is characteristic of more aggressive tumors.
- Genetic predisposition to cancer exists in many patients with colon cancer.
- FAP is autosomal dominant.
- There is a threefold increased risk of colorectal cancer in first-degree relatives of patients with sporadic colorectal cancer.

Risk Factors for Colorectal Cancer

The risk factors for colorectal cancer include the following:

1. Age older than 40—The risk increases sharply at age 40, doubles each decade until age 60, and peaks at age 80.
2. Personal history of adenoma or colon cancer—The risk increases with the number of adenomas; from 2% to 6% of patients with colon cancer have synchronous colon cancer and 1.1% to 4.7% have metachronous colon cancer.
3. Inflammatory bowel disease—Dysplasia precedes cancer; the cancer rate begins to increase after 7 years of chronic ulcerative colitis and increases 10% per decade of disease. After 25 years, the risk is 30%. The risk is greatest for pancolitis. The risk is delayed a decade in left-sided-only colitis and is negligible in ulcerative proctitis.

Cancer risk is not related to the severity of the first attack, disease activity, or age at onset. The rate of colon cancer is also increased 4 to 20 times in Crohn disease or ileocolitis. A family history of colon cancer is a risk factor, and a personal history of female genital or breast cancer carries a twofold increased risk of colon cancer.

- Colorectal cancer risk factor: age older than 40.
- Risk increases with the number of adenomas.
- From 2%-6% of patients with colon cancer have synchronous colon cancer and 1.1%-4.7% have metachronous colon cancer.
- Cancer rate begins to increase after 7 years of chronic ulcerative colitis.
- After 25 years, the risk is 30%.
- The risk is greatest for pancolitis.
- Crohn disease: the rate of colon cancer is increased 4-20 times.

Pathology and Prognostic Indicators

Cancer arises in the epithelium and invades transmurally to penetrate the bowel wall; it then enters the regional lymphatics to reach distant nodes. Hematogenous spread is through the portal vein to the liver. The surgical-pathologic stage of the primary tumor describes the depth of invasion and the extent of regional lymph node involvement, which are important in determining prognosis.

Modified Dukes Classification

Survival is determined by the extent of the invasion, which is categorized according to the modified Dukes classification: A, mucosa, submucosa (95% 5-year survival); B1, into, not through, the muscularis propria without nodal involvement (85%); B2, through the bowel wall without regional nodal involvement (70%-85%); C1, as in B1 but with regional nodes involved (45%-55%); C2, as in B2 but with regional nodes involved (20%-30%); and D, distant metastases (<1%).

Regional Node Involvement and Prognosis

The extent of regional node involvement and prognosis are as follows: 1 to 4 nodes, 35% recur; more than 4 nodes, 61% recur.

Other Pathologic Features and Prognosis

An ulcerating or infiltrating tumor is worse than an exophytic or polypoid tumor. Poorly differentiated histologic features are worse than highly differentiated ones. Venous or lymphatic invasion has a poor prognosis, as does aneuploidy.

Clinical Features and Prognosis

A high preoperative level of carcinoembryonic antigen is associated with a high recurrence rate and a shorter time before recurrence develops. The prognosis is poor if obstruction or perforation is present. The prognosis is worse for younger patients than older patients.

- The depth of invasion and the extent of regional lymph node involvement are important in determining prognosis.
- A high preoperative level of carcinoembryonic antigen is associated with high recurrence and a shorter time before recurrence.
- The prognosis is poor if obstruction or perforation is present.
- The prognosis is worse for younger patients than for older patients.

Diagnosis

The clinical presentation is a slow growth pattern. Disease may be present for 5 years before symptoms appear. The symptoms depend on the location of the disease. Patients with a tumor in the proximal colon may present with symptoms of anemia, abdominal discomfort, or a mass. The left colon is narrower, and patients may present with obstructive symptoms, a change in bowel habits, and rectal bleeding.

If cancer is suspected, perform an air-contrast barium enema and flexible sigmoidoscopy or colonoscopy. If cancer is detected with

an air-contrast barium enema or flexible sigmoidoscopy, colonoscopy is needed to rule out synchronous lesions.

A metastatic survey includes physical examination, evaluation of liver-associated enzymes, and chest radiography. Image the liver if the levels of liver-associated enzymes are abnormal. The preoperative level of carcinoembryonic antigen is helpful for assessing prognosis and for follow-up.

- Proximal colon disease: presenting symptoms may be related to anemia, abdominal discomfort, or a mass.
- Left colon disease: obstructive symptoms, change in bowel habits, and rectal bleeding.
- Preoperative level of carcinoembryonic antigen is helpful for assessing prognosis and for follow-up.

Treatment

For most cases, surgical resection is the treatment of choice. This includes wide resection of the involved segment (5-cm margins), with removal of lymphatic drainage. In rectal carcinoma, a low anterior resection is performed if an adequate distal margin of at least 2 cm can be achieved; this rectal sphincter–saving operation does not make the prognosis worse in comparison with abdominal perineal resection. The tumor may require resection to prevent obstruction or bleeding even if distant metastases are present.

- For most cases, surgical resection is the treatment of choice.

Postoperative Management—No Apparent Metastases

A single colonoscopy either preoperatively or within 6 to 12 months postoperatively is needed to exclude synchronous lesions. If the findings are negative, colonoscopy is repeated every 3 years.

Adjuvant chemotherapy with 5-fluorouracil and levamisole decreases recurrence by 41% and mortality by 33% in colonic stage C; it may be beneficial for stage B2. Radiotherapy plus 5-fluorouracil decreases the recurrence rate in rectal cancer stages B2 and C, but it is not clear whether there is any survival advantage.

- A single colonoscopy is preferred to exclude synchronous lesions; if the findings are negative, colonoscopy is performed every 3 years.
- 5-Fluorouracil and levamisole decrease recurrence by 41% and mortality by 33% in colonic stage C.

Prevention of Colorectal Carcinoma

Primary Prevention

The steps to be taken in primary prevention are not known, although epidemiologic data indicate that a high-fiber, low-fat diet is reasonable.

Secondary Prevention

Secondary prevention involves identifying and eradicating premalignant lesions and detecting cancer while it is still curable. Screening includes occult blood screening and endoscopy. With occult blood screening, earlier stage lesions are detected, but this has not decreased mortality. The Hemoccult test has a 20% to 30% positive predictive value for adenomas and 5% to 10% for carcinomas. With endoscopy, earlier stage lesions are detected, and the removal of adenomas results in a lower than expected incidence of rectosigmoid cancer but not in decreased mortality.

Recommendations for Screening

For average-risk patients (i.e., anyone not in the high-risk group), colonoscopy every 10 years after age 50 has generally become the diagnostic standard; however, an annual occult blood test plus sigmoidoscopy every 3 to 5 years after age 50 is still an alternative. For patients with previous carcinoma or multiple adenomas, colonoscopy should be performed every 3 years until findings are normal (no polyps) and then every 5 years. For a first-degree relative with colorectal cancer, colonoscopy should be performed every 3 years beginning at age 40 or at the age that is 5 years before the youngest case was diagnosed. For patients with hereditary nonpolyposis colorectal cancer (HNPCC) syndromes, colonoscopy should be performed at age 20 and then every 2 years until age 40 and then annually thereafter. For patients with FAP, annual sigmoidoscopy should be performed beginning at puberty until polyposis is diagnosed, and then colectomy should be performed. For patients with ulcerative colitis, annual colonoscopy and multiple biopsies should be performed starting after 8 years of pancolitis or after 15 years of left-sided-only chronic ulcerative colitis; dysplasia indicates the need for more frequent endoscopic follow-up and may lead to colectomy.

- Earlier stage lesions can be detected, but early detection has not been shown to decrease mortality.

Pancreas

Embryology

The pancreas develops in the fourth week of gestation as a ventral and dorsal outpouching or bud from the duodenum. Each bud has its own duct. As the duodenum rotates, the buds appose and join, and the ducts anastomose. If the ducts of the dorsal and ventral pancreas do not fuse, the resulting anomaly is called pancreatic ductus divisum. It is debated whether this condition may predispose to acute or recurrent pancreatitis. If part of the ventral pancreas encircles the duodenum (usually the second part, proximal to the ampulla) and causes obstruction, the anomaly is called annular pancreas.

- Pancreatic ductus divisum: failure of the dorsal and ventral pancreas to fuse. Might predispose to acute pancreatitis.
- Annular pancreas: part of the ventral pancreas encircles the duodenum (usually the second part, proximal to the ampulla) and causes obstruction.

Classification of Pancreatitis

Acute pancreatitis is a reversible inflammation. The two varieties are interstitial pancreatitis and necrotizing pancreatitis. Interstitial pancreatitis, in which perfusion of the pancreas is intact, accounts for 80% of cases, with less than 1% mortality. Necrotizing pancreatitis is more severe and results when perfusion is compromised. It accounts for 20% of cases, with 10% mortality if sterile and 30% if infected.

Chronic pancreatitis is irreversible (i.e., there is structural disease, with endocrine or exocrine insufficiency). It is documented by pancreatic calcifications on abdominal radiography, parenchymal and ductal abnormalities on endoscopic ultrasonography (EUS), ductal abnormalities on endoscopic retrograde cholangiopancreatography (ERCP), scarring on pancreatic biopsy, endocrine insufficiency (diabetes mellitus), or exocrine insufficiency (malabsorption).

- Acute interstitial pancreatitis: perfusion is intact; mortality is <1%.
- Acute necrotizing pancreatitis: perfusion is compromised; mortality is 10% if sterile and 30% if infected.
- Chronic pancreatitis is documented by pancreatic calcifications, ductal abnormalities, endocrine insufficiency (diabetes), or exocrine insufficiency (malabsorption).

Acute Pancreatitis

In acute pancreatitis, activation of pancreatic enzymes causes autodigestion of the gland. The clinical features are abdominal pain, nausea and vomiting ("too sick to eat"), ileus, peritoneal signs, hypotension, and abdominal mass.

Etiologic Factors

Alcohol is the most common cause and gallstones the second most common cause. The third most common cause is idiopathic (approximately 10% of cases). The following drugs cause pancreatitis: azathioprine, 6-mercaptopurine, L-asparaginase, hydrochlorothiazide diuretics, sulfonamides, sulfasalazine, tetracycline, furosemide, estrogens, valproic acid, pentamidine (both parenteral and aerosolized), and the antiretroviral drug didanosine (ddI).

The evidence that the following drugs may also cause pancreatitis is less convincing: corticosteroids, NSAIDs, methyldopa, procainamide, chlorthalidone, ethacrynic acid, phenformin, nitrofurantoin, enalapril, erythromycin, metronidazole, and nonsulfa-linked aminosalicylate derivates (such as 5-ASA and interleukin-2).

Other causes include hypertriglyceridemia, which may cause pancreatitis if the triglyceride level is usually greater than 1,000 mg/dL. Look for types I, IV, and V hyperlipoproteinemia and for associated oral contraceptive use. Hypertriglyceridemia may mask hyperamylasemia. Hypercalcemia may also cause pancreatitis; look for underlying multiple myeloma, hyperparathyroidism, or metastatic carcinoma. In immunocompetent patients, mumps and coxsackievirus cause acute pancreatitis. In AIDS patients, acute pancreatitis has been reported with cytomegalovirus infection. Pancreatic ductus divisum, or incomplete fusion of the dorsal and ventral pancreatic ducts, may predispose some people to acute pancreatitis, although this is a controversial matter.

- In nonalcoholic patients with acute pancreatitis, review all medications, check lipid and calcium levels, and rule out gallstones.
- Several medications definitely cause acute pancreatitis.

Clinical Presentation

Pain

Pain may be mild to severe; it is usually sudden in onset and persistent. The pain is located typically in the upper abdomen and radiates to the back. Relief may be obtained by bending forward or sitting up. The ingestion of food or alcohol commonly exacerbates the pain. Patients without pain have a poor prognosis because they usually present with shock.

Fever

Fever, if present, is low grade, rarely exceeding 101°F in the absence of complications.

Volume Depletion

Most patients are hypovolemic because fluid accumulates in the abdomen.

Jaundice

Patients with pancreatitis may have a mild increase in total bilirubin, but they usually are not clinically jaundiced. When jaundice is present, it generally results from obstruction of the common bile duct by stones, compression by pseudocyst, or inflamed pancreatic tissue.

Dyspnea

A wide range of pulmonary manifestations may occur. In more than half of all cases of acute pancreatitis, some degree of hypoxemia is present, usually from pulmonary shunting. Patients often have atelectasis and may have pleural effusions.

- Fever >101°F suggests infection.

Diagnosis of Acute Pancreatitis

Serum Amylase

Determining the serum level of amylase is the most useful test for acute pancreatitis. The level of amylase increases 2 or 3 hours after an attack and remains increased for 3 or 4 days. The magnitude of the increase does not correlate with the clinical severity of the attack. Serum amylase levels may be normal in some (<10%) patients because of alcohol or hypertriglyceridemia. A persistent increase suggests a complication, for example, pseudocyst, abscess, or ascites. Serum amylase is cleared by the kidney. The urine amylase level remains elevated after the serum amylase level returns to normal. Isoenzyme identification may aid in distinguishing between salivary (nonpancreatic) and pancreatic sources. Serum lipase may help distinguish between pancreatic hyperamylasemia and an ectopic source (lung, ovarian, or esophageal carcinoma). Lipase levels are also increased for a longer time than amylase levels after acute pancreatitis. A CT scan of the abdomen may be useful. If the amylase level is mildly elevated and there is a history of vomiting but no signs of obstruction, one should consider performing an esophagogastroduodenoscopy to rule out a penetrating ulcer.

Nonpancreatic Hyperamylasemia

Nonpancreatic hyperamylasemia may result from parotitis; renal failure; macroamylasemia; intestinal obstruction, infarction, or perforation; ruptured ectopic pregnancy; diabetic ketoacidosis; drugs (such as morphine); burns; pregnancy; and neoplasms (lung, ovary, or esophagus).

- If the presentation for pancreatitis is classic but the amylase value is normal, repeat the amylase test, check urine amylase and serum lipase levels, and scan the abdomen.
- Persistent hyperamylasemia suggests a complication.
- If the amylase level is mildly elevated and there is a history of vomiting but no signs of obstruction, perform esophagogastroduodenoscopy to rule out a penetrating ulcer.

Physical Findings

Physical findings include tachycardia, orthostasis, fat necrosis, and xanthelasmas of the skin. The Grey Turner sign (flank discoloration) and Cullen sign (periumbilical discoloration) suggest retroperitoneal hemorrhage. The abdominal findings often are less impressive than the amount of pain the patient is experiencing.

- Look for metastatic fat necrosis.
- The Grey Turner sign and Cullen sign suggest retroperitoneal hemorrhage.

Imaging Studies

Imaging considerations include the following:

Chest radiography—An isolated left pleural effusion strongly suggests pancreatitis; infiltrates may represent aspiration pneumonia or adult respiratory distress syndrome.

Abdominal plain film—Look for the sentinel loop sign (a dilated loop of bowel over the pancreatic area) and colon cutoff sign (abrupt cutoff of gas in the transverse colon); pancreatic calcifications indicate chronic pancreatitis.

Ultrasonography—The procedure of choice for acute pancreatitis is ultrasonography, although in the presence of ileus, air in the bowel may obscure visualization of the pancreas; ultrasonographic examination gives information about the pancreas and is the best method for delineating gallstones, but it is not a good method to use if the patient is obese.

CT—If visualization of the pancreas is poor with ultrasonography, CT is the next step; it gives the same information as ultrasonography, is slightly less sensitive in detecting stones and texture abnormalities, involves irradiation, and is more expensive; CT is indicated for critically ill patients to rule out necrotizing pancreatitis and is the better imaging choice for obese patients.

ERCP—ERCP has no role in the diagnosis of acute pancreatitis and should be avoided because it may cause infection.

Endoscopic papillotomy—Endoscopic papillotomy is indicated when acute pancreatitis is associated with jaundice and cholangitis.

- An isolated left pleural effusion on chest radiography is strongly suggestive of acute pancreatitis.
- On an abdominal plain film, look for the sentinel loop sign, colon cutoff sign, and pancreatic calcifications.
- Ultrasonography is the procedure of choice for patients with mild acute pancreatitis and for thin patients and to rule out gallstones.
- CT is indicated for obese patients and seriously ill patients to rule out necrotizing pancreatitis.
- ERCP has no role in the diagnosis of acute pancreatitis.

Treatment

Supportive care is the backbone of treatment, with monitoring for and treatment of complications when they occur.

Fluids

Restore and maintain intravascular fluid volume; this usually can be accomplished with crystalloids and peripheral intravenous catheters. Monitor blood pressure, pulse, urine output, daily intake and output, and weight. Eliminate medications that may cause pancreatitis. The use of a nasogastric tube does not shorten the course or severity of pancreatitis, but it should be used in case of ileus or severe nausea and vomiting.

Analgesics

Meperidine (Demerol), 75 to 125 mg given intramuscularly every 3 or 4 hours, is preferred, especially over morphine, because it causes less spasm of the sphincter of Oddi. The efficacy of antisecretory drugs, such as H_2-blockers, anticholinergic agents, somatostatin, or glucagon, has not been documented. Total parenteral nutrition is unnecessary in most cases of pancreatitis. Peritoneal dialysis does not change the overall mortality, although it may decrease early mortality in severe pancreatitis.

- Supportive care is the backbone of treatment.
- Eliminate medications that may cause pancreatitis.
- The use of a nasogastric tube does not shorten the course or severity of pancreatitis.
- Meperidine (Demerol) is preferred because it causes less spasm of the sphincter of Oddi.

Complications

A local complication is phlegmon, a mass of inflamed pancreatic tissue. It may resolve. Pseudocysts, a fluid collection within a nonepithelial-lined cavity, should be expected if there is persistent pain and persistent hyperamylasemia. In 50% to 80% of patients, this resolves within 6 weeks without intervention. A pancreatic abscess develops usually 2 to 4 weeks after the acute episode and causes fever (>101°F), persistent abdominal pain, and persistent hyperamylasemia. If a pancreatic abscess is not drained surgically, the mortality rate is virtually 100%. Give antibiotics that are effective for gram-negative and anaerobic organisms. Jaundice is due to obstruction of the common bile duct. Pancreatic ascites results from disruption of the pancreatic duct or a leaking pseudocyst.

- A local complication of pancreatitis should be suspected if fever, persistent pain, or persistent hyperamylasemia occurs.

A systemic complication is respiratory distress syndrome, a well-recognized complication of acute pancreatitis. Circulating lecithinase probably splits fatty acids off lecithin, producing a faulty surfactant. Pleural effusions occur in approximately 20% of patients with acute pancreatitis. Aspirate analysis shows a high amylase content. Fat necrosis may be due to increased levels of serum lipase.

- Adult respiratory distress syndrome is a complication of acute pancreatitis.
- Pleural effusions occur in approximately 20% of patients with acute pancreatitis and have a high amylase content.

Assessment of Severity

Most patients with acute pancreatitis recover without any sequelae. The overall mortality rate of acute pancreatitis is 5% to 10%, and death is due most often to hypovolemia and shock, respiratory failure, pancreatic abscess, or systemic sepsis. The Ranson criteria and the Acute Physiology and Chronic Health Evaluation (APACHE) criteria are reliable for predicting mortality in acute pancreatitis (Table 7-14). Mortality is as follows: less than three Ranson criteria, 1%; three or four criteria, 15%; five or six criteria, 40%; and seven or more criteria, more than 80%.

- Most patients with acute pancreatitis recover without any sequelae.

Chronic Pancreatitis

Chronic use of alcohol (at least 10 years of heavy consumption) is the most common cause of chronic pancreatitis. Gallstones and hyperlipidemia usually do not cause chronic pancreatitis.

Hereditary pancreatitis is caused by a mutation in the cationic trypsinogen gene, which is inherited as an autosomal dominant trait with variable penetrance. Onset is before age 20, although 20% of patients may present later than this. Hereditary pancreatitis is marked by recurring abdominal pain, positive family history, and pancreatic calcifications. It may increase the risk of pancreatic cancer.

Trauma with pancreatic ductal disruption causes chronic pancreatitis. Protein calorie malnutrition is the commonest cause of chronic pancreatitis in Third World countries.

- Chronic pancreatitis is commonly caused by alcohol but seldom by gallstones or hyperlipidemia.
- Hereditary pancreatitis is seen in young people with a positive family history and pancreatic calcifications.
- Protein calorie malnutrition is the commonest cause of chronic pancreatitis in Third World countries.

Triad of Chronic Pancreatitis

The triad consists of pancreatic calcifications, steatorrhea, and diabetes mellitus. Diffuse calcification is due to heredity, alcohol, or malnutrition. Local calcification is due to trauma, islet cell tumor, or hypercalcemia. By the time steatorrhea occurs, 90% of the gland has been destroyed and lipase output has decreased by 90%.

- Patients with chronic pancreatitis present with abdominal pain, pancreatic calcification, steatorrhea, and diabetes mellitus.
- For steatorrhea to occur, 90% of the gland must be damaged.

Laboratory Diagnosis

Amylase and lipase levels may be normal, and stool fat may be normal. If malabsorption is present, stool fat is more than 10 g/24 h during a 48- to 72-hour stool collection while the patient is consuming a diet with 100 g of fat.

Table 7-14 **Ranson Criteria**

Admission	48 Hours
Age >55 y	Po_2 <60 mm Hg
Leukocyte count >15 × 10^9/L	Hematocrit decrease >10%
Glucose >200 mg/dL	Albumin <3.2 g/dL
Aspartate aminotransferase >250 U/L	Blood urea nitrogen increase >5 mg/dL
Lactate dehydrogenase >350 U/L	Calcium <8 mg/dL
	Estimated fluid sequestration >4 L

Modified from Ranson JHC. Acute pancreatitis: surgical management. In Go VLW, Gardner JD, Brooks FP, Lebenthal E, DiMagno EP, Scheele GA, editors. The exocrine pancreas: biology, pathobiology, and diseases. New York, Raven Press; 1986. p. 503-11. Used with permission.

For the cholecystokinin (CCK)/secretin stimulation test of pancreatic function, secretin and CCK are injected intravenously and then the contents of the small bowel are aspirated and the concentration of pancreatic enzymes is determined.

In the bentiromide test, *para*-aminobenzoic acid (PABA) conjugated with *N*-benzoyl tyrosine (bentiromide) is given orally. If chymotrypsin activity is adequate, the molecule is cleaved and PABA is absorbed and excreted in the urine. This test requires a normal small intestine (normal D-xylose test) and is useful only in severe steatorrhea.

CT shows calcifications, irregular pancreatic contour, dilated duct system, or pseudocysts. ERCP shows protein plugs, segmental duct dilatation, and alternating stenosis and dilatation, with obliteration of branches of the main duct.

- Amylase and lipase levels may be normal, but evidence for structural disease or endocrine or exocrine insufficiency is present.

Pain

The mechanism for pain is not clearly defined; it may be due to ductular obstruction. One-third to one-half of patients have a decrease in pain after 5 years. The possibility of coexistent disease, such as peptic ulcer, should be considered. Abstinence from alcohol may relieve the pain. Analgesics, aspirin, or acetaminophen is used occasionally with the addition of codeine (narcotic addiction is a frequent complicating factor). Celiac plexus blocks relieve pain for 3 to 6 months, but long-term efficacy is less effective. A trial of pancreatic enzyme replacement for 1 or 2 months should be tried. Women with idiopathic chronic pancreatitis are most likely to have a response. Surgical treatment should be considered only after conservative measures have failed. Patients with a dilated pancreatic duct may have a favorable response to a longitudinal pancreatojejunostomy (Puestow procedure).

- Abstinence from alcohol may relieve pain.
- Narcotic addiction is a frequent complicating factor.
- A 1- or 2-month trial of pancreatic enzyme replacement is worthwhile. Women are more likely to have a response.
- Surgical treatment: only after conservative measures have failed.

Malabsorption

Patients have malabsorption not only of fat but also of essential fatty acids and fat-soluble vitamins. The goal of enzyme replacement is to maintain body weight. Diarrhea will not resolve. Enteric-coated or microsphere enzymes are designed to be released at an alkaline pH, thus avoiding degradation by stomach acid. The advantage is that they contain larger amounts of lipase. The disadvantages are that they are expensive and bioavailability is not always predictable.

Pancreatic Carcinoma

Pancreatic carcinoma is more common in men than in women. Patients usually present between the ages of 60 and 80 years. The 5-year survival rate is less than 2%. Risk factors include diabetes mellitus, chronic pancreatitis, hereditary pancreatitis, carcinogens, benzidine, cigarette smoking, and high-fat diet. Patients with pancreatic carcinoma usually present late in the course of the disease. They may have a vague prodrome of malaise, anorexia, and weight loss. Symptoms may be overlooked until pain or jaundice develop. Two signs associated with pancreatic cancer are the Courvoisier sign (painless jaundice with a palpable gallbladder) and the Trousseau sign (recurrent migratory thrombophlebitis). Recent-onset diabetes and nonbacterial (thrombotic) "marantic" endocarditis may be associated with pancreatic cancer.

- Courvoisier sign: painless jaundice with a palpable gallbladder suggests pancreatic cancer.
- Trousseau sign: recurrent migratory thrombophlebitis is associated with pancreatic cancer.
- Recent-onset diabetes and nonbacterial (thrombotic) "marantic" endocarditis may be associated with pancreatic carcinoma.

Routine laboratory blood analysis has limited usefulness. Patients may have increased levels of liver enzymes, amylase, and lipase or anemia, although this is variable. Tumor markers are also nonspecific. Abdominal ultrasonography and CT are both approximately 80% sensitive in localizing pancreatic masses. Either imaging method may be used in conjunction with fine-needle aspiration or biopsy to make a tissue diagnosis. ERCP and EUS are used if the abdominal ultrasonographic or CT results are inconclusive. Both ERCP and EUS have a sensitivity greater than 90%. ERCP also allows aspiration of pancreatic secretions for cytologic analysis. The "double duct" sign is a classic presentation, with obstruction of both the pancreatic and the bile ducts. Biopsy specimens from suspect lymph nodes may be taken at EUS.

- Abdominal ultrasonography and CT are 80% sensitive in localizing pancreatic masses.
- ERCP and EUS have a sensitivity >90%.

Surgical treatment is the only hope for cure; however, most lesions are nonresectable. The criteria for resectability are a tumor smaller than 2 cm, absence of lymph node invasion, and absence of metastasis. Survival is the same for total pancreatectomy and the Whipple procedure: 3-year survival, 33%; 5-year survival, 1%; and operative mortality, 5%.

Radiotherapy may have a role as a radiosensitizer in unresectable cancer. However, survival is unchanged. The results of chemotherapy have been disappointing, and studies have not consistently shown improved survival.

Cystic Fibrosis

Because patients with cystic fibrosis are living longer, internists should know the common intestinal complications of this disease. Exocrine pancreatic insufficiency (malabsorption) is the common (85%-90% of patients) and most important complication. Endocrine pancreatic insufficiency (diabetes mellitus) occurs in 20% to 30% of patients. Rectal prolapse occurs in 20% of patients, and a distal small-bowel obstruction from thick secretions occurs in 15% to 20%. Focal biliary cirrhosis develops in 20% of patients.

- Exocrine pancreatic insufficiency occurs in 85%-90% of patients with cystic fibrosis.

Pancreatic Endocrine Tumors

Zollinger-Ellison syndrome is a non–beta cell islet tumor of the pancreas that produces gastrin and causes gastric acid hypersecretion. This results in peptic ulcer disease (see "Stomach and Duodenum" section).

Insulinoma is the most common islet cell tumor—a beta cell islet tumor that produces insulin, which causes hypoglycemia. The diagnosis is based on finding increased fasting plasma levels of insulin and hypoglycemia. CT, EUS, or arteriography may be useful in localizing the tumor.

Glucagonoma is an alpha cell islet tumor that produces glucagon. Patients present with diabetes, weight loss, and a classic skin rash (migratory necrolytic erythema). The diagnosis is based on finding increased glucagon levels and on the failure of blood glucose to increase after the injection of glucagon.

Pancreatic cholera is a pancreatic tumor that produces vasoactive intestinal polypeptide (VIP), which causes watery diarrhea (see "Secretory Diarrhea" section).

Somatostatinoma is a delta cell islet tumor that produces somatostatin, which inhibits insulin, gastrin, and pancreatic enzyme secretion. The result is diabetes mellitus and diarrhea. The diagnosis is based on finding increased plasma levels of somatostatin.

Octreotide is useful in treating pancreatic endocrine tumors except for somatostatinomas. Octreotide prevents the release of hormone and antagonizes target organ effects.

- Zollinger-Ellison syndrome: non–beta cell islet tumor of the pancreas.
- Insulinoma: commonest islet cell tumor.
- Pancreatic cholera: pancreatic tumor that produces VIP, which causes secretory diarrhea.
- Octreotide prevents hormone release and antagonizes hormone effects.

Part II

John J. Poterucha, MD

Interpretation of Abnormal Liver Test Results

The evaluation of patients who have abnormal liver test results includes many clinical factors: the chief complaints of the patient, patient age, risk factors for liver disease, personal or family history of liver disease, medications, and physical examination findings. Because of these many factors, designing a standard algorithm for the evaluation of abnormal liver test results is difficult and often inefficient. Nevertheless, with basic information, abnormalities can be evaluated in an efficient, cost-effective manner.

Commonly Used Liver Tests

Aminotransferases

Aminotransferases are found in hepatocytes and are markers of liver cell injury or hepatocellular disease. Hepatocellular injury causes these enzymes to "leak" out of the liver cells, and increased levels of these enzymes are detected in the serum within a few hours after liver injury. The aminotransferases consist of alanine aminotransferase (ALT), also known as serum glutamic-pyruvic transaminase (SGPT), and aspartate aminotransferase (AST), also known as serum glutamic-oxaloacetic transaminase (SGOT). ALT is more specific for liver injury than AST. Although AST is found not only in hepatocytes but also in skeletal and cardiac muscle, markedly increased levels of muscle enzymes may be accompanied by increased levels of both AST and ALT. Because some automated blood tests assay only for AST, it is useful to determine the serum level of ALT before embarking on an evaluation for liver disease.

Alkaline Phosphatase

Alkaline phosphatase is found on the hepatocyte membrane that borders the bile canaliculi (the smallest branches of the bile ducts). Because alkaline phosphatase is also found in bone and placenta, an isolated increase in the level of this enzyme should prompt further testing to determine whether the increase is from the liver or other tissues. Determination of alkaline phosphatase isoenzymes is one method of doing this. Another is the determination of γ-glutamyltransferase (GGT), an enzyme of intrahepatic biliary canaliculi that is more sensitive than alkaline phosphatase. Other than to confirm the hepatic origin of an increased level of alkaline phosphatase, GGT has little role in the diagnosis of diseases of the liver because its synthesis can be induced by many medications, thus reducing its specificity for *clinically important* liver disease.

Bilirubin

Bilirubin is the water-insoluble product of heme metabolism that is taken up by the hepatocyte and conjugated with glucuronic acid to form monoglucuronides and diglucuronides. Conjugation makes bilirubin water soluble, allowing it to be excreted in the bile. When bilirubin is measured in the serum, there are direct (conjugated) and indirect (unconjugated) fractions. Diseases characterized by overproduction of bilirubin, such as hemolysis or resorption of a hematoma, are characterized by hyperbilirubinemia that is less than 20% conjugated. Hepatocyte dysfunction or impaired bile flow produces hyperbilirubinemia that is usually more than 50% conjugated. Because conjugated bilirubin is water soluble and may be excreted in the urine, patients with liver disease and hyperbilirubinemia have dark urine. In these patients, the stools have a lighter color because of the absence of bilirubin pigments.

Prothrombin Time and Albumin

Prothrombin time (PT) and serum level of albumin are markers of liver synthetic function. Abnormalities of PT and albumin imply severe liver disease and should prompt an immediate evaluation. PT is a measure of the activity of factors II, V, VII, and X, all of which are synthesized in the liver. Because these factors are also dependent on vitamin K for synthesis, deficiencies of vitamin K also produce abnormalities of PT. Vitamin K deficiency can result from the use of antibiotics during a period of prolonged fasting, small-bowel mucosal disorders such as celiac disease, and severe cholestasis, with an inability to absorb fat-soluble vitamins. True hepatocellular dysfunction is characterized by an inability to synthesize clotting factors even when stores of vitamin K are adequate. A simple way to distinguish between vitamin K deficiency and liver dysfunction in a patient with a prolonged PT is to administer vitamin K. A 10-mg dose of oral vitamin K for 3 days or 10 mg of subcutaneous vitamin K normalizes the PT within 48 hours in a vitamin K–deficient patient but has no effect on the PT in a patient with decreased liver synthetic function.

Because albumin has a half-life of 21 days, serum levels do not decrease suddenly from liver dysfunction. However, the serum level of albumin can decrease relatively quickly in a severe systemic illness such as bacteremia. This rapid decrease most likely results from the release of cytokines and the accelerated metabolism of albumin. A chronic decrease of albumin in a patient without overt liver disease should prompt a search for albumin in the urine.

Hepatocellular Disorders

Hepatocellular disorders are diseases that primarily affect hepatocytes and are characterized predominantly by increases in aminotransferases. The disorders are best considered as "acute" (generally <3 months) or "chronic." Acute hepatitis may be accompanied by malaise, anorexia, abdominal pain, and jaundice. ALT and AST levels are usually greater than 500 U/L. Common causes of acute hepatitis are listed in Table 7-15.

The level and pattern of aminotransferase elevation may be helpful in the differential diagnosis of acute hepatitis. Acute hepatitis due to viruses or drugs generally produces markedly elevated levels of aminotransferases, often in the thousands (units/liter). In

Table 7-15 Common Causes of Acute Hepatitis

Disease	Clinical clue	Diagnostic test
Hepatitis A	Exposure history	IgM anti-HAV
Hepatitis B	Risk factors	HBsAg, IgM anti-HBc
Drug-induced hepatitis	Compatible medication/timing	Improvement after withdrawal of the agent
Alcoholic hepatitis	History of alcohol excess, AST/ALT >2, AST <400 U/L	Liver biopsy, improvement with abstinence
Ischemic hepatitis	History of hypotension and heart disease	Rapid improvement of aminotransferase levels
Acute duct obstruction	Abdominal pain, fever	Cholangiography

ALT, alanine aminotransferase; AST, aspartate aminotransferase; HAV, hepatitis A virus; HBc, hepatitis B core; HBsAg, hepatitis B surface antigen.

general, the concentration of ALT is more elevated than that of AST. An ALT concentration greater than 5,000 U/L is usually due to acetaminophen hepatotoxicity, hepatic ischemia ("shock liver"), or unusual viruses such as herpes simplex. Hepatic ischemia occurs in patients with preexisting cardiac disease after an episode of hypotension. Aminotransferase levels are very high but decrease considerably within a few days. Another cause of transient elevations of aminotransferase levels is transient bile duct obstruction, usually due to a stone. These elevations can be as high as 1,000 U/L but decrease within 24 to 48 hours. In patients with pancreatitis, a transient increase in the AST or ALT concentration suggests gallstone pancreatitis. Alcoholic hepatitis is characterized by more modest increases in aminotransferase levels, which are always less than 400 U/L and, at times, near normal. In patients with alcoholic hepatitis, usually the AST/ALT ratio is greater than 2:1. Finally, patients with alcoholic hepatitis frequently have a markedly elevated level of bilirubin that is out of proportion to the aminotransferase elevations.

Diseases that produce a sustained (>3 months) increase in aminotransferase levels are in the category of chronic hepatitis. The increase (usually twofold to fivefold) in aminotransferase levels is more modest than in acute hepatitis. Patients are usually asymptomatic but occasionally complain of fatigue and right upper quadrant pain. The differential diagnosis of chronic hepatitis is relatively lengthy; the more important and common disorders are listed in Table 7-16.

Cholestatic Disorders

Diseases that predominantly affect the biliary system are called "cholestatic diseases." They can affect the microscopic ducts (e.g., primary biliary cirrhosis) or the large bile ducts (e.g., pancreatic cancer causing obstruction of the common bile duct), or both (e.g., primary sclerosing cholangitis). Generally, the predominant abnormality in these disorders involves alkaline phosphatase. Although diseases that cause an increase in bilirubin are often referred to as "cholestatic," severe hepatocellular injury, as in acute hepatitis, also produces hyperbilirubinemia because of hepatocellular dysfunction. The common causes of cholestasis are listed in Table 7-17.

Jaundice

Evaluation of a patient with jaundice is an important diagnostic skill (Fig. 7-2). Jaundice is visibly evident hyperbilirubinemia, which occurs when the bilirubin concentration exceeds 2.5 mg/dL. It is important to differentiate conjugated from unconjugated hyperbilirubinemia. A common disorder that produces unconjugated hyperbilirubinemia is Gilbert syndrome. Total bilirubin is generally less than 3.0 mg/dL and direct bilirubin 0.3 mg/dL or less. The concentration of bilirubin is generally higher in the fasting state or when the patient is ill. A presumptive diagnosis of Gilbert syndrome

Table 7-16 Common Causes of Chronic Hepatitis

Disease	Clinical clue	Diagnostic test
Hepatitis C	Risk factors	Anti-HCV, HCV RNA
Hepatitis B	Risk factors	HBsAg
Nonalcoholic steatohepatitis	Obesity, diabetes mellitus, hyperlipidemia	Ultrasonography, liver biopsy
Hemochromatosis	Arthritis, diabetes mellitus, family history	Iron studies, gene test, liver biopsy
Alcoholic liver disease	History, AST/ALT >2	Liver biopsy
Autoimmune hepatitis	ALT 200-1,500 U/L, usually female, other autoimmune disease	Antinuclear or anti–smooth muscle antibody, liver biopsy

ALT, alanine aminotransferase; AST, aspartate aminotransferase; HBsAg, hepatitis B surface antigen; HCV, hepatitis C virus.

Table 7-17 Common Causes of Cholestasis

Disease	Clinical clue	Diagnostic test
Primary biliary cirrhosis	Middle-aged woman	Antimitochondrial antibody
Primary sclerosing cholangitis	Association with ulcerative colitis	Cholangiography (ERCP)
Large bile duct obstruction	Jaundice and pain are common	Ultrasonography, ERCP
Drug-induced	Compatible medication/timing	Improvement after withdrawal of the agent
Infiltrative disorder or malignancy	History of malignancy, sarcoidosis, amyloidosis	Ultrasonography, computed tomography
Inflammation-associated cholestasis	Symptoms of underlying inflammatory state	Blood cultures, appropriate antibody tests

ERCP, endoscopic retrograde cholangiopancreatography.

can be made in an otherwise well person with unconjugated hyperbilirubinemia and normal levels of hemoglobin (to exclude hemolysis) and liver enzymes (to exclude liver disease).

Direct hyperbilirubinemia is a more common cause of jaundice than indirect hyperbilirubinemia. Patients with direct hyperbilirubinemia can be categorized as those with nonobstructive conditions and those with obstruction. Abdominal pain, fever, or a palpable gallbladder (or a combination of these) suggests obstruction. Risk factors for viral hepatitis, a bilirubin concentration greater than 15 mg/dL, and persistently high aminotransferase levels suggest that the jaundice is due to hepatocellular dysfunction. A sensitive, specific, and noninvasive test to exclude obstructive causes of cholestasis is hepatic ultrasonography. With diseases characterized by obstruction of a large bile duct, generally ultrasonography demonstrates intrahepatic bile duct dilatation, especially if the bilirubin concentration is greater than 10 mg/dL and the patient has had jaundice for more than 2 weeks. Acute large bile duct obstruction, usually from a stone, may not allow time for the bile ducts to dilate. An important clue to the presence of an acute large duct obstruction is a marked but very transient increase in the levels of aminotransferases. If the clinical suspicion for obstruction of the bile duct is still strong despite negative ultrasonographic results, magnetic resonance cholangiography should be considered. Uncomplicated gallbladder disease, such as cholelithiasis with or without cholecystitis, does not cause jaundice

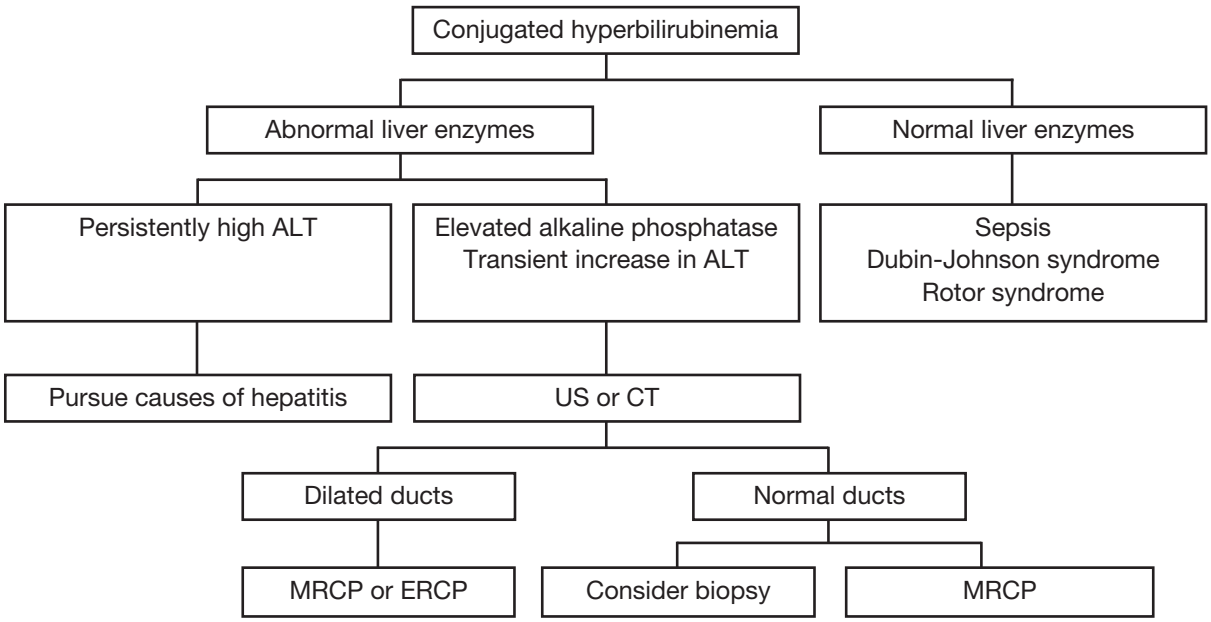

Fig. 7-2. Evaluation of conjugated hyperbilirubinemia. ALT, alanine aminotransferase; CT, computed tomography; ERCP, endoscopic retrograde cholangiopancreatography; MRCP, magnetic resonance cholangiopancreatography; US, ultrasonography. (From Poterucha JJ. Evaluation of the patient with abnormal liver tests. In Hauser SC, editor. Mayo Clinic gastroenterology and hepatology board review. Rochester [MN]: Mayo Clinic Scientific Press and Boca Raton [FL]: CRC Press; 2004. p. 303-8. Used with permission of Mayo Foundation for Medical Education and Research.)

or abnormal liver test results unless a common bile duct stone or sepsis is present.

Algorithms for Patients With Abnormal Liver Test Results

Algorithms for the management of patients with abnormal liver test results are at best guidelines and at worst misleading. The patient's clinical presentation should be considered when interpreting abnormal results. In general, patients with abnormal liver test results that are less than three times the normal value can be observed unless the patient is symptomatic or the albumin level, PT, or bilirubin concentration is abnormal. Persistent abnormalities should be evaluated. Algorithms for the management of patients with increased levels of ALT or alkaline phosphatase are shown in Figures 7-3 and 7-4, respectively.

Specific Liver Diseases

Viral Hepatitis

Hepatitis A

Hepatitis A virus (HAV) accounts for 40% of cases of acute hepatitis in the United States. The disease generally is transmitted by the fecal-oral route and has an incubation period of 15 to 50 days. Major routes of transmission of HAV are ingestion of contaminated food or water and contact with an infected person. Persons living in, or traveling to, developing countries, children in day care centers, and homosexual men are at highest risk of HAV infection. Hepatitis caused by HAV is generally mild in children, who often have a subclinical or nonicteric illness. Infected adults are more ill and usually develop jaundice. The prognosis is excellent, although HAV can rarely cause fulminant hepatic failure. Chronic liver disease does not develop from HAV. Serum IgM anti-HAV is present during an acute illness and generally persists for 2 to 6 months. IgG anti-HAV appears slightly later, persists for life, and offers immunity from further infection. Immune serum globulin and HAV vaccine should be given to household contacts of infected patients and to those exposed to a known food-borne source. Hepatitis A vaccine is recommended for U.S. citizens traveling to highly endemic areas, homosexual men, intravenous drug users, recipients of clotting factor concentrates, and patients with chronic liver disease.

- HAV is transmitted by ingestion of contaminated food or water or contact with an infected person.
- The incubation period is 15-50 days.
- IgM anti-HAV is present during the acute illness.
- The prognosis is excellent.
- Chronic liver disease does not develop.
- Immune serum globulin should be given to household contacts.
- Hepatitis A vaccine should be given to persons at high risk of infection and to patients with chronic liver disease.

Hepatitis B

Hepatitis B virus (HBV) is a DNA virus that is transmitted parenterally or by sexual contact. In high-prevalence areas, for example, certain areas of Asia and Africa, HBV is acquired perinatally or in early childhood. High-risk groups in the United States include injection drug users, persons with multiple sexual contacts, and health care workers. The clinical course of HBV infection varies.

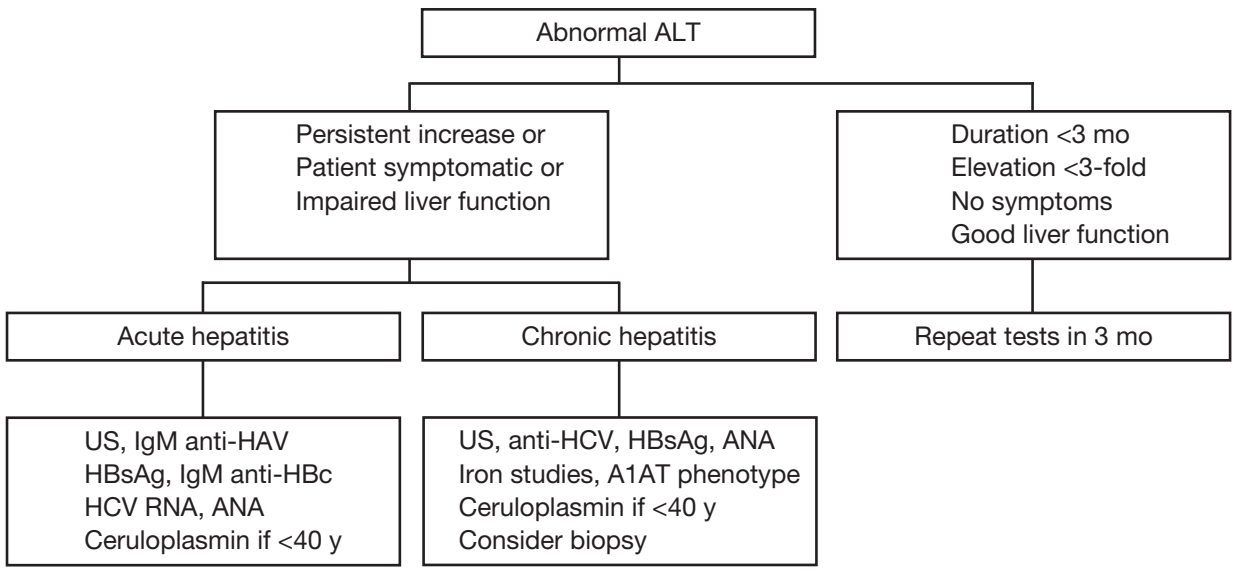

Fig. 7-3. Evaluation of abnormal alanine aminotransferase (ALT) levels. A1AT, α_1-antitrypsin; ANA, antinuclear antibody; anti-HAV, hepatitis A virus antibody; anti-HBc, hepatitis B core antibody; anti-HCV, hepatitis C virus antibody; HBsAg, hepatitis B surface antigen; HCV, hepatitis C virus; US, ultrasonography. (From Poterucha JJ. Evaluation of the patient with abnormal liver tests. In Hauser SC, editor. Mayo Clinic gastroenterology and hepatology board review. Rochester [MN]: Mayo Clinic Scientific Press and Boca Raton [FL]: CRC Press; 2004. p. 303-8. Used with permission of Mayo Foundation for Medical Education and Research.)

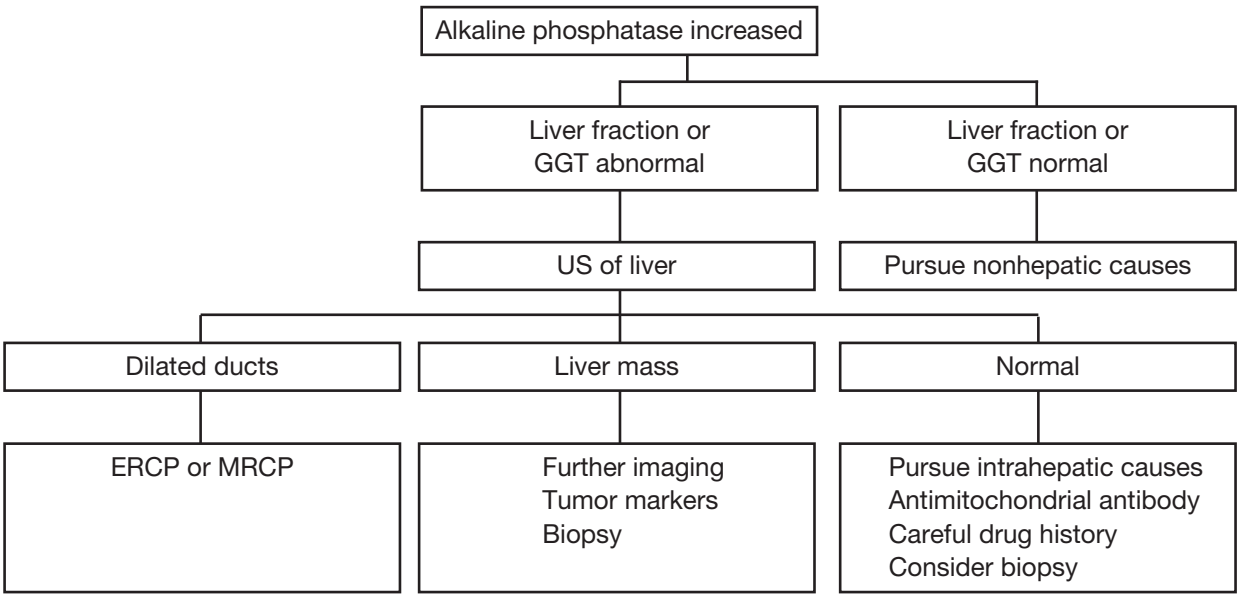

Fig. 7-4. Evaluation of increased levels of alkaline phosphatase. ERCP, endoscopic retrograde cholangiopancreatography; GGT, γ-glutamyltransferase; MRCP, magnetic resonance cholangiopancreatography; US, ultrasonography. (From Poterucha JJ. Evaluation of the patient with abnormal liver tests. In Hauser SC, editor. Mayo Clinic gastroenterology and hepatology board review. Rochester [MN]: Mayo Clinic Scientific Press and Boca Raton [FL]: CRC Press; 2004. p. 303-8. Used with permission of Mayo Foundation for Medical Education and Research.)

Most acute infections in adults are subclinical, and even when symptomatic, the disease resolves within 6 months with subsequent development of immunity. During acute hepatitis, symptoms (when present) are generally more severe than those of HAV infection. Jaundice rarely lasts longer than 4 weeks. Some patients may have preicteric symptoms of "serum sickness," including arthralgias and urticaria. These symptoms may be related to immune complexes, which can also cause polyarteritis and glomerulonephritis.

- HBV is transmitted parenterally or by sexual contact.
- Infants may acquire infection from the mother.
- High-risk groups: injection drug users, persons with multiple sexual contacts, and health care workers.
- Most infections in adults are subclinical.
- Jaundice rarely lasts >4 weeks.

A brief guide to the interpretation of serologic markers of hepatitis B is found in Table 7-18. Viral markers in the blood during a self-limited infection with HBV are shown in Figure 7-5. Note that IgM hepatitis B core antibody (anti-HBc) is nearly always present during acute hepatitis B. Some patients with acute hepatitis B, particularly those with fulminant hepatitis B, may lack hepatitis B surface antigen (HBsAg). Hepatitis B e antigen (HBeAg) and HBV DNA levels greater than 10^5 copies/mL correlate with ongoing viral replication and indicate high infectivity. Spontaneous conversion from an HBeAg-positive state to HBeAg-negativity with the appearance of hepatitis B e antibody (anti-HBe) may be accompanied by an increase in the level of aminotransferases. Patients with hepatitis B mutants may have high HBV DNA levels but lack HBeAg. Commonly encountered serologic patterns of HBV are shown in Table 7-19.

Ten percent of patients who acquire HBV as adults and 90% of those infected as neonates do not clear HBsAg from the serum within 6 months and, thus, become chronically infected. Chronicity occurs more commonly in patients with a defect of the immune system. Patients with chronic hepatitis B but normal findings on liver tests and liver biopsy have inactive chronic hepatitis B and are sometimes called "inactive carriers." They have a good prognosis. Patients with active chronic hepatitis B have increased levels of ALT; the presence of HBeAg or HBV DNA levels greater than 10^5 copies/mL (or both); and histologic inflammation. These patients are at higher risk of cirrhosis, liver failure, and hepatocellular carcinoma than patients with HBV infection who lack these features. Patients with chronic hepatitis B and cirrhosis are at high risk of hepatocellular carcinoma, and liver ultrasonography should be performed every 6 to 12 months. Patients with neonatal acquisition of hepatitis B may develop hepatocellular carcinoma even in the absence of cirrhosis.

- IgM anti-HBc is nearly always present during acute hepatitis B.
- HBV DNA level >10^5 copies/mL and HBeAg correlate with ongoing viral replication and indicate high infectivity.
- HBsAg is not cleared in 10% of patients acquiring HBV as adults and in 90% of those infected as neonates.
- Inactive carriers of HBsAg have essentially a normal liver histologically and a good prognosis.
- Chronic hepatitis due to HBV may lead to cirrhosis.
- Patients with HBV-induced cirrhosis are at high risk of hepatocellular carcinoma.

Patients with chronic hepatitis B, an abnormal ALT level, and active viral replication (HBeAg or HBV DNA level >10^5 copies/mL) are

Table 7-18 Hepatitis B Serologic Markers

Test	Interpretation of positive results
Hepatitis B surface antigen (HBsAg)	Current infection
Antibody to hepatitis B surface (anti-HBs)	Immunity (immunization or resolved infection)
IgM antibody to hepatitis B core (IgM anti-HBc)	Usually recent infection, occasionally "reactivation" of chronic infection
IgG antibody to hepatitis B core (IgG anti-HBc)	Remote infection
Hepatitis B e antigen (HBeAg) and/or HBV DNA >10^5 viral copies/mL	Active viral replication (high infectivity)
Antibody to hepatitis B e (anti-HBe)	Remote infection

HBV, hepatitis B virus.

Modified from Poterucha JJ. Chronic viral hepatitis. In Hauser SC, editor. Mayo Clinic gastroenterology and hepatology board review. Rochester (MN): Mayo Clinic Scientific Press and Boca Raton (FL): CRC Press; 2004. p. 317-25. Used with permission of Mayo Foundation for Medical Education and Research.

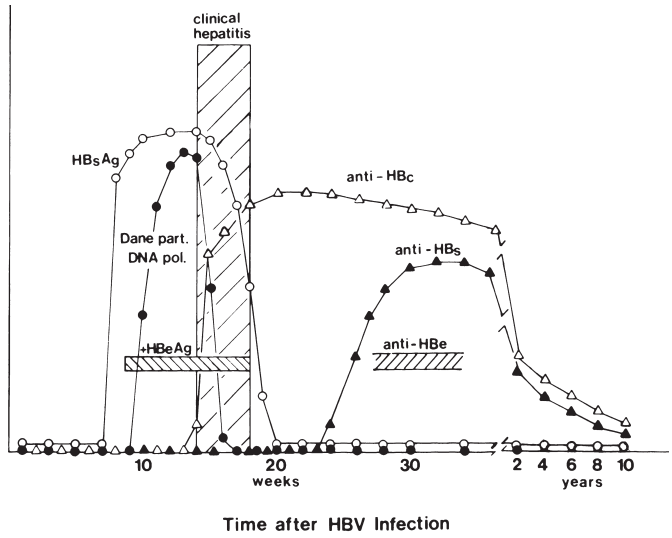

Fig. 7-5. Viral markers in blood during self-limited hepatitis B virus (HBV) infection. Anti-HBc, hepatitis B core antibody; anti-HBe, hepatitis B e antibody; anti-HBs, hepatitis B surface antibody; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; part, particle; pol, polymerase. (From Robinson WS. Biology of human hepatitis viruses. In Zakim D, Boyer TD, editors. Hepatology: a textbook of liver disease. Vol 2. 2nd ed. Philadelphia: WB Saunders Company; 1990. p. 890-945. Used with permission.)

potential candidates for therapy. Treatment with interferon alfa results in a 30% to 40% response rate as measured by the loss of HBeAg and HBV DNA and the appearance of anti-HBe. A few patients also clear HBsAg. Patients more likely to respond to interferon therapy include those with a relatively recent diagnosis of chronic hepatitis B, high serum levels of aminotransferases, active hepatitis without evidence of cirrhosis on biopsy, and low serum levels of HBV DNA. Patients with HBV infection who have a response to interferon therapy may have a transient increase in aminotransferase levels after about 8 weeks of treatment. An acute hepatitis syndrome may be precipitated and interferon should be given with caution, if at all, to patients with cirrhosis. Lamivudine, adefovir, and entecavir are oral agents that decrease HBV DNA levels and may result in clinical improvement. About 20% to 30% of patients who take lamivudine or adefovir have seroconversion to anti-HBe. Lamivudine-resistant mutations occur in 30% of patients who have received treatment for 1 year, but the mutations are less virulent than the wild-type strain. Adefovir and entecavir resistance is less common than lamivudine resistance. The oral drugs are safer than interferon for patients with cirrhosis because flares of hepatitis and infectious complications are uncommon.

Hepatitis B immune globulin should be given to household and sexual contacts of patients with acute hepatitis B. Infants and previously unvaccinated 10- to 12-year-old children (who are reaching the age when they will be at highest risk of acquiring the disease) should receive hepatitis B vaccine. The marker of immunity is hepatitis B surface antibody (anti-HBs). Neonates often acquire hepatitis B perinatally if the mother is infected. Because infected neonates are at high risk of chronic infection, all pregnant women should be tested for HBsAg. If a pregnant woman is HBsAg-positive, the infant should receive both hepatitis B immunoglobulin and hepatitis B vaccine.

Hepatitis D

Hepatitis D virus (HDV), or delta agent, is a small RNA particle that requires the presence of HBsAg to cause infection. HDV infection can occur simultaneously with acute HBV infection (coinfection) or HDV may infect a chronic HBsAg carrier (superinfection). HDV is strongly associated with injection drug abuse. Infection with HDV should be considered only in patients with HBsAg; it is diagnosed by anti-HDV seroconversion.

- HDV requires the presence of HBsAg to cause infection.
- HDV is strongly associated with injection drug abuse.
- HDV infection is diagnosed by anti-HDV seroconversion.

Hepatitis C

Hepatitis C virus (HCV), an RNA virus, is the most common chronic blood-borne infection in the United States. Although the number of new cases of hepatitis C infection is decreasing, the propensity of the virus to cause chronic infection continues to result in an increasing number of deaths. HCV has a role in 40% of all cases of chronic liver disease and is the number one indication for liver transplantation. HCV is a parenterally transmitted virus. The

Table 7-19 Interpretation of Hepatitis B Serologic Patterns

HBsAg	Anti-HBs	IgM anti-HBc	IgG anti-HBc	HBeAg	Anti-HBe	HBV DNA, viral copies/mL	Interpretation
+	–	+	–	+	–	+	Acute infection; occasionally "reactivation" of chronic hepatitis B
–	+	–	+	–	–/+	–	Prior infection with immunity
–	+	–	–	–	–	–	Vaccination with immunity
+	–	–	+	–	+	$<10^5$	Chronic hepatitis B without replication
+	–	–	+	+	–	$>10^5$	Chronic hepatitis B with replication
+	–	–	+	–	+	$>10^5$	Chronic hepatitis B with precore mutant

Anti-HBc, hepatitis B core antibody; anti-HBe, hepatitis B e antibody; anti-HBs, hepatitis B surface antibody; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; HBV, hepatitis B virus.

Modified from Poterucha JJ. Chronic viral hepatitis. In Hauser SC, editor. Mayo Clinic gastroenterology and hepatology board review. Rochester (MN): Mayo Clinic Scientific Press and Boca Raton (FL): CRC Press; 2004. p. 317-25. Used with permission of Mayo Foundation for Medical Education and Research.

most common risk factor is illicit drug use. Persons with a history of transfusion of blood products before 1990 (when routine testing of blood products for HCV was introduced) are also at considerable risk of infection with HCV. Sexual transmission of HCV occurs but seems to be inefficient. The risk of transmission of HCV to health care workers by percutaneous (needlestick) exposure is also low, approximately 2%. For a health care worker who has a needlestick exposure from a patient with hepatitis C, baseline testing for anti-HCV and ALT is recommended. Follow-up testing can be with HCV RNA at 4 to 6 weeks or anti-HCV and ALT at 4 to 6 months (or both). Prophylactic treatment with immune globulin or anti-hepatitis C therapy is not recommended.

Antibodies to HCV (anti-HCV) indicate exposure to the virus and are not protective. The presence of anti-HCV can indicate either current infection or a previous infection with subsequent clearance. The presence of anti-HCV in a patient with an abnormal ALT level and risk factors for hepatitis C acquisition is strongly suggestive of current HCV infection. The initial test used for anti-HCV determination is enzyme-linked immunosorbent assay (ELISA). Although this test is very sensitive (few false-negative results), its specificity is variable. If the result for anti-HCV by EIA is negative, the patient is unlikely to have hepatitis C. The specificity of EIA is improved with the addition of the recombinant immunoblot assay (RIBA) for anti-HCV. A guide to the interpretation of anti-HCV test results is given in Table 7-20.

The reference standard for the diagnosis of HCV infection is the presence of HCV RNA, as determined with the polymerase chain reaction (PCR). HCV levels do not correlate with disease severity, and the main use of quantitative assays is to stratify the response to therapy.

- HCV is a parenterally transmitted virus and a common cause of chronic hepatitis.
- Common modes of transmission are illicit drug use and transfusion of blood products before 1990.
- The presence of HCV RNA, determined by PCR, is the reference standard for diagnosis.

Patients with HCV infection rarely present with acute hepatitis. The natural history of hepatitis C is summarized in Figure 7-6. About

Table 7-20 Interpretation of Anti-HCV Results

Anti-HCV by EIA	Anti-HCV by RIBA	Interpretation
Positive	Negative	False-positive ELISA; patient does not have true antibody
Positive	Positive	Patient has antibody*
Positive	Indeterminate	Uncertain antibody status

ELISA, enzyme-linked immunosorbent assay; HCV, hepatitis C virus; RIBA, recombinant immunoblot assay.

*Anti-HCV does not necessarily indicate current hepatitis C infection (see text).

60% to 85% of persons acquiring hepatitis C develop a chronic infection, and subsequent spontaneous loss of the virus is rare. Consequently, most patients with hepatitis C present with chronic hepatitis with mild to moderate increases in ALT levels. Some patients have fatigue or vague right upper quadrant pain. Patients may also come to medical attention because of complications of end-stage liver disease or, rarely, extrahepatic complications such as cryoglobulinemia or porphyria cutanea tarda. Up to 30% of patients chronically infected with HCV have a persistently normal ALT level. Because the majority of patients with hepatitis C are asymptomatic, treatment is generally aimed at preventing future complications of the disease. About 20% to 30% of patients with chronic hepatitis C develop cirrhosis over 10 to 20 years. Patients with cirrhosis due to HCV generally have had HCV infection for more than 20 years.

Pegylated interferon alfa in combination with ribavirin is the current standard of care for patients with hepatitis C who are deemed candidates for treatment. This combination, given for 6 to 12 months, results in sustained clearance of HCV RNA from the serum in 60% of patients. Patients with genotype 2 or 3 and without clinical or biochemical evidence of advanced liver disease have an 80% to 90% chance of a sustained response to therapy and, thus, may be treated without liver biopsy. Patients with genotype 1 or 4 usually have a liver biopsy to aid in the decision about treatment because response rates are less than 50% and the potential risks of therapy may outweigh benefits. On the basis of the natural history of hepatitis C and the response to therapy, an algorithm for patients without any contraindication to treatment can be proposed, although deviations are common because of patient preference or transmission issues (Fig. 7-7). These guidelines apply generally to the large percentage of patients with hepatitis C who are asymptomatic or who have nonspecific symptoms such as fatigue. Therapy should be recommended to patients with extrahepatic manifestations of hepatitis C, such as vasculitis related to cryoglobulinemia. Contraindications to pegylated interferon alfa and ribavirin are advanced age, major comorbid illnesses, severe autoimmune disease, severe psychiatric disease, and uncontrolled substance abuse.

Patients who are not candidates for treatment should be evaluated annually with routine liver tests. Patients with cirrhosis are at increased risk of hepatocellular carcinoma, particularly if there is a history of alcohol excess. The risk of hepatocellular carcinoma complicating hepatitis C with cirrhosis is 1% to 4% per year. Surveillance with liver ultrasonography every 6 to 12 months is advised for patients who are potential candidates for treatment with liver transplantation or percutaneous ablation. Patients with HCV infection and decompensated cirrhosis should be considered for liver transplantation.

- Symptomatic, clinically recognized acute hepatitis C is unusual.
- Of the patients who acquire HCV, 60%-85% remain chronically infected.

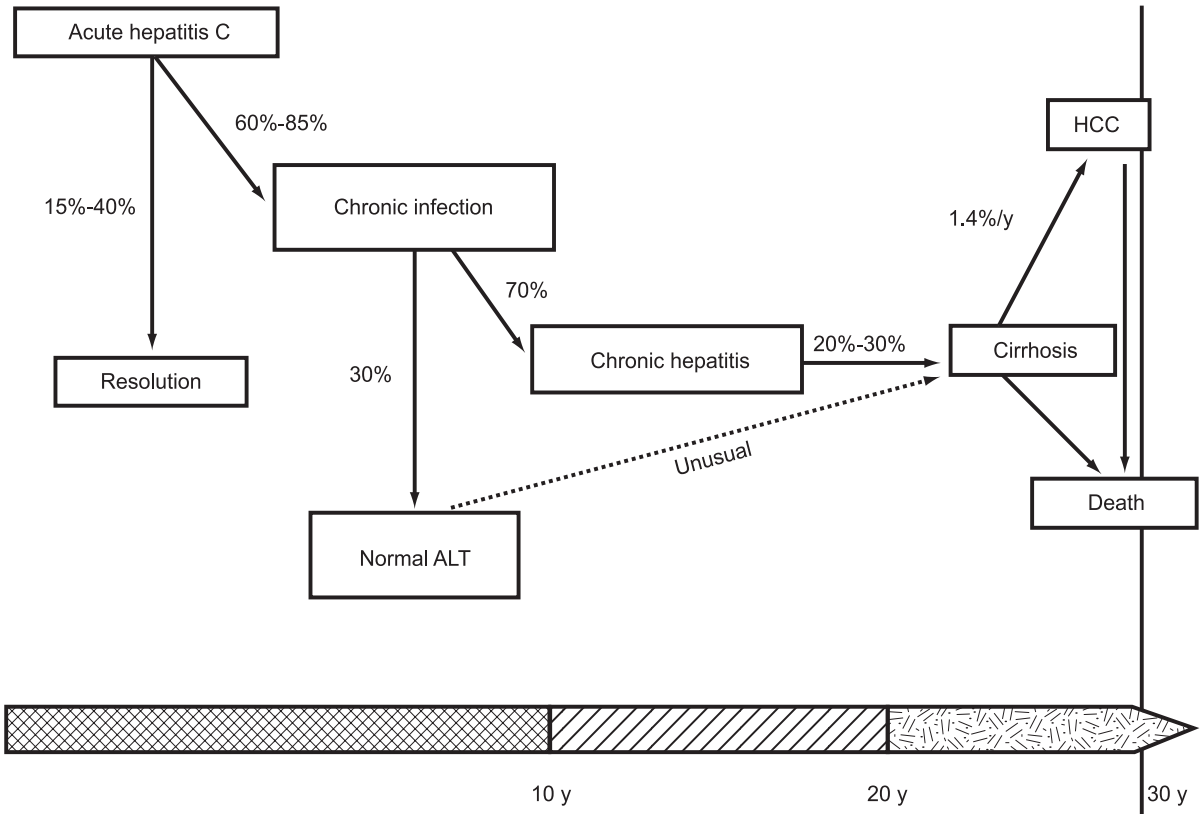

Fig. 7-6. Natural history of hepatitis C. ALT, alanine aminotransferase; HCC, hepatocellular carcinoma. Percent values are percentage of patients.

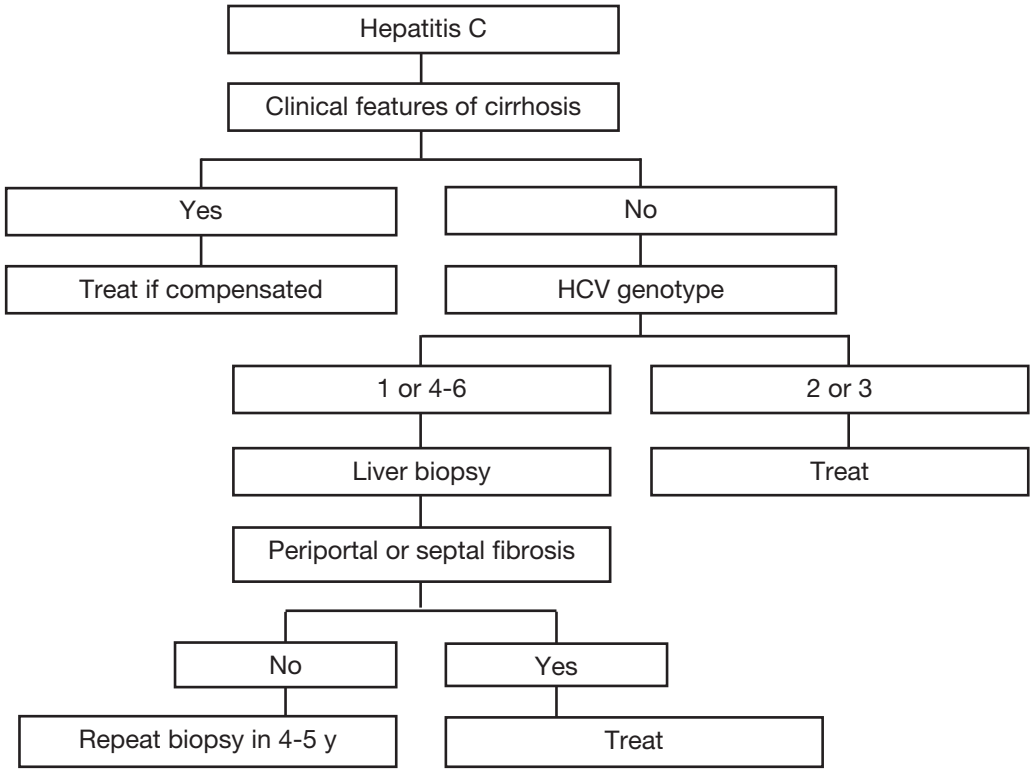

Fig. 7-7. Treatment algorithm for patients with hepatitis C and no contraindications to therapy. HCV, hepatitis C virus.

- Of the patients with chronic hepatitis C, 20%-30% develop cirrhosis over 20 years.
- The combination of pegylated interferon alfa and ribavirin results in sustained clearance of HCV RNA in approximately 60% of patients.
- Patients with cirrhosis due to hepatitis C are at increased risk of hepatocellular carcinoma, particularly if there is also a history of alcohol excess.

Hepatitis E

Hepatitis E virus (HEV) is an enterically transmitted RNA virus that causes acute hepatitis in patients from endemic areas (India, Pakistan, Mexico, and Southeast Asia) and in travelers returning from these regions. Clinically, hepatitis E resembles hepatitis A. Women who acquire the infection during pregnancy have a high risk of fulminant hepatitis E. Chronic hepatitis E does not occur.

- HEV is an enterically transmitted RNA virus that clinically resembles hepatitis A.
- Women who acquire the infection during pregnancy have a high risk of fulminant hepatitis E.

Miscellaneous

Epstein-Barr virus, cytomegalovirus, and herpesvirus have been implicated as causes of acute viral hepatitis, which may be most serious in immunocompromised patients. Patients with infectious mononucleosis syndromes commonly have abnormal liver test results and mild increases in bilirubin levels, although clinically recognized jaundice is unusual. Herpes hepatitis generally occurs in immunosuppressed or pregnant patients and is characterized by fever, mental status changes, absence of jaundice, and AST and ALT levels greater than 5,000 U/L.

Autoimmune Hepatitis

Autoimmune hepatitis was previously called "autoimmune chronic active hepatitis" because the diagnosis required 3 to 6 months of abnormal liver enzyme test results. However, 40% of patients with autoimmune hepatitis present with acute hepatitis. Autoimmune hepatitis can affect patients of any age, predominantly females. The onset is usually insidious, and an initial liver biopsy specimen may show cirrhosis.

By definition, patients with autoimmune hepatitis should not have a history of drug-related hepatitis, HBV, HCV, or Wilson disease. Immunoserologic markers, such as antinuclear antibody (ANA), smooth muscle antibody, soluble liver antigen antibodies, or antibodies to liver/kidney microsomal (LKM) antigens, are usually detected. Patients with autoimmune hepatitis may have other autoimmune diseases, including Hashimoto thyroiditis. Marked increases in serum levels of gamma globulin are common, and aminotransferase levels are generally 4 to 20 times normal. Corticosteroids (30-60 mg daily) produce improvement in the majority of patients, and the improvement in liver test results and gamma globulin levels is often dramatic.

Azathioprine may be added to allow the use of lower doses of prednisone. Immunosuppressive doses should be decreased to control symptoms and to maintain the serum level of aminotransferases less than five times the reference value. Even after an excellent response to corticosteroids, relapse often occurs and the control of autoimmune hepatitis usually requires maintenance therapy.

- Autoimmune hepatitis is a chronic condition, but patients may present with an acute hepatitis.
- There should not be a history of drug-related hepatitis, HBV, HCV, or Wilson disease.
- Immunoserologic markers are often detected.
- Marked increases in serum levels of gamma globulin are common.
- Most patients have improvement with corticosteroid therapy, and the improvement in liver test results and gamma globulin levels is often dramatic.
- The control of autoimmune hepatitis usually requires maintenance therapy.

Alcoholic Liver Disease

Alcoholic Hepatitis

Long-term excessive use of alcohol (>20 g/d in women and >40 g/d in men) can produce advanced liver disease. Alcoholic hepatitis is characterized histologically by fatty change, degeneration and necrosis of hepatocytes (with or without Mallory bodies), and an inflammatory infiltrate of neutrophils. Almost all patients have fibrosis, and they may have cirrhosis. Clinically, patients may be asymptomatic or icteric and critically ill. Common symptoms include anorexia, nausea, vomiting, abdominal pain, and weight loss. The most common sign is hepatomegaly, which may be accompanied by ascites, jaundice, fever, splenomegaly, and encephalopathy. The level of AST is increased in 80% to 90% of patients, but it is almost always less than 400 U/L. Aminotransferase levels greater than 400 U/L are not a feature of alcoholic liver disease, and a search for other causes (e.g., ingestion of acetaminophen) should be pursued. The AST/ALT ratio is frequently greater than 2. Leukocytosis is commonly present, particularly in severely ill patients. Although the constellation of symptoms may mimic biliary disease, the clinical features are characteristic in an alcoholic patient. Because cholecystectomy carries a high morbidity in patients with alcoholic hepatitis, the clinical distinction is important and empirical cholecystectomy is contraindicated.

- Alcoholic hepatitis is characterized by fatty change, degeneration and necrosis of hepatocytes (with or without Mallory bodies), and an inflammatory infiltrate of neutrophils.
- Common symptoms include anorexia, nausea, vomiting, abdominal pain, and weight loss.
- Common signs are hepatomegaly, ascites, jaundice, fever, splenomegaly, and encephalopathy.
- The level of AST is increased (but is almost always <400 U/L) in 80%-90% of patients.
- The AST/ALT ratio is frequently >2.
- Leukocytosis occurs in severely ill patients.

Poor prognostic markers of alcoholic hepatitis include encephalopathy, spider angiomata, ascites, renal failure, prolonged PT, and a bilirubin concentration greater than 20 mg/dL. Many patients have progression to cirrhosis, particularly if alcohol intake is not curtailed. Corticosteroid therapy may be beneficial as an acute treatment of alcoholic hepatitis in patients with severe disease characterized by encephalopathy and a markedly prolonged PT. Pentoxifylline is a safe agent that has shown benefit in one study. A discriminant function greater than 32 helps to identify patients with a poor prognosis.

$$\text{Discriminant function} = 4.6\,(PT_{patient} - PT_{control}) + \text{bilirubin (mg/dL)}$$

- Poor prognostic markers of alcoholic hepatitis: encephalopathy, ascites, renal failure, prolonged PT, and bilirubin >20 mg/dL.
- Corticosteroid therapy may be beneficial in severe disease.

Alcoholic Cirrhosis

Cirrhosis is defined histologically by septal fibrosis with nodular parenchymal regeneration. Only 60% of patients with alcoholic cirrhosis have signs or symptoms of liver disease, and most patients with cirrhosis have no clinical history of alcoholic hepatitis. Liver enzyme levels may be relatively normal in cirrhosis without alcoholic hepatitis. Concomitant HCV infection is common in patients with alcoholic liver disease. The prognosis of alcoholic cirrhosis depends on whether patients continue to consume alcohol and whether there are signs (jaundice, ascites, or gastrointestinal bleeding) of chronic liver disease. The 5-year survival rate for patients without ascites, jaundice, or hematemesis and who abstain from alcohol is 89% and for those with signs and who continue to consume alcohol, 34%. Liver transplantation is an option for patients with end-stage alcoholic liver disease if they demonstrate that they can maintain abstinence from alcohol.

- Only 60% of patients with alcoholic cirrhosis have signs or symptoms of liver disease.
- Liver enzyme levels may be relatively normal.
- The 5-year survival for patients without ascites, jaundice, or hematemesis and who abstain from alcohol is 89%.
- The 5-year survival for those with symptoms and who continue to consume alcohol is 34%.
- Liver transplantation is an option for patients who can demonstrate a pattern of abstinence from alcohol.

Nonalcoholic Fatty Liver Disease

Nonalcoholic fatty liver disease is a common cause of abnormal levels of liver enzymes. A subset of nonalcoholic fatty liver disease is nonalcoholic steatohepatitis (NASH), which is characterized histologically by fatty change and inflammation. Characteristically, patients with nonalcoholic fatty liver disease are obese and have hyperlipidemia or diabetes mellitus. The aminotransferase levels are mildly abnormal, and the alkaline phosphatase level is increased in about one-third of patients. When advanced cirrhosis develops, fat may not be recognizable in liver tissue, and NASH most likely accounts for some cases of "cryptogenic" cirrhosis. The pathogenesis of NASH

is unknown, and the effect of weight loss and control of hyperlipidemia and hyperglycemia is variable. In 20% of patients, NASH progresses to cirrhosis; the risk factors for more advanced disease are advanced age, marked obesity, and diabetes. Other than to control risk factors, there is no effective therapy for NASH. In patients with fat in the liver, it is important to rule out other diseases that result in steatosis, including hepatitis C, celiac disease, Wilson disease, alcoholic liver disease, and rapid weight loss.

Medical treatment of hyperlipidemia and diabetes are not contraindicated in patients with NASH. In fact, agents such as pioglitazone and rosiglitazone have resulted in biochemical and histologic improvement. For patients with NASH who are given potentially hepatotoxic medications, liver enzymes should be monitored regularly and medications can be continued as long as liver enzyme levels are less than fivefold the reference value and liver function remains preserved.

Chronic Cholestatic Liver Diseases

Primary Biliary Cirrhosis

Primary biliary cirrhosis (PBC) is a chronic, progressive, cholestatic liver disease that primarily affects middle-aged women. Its cause is unknown but appears to involve an immunologic disturbance resulting in small bile duct destruction. In many patients, the disease is identified by an asymptomatic increase in alkaline phosphatase. Common early symptoms are pruritus and fatigue. Patients may have Hashimoto thyroiditis or sicca complex. Biochemical features include increased levels of alkaline phosphatase and IgM. When PBC is advanced, the concentration of bilirubin is high, the serum level of albumin is low, and PT is prolonged. Steatorrhea may occur because of progressive cholestasis. Fat-soluble vitamin deficiencies and metabolic bone disease are common.

Antimitochondrial antibodies are present in 90% to 95% of patients with PBC. The classic histologic lesion is granulomatous infiltration of septal bile ducts. Ursodiol treatment benefits patients who have this disease by improving survival and delaying the need for liver transplantation. Cholestyramine and rifampin may be beneficial in the management of pruritus.

- PBC primarily affects middle-aged women.
- Common early symptoms: pruritus and fatigue.
- Alkaline phosphatase and IgM levels increase.
- Fat-soluble vitamin deficiencies and metabolic bone disease are common.
- Antimitochrondrial antibodies are present in 90% to 95% of patients.
- Classic histologic lesion: granulomatous infiltration of septal bile ducts.
- Treatment: ursodiol.

Primary Sclerosing Cholangitis

Primary sclerosing cholangitis (PSC) is a chronic cholestatic liver disease characterized by obliterative inflammatory fibrosis of extrahepatic and intrahepatic bile ducts. An immune mechanism has been implicated. Patients may have an asymptomatic increase in the alkaline phosphatase level or progressive fatigue, pruritus, and jaundice. Bacterial cholangitis may occur in patients with dominant strictures or in whom instrumentation has been performed. Cholangiography establishes the diagnosis of PSC, showing short strictures of bile ducts with intervening segments of normal or slightly dilated ducts, producing a beaded appearance. This cholangiographic appearance may be mimicked by acquired immunodeficiency syndrome (AIDS) cholangiopathy (due to cytomegalovirus or cryptosporidium) and ischemic cholangiopathy after intra-arterial infusion of fluorodeoxyuridine.

- PSC: obliterative inflammatory fibrosis of extrahepatic and intrahepatic bile ducts.
- Asymptomatic increase in the alkaline phosphatase level.
- Cholangiography establishes the diagnosis.
- AIDS cholangiopathy mimics the cholangiographic appearance of PSC.

Seventy percent of patients with PSC have ulcerative colitis, which may antedate, accompany, or even follow the diagnosis of PSC. Treatment of ulcerative colitis has no effect on the development or clinical course of PSC. Patients with PSC are at higher risk of cholangiocarcinoma; its development may be manifested by rapid clinical deterioration, jaundice, weight loss, and abdominal pain. There is no effective medical therapy for PSC, and many patients have progressive liver disease and require liver transplantation. Percutaneous or endoscopic balloon dilatation of bile duct strictures may offer palliation, especially in patients with recurrent cholangitis.

- Ulcerative colitis occurs in 70% of patients with PSC.
- Treatment of ulcerative colitis has no effect on the development of PSC.
- PSC patients are at higher risk of cholangiocarcinoma.
- Treatment of PSC is generally supportive.
- Many patients require liver transplantation.

Hereditary Liver Diseases

Genetic Hemochromatosis

Genetic hemochromatosis is an autosomal recessively transmitted disorder characterized by iron overload. The physiologic defect appears to be an inappropriately high absorption of iron from the gastrointestinal tract. The *HFE* gene for genetic hemochromatosis has been identified. In the general population, the heterozygote frequency is 10%. Only homozygotes manifest progressive iron accumulation.

- Genetic hemochromatosis is a disorder of iron metabolism.
- Characteristic: high absorption of iron from the gastrointestinal tract.
- Autosomal recessive transmission.
- Only homozygotes have progressive iron accumulation.

Patients often present with end-stage disease, although an increased sensitivity to screening is aiding in earlier diagnosis. The peak incidence of clinical presentation is between the ages of 40 and 60 years. Iron

overload is manifested more often and earlier in men than in women because women are protected by the iron losses of menstruation and pregnancy. Clinical features include arthropathy, hepatomegaly, skin pigmentation, diabetes mellitus, cardiac dysfunction, and hypogonadism. Hemochromatosis should be considered in patients presenting with symptoms or diseases such as arthritis, diabetes, cardiac arrhythmias, or sexual dysfunction. Routine liver biochemistry studies generally show few abnormalities. The serum level of iron is increased, the transferrin saturation is greater than 50%, and the serum levels of ferritin are high. Increased levels of iron and ferritin may occur in other liver diseases, particularly advanced cirrhosis. Testing for mutations in the *HFE* gene and liver biopsy with quantification of hepatic iron concentration are standard methods for diagnosing hemochromatosis. Of patients with hemochromatosis, 80% to 90% are homozygous for the C282Y mutation that is the basis for genetic testing. Generally, hepatic iron levels in hemochromatosis are greater than 10,000 μg/g dry weight. A diagnostic algorithm is shown in Figure 7-8.

- Iron overload is more common in men.
- Clinical features: arthropathy, hepatomegaly, skin pigmentation, diabetes mellitus, cardiac dysfunction, and hypogonadism.
- Iron saturation and serum levels of ferritin are high.
- Standard tests for making the diagnosis: genetic testing and liver biopsy with quantification of hepatic iron concentration.

Hemochromatosis is treated with removal of iron by repeated phlebotomies. The standard recommendation is to remove 500 mL weekly to the point of mild anemia. A maintenance program of four to eight phlebotomies annually is then required. When initiated in the precirrhotic stage, removal of iron can render the liver normal and may improve cardiac function and diabetes mellitus. Treatment does not reverse arthropathy or hypogonadism, nor does it eliminate the increased risk (30%) of hepatocellular carcinoma if cirrhosis has already developed. All first-degree relatives of patients should be evaluated for hemochromatosis.

- Hemochromatosis is treated with repeated phlebotomies.
- Treatment does not reverse arthropathy or hypogonadism or eliminate the increased risk of hepatocellular carcinoma.
- First-degree relatives should be tested for hemochromatosis.

Wilson Disease

Wilson disease is an autosomal recessive disorder characterized by increased amounts of copper in tissues. The basic defect involves

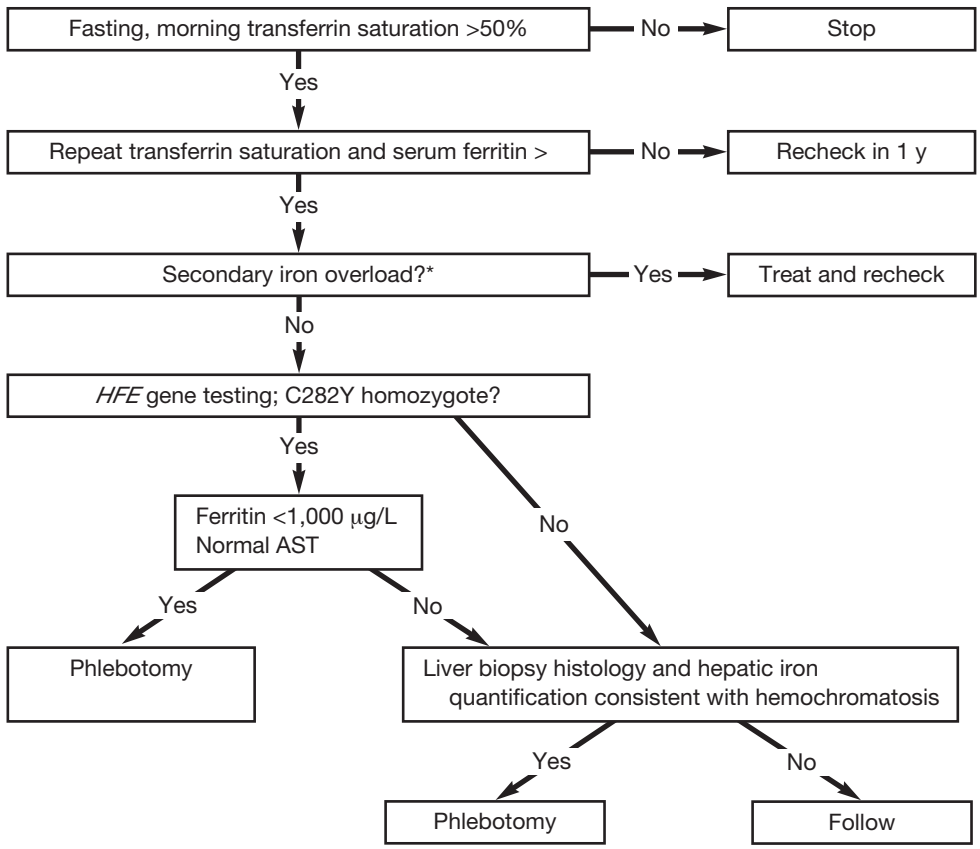

Fig. 7-8. Diagnostic algorithm for genetic hemochromatosis. AST, aspartate aminotransferase. *Anemias with ineffective erythropoiesis, multiple blood transfusions, oral/parenteral iron supplement. (From Brandhagen DJ, Gross JB Jr. Metabolic liver disease. In Hauser SC, editor. Mayo Clinic gastroenterology and hepatology board review. Rochester [MN]: Mayo Clinic Scientific Press and Boca Raton [FL]: CRC Press; 2004. p. 381-92. Used with permission of Mayo Foundation for Medical Education and Research.)

an inability of the liver to prepare copper for biliary excretion. The liver is chiefly involved in children, whereas neuropsychiatric manifestations are more prominent in older patients. The Kayser-Fleischer ring is a brownish pigmented ring at the periphery of the cornea. It is not invariably present and is more frequent in patients with neurologic manifestations. Hepatic forms of Wilson disease include fulminant hepatitis (often accompanied by hemolysis and renal failure), chronic hepatitis, steatohepatitis, and insidiously developing cirrhosis. The development of hepatocellular carcinoma is rare. Neurologic signs include tremor, rigidity, altered speech, and changes in personality. Fanconi syndrome and premature arthritis may occur.

- Wilson disease: an autosomal recessive disorder characterized by increased copper in tissues.
- Basic defect: inability of the liver to prepare copper for biliary excretion.
- Kayser-Fleischer ring: brownish pigmented ring at the periphery of the cornea.
- Hepatocellular carcinoma is rare.
- Neurologic signs: tremor, rigidity, altered speech, and changes in personality.

Evidence of hemolysis (total bilirubin increased out of proportion to direct bilirubin), a low or normal level of alkaline phosphatase, and a low serum level of uric acid (due to Fanconi syndrome) suggest Wilson disease. The diagnosis is established on the basis of a low level of ceruloplasmin and an increased urinary concentration of copper. Ceruloplasmin levels may be misleading—they may be increased by estrogen or biliary obstruction and decreased by liver failure of any cause. High concentrations of copper in the liver are found in Wilson disease, although similarly high values can also occur in cholestatic syndromes. Genetic testing for Wilson disease is developing but is currently most reliable for screening first-degree relatives when a specific mutation in the proband has been identified. The treatment of choice for Wilson disease is penicillamine, which chelates and increases the urinary excretion of copper. Trientine is an alternative to penicillamine. Zinc inhibits absorption of copper by the gastrointestinal tract and can be used as adjunctive therapy. All siblings of patients should be evaluated for Wilson disease. Liver transplantation corrects the metabolic defect of the disease.

- Diagnosis: low ceruloplasmin level and increased urinary concentration of copper.
- Treatment: penicillamine or trientine; zinc.
- Liver transplantation corrects the metabolic defect.

α_1-Antitrypsin Deficiency

α_1-Antitrypsin is synthesized in the liver. The gene is on chromosome 14. M is the common normal allele, and Z and S are abnormal alleles. Intrahepatic accumulation of α_1-antitrypsin in the ZZ phenotype causes liver disease; however, disease occurs in only 10% to 20% of patients with the ZZ phenotype. During the first 6 months of life, patients often have a history of cholestatic jaundice that resolves. In later childhood or adulthood, cirrhosis may develop. Patients with α_1-antitrypsin–induced liver disease often have no clinically important lung disease. The prevalence of cirrhosis in patients with the MZ phenotype is likely increased, but the risk is small. Hepatocellular carcinoma may complicate α_1-antitrypsin deficiency, especially in males. The diagnosis of α_1-antitrypsin deficiency is made by determining the α_1-antitrypsin phenotype. The serum levels of α_1-antitrypsin may vary and be unreliable. Liver transplantation corrects the metabolic defect and changes the recipient's phenotype to that of the donor.

- Intrahepatic accumulation of α_1-antitrypsin causes liver disease.
- The diagnosis is made by determining the α_1-antitrypsin phenotype.
- Hepatocellular carcinoma can complicate α_1-antitrypsin deficiency, especially in males.
- Liver transplantation corrects the metabolic defect.

Fulminant Hepatic Failure

Fulminant hepatic failure is defined as hepatic failure with encephalopathy developing less than 8 weeks after the onset of jaundice in patients with no history of liver disease. The common causes are listed in Table 7-21. Poor prognostic markers include a drug-induced cause (other than acetaminophen), older age, grade 3 or 4 encephalopathy, acidosis, and international normalized ratio (INR) greater than 3.5. Treatment is supportive, and patients should be transferred to a medical center where liver transplantation is available.

- Fulminant hepatic failure: hepatic failure with encephalopathy developing <8 weeks after the onset of jaundice and in patients with no history of liver disease.
- Poor prognostic markers: drug-induced (not acetaminophen), older age, grade 3 or 4 encephalopathy, and INR >3.5.

Drug-Induced Liver Disease

Drugs cause toxic effects in the liver in different ways, often mimicking naturally occurring liver disease. Most drug-induced liver disorders are idiosyncratic and not dose-related; 2% of the cases of jaundice in hospitalized patients and 25% of the cases of fulminant hepatitis are drug-induced. Consequently, all drugs that have been used by a patient with liver disease must be identified.

Acetaminophen toxicity is the most common cause of fulminant liver failure. Toxicity may occur at relatively low doses in alcoholics because alcohol induces hepatic microsomal P-450 enzymes, which metabolize acetaminophen to its toxic metabolite. Acetaminophen hepatotoxicity is characterized by aminotransferase values greater than 5,000 U/L and often by renal failure. *N*-acetylcysteine should be used liberally. Fulminant hepatic failure due to acetaminophen carries a better prognosis than that from other causes.

Amoxicillin/clavulanate causes severe cholestatic hepatitis, and valproic acid, tetracycline, and zidovudine may cause severe microvesicular steatosis associated with encephalopathy. Hepatotoxicity due to amiodarone may have histologic features that mimic those of alcoholic hepatitis or nonalcoholic steatohepatitis. Methotrexate in a long-term, cumulative oral dose of more than 2 g may cause

Table 7-21 Common Causes of Fulminant Hepatic Failure

Infective
Hepatitis virus A, B, C (rare), D, and E
Herpesvirus
Drug reactions and toxins
Acetaminophen
Antituberculous agents
Mushroom poisoning
Vascular
Ischemic hepatitis ("shock" liver)
Acute Budd-Chiari syndrome
Metabolic
Wilson disease
Fatty liver of pregnancy
Miscellaneous
Massive malignant infiltration
Autoimmune hepatitis

hepatic fibrosis; some physicians advocate periodic liver biopsy in patients receiving long-term methotrexate treatment for psoriasis or rheumatoid arthritis. Intravenous cocaine may cause massive necrosis and death, probably because of ischemia. Antituberculous agents, including isoniazid, rifampin, and ethambutol, may cause acute hepatitis.

- Most drug-induced liver disorders are idiosyncratic, not dose-related.
- Drugs cause 2% of the cases of jaundice (in hospitalized patients) and 25% of the cases of fulminant hepatitis.
- In alcoholics, acetaminophen toxicity may occur at relatively low doses.
- Amoxicillin/clavulanate causes severe cholestatic hepatitis.
- Amiodarone may cause hepatotoxicity that histologically mimics alcoholic hepatitis or nonalcoholic steatohepatitis.
- A long-term, cumulative oral dose of methotrexate >2 g may cause hepatic fibrosis.
- Intravenous cocaine can cause massive necrosis.

Liver Tumors

Hepatocellular Carcinoma

The majority of hepatocellular carcinoma (HCC) cases occur with cirrhosis. The risk of HCC is increased in cirrhosis of nearly any cause but particularly if due to HBV, HCV, hemochromatosis, or alcohol. The level of α-fetoprotein is increased in only 50% of patients with HCC; however, a level of α-fetoprotein greater than 400 ng/mL in a cirrhotic patient with a liver mass is essentially diagnostic of HCC. Common metastatic sites are lymph nodes, lung, bone, and brain. Paraneoplastic syndromes are rare but include anemia, fever, hypercalcemia, hypoglycemia, and clubbing. Liver transplantation is an option for patients with three or fewer lesions (largest <3 cm) or a single lesion smaller than 5 cm. Transplantation is advised particularly for patients with cirrhosis who may not tolerate resection because of poor liver reserve. Transarterial chemoembolization and percutaneous alcohol ablative techniques, such as alcohol injection or radiofrequency ablation, may be useful as neoadjuvant therapy or as primary treatment for patients who are candidates for surgery or for liver transplantation.

- The risk of HCC is increased in cirrhosis of nearly any cause.
- The α-fetoprotein level is increased in 50% of patients with HCC.
- Common metastatic sites: lymph nodes, lung, bone, and brain.
- Paraneoplastic syndromes: anemia, fever, hypercalcemia, hypoglycemia, and clubbing.
- Liver transplantation: an option for selected patients.

Cholangiocarcinoma

The incidence of cholangiocarcinoma is increased in patients with PSC, *Opisthorchis* infection, and a history of choledochal cysts. Cholangiocarcinoma may be difficult to diagnose, especially in patients with PSC. For most patients, surgical resection is the treatment of choice, although resection is not possible in many patients. Liver transplantation is an option in selected patients with cholangiocarcinoma.

Adenoma

Adenomas are associated with the use of oral contraceptives or estrogen. Patients can present with acute right upper quadrant pain and hemodynamic compromise because of bleeding.

Cavernous Hemangioma

Cavernous hemangioma is the most common benign tumor of the liver. Computed tomography (CT) with contrast agent is often diagnostic, demonstrating peripheral enhancement of the lesion. Cavernous hemangiomas generally require no treatment and are not estrogen-dependent.

Metastases

Metastases are more common than primary tumors of the liver. Frequent primary sites are the colon, stomach, breast, lung, and pancreas. Surgical resection of isolated colon cancer metastases has a limited effect on long-term survival.

Complications of End-Stage Liver Disease

Ascites

The pathogenesis of ascites involves stimulation of the renin-angiotensin-aldosterone system, resulting in inappropriate renal sodium retention with expansion of plasma volume. Patients with ascites generally have a low urinary concentration of sodium. The treatment of ascites involves dietary sodium restriction and diuretics. Spironolactone (100-200 mg daily) and furosemide (20-40 mg) are usually used initially. The goal is to increase urinary sodium and to allow the loss of 1 L of ascitic fluid (1 kg of body weight) per day. Paracentesis is indicated for diagnostic purposes and should

be performed therapeutically in patients with tense ascites or with respiratory compromise from abdominal distention. Large-volume or even total paracentesis in combination with 6 to 8 g of albumin per liter of ascitic fluid removed is safe and well tolerated.

- The pathogenesis of ascites probably involves stimulation of the renin-angiotensin-aldosterone system, resulting in inappropriate renal sodium retention with expansion of plasma volume.
- Patients generally have a low urinary concentration of sodium.
- Treatment: sodium restriction and diuretics.
- Large-volume paracentesis is safe and well tolerated.

Pleural effusion (hepatic hydrothorax) occurs in 6% of patients with cirrhosis and is right-sided in 67%. Edema usually follows ascites and is related to hypoalbuminemia and possibly to increased pressure on the inferior vena cava by the intra-abdominal fluid. The sudden onset of ascites should raise the possibility of hepatic venous outflow obstruction (Budd-Chiari syndrome). Tests most useful for determining the cause of ascites are measurements of total protein and the serum–ascitic fluid albumin gradient (SAAG), which is calculated as

$$\text{SAAG} = [\text{serum albumin}] - [\text{ascitic fluid albumin}]$$

A SAAG of 1.1 g/dL or more indicates portal hypertension. Ascites due to portal hypertension induced by congestive heart failure can be distinguished from cirrhotic ascites because congestive heart failure usually has an ascitic fluid protein level of 2.5 g/dL or more. Ascites from cancer or tuberculosis generally has an ascitic fluid protein level of 2.5 g/dL or more and a SAAG of less than 1.1 g/dL (Table 7-22).

Refractory ascites is uncommon. Most physicians advocate therapeutic paracentesis as needed. Transjugular intrahepatic portosystemic shunt (TIPS) is effective in some patients with refractory ascites and is particularly useful for cirrhotic patients with pleural effusion as the main manifestation of fluid retention. Peritoneovenous shunts are complicated by disseminated intravascular coagulation and shunt malfunction and are rarely performed.

- Pleural effusion occurs in 6% of patients with cirrhosis and is right-sided in 67%.
- The sudden onset of ascites raises the possibility of hepatic venous outflow obstruction (Budd-Chiari syndrome).
- A SAAG >1.1 g/dL almost always indicates portal hypertension.

Spontaneous Bacterial Peritonitis

Spontaneous bacterial peritonitis (SBP) occurs in 10% to 20% of patients with cirrhosis who have ascites. It is defined as a bacterial infection of ascitic fluid without any intra-abdominal source of infection. Fever, abdominal pain, and abdominal tenderness are classic symptoms; however, many patients have few or no symptoms. SBP should be suspected in any patient with cirrhotic ascites. For all patients, diagnostic paracentesis is advisable as an initial step. Coagulopathy and thrombocytopenia are not contraindications for diagnostic paracentesis. A cell count and culture of ascitic fluid should be performed for all patients. Bedside inoculation of blood culture bottles with ascitic fluid increases the diagnostic yield. SBP is more common in patients with large-volume ascites and in patients with a low ascitic fluid protein concentration (<1.5 g/dL). Also, blood from all patients with SBP should be cultured because almost 50% of these cultures are positive. Variants of SBP are listed in Table 7-23.

SBP and culture-negative neutrocytic ascites should be treated, usually with a third-generation cephalosporin. A polymicrobial infection of ascitic fluid should prompt a search for an intra-abdominal focus of infection; SBP nearly always involves only one organism. Patients with an episode of SBP are at high risk of recurrence, and prophylactic therapy with norfloxacin is recommended. Prophylactic therapy for 7 days is also advised for any patient with cirrhosis who is hospitalized for gastrointestinal tract bleeding regardless of whether ascites or SBP is present.

- SBP occurs in 10%-20% of patients with cirrhosis who have ascites.
- Classic symptoms: fever, abdominal pain, and abdominal tenderness.
- Many patients have few or no symptoms.
- Bedside inoculation of blood culture bottles with ascitic fluid increases the diagnostic yield.
- SBP is more common in patients with large-volume ascites and in patients with low ascitic fluid protein (<1.5 g/dL).
- Spontaneous bacterial peritonitis nearly always involves only one organism.
- Prophylactic therapy is advised for patients with a previous episode of SBP and for cirrhotic patients with gastrointestinal tract bleeding.

Hepatorenal Syndrome

Hepatorenal syndrome, or functional renal failure, consists of renal failure with normal tubular function in patients with portal hypertension. The differential diagnosis is given in Table 7-24. Hepatorenal syndrome is difficult to differentiate from prerenal azotemia; thus, a brief trial of colloid expansion may be indicated. Hepatorenal

Table 7-22 Use of Serum-Ascites Albumin Gradient (SAAG) and Ascites Protein to Determine the Cause of Ascites

SAAG, g/dL	Ascites protein <2.5 g/dL	Ascites protein ≥2.5 g/dL
≥1.1	Portal hypertension due to cirrhosis	Portal hypertension due to hepatic venous outflow obstruction (including right heart failure)
<1.1	Nephrotic syndrome	Malignancy, tuberculosis

Table 7-23 Variants of Spontaneous Bacterial Peritonitis

Condition	Ascitic fluid: Polymorphonuclear cells/mL	Ascitic fluid: Culture results	Management
Spontaneous bacterial peritonitis	>250	Positive	Antibiotics
Culture-negative neutrocytic ascites	>250	Negative	Antibiotics
Bacterascites	<250	Positive	Treat if symptoms of infection are present; otherwise, repeat paracentesis for cell count and cultures

syndrome is often precipitated by vigorous diuretic therapy. Treatment is supportive, although vasoconstrictors, octreotide with albumin infusion, and TIPS may be useful. After liver transplantation is performed, renal function returns to normal.

- Hepatorenal syndrome: renal failure with normal tubular function in a patient with portal hypertension.
- It is difficult to differentiate from prerenal azotemia.
- It is often precipitated by vigorous diuretic therapy.
- After liver transplantation, renal function returns to normal.

Portal Systemic Encephalopathy

Portal systemic encephalopathy is a reversible decrease in the level of consciousness of patients with severe liver disease. Disturbed consciousness, personality change, intellectual deterioration, and slowed speech are common manifestations. The electroencephalogram is frequently abnormal, and patients often demonstrate asterixis (flapping tremor). The grading system commonly used for this condition is given in Table 7-25.

The sudden development of portal systemic encephalopathy in patients with stable cirrhosis should prompt a search for bleeding, infection (especially SBP), or electrolyte disturbances; however, simple precipitating events may include increased dietary protein, constipation, or sedatives. Serum and arterial levels of ammonia are usually increased. Lactulose has a laxative effect that decreases the nitrogenous compounds presented to the liver and is the first-line treatment for hepatic encephalopathy. Oral neomycin or protein restriction (or both) is considered for patients refractory to lactulose.

- Portal systemic encephalopathy: reversible decrease in the level of consciousness of patients with severe liver disease.
- Patients often have asterixis or flapping tremor.
- If portal systemic encephalopathy develops suddenly, look for bleeding, infection, or electrolyte disturbances.
- Treatment: lactulose.

Variceal Hemorrhage

Esophageal varices are collateral vessels that develop because of portal hypertension. Varices also can occur in other parts of the gut. Most patients with cirrhosis who have varices do not hemorrhage, but patients with a first hemorrhage have a 10% to 30% mortality. For patients who have cirrhosis but have not had bleeding, endoscopy to assess for the presence of varices is advised. Patients with moderate- or large-sized varices, especially if there are red marks on the varices, should be treated with nadolol or propranolol to prevent bleeding.

Bleeding from esophageal varices is generally massive. For patients with acute bleeding, early endoscopy is indicated for diagnosis and treatment. Endoscopic therapy consists of band ligation or, less commonly, sclerotherapy. Octreotide decreases portal venous pressure and should also be given for acute variceal bleeding.

- Esophageal varices are collateral vessels that result from portal hypertension.

Table 7-24 Differential Diagnosis for Hepatorenal Syndrome

Variable	Prerenal azotemia	Hepatorenal syndrome	Acute renal failure (acute tubular necrosis)
Urinary sodium concentration, mEq/L	<10	<10	>30*
Urine-to-plasma creatinine ratio	<30:1	>30:1	<20:1
Urinary osmolality	At least 100 mOsm >plasma osmolality	At least 100 mOsm >plasma osmolality	Equal to plasma osmolality
Urinary sediment	Normal	Unremarkable	Casts, debris

*Radiocontrast agents and sepsis may lower urinary sodium concentration in patients with acute tubular necrosis.

From Epstein M. Hepatorenal syndrome. In: Epstein M, editor. The kidney in liver disease. 4th ed. Philadelphia: Hanley & Belfus, Inc.; 1996. p. 75-108. Used with permission.

Table 7-25 Grading System for Portal Systemic Encephalopathy

Grade of encephalopathy	Level of consciousnesss
0	Normal
1	Trivial lack of awareness Personality change Day-night reversal
2	Lethargic Inappropriate behavior
3	Asleep but arousable Confused when awake
4	Unarousable

Modified from Schafer DF, Jones EA. Hepatic encephalopathy. In Zakim D, Boyer TD, editors. Hepatology: a textbook of liver disease. Vol 1. 2nd ed. Philadelphia: WB Saunders Company; 1990. p. 447-60. Used with permission.

- Most patients with cirrhosis who have varices do not hemorrhage.
- First hemorrhage: 10%-30% mortality.
- Bleeding is generally massive.
- Early endoscopy is indicated for diagnosis and treatment.

Of patients with esophageal varices, 80% to 100% have recurrent bleeding within 2 years after the first episode. Oral propranolol or nadolol may prevent rebleeding, although most physicians advocate endoscopic variceal ligation until the varices have been obliterated. Patients with refractory bleeding are candidates for shunting procedures. The use of surgical shunts is accompanied by a high rate of mortality and morbidity and is complicated by portal systemic encephalopathy. TIPS is effective in controlling bleeding, and the patient has the advantage of avoiding an operation. The incidence of portal systemic encephalopathy after TIPS is 10% to 40%, but this complication usually can be controlled with medical therapy. Isolated gastric varices without esophageal varices can occur with sinistral (left-sided) portal hypertension due to splenic vein thrombosis.

- Recurrent bleeding occurs in 80%-100% of patients.
- Patients with refractory bleeding are candidates for shunting.
- The incidence of portal systemic encephalopathy after TIPS is 10%-40%.

Biliary Tract Disease

Gallstones and Cholecystitis

The two types of gallstones are cholesterol and pigment. Cholesterol gallstones occur when bile is supersaturated with cholesterol relative to bile salts. Excessive cholesterol secretion (in females or with obesity or use of exogenous estrogens) or deficient bile acid secretion (bile acid sequestrant therapy) may lead to cholesterol gallstones. Pigment stones are a manifestation of hemolysis or cirrhosis, although there usually is no identifying cause. Gallstones can cause uncomplicated biliary pain, acute cholecystitis, common bile duct obstruction with cholangitis, and acute pancreatitis. Biliary pain is generally felt in the epigastrium or right upper quadrant and is usually severe and steady, lasting several hours. Intolerance to fatty food is not a feature of biliary disease. Ultrasonography is 90% to 97% sensitive for detecting gallstones. Cholecystitis may be suggested by gallbladder contraction, marked distention, surrounding fluid, or wall thickening. Ultrasonography also offers the opportunity to detect dilated bile ducts. If performed during an episode of pain, radionuclide biliary scanning is helpful in diagnosing cystic duct obstruction with cholecystitis. Positive test results are marked by nonvisualization of the gallbladder despite biliary excretion of radioisotope.

Asymptomatic gallstones require no therapy, even in high-risk patients. Patients with episodes of biliary colic or acute cholecystitis should have cholecystectomy. Patients with high surgical risk may undergo percutaneous cholecystostomy.

- Cholesterol gallstones occur when bile is supersaturated with cholesterol.
- Pigment stones can occur with hemolysis or cirrhosis.
- Ultrasonography is 90%-97% sensitive for detecting gallstones.
- Radionuclide biliary scanning helps diagnose cystic duct obstruction with cholecystitis.
- Asymptomatic gallstones require no therapy.

Bile Duct Stones

Most bile duct stones originate in the gallbladder, although a few patients have primary duct stones. CT and ultrasonography are relatively insensitive for common bile duct stones, and diagnosis generally requires magnetic resonance cholangiography, endoscopic retrograde cholangiopancreatography (ERCP), or endoscopic ultrasonography. ERCP offers therapeutic potential for patients with bile duct stones.

Patients with bile duct stones can have minimal or no symptoms, or they can have life-threatening cholangitis with abdominal pain, fever, and jaundice. Common bile duct stones should be removed. In 90% of patients, this can be performed with ERCP. The urgency of the procedure depends on the clinical presentation. Patients with minimal symptoms can have elective ERCP, but those with cholangitis and fever unresponsive to antibiotics should have urgent endoscopic treatment. Patients with gallbladder stones who have a sphincterotomy and clearance of their duct stones have only a 10% chance of having additional problems with their gallbladder stones; thus, cholecystectomy can be avoided in patients who are at high risk of complications with surgery.

- Most bile duct stones originate in the gallbladder.
- Diagnosis of common bile duct stones usually requires magnetic resonance cholangiography.
- Common bile duct stones should be removed.
- Urgent endoscopic treatment is needed if cholangitis and fever are unresponsive to antibiotics.

Malignant Biliary Obstruction

Malignant biliary obstruction is usually the result of carcinoma of the head of the pancreas, bile duct cancer, or metastatic malignancy to hilar nodes. If the disease is unresectable, palliative endoscopic or

percutaneous stenting is as effective as surgical bypass. Patients with malignant biliary obstruction and impending duodenal obstruction are usually considered for palliative surgery, although endoscopic techniques can be attempted by expert endoscopists.

Gallbladder Carcinoma

Gallbladder carcinoma has a strong association with calcified (porcelain) gallbladder. For this reason, cholecystectomy is advised for patients with porcelain gallbladder.

Sphincter of Oddi Dysfunction

Sphincter of Oddi dysfunction is a poorly defined entity characterized by right upper quadrant pain without any structural cause. Patients with typical biliary-type pain, increased values on liver tests during the episode of pain, a dilated common bile duct, and delayed drainage of contrast medium after cholangiography often have improvement after sphincterotomy. Patients without each of these criteria generally have a poor response to sphincterotomy.

Gastroenterology Pharmacy Review

Virginia H. Thompson, RPh, Alma N. Adrover, PharmD, MS

Review of H_2 Receptor Antagonists, Proton Pump Inhibitors, and Antacids

Drug	Indication	Dosage	Toxic/adverse effects	Comments
H_2 receptor antagonists*				
Cimetidine	Duodenal ulcer		Adjust dose in severe liver or renal disease	Absorption may be affected by antacids (avoid simultaneous administration)
	Active phase	800 mg po hs† × 4-6 wk	Reduces liver metabolism of drugs metabolized via cytochrome P-450 pathway; multiple drug interactions; may cause CNS side effects	Injectable form available
	Maintenance	400 mg po hs†		
	Gastric ulcer			
	Active phase	800 mg po hs† × 6 wk *or* 300 mg po qid × 6 wk		
	Maintenance	400 mg po hs†		
	GERD	400-800 mg po bid × 12 wk		
	Heartburn (OTC)	100 mg po prn, max 400 mg/d		
Famotidine	Duodenal ulcer		Adjust dose in renal insufficiency (CrCl <50 mL/min)	Absorption may be affected by antacids (avoid simultaneous administration)
	Active phase	40 mg po hs† × 4-6 wk *or* 20 mg po bid × 4-6 wk		Does not inhibit cytochrome P-450 pathway
	Maintenance	20 mg po hs†		Injectable form available
	Gastric ulcer			For heartburn, take 1 h before consuming foods or drinks suspected of causing GI distress
	Active phase	40 mg po hs† × 8 wk		
	Maintenance	20 mg po hs†		
	GERD	20 mg po bid × 6 wk		
	Heartburn (OTC)	10 mg po prn, max 20 mg/d		
Nizatidine	Duodenal ulcer		Adjust dose in moderate or severe renal disease	Absorption may be affected by antacids (avoid simultaneous administration)
	Active phase	300 mg po hs† *or* 150 mg po bid	May cause CNS side effects	Does not inhibit cytochrome P-450 pathway; undergoes little hepatic metabolism
	Maintenance	150 mg po hs†		For heartburn, take 1 h before consuming foods or drinks suspected of causing GI distress
	Benign gastric ulcer	300 mg po hs† *or* 150 mg po bid		
	GERD	150 mg po bid × 6 wk		
	Heartburn (OTC)	75 mg po prn, max 150 mg/d		

Gastroenterology Pharmacy Review (continued)

Review of H_2 Receptor Antagonists, Proton Pump Inhibitors, and Antacids (continued)

Drug	Indication	Dosage	Toxic/adverse effects	Comments
H_2 receptor antagonists* (continued)				
Ranitidine	Duodenal ulcer		Adjust dose in renal insufficiency (CrCl <50 mL/min)	Zantac EFFERdose (effervescent formula) is available; dissolve tablets in 6-8 oz water before drinking
	Active phase	150 mg po bid *or* 300 mg po hs†	May cause CNS side effects	Binds only weakly to cytochrome P-450
	Maintenance	150 mg po hs†		Injectable form available
	Gastric ulcer			
	Active	150 mg po bid		
	Maintenance	150 mg po hs†		
	GERD	150 mg po bid × 6 wk		
	Heartburn (OTC)	75 mg po prn, max 100 mg/d		
Proton pump inhibitors‡				
Omeprazole	Duodenal ulcer	20 mg po qd × 4-8 wk	No dose adjustment needed in severe renal disease	Take 1 h before meals
	Helicobacter pylori	20 mg po qd§	Dose adjustment suggested in severe liver disease	Swallow whole; do not chew, crush, or split capsule
	Gastric ulcer	40 mg po qd × 4-8 wk	Inhibits metabolism of drugs metabolized by cytochrome P-450 system	Available in generic form
	GERD	20 mg po qd × 4-8 wk		Omeprazole magnesium available OTC
				Available as immediate-release powder packets formulated with sodium bicarbonate to prevent acid degradation (Zegerid)
Esomeprazole	Gastric ulcer		Same as omeprazole	Isomer of omeprazole
	NSAID associated	20-40 mg po qd for up to 6 mo		Take 1 h before meals
	H. pylori	40 mg po qd§		Swallow whole; do not chew or crush capsule
	GERD	20 mg po qd × 4-8 wk		
Lansoprazole	Duodenal ulcer	15 mg po qd × 4 wk	Consider dose reduction in severe liver disease—primarily biliary elimination	Take 1 h before meals
	H. pylori	30 mg po qd§		Swallow whole; do not chew or crush capsule
	Gastric ulcer	30 mg po qd for up to 8 wk		Oral suspension packets and orally disintegrating tablets available
	GERD	15 mg po qd × 8-16 wk		Injectable form available
Rabeprazole	Duodenal ulcer	20 mg po qd after morning meal for up to 4 wk	Does not appear to interact with hepatic cytochrome P-450	Swallow whole; do not chew, crush, or split tablet
	Gastric ulcer	20 mg po qd × 6 wk		
	H. pylori	20 mg po bid × 7 d§		
	GERD	20 mg po qd × 4-8 wk		

Gastroenterology Pharmacy Review (continued)

Review of H_2 Receptor Antagonists, Proton Pump Inhibitors, and Antacids (continued)

Drug	Indication	Dosage	Toxic/adverse effects	Comments
Proton pump inhibitors‡ (continued)				
Pantoprazole	Duodenal ulcer	40 mg po qd × 8 wk	Lowest potential for P-450 metabolism and drug interactions	May be given with or without food Swallow whole; do not chew, crush, or split tablet Injectable form available
	Gastric ulcer	40 mg po qd × 8 wk		
	GERD	40 mg po qd for up to 8 wk		
Antacids//	Duodenal ulcer,			
Aluminum hydroxide	gastric ulcer, or GERD	500-1,500 mg po, 3-6 × qd	Binds with phosphate ions May cause constipation Use with caution in Alzheimer disease Guard against accumulation in renal disease	May have cytoprotective effect Useful in biliary reflux
Calcium carbonate		500-1,500 mg po prn	Milk-alkali syndrome	40% elemental calcium
Magaldrate		30 mL po prn		Chemical entity of aluminum and magnesium hydroxide
Magnesium hydroxide		30 mL po prn	Cathartic effect at higher doses Guard against accumulation in renal disease	May have cytoprotective effect
Sodium bicarbonate		300-2,000 mg po 1-4 × qd	Avoid sodium overload Milk-alkali syndrome	Most rapidly acting antacid
Sodium citrate		30 mL po qd	Increases absorption of aluminum from aluminum-containing antacids, potentiating aluminum toxicity in renal disease Conversion to bicarbonate may be impaired in the presence of liver disease	May chill & dilute with water before using

bid, twice daily; CNS, central nervous system; CrCl, creatinine clearance; GERD, gastroesophageal reflux disease; GI, gastrointestinal; max, maximal dosage; NSAID, nonsteroidal anti-inflammatory drug; OTC, over-the-counter (nonprescription); po, orally; prn, as needed; qd, daily; hs, at bedtime; qid, 4 times daily.

*Indicated for phase 2 therapy in the treatment of reflux disease and for the prevention of bleeding associated with stress ulcers. Ineffective in preventing gastric ulcers and in decreasing the frequency of NSAID-induced mucosal erosions.

†Nocturnal acid secretion may be better controlled with administration at 6 PM instead of 10 PM because highest acid production starts at 7 PM.

‡Indicated for healing and prevention of NSAID-induced gastric ulcers. This class of drugs provides the most complete control of acid production and better overall symptom control and mucosal healing. The class is most effective in treatment of GERD. Proton pump inhibitors may interact with drugs for which gastric pH is an important determinant of bioavailability, i.e., ketoconazole, ampicillin, iron, digoxin, cyanocobalamin.

§Used in combination as described in text in section on *H. pylori* treatment.

//All antacids should be administered 30 minutes after meals and at bedtime. Coadministration of antacids with fluoroquinolones may result in crystalluria and nephrotoxicity. Give 2 hours before or 8 hours after antacid. Antacids reduce absorption of ketoconazole and tetracyclines. Do not give antacids within 3 hours of these drugs. Coadministration of enteric coated drugs (such as bisacodyl) and antacids may cause coating to dissolve too rapidly, resulting in gastric or duodenal irritation. Magnesium-containing antacids may cause diarrhea and hypermagnesemia—use with caution in patients with renal insufficiency. Antacids may also contain considerable amounts of sodium, causing overload in susceptible patients.

Gastroenterology Pharmacy Review (continued)

Review of Adjuvants for Treating Gastrointestinal Disorders

Drug	Dosage	Toxic/adverse effects	Comments
Anticholinergics			
Atropine	0.4-0.6 mg po q 4-6 h prn	Drowsiness, dizziness, dry mouth, blurred vision, urinary retention	Take 30-60 min before meals
Hyoscyamine	0.125-0.25 mg po tid-qid	Susceptibility to heat stroke	Increase dental hygiene because of decreased salivary secretion
Belladonna alkaloids	0.18-0.3 mg po tid-qid		
Scopolamine	0.4-0.8 mg po qd Patch: 1.5 mg/3 d	Vision changes, drowsiness	Inhibits excessive motility of GI tract Used for motion sickness
Glycopyrrolate	1-2 mg po bid-tid		
Antispasmodics			
Dicyclomine	20-40 mg po qid	Drowsiness, dizziness, dry mouth	Available for IM use
Antiflatulents			
Simethicone	40-120 mg po prn Maximum: 500 mg/d		Take after meals and before bedtime Defoaming action—chew tablets completely
Charcoal	520 mg after meals po prn	Can absorb other drugs in GI tract	Limit use to no more than 2 d
Prokinetic			
Metoclopramide	10 mg po up to qid	Dopamine antagonist—increases LES Extrapyramidal symptoms may occur Dizziness, drowsiness, crosses BBB Avoid in depressed patients Avoid in epileptic patients	Take before meals & before bedtime Effective in decreasing symptoms but not in healing Injectable form available
Bethanechol	25 mg po qid after meals		Useful in combination with other agents Increases LES Increases esophageal clearance Injectable form available
Cytoprotective agents			
Misoprostol	200 µg po qid with food	Diarrhea, cramping Do not use in pregnant women or women of childbearing age without prior pregnancy test	Abortifacient properties Used for prevention of NSAID-induced gastric ulcers and treatment of duodenal ulcers
Sucralfate	Active duodenal ulcer—1 g po qid × 4-8 wk	Complexed with aluminum hydroxide—use with caution in renal failure (possible aluminum accumulation) Do not give antacids within 30 min of administration	Local action—not absorbed systemically Adheres to damaged mucosa and protects it against acid, pepsin, and bile salts Give 1 h before meals and before bedtime May decrease nosocomial pneumonia in ventilator-dependent patients

BBB, blood-brain barrier; bid, twice daily; GI, gastrointestinal; IM, intramuscular; LES, lower esophageal sphincter; NSAID, nonsteroidal anti-inflammatory drug; po, orally; prn, as needed; q, every; qd, daily; qid, 4 times daily; tid, 3 times daily.

Gastroenterology Pharmacy Review (continued)

Review of Drugs for Treating Diarrhea, Constipation, Ulcerative Colitis, Crohn Disease, and Irritable Bowel Syndrome

Drug	Dosage	Toxic/adverse effects	Comments
Diarrhea			
Bismuth subsalicylate	2 tablets or 30 mL po prn up to 8 doses/24 h	Salicylate toxicity Decreases bioavailability of tetracycline Discoloration of tongue and stools Avoid in renal failure	Antacid and absorbent properties Used in prevention of traveler's diarrhea Do not use in patients with influenza or chicken pox because of risk of Reye syndrome Do not use in pregnancy (third trimester) Avoid in aspirin hypersensitivity
Diphenoxylate with atropine	2 tablets po qid, for up to 2 d	Has central opiate effects and may cause cholinergic side effects: dizziness, drowsiness, dry mouth, miosis	Diphenoxylate is a meperidine congener without analgesic properties
Loperamide	4 mg po × 1, then 2 mg po prn; max 16 mg/d	Drowsiness	Slows intestinal motility Effective in treating traveler's diarrhea
Cholestyramine	4 g po qd to tid	Steatorrhea Long-term use may decrease absorption of iron, calcium, folic acid	Binds bile acids Mix powder with fluids Administer other medicines 1-2 h before or 6 h after
Octreotide*	50-250 µg SQ tid	Flushing, bradycardia, dizziness	Somatostatin analogue Useful for secretory diarrhea
Constipation			
Fiber (bulk producing)		Bloating, flatulence, iron & calcium malabsorption	Recommended initial treatment for most forms of constipation
Methylcellulose	5 mL po up to tid		
Polycarbophil	2-4 tablets po qd	Decreases effects of digoxin, warfarin, salicylates, tetracyclines, nitrofurantoin	Increases stool bulk Decreases transit time Drink a full glass of liquid with each dose
Psyllium	5 mL po up to tid	Watch for symptoms of esophageal obstruction in elderly patients Contraindicated in patients with intestinal ulceration and stenosis	
Stool softeners			
Docusate (sodium, calcium, potassium)	100 mg po bid	Avoid taking with mineral oil	Best agent for constipation prevention Surfactant
Hyperosmolar agents			
Glycerin	1 suppository per rectum prn	Local irritation if used rectally	
Lactulose†	30 mL po qd	Abdominal cramps (lactulose & sorbitol)	Sweet taste (lactulose & sorbitol)
Sorbitol	15-30 mL po qd	Use with caution in patients with diabetes or renal impairment (lactulose & sorbitol)	

Gastroenterology Pharmacy Review (continued)

Review of Drugs for Treating Diarrhea, Constipation, Ulcerative Colitis, Crohn Disease, and Irritable Bowel Syndrome (continued)

Drug	Dosage	Toxic/adverse effects	Comments
Constipation (continued)			
Stimulants			
Bisacodyl	10 mg po or per rectum qd	Rectal irritation (rectal bisacodyl) Avoid coadministration with antacids, H_2 receptor antagonists, & milk products (oral bisacodyl—enteric-coated) Urine discoloration (senna)	Limit use to ≤1 wk
Senna	2 tablets po qd		
Castor oil	30 mL po qd		
Saline			
Milk of magnesia	30 mL po qd	Contraindicated in renal disease and CHF Watch for symptoms of magnesium toxicity May alter fluid & electrolyte balance	Limit use to ≤1 wk
Magnesium citrate	30 mL po qd		
Polyethylene glycol (PEG)	17 g po qd	Do not use in patients with suspected GI obstruction or perforation	For occasional use only Dissolve in 8 oz of liquid before taking
Emollient/Lubricant			
Mineral oil	15-45 mL po qd	Lipid pneumonia Malabsorption of lipid-soluble vitamins Reduces absorption of anticoagulants, oral contraceptives, & digoxin	Not for routine use
Ulcerative Colitis and Crohn Disease			
Mesalamine (5-ASA)	2.4-4 g po qd in divided doses 1 g qd per rectum (suppository or retention enema)	Overdose: symptoms of salicylate toxicity; if chest pain develops, consider pericarditis	Effective in treatment of mild or moderate active phases Swallow tablets whole May give oral and rectal therapy concurrently Available as Asacol and Pentasa, which release 5-ASA in the terminal ileum & small bowel, respectively
Olsalazine	1.5-3 g po qd in divided doses	Monitor for renal abnormalities Causes diarrhea	Take with food Bioconverted to 5-ASA in colon Effective in treatment of mild or moderate active phases
Sulfasalazine	3-4 g po qd in divided doses	Use with caution in asthmatic patients and patients with glucose-6-phosphate dehydrogenase deficiency Cross-sensitivity with sulfonamides May impair folic acid absorption Orange-yellow discoloration of the urine, skin, & soft contact lenses	Effective in treating acute disease & maintaining remission in ulcerative colitis Does not maintain remission in Crohn disease Swallow whole Metabolized to sulfapyridine and 5-ASA by intestinal bacteria Slow and fast acetylators exhibit differences in metabolism Maintain adequate fluid intake

Gastroenterology Pharmacy Review (continued)

Review of Drugs for Treating Diarrhea, Constipation, Ulcerative Colitis, Crohn Disease, and Irritable Bowel Syndrome (continued)

Drug	Dosage	Toxic/adverse effects	Comments
Ulcerative Colitis and Crohn Disease (continued)			
Balsalazide	6.75 g po qd in divided doses	Monitor for renal abnormalities	Bioconverted to 5-ASA in colon
Prednisone	40-60 mg po qd Use topically for mild or moderate active disease in distal colon	Osteoporosis Cushingoid appearance Muscle weakness Adrenal suppression	Most effective in maintaining remission in ulcerative colitis Most effective in acute exacerbation of Crohn disease Use prednisolone in patients with cirrhosis
Azathioprine	2-5 mg/kg po qd	Immunosuppression	Metabolized to 6-mercaptopurine Drug interaction with allopurinol Injectable form available
6-Mercaptopurine	2.5-5 mg/kg po qd		Steroid-sparing effect
Metronidazole (perianal disease)	20 mg/kg po qd	Metallic taste, dark urine	Recurrence on discontinuation
Infliximab (Crohn disease)	5 mg/kg IV infusion over 2 h	Associated with severe acute infusion reaction, delayed hypersensitivity, & increased risk of infection Avoid in moderate or severe heart failure	For moderate or severe active Crohn disease refractory to conventional therapy & in fistulizing Crohn disease Perform tuberculosis test before therapy
Tegaserod (IBS)	6 mg po bid before meals for 4-6 wk	Not recommended in severe hepatic or renal impairment or symptomatic gallbladder disease Discontinue therapy if diarrhea, hypotension, or syncope develop	For treatment of IBS, especially in women with constipation Approved for chronic idiopathic constipation in both men and women

bid, twice daily; CHF, congestive heart failure; GI, gastrointestinal; IBS, irritable bowel syndrome; IV, intravenous; max, maximal dosage; po, orally; prn, as needed; qd, daily; qid, 4 times daily; SQ, subcutaneously; tid, 3 times daily.

*Also indicated in the treatment of carcinoid syndrome.

†Also indicated in the treatment of portal systemic encephalopathy.

Gastroenterology Pharmacy Review (continued)

Review of *Helicobacter pylori* Treatment Regimens

Regimen	Drug combination	Dosage given orally for 7-14 days	Comment
1	PPI	Standard dose bid*	
	Clarithromycin	500 mg bid	Metallic taste Drug interaction with terfenadine, astemizole, & cisapride
	Amoxicillin†	1 g bid	Be aware of penicillin allergy May cause nausea and diarrhea
2	PPI	Standard dose bid*	
	Tetracycline†	250 mg qid	Reduces effectiveness of oral contraceptives Absorption is reduced in presence of divalent and trivalent cations (Ca, Mg, Fe, Al) Photosensitivity—avoid exposure to sunlight
	Metronidazole‡	500 mg bid	Avoid alcohol use May cause nausea and diarrhea
	Bismuth	2 tablets qid	Darkening of tongue & stools

bid, twice daily; po, orally; PPI, proton pump inhibitor; qid, 4 times daily.
*Standard PPI doses: esomeprazole 40 mg, lansoprazole 30 mg, omeprazole 20 mg, pantoprazole 40 mg, or rabeprazole 20 mg.
†If unable to use amoxicillin or tetracycline, use metronidazole 500 mg po bid × 7 days.
‡If resistant to metronidazole, use amoxicillin 1 g po bid × 7 days.

General Internal Medicine

Scott C. Litin, MD

The goal of this chapter is to discuss important topics that are not covered thoroughly in other chapters. The interpretation of diagnostic tests and results of therapy must be well understood by internists because these skills are used every day in practice. Frequently, internists are asked to make a preoperative risk assessment of a medical patient who is about to have a noncardiac operation. Managing patients who are receiving anticoagulants, assessing risk and treating patients who have hyperlipidemia, and managing other disorders frequently encountered in the office are also important. This chapter discusses these topics.

Interpretation of Diagnostic Tests

Diagnostic tests are tools that either increase or decrease the likelihood of disease. When a diagnostic test is applied to a population at risk of a particular disease, patients in the studied population can be assigned to one of four groups on the basis of disease status and the test result. Table 8-1 illustrates the concept.

By convention, the four groups are assigned the letters *a* for true-positive (TP), *b* for false-positive (FP), *c* for false-negative (FN), and *d* for true-negative (TN) (Table 8-2). On the basis of this table (called a *2 × 2 table*), the following test characteristics can be defined:

1. *Sensitivity*
   Positive (test) in disease (PID)
   True positivity rate—proportion of patients with the disease who have a positive test result

Table 8-1 **Four Outcomes of a Diagnostic Test**

Outcome	Disease status	Test result
True-positive	Present	Abnormal
False-positive	Absent	Abnormal
False-negative	Present	Normal
True-negative	Absent	Normal

$$\text{Sensitivity: } \frac{TP}{TP + FN}$$

The 2 × 2 table definition: a/(a + c)
Rules to remember:
SN out—if a test has 100% sensitivity, a negative test rules **out** the disorder
Screening tests are used to maximize sensitivity and avoid missing a person who has the disease
Characteristic of test—not affected by the prevalence of disease in the population

2. *Specificity*
   Negative (test) in health (NIH)
   True negativity rate—proportion of patients without the disease who have a negative test result

Table 8-2 **2 × 2 Table**

		Target disorder: Present	Target disorder: Absent	
Diagnostic test result	Positive	True-positive a	False-positive b	a+b
	Negative	False-negative c	True-negative d	c+d
		a+c	b+d	a+b+c+d

Prevalence = (a+c)/(a+b+c+d)
Test characteristics
  Sensitivity = a/(a+c)
  Specificity = d/(b+d)
Frequency-dependent properties
  Positive predictive value = a/(a+b)
  Negative predictive value = d/(c+d)

Specificity: $\frac{TN}{TN + FP}$

The 2 × 2 table definition: d/(b + d)
Rules to remember:
SP in—if a test has 100% specificity, a positive test rules **in** the disorder
Confirmatory tests are used in follow-up of screening to maximize specificity and avoid incorrectly labeling a healthy person as having disease
Characteristic of test—not affected by the prevalence of disease in the population

3. *Positive predictive value*

When a patient's illness is evaluated by interpreting a diagnostic test, the 2 × 2 table is read horizontally, not vertically. One really wants to know whether a patient with positive test results actually has the disease, that is, how well the test results predict a disease compared with the reference standard for that disease. Thus, the horizontal properties of the diagnostic test are of primary interest. Among all patients with a positive diagnostic test result (TP + FP), in what proportion, $\frac{TP}{TP + FP}$, has the diagnosis been predicted correctly or ruled in? This proportion is the positive predictive value (PPV).

- PPV is the proportion of patients who have the disease among all the patients who test positive for the disease.
- This provides information most useful in clinical practice.
- PPV is affected by the prevalence of the disease in the population.
- The 2 × 2 table definition: PPV = $\frac{TP}{TP + FP}$ = a/(a + b).

4. *Negative predictive value*

It is also important to know the percentage of patients with a negative test result (FN + TN) who actually do not have the disease. This proportion, $\frac{TN}{FN + TN}$, is the negative predictive value (NPV).

- NPV is the proportion of patients who do not have the disease of interest among all the patients who test negative for the disease.
- NPV is affected by the prevalence of disease in the population.
- The 2 × 2 table definition: NPV = $\frac{TN}{FN + TN}$ = d/(c + d).

5. *Prevalence*

Prevalence is defined as the proportion of persons with the disease in the population to whom the test has been applied. In the 2 × 2 table, prevalence is written

$$\frac{TP + FN}{TP + FP + FN + TN} = \frac{a + c}{a + b + c + d}$$

How to Construct a 2 × 2 Table

The sensitivity, specificity, and predictive values of normal and abnormal test results can be calculated with even a limited amount of information. For example, assume that a new diagnostic test is positive in 90% of patients who have the disease and is negative in 95% of patients who are disease-free. The prevalence of the disease in the population to which the test is applied is 10%. This provides the following information:

Sensitivity = 90%
Specificity = 95%
Prevalence = 10%

This test is now ready to be applied to a group of patients by filling in a 2 × 2 table (Table 8-3). The calculation is often made easier if the test is applied to a large number of patients. For example, if it is applied to 1,000 patients, a + b + c + d = 1,000.

Because the prevalence of the disease is 10%, 100 patients have the disease (0.1 × 1,000 = 100, or a + c = 100). Of the patients, 90%, or 900, are disease-free (0.9 × 1,000 = 900, or b + d = 900).

Sensitivity of 90% means that 90% of the 100 patients with disease have a positive test result (a = 0.9 × 100 = 90) and 10% have a negative result (c = 0.1 × 100 = 10).

Specificity of 95% means that 95% of the 900 patients who are disease-free have a negative test result (d = 0.95 × 900 = 855) and 5% have a positive test result (b = 0.05 × 900 = 45).

The 2 × 2 table (Table 8-3) shows that 135 patients (a + b) have a positive test result; however, only 90 of these 135 patients actually have the disease. Therefore, the PPV of a positive test is $\frac{a}{a + b} = \frac{90}{135}$ = 66.7%. That is, only two-thirds of all patients with a positive test result will actually have the disease. Similarly, one can determine that 865 patients (c + d) have a negative test result; 855 of these 865 patients are disease-free. Therefore, the NPV of the test is $\frac{d}{c + d} = \frac{855}{865}$ = 98.8%.

Clinicians should be able to perform these simple calculations. Clinical decision making by internists is more likely to depend on the PPV and NPV of test results for a given population than on the sensitivity or specificity of the test.

For example, if the prevalence of the disease in the clinician's population is 2% instead of 10%, the PPV and NPV can be recalculated. The PPV of abnormal test results decreases to 26.9%, which is quite different from 66.7% (based on a prevalence of 10%), although the sensitivity and specificity of the test (90% and 95%, respectively) have not changed (Table 8-4).

- An important factor in interpreting a patient's test result is knowledge of the prevalence of the disease in the population being tested.
- High-risk populations (high prevalence of disease) tend to improve the PPV of an abnormal test result.
- Low-risk populations (screening tests) make the NPV of a normal test result look impressive.

Use of Odds and Likelihood Ratios

Some physicians prefer interpreting diagnostic test results by using the likelihood ratio. This ratio takes properties of a diagnostic test (sensitivity and specificity) and makes them more helpful in clinical decision making. It helps the clinician determine the probability of disease in a specific patient after a diagnostic test has been performed.

The formula for a likelihood ratio for a positive test result (LR+) is

$$LR+ = \frac{+\text{ Test in Disease}}{+\text{ Test in No Disease}} = \frac{\text{Sensitivity}}{1 - \text{Specificity}}$$

The formula for a likelihood ratio for a negative test result (LR –) is

$$LR- = \frac{-\text{ Test in Disease}}{-\text{ Test in No Disease}} = \frac{1 - \text{Sensitivity}}{\text{Specificity}}$$

For example, if test A has a sensitivity of 95% and a specificity of 90%,

$$LR+ = \frac{\text{Sensitivity}}{1 - \text{Specificity}} = 95/10 = 9.5$$

$$LR- = \frac{1 - \text{Sensitivity}}{\text{Specificity}} = \frac{5}{90} = 0.06$$

However, if test B has a sensitivity of 20% and a specificity of 80%, then

$$LR+ = \frac{\text{Sensitivity}}{1 - \text{Specificity}} = \frac{20}{20} = 1$$

$$LR- = \frac{1 - \text{Sensitivity}}{\text{Specificity}} = \frac{80}{80} = 1$$

As a general rule, diagnostic tests with an LR+ greater than 10 or an LR– less than 0.1 have a greater influence on the posttest probability of disease (i.e., are better tests) than diagnostic tests with likelihood ratios between 10 and 0.1. In the two examples above, test A is more likely to rule in or rule out disease than test B.

Sample likelihood ratios are provided in the example below and in Table 8-5.

Example

A 40-year-old white man is admitted to the hospital for pneumonia. He says that he consumes 2 six-packs of beer each week. On the basis of this history and your clinical judgment, you assume that he has a pretest probability of 20% for a diagnosis of alcoholism. You perform the CAGE questionnaire, and his responses are positive for all four questions. You notice that the LR+ for three or more CAGE questions is 250.

At this point, you have two choices. The first is to use a nomogram (Fig. 8-1) and take a straightedge and connect the pretest probability of 20% and the LR+ of 250 to the posttest probability. This shows that the posttest probability for a diagnosis of alcoholism is 99%.

The second option should be used when there is no nomogram for performing this simple calculation. Without a nomogram, the following must be done: 1) convert the pretest probability to pretest odds, 2) multiply the pretest odds by the likelihood ratio to obtain the posttest odds, and 3) convert the posttest odds to posttest probability.

Probability and odds can be converted somewhat interchangeably with the following formulas:

$$\text{Odds} = \frac{\text{Probability}}{1 - \text{Probability}}$$

$$\text{Probability} = \frac{\text{Odds}}{1 + \text{Odds}}$$

In the example, step 1 involves converting pretest probability to pretest odds. In this case, you estimated that the pretest probability

Table 8-3 2 × 2 Table for Test With 90% Sensitivity, 95% Specificity, and 10% Prevalence

		Disease present	Disease absent	
Diagnostic test result	Positive	90 a	45 b	135 a+b
	Negative	c 10	d 855	c+d 865
		a+c	b+d	a+b+c+d
	Total	100	900	1,000

Prevalence = (a+c)/(a+b+c+d) = 100/1,000 = 10%
Test characteristics
Sensitivity = a/(a+c) = 90/100 = 90%
Specificity = d/(b+d) = 855/900 = 95%
Frequency-dependent properties
Positive predictive value = a/(a+b) = 90/135 = 66.7%
Negative predictive value = d/(c+d) = 855/865 = 98.8%
Likelihood ratio (LR) for a positive test result:
LR+ = Sensitivity/(1 – Specificity) = 90%/5% = 18
Likelihood ratio for a negative test result:
LR– = (1 – Sensitivity)/Specificity = 10%/95% = 0.11
Pretest Odds = Prevalence/(1 – Prevalence) = 10%/90% = 0.11
Posttest Odds = Pretest Odds × Likelihood Ratio
Posttest Probability = Posttest Odds/(Posttest Odds + 1)

Table 8-4 2 × 2 Table for Test With 90% Sensitivity, 95% Specificity, and 2% Prevalence

		Disease present	Disease absent	
Test result	Positive	18 a	49 b	67 a+b
	Negative	c 2	d 931	c+d 933
		a+c	b+d	a+b+c+d
	Total	20	980	1,000

Prevalence = (a+c)/(a+b+c+d) = 20/1,000 = 2%
Test characteristics
Sensitivity = a/(a+c) = 18/20 = 90%
Specificity = d/(b+d) = 931/980 = 95%
Frequency-dependent properties
Positive predictive value = a/(a+b) = 18/67 = 26.9%
Negative predictive value = d/(c+d) = 931/933 = 99.8%

Table 8-5 Examples of Symptoms, Signs, and Tests and the Likelihood Ratio (LR)

Target disorder	Symptom, sign, test		Patient population	Health care setting	LR
Alcohol abuse or dependency	Yes to ≥3 questions on CAGE		Patients admitted to orthopedic or medical services over a 6-month period	Teaching hospital in U.S.	250
Sinusitis (by further investigation)	Maxillary toothache or purulent nasal secretion or poor response to nasal decongestants or abnormal trans-illumination or history of colored nasal discharge	≥4 signs or symptoms	Patients with nasal complaints	Teaching hospital in U.S.	6.4
		3 signs or symptoms			2.6
		2 signs or symptoms			1.1
		1 sign or symptom			0.5
		None			0.1
Ascites	Presence of fluid wave (done by internal medicine residents)		Male veteran patients	Veterans' hospital in U.S.	9.6

Data from Bush B, Shaw S, Cleary P, Delbanco TL, Aronson MD. Screening for alcohol abuse using the CAGE questionnaire. Am J Med. 1987;82:231-5; Williams JW Jr, Simel DL. Does this patient have sinusitis? Diagnosing acute sinusitis by history and physical examination. JAMA. 1993;270:1242-6; Williams JW Jr, Simel DL, Roberts L, Samsa GP. Clinical evaluation for sinusitis: making the diagnosis by history and physical examination. Ann Intern Med. 1992;117:705-10; Williams JW Jr, Simel DL. Does this patient have ascites? How to divine fluid in the abdomen. JAMA. 1992;267:2645-8; Simel DL, Halvorsen RA Jr, Feussner JR. Quantitating bedside diagnosis: clinical evaluation of ascites. J Gen Intern Med. 1988;3:423-8.

of alcoholism is 20%. With the formulas above,

$$\text{Pretest odds} = \frac{0.20}{1 - 0.20} = 0.25$$

Therefore, the pretest odds of having the condition are 0.25. Step 2 involves determining the posttest odds for a positive test. This can be determined by multiplying the pretest odds (0.25) by the LR+ for 3 or more positive questions on the CAGE questionnaire (250): 0.25 × 250 = 62.5. Step 3 allows conversion of posttest odds to posttest probability by placing the numbers in the formula:

$$\text{Probability} = \frac{\text{Odds}}{1 + \text{Odds}}$$

$$\text{Posttest Probability} = \frac{62.5}{63.5} = 98.4\%$$

In conclusion, the posttest probability for the diagnosis of alcoholism for this patient is 98.4%, which is close to the value obtained from the nomogram.

Interpretation of Therapeutic Results

Physicians often make treatment decisions on the basis of the results of randomized controlled trials (RCTs). To understand whether the results of such trials are impressive, the physician is required to translate these results into language understandable to both physicians and patients. This terminology can also be used to compare various therapies for the disease of interest. Several authors have coined terms and derived useful equations to help physicians make sense of RCTs concerned with therapy.

Relative Risk Reduction

The results of RCTs of anticoagulant therapy to prevent stroke in patients with atrial fibrillation have been published and summarized. In primary prevention studies, the average 1-year risk for stroke in the placebo group was 5% per year. Because no therapy was administered to that group, this can be called the *control event rate* (CER). In these studies of patients with atrial fibrillation treated with adjusted-dose warfarin (international normalized ratio [INR] 2.0-3.0), the approximate stroke risk was reduced to 2% per year. This can be called the *experimental event rate* (EER) because the patients received a particular therapy.

The traditional measure often used to report the difference between the treated and untreated groups is the *relative risk reduction* (RRR), which is calculated as $\frac{\text{CER} - \text{EER}}{\text{CER}}$. This measure relates the reduction in risk for the outcome event with the intervention compared with the baseline risk rate (CER). In this example, the RRR is $\frac{5\% - 2\%}{5\%} = 60\%$. Therefore, anticoagulant therapy reduced the yearly risk of a stroke developing in patients with atrial fibrillation by 60% compared with the baseline risk of a stroke developing with no therapy. However, the RRR often is not clinically helpful because the number itself does not provide information about the baseline risk rate (i.e., CER). For example, even if only a

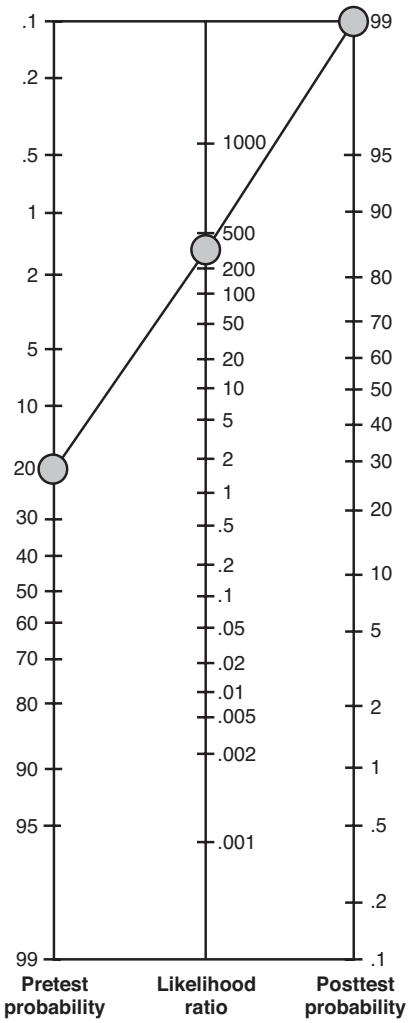

Fig. 8-1. Nomogram.

very small number of control patients (0.005%) and patients receiving anticoagulation (0.002%) experience stroke, the RRR is unchanged: $\frac{0.005\% - 0.002\%}{0.005\%} = 60\%$. Therefore, the RRR often is not useful to the clinician or patient, although a large RRR can be used to make a dramatic endorsement for therapy by proponents of that therapy.

- RRR = $\frac{\text{CER} - \text{EER}}{\text{CER}}$
- Often RRR is not clinically useful because it does not provide information about the baseline risk rate.

Absolute Risk Reduction

In the example above, it would be useful for the physician and patient to know the absolute difference in rates of stroke between the control group and the atrial fibrillation group given anticoagulants (CER – EER). This measure is called the *absolute risk reduction* (ARR). In the combined Stroke Prevention in Atrial Fibrillation (SPAF) trials, the ARR or (CER – EER) = (5% – 2%) = 3% per year.

- ARR = (CER – EER)
- ARR is clinically more useful to interpret therapeutic results.

Number Needed to Treat

The physician and patient often want to know the number of patients needed to treat (NNT) with a therapy to prevent one additional bad outcome. That number can be calculated with $\frac{1}{\text{ARR}}$. Therefore, the NNT to prevent one stroke by using the adjusted dose of warfarin in patients with atrial fibrillation would be $\frac{1}{0.03} = \frac{1}{3\%} = 33$. Therefore, the NNT would be 33 patients; that is, 33 patients would need to be treated with warfarin (INR 2.0-3.0) for 1 year to prevent one additional stroke.

- NNT identifies the number of patients who need to be treated with a therapy to prevent one additional bad outcome.
- NNT = $\frac{1}{\text{ARR}}$

Number Needed to Harm

Conversely, if the rate of adverse events caused by the experimental therapy is known and compared with the rate of adverse events in the placebo group, the number needed to harm (NNH) can be calculated. This useful number tells the physician how many treated patients it takes to produce one additional harmful event. In the studies dealing with stroke prevention in atrial fibrillation, the average risk of intracranial hemorrhage for the group given warfarin was 0.3% per year, compared with 0.1% per year for the placebo group. Therefore, the NNH can be calculated as the reciprocal of the absolute risk increase (ARI). The ARI can be calculated by subtracting the harm CER from the harm EER or, in this case, 0.3% – 0.1% = 0.2%. In this example, NNH = $\frac{1}{0.2\%} = \frac{1}{0.002} = 500$. Therefore, 500 patients would need to be treated with anticoagulant for 1 year to cause one additional intracranial hemorrhage, compared with the control group.

- NNH identifies how many treated patients are needed to produce one additional harmful event.
- NNH = $\frac{1}{\text{Harm EER} - \text{Harm CER}}$

Preoperative Medical Evaluation

The Art of Medical Consultation

Recommendations have been made to guide internists in advising surgeons on assessing preoperative risk and managing perioperative problems (J Gen Intern Med. 1987;2:257-69). The following guidelines will help internists to optimize compliance with the advice they give:

1. Limit the number of recommendations to five or fewer.
2. Focus on crucial recommendations and avoid diluting the management plan with trivial suggestions.
3. Be specific, especially about drug dosages. Recommend not only which drug to use but also specify the dose and frequency of administration.
4. Advice about therapy (i.e., initiating or discontinuing drug therapy) is heeded more often than diagnostic suggestions (i.e., ordering tests).

5. Labor-intensive advice that requires the surgeon to do something (e.g., look at a blood smear or perform a procedure) is poorly heeded. If such tasks must be performed, the medical consultant should do them personally.
6. Oral communication with a surgeon usually enhances compliance.
7. Follow-up visits and notes further improve compliance.

Successfully communicating one's assessment and plan is an art. A three-step approach of "diagnosis–treatment–prognosis" is often helpful.

1. Diagnosis—the internist creates a problem list that is a table of contents for anyone involved in the care of the patient. It is particularly useful to anesthesiologists and surgeons.
2. Treatment—the internist offers recommendations that will diminish the surgical risks associated with the patient's problem. The emphasis is on therapeutics aimed only at diminishing surgical risk.
3. Prognosis—the internist states the surgical and anesthetic risk for each problem (often available in published literature). When this information is lacking, the internist substitutes personal judgment.

The internist should comment on the cumulative risk for a patient with multiple medical problems, such as cardiac, pulmonary, and liver disease. The risk in such patients may become prohibitive.

- Diagnosis—a problem list.
- Treatment—recommendations only for decreasing surgical risk.
- Prognosis—surgical and anesthetic risk for each problem.
- The internist should comment on the cumulative risk for a patient with multiple medical problems.

Risks of Anesthesia and the Operation

Operative deaths are uncommon because of the many technical advances that have been made in surgery and anesthesia and the assessment of the risk. The risk of dying during the perioperative period (i.e., intraoperatively or within 48 hours postoperatively) is about 0.3% when all operations are considered. For major surgical procedures, the mortality risk is less than 1% for patients younger than 65 years but increases to about 5% for those between 65 and 80 years. Deaths occur during three periods: anesthetic induction (10%), intraoperatively (35%), and during the first 48 hours postoperatively (55%). Postoperative mortality between 48 hours and 6 weeks is usually due to pneumonia, sepsis, cardiac arrest, pulmonary embolus, or renal failure. The American Society of Anesthesiologists (ASA) has published a classification scheme to aid clinicians (Table 8-6). This classification is subjective, and many physicians favor a systematic assessment instead of a global impression. However, ASA class IV and class V patients have roughly 100 times the mortality of class I patients for a surgical procedure. In addition, an emergency procedure almost doubles the risk in any ASA classification of patients.

- The risk of dying during the perioperative period is 0.3% for all operations.
- Three periods during which deaths occur: anesthetic induction (10%), intraoperatively (35%), and within 48 hours postoperatively (55%).

Many physicians have mistakenly assumed that spinal anesthesia is safer than general anesthesia for high-risk patients. From a cardiopulmonary standpoint, this is not the case. Spinal anesthesia may be associated with wide fluctuations in blood pressure, anxiety, and less control of the airway and ventilation. Thus, it is inappropriate for the internist to write, "Patient too ill for general anesthesia; okay if done under spinal." The final decision about the type of anesthesia is ultimately the responsibility of the anesthesiologist.

- From a cardiopulmonary point of view, spinal anesthesia is not safer than general anesthesia.
- Spinal anesthesia may be associated with wide fluctuations in blood pressure.
- The final decision about the type of anesthesia is the responsibility of the anesthesiologist.

The type of operation performed is an important determinant of cardiovascular morbidity and mortality (Table 8-7).

However, the importance of associated disease in determining surgical risk may outweigh the nature of the procedure or the type of anesthesia used in predicting outcome. The following sections discuss risk assessment and management strategies grouped by organ system.

Table 8-6 American Society of Anesthesiologists Classification of Anesthetic Mortality Within 48 Hours Postoperatively

Class	Physical status	48-Hour mortality
I	Normal healthy person <80 years old	0.07%
II	Mild systemic disease	0.24%
III	Severe but not incapacitating systemic disease	1.4%
IV	Incapacitating systemic disease that is a constant threat to life	7.5%
V	Moribund patient not expected to survive 24 hours, regardless of surgery	8.1%
E	Suffix added to any class indicating emergency procedure, e.g., IE, IIE, IIIE	Doubles risk

Pulmonary Risks and Management

Pulmonary complications (hypoventilation, atelectasis, and pneumonia) develop in a significant number of patients postoperatively. These complications account for an increase in the number of days spent in the hospital as well as an increase in perioperative mortality. Patients with increased risk can be identified on the basis of patient-related risk factors and procedure-related risk factors. Patient-related pulmonary risk factors include smoking, poor exercise capacity, poor general health status, age older than 70, chronic obstructive pulmonary disease, and asthma. Obesity alone is not a significant risk factor for pulmonary complications. Procedure-related pulmonary risk factors include the surgical site (with the exception of laparoscopic procedures, risk increases as the incision approaches the diaphragm), procedure duration of more than 3 hours, and use of long-acting neuromuscular blockers.

- Patient-related risk factors include smoking, poor exercise capacity, poor general health status, age older than 70, chronic obstructive pulmonary disease, and asthma.
- Obesity alone is not a significant risk factor for pulmonary complications.
- Procedure-related risk factors include the surgical site (with the exception of laparoscopic procedures, risk increases as the incision approaches the diaphragm), procedure duration of more than 3 hours, and use of long-acting neuromuscular blockers.

Preoperative pulmonary function testing is most useful in the evaluation of high-risk patients, such as patients with lung disease undergoing thoracic surgery. The interpretation of these tests regarding risk assessment is controversial. However, most authors agree that the simple spirometric measurement of forced expiratory volume in 1 second (FEV_1) is probably as good a predictor of surgical risk as any. Generally, with an FEV_1 >2 L, the patient can safely undergo the procedure, and with an FEV_1 <1 L, the patient has a high risk of postoperative pulmonary complication. Also, poor exercise capacity identifies patients at risk.

- FEV_1 is a good predictor of surgical risk.
- FEV_1 >2 L, patient can safely undergo procedure.
- FEV_1 <1 L, high risk of postoperative pulmonary complication.
- Poor exercise capacity also identifies patients at risk.

Several measures have been advocated for decreasing pulmonary risks. They are summarized in Table 8-8.

Cardiac Risks and Management

Annually, of every 10 U.S. citizens, about one undergoes a noncardiac operation. Because of the increasing prevalence of surgical procedures in the elderly, about one-third of all noncardiac surgical patients are at risk of cardiac morbidity or mortality after taking into account the prevalence of coronary artery disease (CAD) or the high-risk status in

Table 8-7 Cardiac Risk* Stratification for Noncardiac Surgical Procedures

Risk	Procedure
High	
Reported cardiac risk often >5%	Emergent major operations, particularly in the elderly Aortic and other major vascular procedures Peripheral vascular procedures Anticipated prolonged surgical procedures associated with large fluid shifts and/or blood loss
Intermediate	
Reported cardiac risk generally <5%	Carotid endarterectomy Head and neck operations Intraperitoneal and intrathoracic procedures Orthopedic procedures Prostate operations
Low†	
Reported cardiac risk generally <1%	Endoscopic procedures Superficial procedure Cataract extraction Breast operation

*Combined incidence of cardiac death and nonfatal myocardial infarction.
†Do not generally require further preoperative cardiac testing.
From Eagle KA, Berger PB, Calkins H, Chaitman BR, Ewy GA, Fleischmann KE, et al. ACC/AHA guideline update for perioperative cardiovascular evaluation for noncardiac surgery: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee to update the 1996 guidelines on perioperative cardiovascular evaluation for noncardiac surgery). Circulation. 2002;105:1257-67. Used with permission.

this population. Patients with known or suspected cardiac disease commonly are referred for assessment before a noncardiac procedure is performed. Important questions are posed during these consultations:

1. How can a high-risk patient be identified?
2. What selective testing needs to be performed (if any) to further define risk?
3. What intervention or perioperative management is appropriate to decrease cardiac-related morbidity and mortality during noncardiac surgical procedures?

The American College of Cardiology/American Heart Association (ACC/AHA) Task Force has published updated guidelines to instruct physicians in the perioperative cardiovascular evaluation of patients for noncardiac surgical procedures (Circulation. 2002;105:1257-67). These guidelines present a framework for determining which patients are candidates for preoperative cardiac testing and which are surgical candidates without further cardiac testing. The physician must consider several interacting variables and assess the appropriate weight of each variable. Because no adequately controlled or randomized clinical trials have defined this process, a collection of outcome data and expert opinion is the basis of the algorithmic approach. Information needed to determine appropriate preoperative cardiac assessment includes the risk of the surgical procedure, clinical predictors, and functional status of the patient (Fig. 8-2). Additional details about the use of the algorithm and references can be reviewed elsewhere (Circulation. 2002;105:1257-67).

Table 8-8 Risk-Reduction Strategies

Preoperative
Encourage cessation of cigarette smoking for at least 8 weeks
Treat airflow obstruction in patients with chronic obstructive pulmonary disease or asthma
Administer antibiotics and delay surgery if respiratory infection is present
Begin patient education regarding lung-expansion maneuvers
Intraoperative
Limit duration of surgery to less then 3 hours
Use spinal or epidural anesthesia*
Avoid use of pancuronium
Use laparoscopic procedures when possible
Substitute less ambitious procedure for upper abdominal or thoracic surgery when possible
Postoperative
Use deep-breathing exercise or incentive spirometry
Use continuous positive airway pressure
Use epidural analgesia*
Use intercostal nerve blocks*

*This strategy is recommended, although variable efficacy has been reported in the literature.

From Smetana GW. Preoperative pulmonary evaluation. N Engl J Med. 1999;340:937-44. Used with permission.

- Information needed to determine appropriate preoperative cardiac assessment: the risk of the surgical procedure, clinical predictors, and functional status of the patient.

Myocardial infarction (MI) is the most feared perioperative complication. Of perioperative MIs, 50% are fatal and 60% are not accompanied by anginal pain. The risk of perioperative MI peaks intraoperatively to 48 hours postoperatively. Patients who have had an MI recently are at greatest risk of perioperative MIs. The risk of perioperative MI without cardiac disease is 0.2%. In retrospective studies, the risk of perioperative MI in patients with a recent MI (<3 months) is 27%; if the MI occurred 3 to 6 months earlier, 11%; and if the MI was more than 6 months earlier, 5%. In the past it was recommended that nonemergent surgery be delayed for at least 6 months after an MI. This is no longer a standard of care. It has become possible to risk-stratify MI patients during convalescence (Fig. 8-2). If a recent stress test has shown no residual myocardium at risk, the likelihood of reinfarction after noncardiac surgery would be low. Thus, surgery may be performed in selected MI patients 4 to 6 weeks after the infarction. Preoperative interventions (percutaneous transluminal coronary angioplasty [PTCA] or coronary artery bypass graft [CABG] are not indicated simply to assist the patient during a noncardiac surgery; they should be done only for specific indications (e.g., left main coronary artery or triple-vessel disease).

- Of perioperative MIs, 50% are fatal and 60% are silent.
- The risk of perioperative MI peaks intraoperatively to 48 hours postoperatively.
- Patients with a recent MI are at greatest risk of perioperative MI.
- If a stress test has shown no residual myocardium at risk, the likelihood of reinfarction is low and the patient could be considered for elective surgery 4-6 weeks after the infarction.
- Preoperative interventions (PTCA or CABG) are not indicated to simply help a patient through a noncardiac surgery; they should be done only for specific indications (e.g., left main coronary artery or triple-vessel disease).

Perioperative Medical Therapy

Studies suggest that appropriately administered β-blockers reduce perioperative ischemia and may reduce cardiac events in high-risk patients and patients who are undergoing vascular surgery. Ideally, treatment with β-blockers should be started a few days before elective surgery, with the dose titrated to achieve a resting heart rate between 50 and 60 beats/minute. β-Blocker therapy required in the recent past to control symptoms of angina, symptomatic arrhythmias, or hypertension should be restarted or continued. Treatment with β-blockers should be instituted preoperatively in appropriate candidates with untreated hypertension or known CAD or those at major risk of CAD.

- β-Blocker therapy required in the recent past to control symptoms of angina, symptomatic arrhythmias, or hypertension should be restarted or continued.
- β-Blocker therapy should be started preoperatively in appropriate candidates with ischemia on preoperative testing who are undergoing vascular surgery.

- β-Blocker therapy should be started preoperatively in appropriate candidates with untreated hypertension or known CAD or those at major risk of CAD.

Monitoring for Perioperative Myocardial Ischemia

For patients without documented CAD, monitoring and surveillance should be restricted to patients who have perioperative signs of cardiovascular dysfunction. In high-risk patients undergoing noncardiac operations, early postoperative myocardial ischemia is an important correlate of adverse cardiac outcomes. For patients at increased risk of perioperative myocardial ischemia, the ACC/AHA guidelines recommend electrocardiography (ECG) preoperatively, immediately postoperatively, and daily for the first 2 days after the operation. Troponin levels should be checked 24 hours postoperatively and on day 4 in this subset of patients. Subgroups of patients who are at high risk of postoperative ischemia and who might benefit most from intensive ST-segment monitoring in the postoperative period can be identified preoperatively: left ventricular hypertrophy, CAD, diabetes mellitus, hypertension, and digoxin therapy. If high-risk patients are identified and monitored postoperatively with real-time monitors with alarms triggered by ST-segment depression, theoretically ischemia could be identified instantaneously and rapid intervention could potentially prevent clinical ischemia. However, this hypothesis has not been studied and has not been proved. These interventions, if performed in all at-risk patients, would drive up costs tremendously.

- Early postoperative myocardial ischemia is an important correlate of adverse cardiac outcomes in high-risk noncardiac surgical patients.

Valvular Heart Disease

Patients with valvular heart disease present specific risks in noncardiac surgery. Marked aortic stenosis is associated with a "fixed" cardiac output that cannot increase in response to surgical stress. Although these patients have minimal risk with local anesthesia, spinal anesthesia increases the risk because of the frequent induction of vasodilatation, which can cause cardiovascular collapse. General anesthesia can be performed with acceptable risks (≤10% mortality risk) in selected hemodynamically monitored patients with severe aortic stenosis, but conventional wisdom is to repair the valve preoperatively (when possible) in patients with critical aortic stenosis.

- Marked aortic stenosis is associated with a "fixed" cardiac output that cannot increase with surgical stress.
- Selected patients with severe aortic stenosis can tolerate general anesthesia (mortality risk ≤10%), but the valve should be repaired preoperatively when possible in those with severe or symptomatic aortic stenosis.

When mitral or aortic valve regurgitation is present, the status of left ventricular function is of primary importance. Patients with severe mitral regurgitation may benefit from afterload reduction and diuretics. AHA recommendations for prophylactic treatment of endocarditis should be followed for patients with valvular heart disease.

- Patients with severe mitral regurgitation may benefit from afterload reduction and the administration of diuretics.
- Patients with valvular heart disease should receive prophylactic treatment of endocarditis in accordance with the standard recommendations of the AHA.

Anticoagulation Issues in Patients With Mechanical Prosthetic Heart Valves Undergoing Noncardiac Operations

No randomized controlled trials have been conducted on anticoagulation in noncardiac surgical patients who have mechanical heart valves. Anticoagulation in these patients substantially decreases the incidence of thromboemboli but never eliminates it entirely. The following suggestions are offered:

1. Consult with the surgeon to determine whether the intensity of anticoagulation needs to be altered. Procedures such as dental extractions, cataract removal, and other minor operations may often be performed safely with minimal or no decrease in the intensity of anticoagulation.
2. Many factors must be considered when determining a risk-to-benefit assessment of continuous anticoagulation in patients with mechanical prosthetic cardiac valves. Mitral prosthetic valves are more thrombogenic than aortic prostheses, regardless of the type of valve that has been used. Generally, the older caged-ball valves (Starr-Edwards) are more thrombogenic than the bileaflet valves (St. Jude Medical). Bioprosthetic valves are the least thrombogenic. Associated factors such as atrial fibrillation, severely impaired left ventricular function, or a history of previous thromboembolism also increase the risk of thromboembolism. In patients with mechanical prosthetic cardiac valves, anticoagulation decreases the incidence of thromboemboli but does not eliminate it.
3. After a risk-to-benefit assessment has been completed, one of the following strategies can be chosen: a) discontinue warfarin therapy for several days before the procedure to allow the INR to decrease to less than 1.5 (a level at which it is considered safe to perform surgery) in an outpatient setting; b) decrease the dose of warfarin (outpatient setting) to maintain the intensity of anticoagulation in a lower or subtherapeutic range during the procedure (discuss this with the surgeon); c) discontinue warfarin therapy and institute unfractionated heparin therapy coverage (inpatient setting)—administration of heparin can be discontinued 4 hours before the operation and reinstituted postoperatively, in conjunction with oral anticoagulant therapy, when it is considered safe; or d) discontinue warfarin therapy and institute coverage with low-molecular-weight heparin (LMWH) (outpatient setting)—discontinuing the LMWH 12 to 24 hours before the operation and then postoperatively reinstituting it in conjunction with oral anticoagulant therapy when it is considered safe.

In many situations, strategy *3 a* or *3 b* may be undertaken safely at considerable cost advantage (because of the need for fewer hospitalization days or heparin-related costs) without an appreciable increase in risk to the patient. Preoperative heparin therapy during

warfarin withdrawal is recommended for situations in which the risk of operative bleeding with anticoagulant therapy and the risk of thromboembolism without anticoagulant therapy are high (e.g., major surgical procedure in a patient with mitral valve prosthesis, cardiomyopathy, and previous thromboembolism). Reinstitution of anticoagulant therapy as early as safely possible is appropriate for all the strategies mentioned above.

- Consult with the surgeon to determine whether the intensity of anticoagulation needs to be altered.
- Usually, tooth extractions, cataract operations, and other minor procedures may be performed safely with therapeutic levels of anticoagulation.
- Prosthetic valves in the mitral position are more thrombogenic than aortic prostheses.
- Older caged-ball valves are more thrombogenic than bileaflet valves.
- Bioprosthetic valves are least thrombogenic.
- Anticoagulation in patients with mechanical prosthetic cardiac valves substantially decreases the incidence of thromboemboli but never eliminates it entirely.

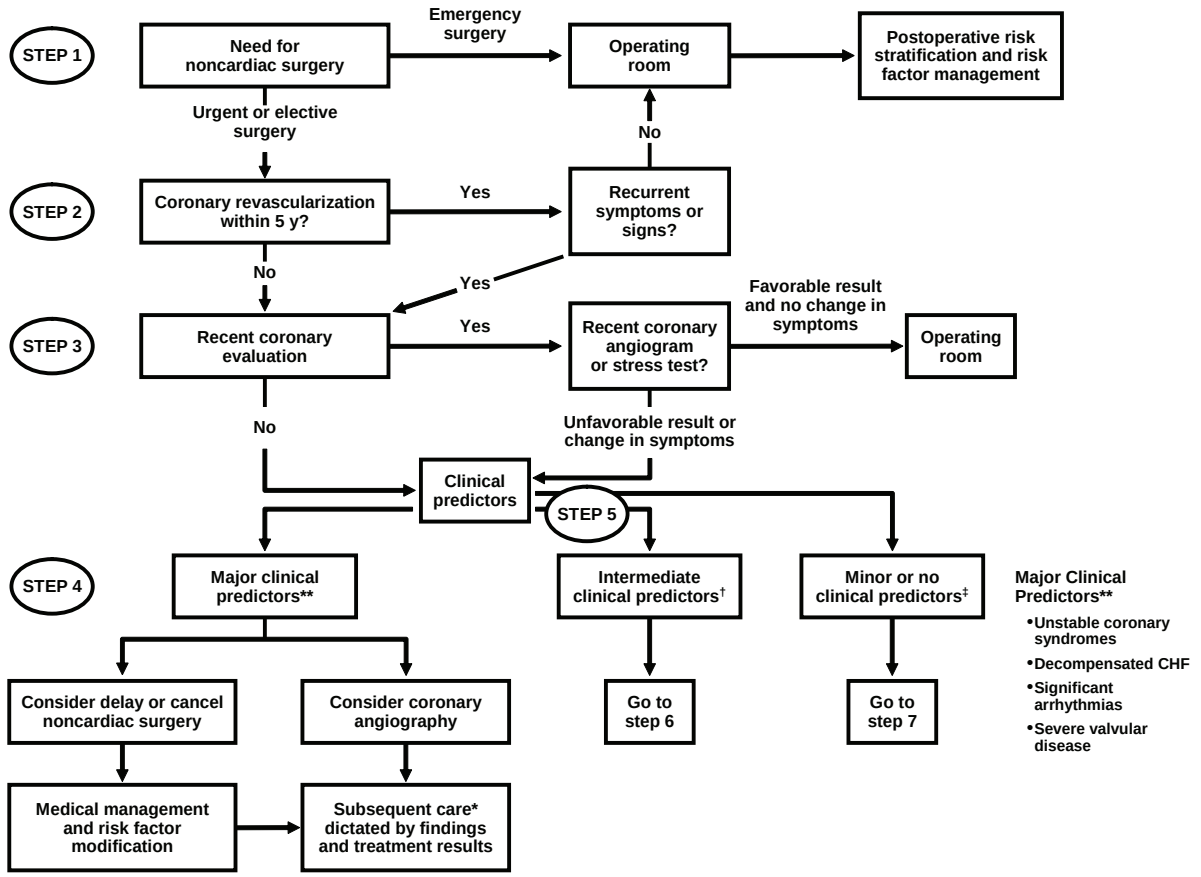
Congestive Heart Failure

Patients with congestive heart failure (CHF) have an incidence of perioperative pulmonary edema ranging from 3% (New York Heart Association class I) to 25% (class IV). Patients with a history of CHF but no preoperative evidence of this disorder have a 6% incidence of perioperative pulmonary edema. Preoperative CHF is the greatest risk factor for the development of pulmonary edema; however, 50% of those with this complication have no history of CHF. In most patients in whom CHF develops perioperatively, it does so in the first hour after the termination of anesthesia. CHF should be treated aggressively preoperatively, and therapy for chronic compensated CHF should be maintained during the perioperative period.

- The incidence of perioperative pulmonary edema among patients with CHF is from 3% to 25%.
- The greatest preoperative risk for developing pulmonary edema is CHF.
- If CHF develops perioperatively, it usually does so in the first hour after anesthesia is terminated.
- Treat CHF aggressively preoperatively; in the perioperative period, maintain therapy for chronic compensated CHF.

Hypertension

Ideally, patients should have well-controlled hypertension (i.e., ≤140/90 mm Hg) for several months preoperatively to minimize lability of intraoperative blood pressure as well as postoperative and neurologic complications. However, studies have shown that when hypertension is stable and diastolic blood pressure is 110 mm Hg



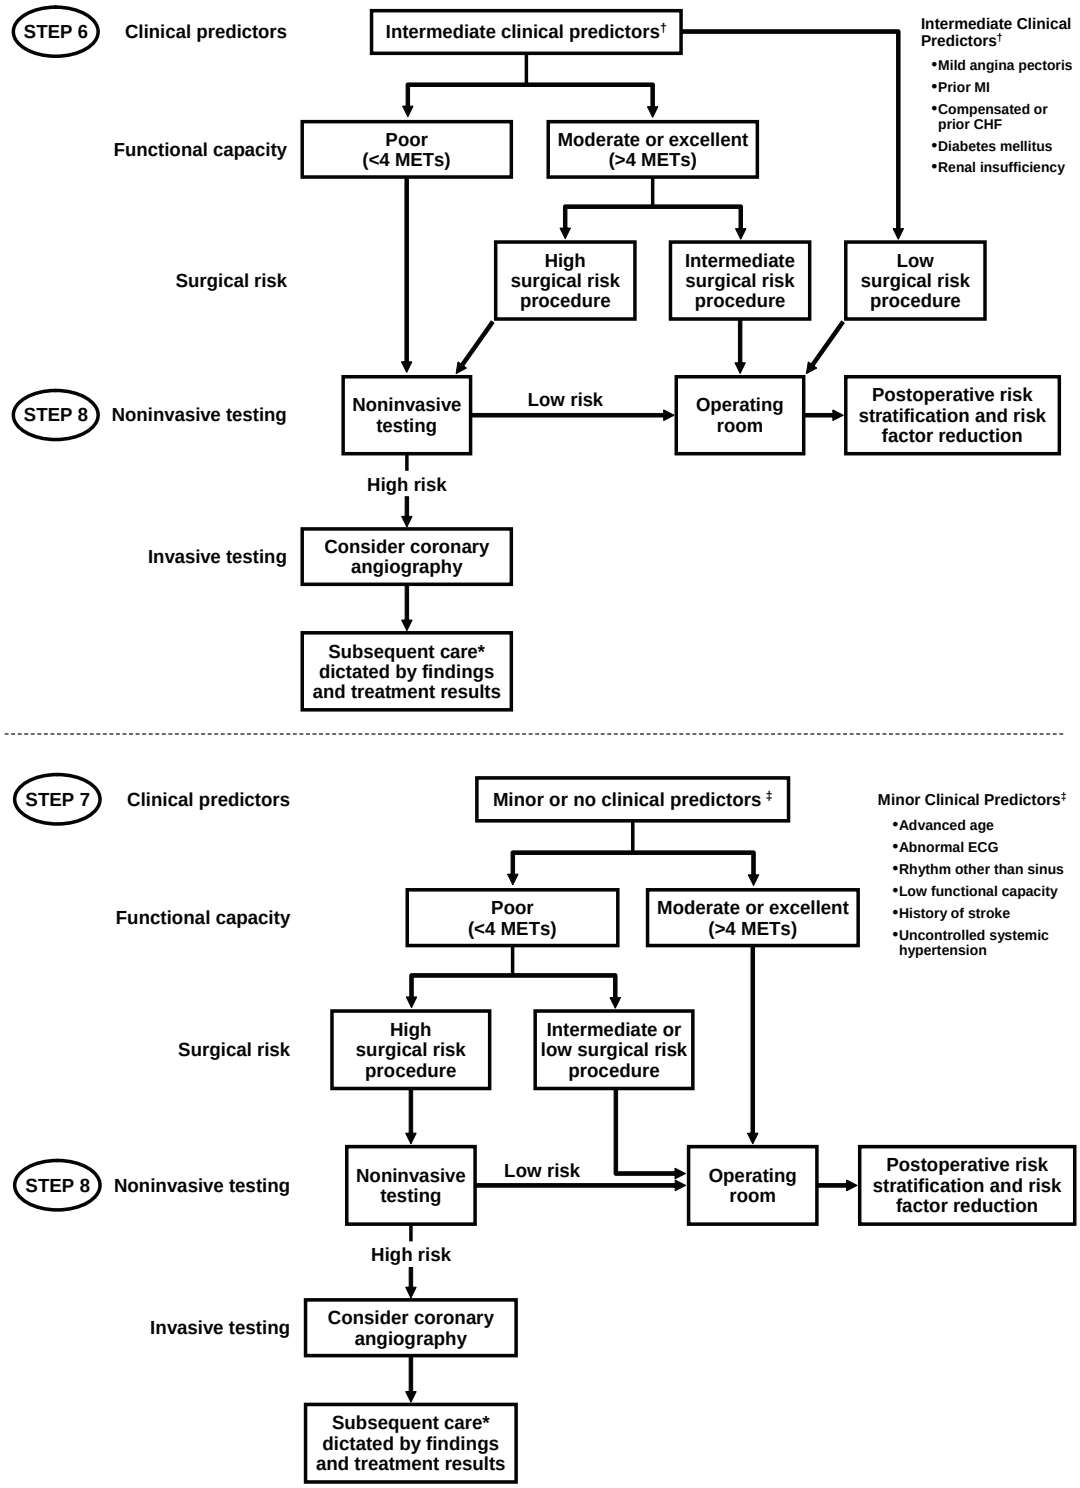


Fig. 8-2. Stepwise approach to preoperative cardiac assessment. >4 METs: the ability to climb a flight of stairs or walk up a hill; the ability to walk on level ground at 4 miles/hour or run a short distance; the ability to do heavy housework, e.g., scrubbing floors or lifting or moving heavy furniture. High-, intermediate-, and low-risk surgical procedures are defined in Table 8-7. *Subsequent care may include cancellation or delay of surgery, coronary revascularization followed by noncardiac surgery, or intensified care. CHF, congestive heart failure; ECG, electrocardiogram; METs, metabolic equivalents; MI, myocardial infarction. (From Eagle KA, Berger PB, Calkins H, Chaitman BR, Ewy GA, Fleischmann KE, et al. ACC/AHA guideline update for perioperative cardiovascular evaluation for noncardiac surgery: executive summary: a report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines [Committee to update the 1996 guidelines on perioperative cardiovascular evaluation for noncardiac surgery]. Circulation. 2002;105:1257-67. Used with permission.)

or less, no benefit is derived from postponing elective procedures to achieve better control. If the diastolic blood pressure is greater than 110 mm Hg, it should be stabilized preoperatively to diminish cardiovascular risk. Although the systolic blood pressure is less well studied, most medical consultants suggest that systolic blood pressure be controlled to less than 180 mm Hg before the induction of anesthesia for elective procedures. β-Blockers are particularly effective agents to use. Initiating treatment for mild hypertension immediately preoperatively with anything other than β-blockers may cause wide blood pressure swings intraoperatively, and therefore such treatment should probably be delayed until the postoperative outpatient visit. However, previously used antihypertensive agents should be continued in the perioperative period. Parenteral agents should be substituted for oral medications in patients who are unable to take pills by mouth or nasogastric tube.

- Diastolic blood pressure >110 mm Hg should be stabilized preoperatively.

Hematologic Risks and Management

Patients with poorly controlled polycythemia vera have a high rate of surgical morbidity and mortality because of an excess of thromboembolic events and a decrease in oxygen transport from high blood viscosity. In polycythemia vera, phlebotomy should be performed to decrease the hematocrit to less than 47% before elective operations. Platelet counts less than 50×10^9/L (50,000/μL) or greater than 650×10^9/L (650,000/μL) should be evaluated preoperatively. A platelet count of 50×10^9/L (50,000/μL) usually provides adequate hemostasis for most surgical procedures. If the platelet count is less than 20×10^9/L (20,000/μL), spontaneous bleeding is a common complication. Bleeding time, activated partial thromboplastin time (APTT), prothrombin time (PT), and fibrinogen level should be determined preoperatively only if the medical history and physical examination results indicate increased bleeding risk, such as previous bleeding with a major or minor surgical procedure, easy bruisability, or a family history of bleeding disorder. The decision to give a transfusion should be based on the patient's hemoglobin level and oxygen demands rather than on only the hemoglobin level.

- Patients with poorly controlled polycythemia vera have a high rate of surgical morbidity and mortality due to thromboembolic events and high blood viscosity.
- In polycythemia vera, perform phlebotomy to decrease hematocrit to <47% before an elective operation.
- A platelet count of 50×10^9/L (50,000/μL) usually provides adequate hemostasis for most operations.
- Preoperatively, determine the bleeding time, APTT, fibrinogen level, and PT only if the medical history and physical examination findings indicate increased bleeding risk.
- Transfusions for preoperative anemia should not be given on the basis of a predefined hemoglobin level but according to the level of hemoglobin needed to support the patient's oxygen demands.

Liver Risks and Management

Patients with chronic liver disease, particularly those with progressive hepatic failure, have a considerable operative risk. Preoperatively, one should concentrate on correcting electrolyte abnormalities and abnormal clotting variables, reducing ascites, treating encephalopathy, and improving the patient's nutritional status.

Endocrinologic Risks and Management

Patients who are thyrotoxic are at high risk of surgical complications, such as arrhythmias, high-output CHF, and death. Thyroid storm occurs in 20% to 30% of these patients. Thus, elective surgery should be postponed and treatment (antithyroid drugs or radioiodine) should be given for at least 3 months until the patient is euthyroid. If an operation is emergent, a patient who is thyrotoxic should be pretreated with propranolol and propylthiouracil. A patient who is hypothyroid may undergo a surgical procedure at very low risk. Patients with severe myxedema should be given thyroxine replacement therapy and receive careful monitoring and supportive therapy, including free water restriction and diuretics.

- Patients who are thyrotoxic are at high risk of surgical complications.
- Thyrotoxicosis should be treated for 3 months or until the patient is euthyroid before any elective operation is performed.
- In the case of an emergency operation, pretreatment is with propranolol and propylthiouracil.

Patients with diabetes mellitus have a greater risk of surgical complications due to underlying cardiovascular and cerebrovascular disease. In addition, patients with hyperglycemia (regardless of known history of diabetes) are at increased risk of infection. It is important to control hyperglycemia preoperatively to diminish the risk of infection. During the perioperative period, the patient may not be able to recognize the signs and symptoms of hypoglycemia. Therefore, oral diabetic agents are withheld and the insulin dose is cut in half on the day of the operation. If glucose goals cannot be achieved, intravenous insulin infusion should be initiated. Use of metformin, a nonsulfonylurea oral diabetic agent, is discontinued before the operation to avoid possibly inducing lactic acidosis in situations in which renal function may fluctuate unpredictably. The serum glucose level should be maintained at 100 to 150 mg/dL for patients in wards and 80 to 120 mg/dL for patients in intensive care units.

- In cases of diabetes mellitus, there is greater risk of surgical complications because of underlying cardiovascular and cerebrovascular disease.
- Withhold oral diabetic agents, cut the insulin dose in half on the day of the operation, and maintain the serum glucose level at 100 to 150 mg/dL for patients in wards and 80 to 120 mg/dL for patients in intensive care units.

Adequate preoperative and perioperative corticosteroid replacement preparation should be given to any patient who has received suppressive doses of corticosteroids for 2 weeks or longer during the past year.

Nutrition

Perioperatively, malnourished patients have increased complications related to wound infection, pneumonia, respiratory insufficiency, and adversely affected cellular and humoral immune function. In a nutritional assessment, the clinical judgment of malnutrition is as accurate as objective measurements. Thus, detailed laboratory measurements of albumin and other substances are not usually required. There is rationale for considering preoperative nutritional supplementation if patients have recently had a 10% weight loss and are expected to require nutritional support for at least 1 week.

Thromboembolism Prophylaxis

Although all surgical patients are at some risk of venous thromboembolic disease, certain patients form a high-risk subset, including those who are elderly or those who have prolonged anesthesia or a prolonged operation, previous venous thromboembolic disease, hereditary disorders of thrombosis, prolonged immobilization or paralysis, malignancy, obesity, varicosities, or pharmacologic estrogen use. Reasonable guidelines for thromboembolism prophylaxis in surgical patients to decrease the overall risk of deep venous thrombosis or pulmonary embolism are given in Table 8-9.

Table 8-9 Prevention of Venous Thromboembolism

Patient characteristics	Recommended therapy
Low-risk general surgery patients	Early ambulation
Moderate-risk general surgery patients	LDUH, LMWH
Higher risk general surgery patients	LDUH or higher dosage LMWH
Higher risk general surgery patients prone to wound complications, e.g., hematomas and infection	IPC with ES is an alternative
Very high-risk general surgery patients with multiple risk factors	LDUH or LMWH, combined with IPC and ES
Selected very high-risk general surgery patients	Perioperative warfarin (goal INR, 2.5; range, 2.0-3.0)
Patients undergoing total hip replacement surgery*	LMWH, started 12-24 h after surgery; or warfarin, started before or immediately after surgery (goal INR, 2.5; range, 2.0-3.0); or fondaparinux, started 6 to 8 h after surgery; possible adjuvant use of ES or IPC†
Patients undergoing total knee replacement surgery*	LMWH, warfarin, or fondaparinux; optimal use of IPC is alternative
Patients undergoing hip fracture surgery	Fundaparinox, LMWH, or warfarin (goal INR, 2.5; range, 2.0-3.0) started preoperatively or immediately after surgery
High-risk patients undergoing orthopedic surgery	IVC filter placement, only if other forms of anticoagulant-based prophylaxis are not feasible because of active bleeding; this should rarely be necessary
Patients undergoing intracranial neurosurgery	IPC with or without ES: LMWH and LDUH may be acceptable alternatives; consider IPC or ES, with LMWH or LDUH, for high-risk patients
Patients with acute spinal cord injury	LMWH; although ES and IPC appear ineffective when used alone, ES and IPC may have benefit when used with LMWH, or if anticoagulants are contraindicated; during rehabilitation, consider continuation of LMWH or conversion to full-dose oral anticoagulation
Trauma patients with an identifiable risk factor for thromboembolism	LMWH, as soon as considered safe; consider initial prophylaxis with IPC if administration of LMWH will be delayed or is contraindicated; in high-risk patients with suboptimal prophylaxis, consider screening with duplex ultrasonography
General medical patients with clinical risk factors for venous thromboembolism, particularly those with CHF or chest infections	LDUH or full-dose anticoagulation; IPC and possibly ES may be useful when heparin is contraindicated
Patients having spinal puncture or epidural catheters placed for regional anesthesia or analgesia	LMWH should be used with caution and guidelines followed

CHF, congestive heart failure; ES, elastic stockings; INR, international normalized ratio; IPC, intermittent pneumatic compression; IVC, inferior vena cava; LDUH, low-dose unfractionated heparin; LMWH, low-molecular-weight heparin; MI, myocardial infarction.

*Optimal duration of prophylaxis is uncertain. Duration of 7 to 10 days is recommended with LMWH or warfarin; 29 to 35 days with LMWH may offer additional protection.

†LDUH, aspirin, dextran, and IPC reduce the overall incidence of venous thromboembolism but are less effective.

Data from Geerts WH, Pineo GF, Heit JA, Bergqvist D, Lassen MR, Colwell CW, et al. Prevention of venous thromboembolism: the Seventh ACCP Conference on Antithrombotic and Thrombolytic Therapy. Chest. 2004;126 Suppl:338S-400S.

Perioperative Antibiotic Prophylaxis

Antibiotics are given perioperatively to prevent infection of normal sterile tissues by direct contamination during the surgical procedure. The risk of wound infection depends mainly on the type of operation. "Clean" operations are ones in which the gastrointestinal, genitourinary, and respiratory tracts are not entered and there is no surrounding inflammation. Previously, antibiotic prophylaxis was not required for this type of procedure because the risk of infection was only about 5%, as compared with a much higher risk for other procedures that required prophylactic treatment with antibiotics to prevent wound infection (clean-contaminated, contaminated, and dirty operations). However, antibiotic prophylaxis, cefazolin 1 g intravenously, is now recommended for simple clean procedures such as inguinal hernia repair and breast surgery. A short course of prophylactic therapy (begin antibiotic infusion within 1 hour of the first surgical incision and do not give the antibiotic beyond 24 hours postoperatively) is as effective as longer regimens and is less likely to be associated with toxicity or development of resistant organisms in clean or clean-contaminated operations. Technically, the antibiotics used in dirty or contaminated procedures are for treatment of established infection rather than for prophylaxis and are often continued for 5 to 10 days postoperatively. When possible, narrow-spectrum antibiotics should be used to avoid resistance.

- Begin antibiotic infusion within 60 minutes of the first surgical incision.
- Discontinue use of antibiotics within 24 hours after the end of surgery.
- In general, use narrow-spectrum antibiotics to avoid resistance.

Preoperative Laboratory Tests

Few laboratory tests should be ordered solely because an operation is planned. In the absence of symptoms, signs, or risk factors for a disease, results of routinely ordered tests are usually normal, and when abnormal, they are often ignored. Authors who have evaluated specific preoperative tests have suggested that chest radiography, ECG, PT, APTT, and bleeding time are not justified as "routine" preoperative tests for young healthy persons. Tests should be performed for specific clinical indications and not because a patient is being evaluated in the outpatient clinic, hospital, or operating room (Table 8-10).

- Chest radiography, ECG, PT, APTT, and bleeding time are not "routine" preoperative tests for young healthy persons.
- Tests should be performed for specific clinical indications.

Geriatric Surgical Patients

The number of surgical procedures performed on elderly patients has steadily increased. Elderly patients comprise 15% of the population but account for one-third of all surgical procedures, one-half of all emergency surgical procedures, and three-fourths of overall surgical mortality. Age is an independent risk factor for perioperative cardiovascular morbidity, and geriatric patients have a much higher prevalence of CAD. Most elderly patients have at least one associated chronic medical illness. This and the pathophysiologic effects of aging on the cardiovascular and pulmonary systems probably explain why geriatric patients have a higher perioperative mortality rate than younger patients. Intervention aimed at meticulously looking for and treating perioperative complications (anemia, infection, or pneumonia) leads to improved outcomes (less postoperative delirium and fewer hospital days) in geriatric patients. The most important outcome predictor for geriatric patients is functional status.

- Elderly patients account for one-third of all surgical procedures.
- Age is an independent risk factor for perioperative cardiovascular morbidity.

Table 8-10 Recommendations for Laboratory Testing Before Elective Surgery

Test	Indications
Hemoglobin	Anticipated major blood loss or symptoms of anemia
White blood cell count	Symptoms suggest infection, myeloproliferative disorder, or myelotoxic medications
Platelet count	History of bleeding diathesis, myeloproliferative disorder, or myelotoxic medications
Prothrombin time	History of bleeding diathesis, chronic liver disease, malnutrition, or recent or long-term antibiotic use
Partial thromboplastin time	History of bleeding diathesis
Electrolytes	Known renal insufficiency, congestive heart failure, or medications that affect electrolytes
Renal function	Age >50 y, hypertension, cardiac disease, major surgery, or medications that may affect renal function
Glucose	Obesity or known diabetes
Liver function tests	No indication; consider albumin measurement for major surgery or chronic illness
Urinalysis	No indication
Electrocardiogram	Men >40 y, women >50 y, known CAD, diabetes, or hypertension
Chest radiograph	Age >50 y, known cardiac or pulmonary disease, or symptoms or examination suggests cardiac or pulmonary disease

CAD, coronary artery disease.

Modified from Smetana GW, Macpherson DS. The case against routine preoperative laboratory testing. Med Clin N Am. 2003;87:7-40. Used with permission.

- Geriatric patients have a much higher prevalence of CAD.
- Geriatric patients have a higher perioperative mortality rate.
- The most important outcome predictor for geriatric patients is functional status.

Perioperative Medication Management

The internist tailors perioperative drug therapy to individual circumstances, with particular attention to three factors:

1. Have the indications and doses for the specific drug been clearly defined?
2. What are the likely anesthetic and surgical interactions and complications?
3. Is a clinically important withdrawal syndrome likely, and how can it be managed safely?

Most drugs used to manage chronic medical conditions can and should be continued through the perioperative period. However, special consideration must be given when patients are taking anticoagulants, diabetic medications, or monoamine oxidase inhibitors. Often, patients can receive medications with sips of water on the morning of the operation and resume oral medications or parenteral substitution later in the day. Should particular questions occur about the continuation of a specific drug, communication with an anesthesiologist is important.

- Most drugs for chronic medical conditions should continue to be taken through the perioperative period.

Current Concepts in Anticoagulant Therapy

INR

What Are Recommended INR Therapeutic Ranges for Oral Anticoagulant Therapy?

The recommended INR therapeutic ranges are summarized in Table 8-11. In short, an INR of 2.0 to 3.0 is used for most indications except for the few high-risk conditions (e.g., mechanical prosthetic heart valves) in which a slightly higher INR is suggested.

Table 8-11 Recommended Therapeutic Range for Oral Anticoagulant Therapy

Indication	INR
Prophylaxis for venous thrombosis (high-risk surgery)	2.0-3.0
Treatment of venous thrombosis	2.0-3.0
Treatment of pulmonary embolism	2.0-3.0
Prevention of systemic embolism	
Tissue heart valves*	2.0-3.0
Acute myocardial infarction (to prevent systemic embolism)†	2.0-3.0
Valvular heart disease	2.0-3.0
Atrial fibrillation	2.0-3.0
Mechanical prosthetic heart valves	
AVR and no risk factors‡	
Bileaflet valve	2.0-3.0
Other disk valve or Starr-Edwards	2.5-3.5
AVR and risk factor§	2.5-3.5
MVR§	2.5-3.5

AVR, aortic valve replacement; INR, international normalized ratio; MVR, mitral valve replacement.

*Treatment is usually for 3 months unless other risk factors continue.

†If oral anticoagulant therapy is elected to prevent recurrent myocardial infarction, an INR of 2.5 to 3.5 is recommended, consistent with Food and Drug Administration recommendations.

‡Risk factors: atrial fibrillation, left ventricular dysfunction, previous thromboembolism, hypercoagulable state.

§Consider addition of aspirin, 80 to 100 mg once daily to decrease embolic risk.

Modified from Litin SC, Gastineau DA. Current concepts in anticoagulant therapy. Mayo Clin Proc. 1995;70:266-72. By permission of Mayo Foundation for Medical Education and Research, and data from Bonow RO, Carabello B, de Leon AC Jr, Edmunds LH Jr, Fedderly BJ, Freed MD, et al. ACC/AHA guidelines for the management of patients with valvular heart disease: executive summary. A report of the American College of Cardiology/American Heart Association Task Force on Practice Guidelines (Committee on Management of Patients With Valvular Heart Disease). Circulation. 1998;98:1949-84.

Antithrombotic Therapy for Venous Thromboembolic Disease

Guidelines for anticoagulation in patients with venous thromboembolic disease are summarized in Table 8-12.

Anticoagulation in Patients With Prosthetic Heart Valves

What Are the Recommendations for Anticoagulation in Patients With Mechanical Prosthetic Heart Valves?

It is strongly recommended that all patients with mechanical prosthetic heart valves receive warfarin. Levels of warfarin that maintain the INR at 2.5 to 3.5 are recommended in most situations. Patients with bileaflet valves in the aortic position and no other risk factors may have an INR of 2.0 to 3.0. Levels of warfarin producing an INR less than 1.8 result in a high risk of thromboembolic events, and levels that increase the INR to more than 4.5 result in a high risk of excessive bleeding. For high-risk patients with prosthetic heart valves, aspirin (80-100 mg daily) in addition to warfarin further decreases the risk of thromboembolism without increasing the risk of major bleeding, although minor bleeding is increased.

- All patients with mechanical prosthetic heart valves should receive warfarin.
- In most cases, use warfarin levels that maintain the INR at 2.5-3.5.
- Warfarin levels that decrease the INR to <1.8 result in a high risk of thromboembolic events, and warfarin levels that increase the INR to >4.5 result in a high risk of excessive bleeding.
- In patients with prosthetic heart valves, a low dose of aspirin plus warfarin may have an additive benefit without causing major bleeding (although minor bleeding may increase).

Table 8-12 Guidelines for Anticoagulation in Adults With Venous Thromboembolic Disease

Deep venous thrombosis or pulmonary embolus	Guidelines for anticoagulation
Suspected	Obtain baseline APTT, PT, and CBC (and creatinine if LMWH is to be used) Check for contraindication to heparin therapy Give unfractionated heparin, 5,000 U IV, or weight-adjusted dose of LMWH SQ, and order imaging study
Confirmed	Rebolus with heparin, 80 U/kg IV, and start maintenance infusion at 18 U/kg per hour* or use appropriate weight-adjusted dose of LMWH SQ Start warfarin therapy on first day at 5 mg and then administer warfarin daily at estimated maintenance dose Discontinue LMWH or unfractionated heparin when it has been administered jointly with warfarin for at least 4 or 5 d and the INR ≥2.0 Anticoagulate with warfarin for at least 3 mo at an INR of 2.0-3.0 (longer treatment should be given to patients with ongoing risk factors or recurrent thrombosis)

APTT, activated partial thromboplastin time; CBC, complete blood count; INR, international normalized ratio; IV, intravenously; LMWH, low-molecular-weight heparin; PT, prothrombin time; SQ, subcutaneously.
*If unfractionated heparin is used, check APTT at 6 hours to keep APTT between 1.5 and 2.5 times control (anti-Xa heparin level of 0.3-0.7 IU/mL) and check platelet count daily.

What Is Recommended if a Patient With a Prosthetic Heart Valve Has a Systemic Embolism Despite Adequate Therapy With Warfarin (INR, 2.5-3.5)?

If a patient with a prosthetic heart valve has a systemic embolism with adequate warfarin therapy, aspirin (80-100 mg daily) should be added to the regimen. These patients may respond to a slight increase in the warfarin dose (increasing the INR to 3.5-4.5) if they are already taking low-dose aspirin. However, no regimen completely eliminates the risk of systemic embolization or the risk of bleeding.

- No regimen ever totally eliminates the risk of systemic embolization or the risk of bleeding.

What Are the Recommendations for Anticoagulation in Patients With Bioprosthetic Heart Valves?

It is recommended that all patients with bioprosthetic valves in the mitral position receive warfarin therapy (INR, 2.0-3.0) for the first 3 months. Anticoagulant therapy is also reasonable during the first 3 months for patients with bioprosthetic valves in the aortic position who are in sinus rhythm. Certain patients with bioprosthetic valves have underlying conditions (i.e., atrial fibrillation or left atrial thrombosis) that require long-term warfarin therapy to prevent systemic emboli. For patients with bioprosthetic heart valves who are in sinus rhythm, long-term therapy with aspirin (325 mg daily) may offer protection against thromboembolism and appears reasonable for those without contraindication.

- Patients with bioprosthetic valves receive warfarin therapy (INR, 2.0-3.0) for 3 months.
- Patients with bioprosthetic valves who have atrial fibrillation or left atrial thrombosis require long-term warfarin therapy to prevent systemic emboli.
- Long-term therapy with aspirin may protect patients with bioprosthetic heart valves who are in sinus rhythm against thromboembolism.

Hemorrhagic Complications of Anticoagulation

When the Anticoagulant Effect of Warfarin Needs to Be Reversed, What Is the Best Way to Reverse It?

The anticoagulant effect of warfarin can be reversed by stopping treatment, administering vitamin K, or, in urgent situations with pronounced bleeding, replacing vitamin K-dependent coagulation factors with fresh frozen plasma. In urgent situations, fresh frozen plasma produces an immediate effect and is the treatment of choice. When warfarin therapy is discontinued, no marked effect is seen on the INR for 2 days or more because of the half-life of warfarin (36-42 hours) and the delay before newly synthesized functional coagulation factors replace dysfunctional coagulation factors.

Administering vitamin K rapidly lowers the INR, depending on the dosage of vitamin K and the severity of the anticoagulant effect. When high doses of vitamin K are administered, reversal occurs in about 6 hours. The disadvantage is that patients often remain resistant to warfarin for up to a week, making continued warfarin treatment difficult. This problem can be overcome by giving much lower doses of vitamin K (1-2.5 mg) orally, subcutaneously, or by slow intravenous infusion.

- The anticoagulant effect of warfarin can be reversed by stopping treatment, giving vitamin K, or replacing vitamin K-dependent coagulation factors with fresh frozen plasma.
- In cases of life-threatening bleeding or serious warfarin overdosages, replacement of vitamin K-dependent coagulation factors with fresh frozen plasma produces an immediate effect and is the treatment of choice.
- In nonurgent situations, a low dose of vitamin K (1-2.5 mg) may be given orally to decrease the INR and avoid warfarin resistance.

Are There Certain Patient Characteristics That Increase the Risk of Hemorrhagic Complications of Anticoagulant Treatment?

A strong relationship between the intensity of anticoagulant therapy and the risk of bleeding has been reported in patients receiving treatment for deep venous thrombosis and prosthetic heart valves. The concurrent use of drugs that interfere with hemostasis and produce gastric erosions (aspirin and nonsteroidal anti-inflammatory drugs) increases the risk of serious upper gastrointestinal tract bleeding. Other drugs, such as trimethoprim-sulfamethoxazole, amiodarone, and omeprazole, inhibit the clearance of warfarin, thus potentiating its effect. Physicians should consider any medication a potential source of interaction until proven otherwise. Several existing disease states associated with increased bleeding during warfarin therapy include treated hypertension, renal insufficiency, hepatic insufficiency, and cerebrovascular disease.

- The relationship between the intensity of anticoagulant therapy and the risk of bleeding is strong.
- The concurrent use of drugs that interfere with hemostasis and produce gastric erosions increases the risk of serious upper gastrointestinal tract bleeding.
- Trimethoprim-sulfamethoxazole, amiodarone, and omeprazole potentiate the effect of warfarin and increase bleeding risk.

Common Clinical Problems in General Internal Medicine

Treatment of Hyperlipidemia

Case

A 55-year-old man with stable class II angina is referred for consideration of drug treatment for hyperlipidemia. He is otherwise healthy. He quit smoking cigarettes 2 years previously and has no other known risk factors for CAD. He has closely followed the advice of a dietitian for the past 6 months, but his cholesterol levels have shown no marked decrease. His most recent values are total cholesterol 240 mg/dL, high-density lipoprotein cholesterol (HDL-C) 35 mg/dL, and triglycerides 75 mg/dL.

Discussion

Evidence has shown that lowering increased levels of low-density lipoprotein cholesterol (LDL-C) is associated with both primary and secondary prevention of coronary events. Moreover, several angiographic trials have shown consistent decreases in progression and increases in regression of atherosclerotic plaques that have been followed up for several years.

The third report of the National Cholesterol Education Program's Adult Treatment Panel (ATP III) identified patients with definite CAD or CAD risk equivalents (clinical atherosclerotic disease or diabetes mellitus) to be at very high risk (>20% chance of having cardiac events within 10 years) and suggested aggressive treatment.

In ATP II, the risk level was assigned by counting risk factors to identify the patient with multiple (≥2) risk factors. The risk factors were those that are used to modify LDL-C goals. In ATP III, the risk level is assigned by means of counting risk factors, followed by assessing a 10-year risk (Framingham risk scoring) in the patient who has multiple risk factors. The risk factors used for modifying LDL-C goals include the following:

- Cigarette smoking.
- Hypertension (blood pressure 140/90 mm Hg or taking antihypertensive medication).
- Low HDL-C (<40 mg/dL).
- Family history of premature CAD (CAD in male first-degree relative ≤55 years old; CAD in female first-degree relative ≤65 years old).
- Age (men ≥45 years; women ≥55 years).
- If patient has a high HDL-C (≥60 mg/dL), one risk factor is subtracted from the count.

LDL-C is used to monitor patients with hypercholesterolemia and is calculated from the following formula:

$$\text{LDL-C} = \text{Total Cholesterol} - \text{HDL-C} - \frac{\text{Triglycerides}}{5}$$

In this patient, LDL-C = 240 – 35 – (75/5) = 190 mg/dL.

Secondary causes of hyperlipidemia, such as the following, should be ruled out in all patients: diet (alcohol abuse or increased saturated fats), diseases (hypothyroidism, diabetes, nephrotic syndrome, renal failure, and obstructive liver disease), and drugs (corticosteroids, progestins, thiazides, or β-blockers).

- Rule out secondary causes of hyperlipidemia in all patients: diet, diseases, and drugs.

The first line of therapy involves weight reduction for overweight patients, increased physical activity, and dietary therapy. Both weight reduction and exercise not only promote lowering of cholesterol levels but also provide other benefits, such as decreasing triglycerides, increasing HDL-C, decreasing blood pressure, decreasing the risk of diabetes mellitus, and prolonging life.

Therapeutic lifestyle changes (weight reduction, physical activity, and intensive diet therapy) are initiated for patients without CAD or risk equivalents if LDL-C is 160 mg/dL or more, for patients without CAD but who have at least two risk factors if LDL-C is 130 mg/dL or more, and for patients with CAD or CAD risk equivalents if LDL-C is more than 100 mg/dL. Strategies for LDL-C

management by CAD risk are summarized in Table 8-13 and are modified from the ATP III goals on the basis of more recent clinical trial evidence.

If hypolipidemic drugs are prescribed, the choice of drug depends on the mechanism of action, side-effect profile, efficacy, and cost. The following discussion considers the most common classes of drugs used in the treatment of hyperlipidemia.

Bile acid sequestrants (e.g., cholestyramine, colestipol, and colesevelam)—Clinical trials have documented their benefit and safety. Their mechanism of action involves removing plasma LDL by depleting the bile acid pool, which causes an increase in liver LDL receptors. These drugs are often given alone (to patients with mild increases in LDL-C levels) or in combination with other drugs (to patients with greater increases in LDL-C levels). Side effects include gastrointestinal symptoms, binding of other concurrently administered drugs, constipation, and increased triglyceride levels, especially in patients who begin with increased levels.

Nicotinic acid (niacin)—This agent is effective in decreasing total cholesterol and triglyceride levels as well as increasing HDL-C levels. Side effects are common and limit the use of this drug in many patients. Side effects include flushing, nausea, abdominal discomfort, and skin itching. Also, the levels of plasma glucose, uric acid, and liver enzymes may increase. Slow-release preparations reduce the side effect of flushing, but the incidence of liver dysfunction increases markedly, especially with higher doses. Small doses of aspirin taken before niacin may block flushing.

HMG-CoA reductase inhibitors, or statins (e.g., lovastatin, pravastatin, simvastatin, atorvastatin, and rosuvastatin)—These drugs are highly effective in decreasing LDL-C by blocking liver cholesterol synthesis, which causes an increase in LDL liver receptors. They are the only drugs to consistently reduce mortality of subjects in both primary and secondary prevention studies. They have few side effects, although myalgias, myopathy, and an increase in liver enzymes may occur. Myopathy can increase with concurrent use of

Table 8-13 ATP III LDL-C Goals and Cutpoints for TLC and Drug Therapy in Different Risk Categories and Proposed Modifications Based on Recent Clinical Trial Evidence

Risk category	LDL-C goal	Initiate TLC	Consider drug therapy*
High risk: CHD† or CHD risk equivalents‡ (10-year risk >20%)	<100 mg/dL (optional goal: <70 mg/dL)§	≥100 mg/dL//	≥100 mg/dL (<100 mg/dL: consider drug options)¶
Moderately high risk: ≥2 risk factors# (10-year risk 10%-20%)**	<130 mg/dL††	≥130 mg/dL//	≥130 mg/dL (100-129 mg/dL: consider drug options)‡‡
Moderate risk: ≥2 risk factors# (10-year risk <10%)**	<130 mg/dL	≥130 mg/dL	≥160 mg/dL
Lower risk: 0 or 1 risk factor§§	<160 mg/dL	≥160 mg/dL	≥190 mg/dL (160-189 mg/dL: LDL-lowering drug optional)

ATP III, third report of the National Cholesterol Education Program's Adult Treatment Panel; CHD, coronary heart disease; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol; TLC, therapeutic lifestyle changes.

*When LDL-lowering drug therapy is used, the intensity of therapy should be sufficient to achieve at least a 30%-40% reduction in LDL-C levels.

†CHD includes history of myocardial infarction, unstable angina, stable angina, coronary artery procedures (angioplasty or bypass surgery), or evidence of clinically significant myocardial ischemia.

‡CHD risk equivalents include clinical manifestations of noncoronary forms of atherosclerotic disease (peripheral arterial disease, abdominal aortic aneurysm, and carotid artery disease [transient ischemia attacks or stroke of carotid origin or >50% obstruction of a carotid artery]), diabetes, and ≥2 risk factors with 10-year risk for hard CHD >20%.

§Very high risk favors the optional LDL-C goal of <70 mg/dL, and in patients with high triglycerides, non–HDL-C <100 mg/dL.

//Any person at high risk or moderately high risk who has lifestyle-related risk factors (e.g., obesity, physical inactivity, elevated triglycerides, low HDL-C, or metabolic syndrome) is a candidate for TLC to modify these risk factors regardless of LDL-C level.

¶If baseline LDL-C is <100 mg/dL, institution of an LDL-lowering drug is a therapeutic option on the basis of available clinical trial results. If a high-risk person has high triglycerides or low HDL-C, combining a fibrate or nicotinic acid with an LDL-lowering drug can be considered.

#Risk factors include cigarette smoking, hypertension (blood pressore ≥140/90 mm Hg or taking antihypertensive medication), low HDL-C (≤40 mg/dL), family history of premature CHD (CHD in male first-degree relative <55 years of age; CHD in female first-degree relative <65 years of age), and age (men ≥45 years; women ≥55 years).

**Electronic 10-year risk calculators are available at www.nhlbi.nih.gov/guidelines/cholesterol.

††Optional LDL-C goal <100 mg/dL.

‡‡For moderately high-risk persons, when LDL-C level is 100-129 mg/dL, at baseline or on lifestyle therapy, initiation of an LDL-lowering drug to achieve an LDL-C level <100 mg/dL is a therapeutic option on the basis of available clinical trial results.

§§Almost all people with ≤1 risk factor have a 10-year risk <10%, and 10-year risk assessment in people with ≤1 risk factor is thus not necessary.

From Grundy SM, Cleeman JI, Merz CNB, Brewer HB Jr, Clark LT, Hunninghake DB, et al. Implications of recent clinical trials for the National Cholesterol Education Program Adult Treatment Panel III Guidelines. Circulation. 2004;110:227-39. Used with permission.

cyclosporine, niacin, erythromycin, and fibrates (fibric acid derivatives). Primary prevention studies have shown decreased mortality risks with the use of statins. In large secondary prevention trials, statin drugs have been shown to reduce total mortality, cardiac mortality, and the incidence of stroke. They are effective in treating severe forms of hypercholesterolemia.

Fibrates (e.g., gemfibrozil and fenofibrate)—These are the drugs of choice for decreasing isolated increased levels of triglycerides. In some patients, these drugs slightly decrease LDL-C and increase HDL-C levels. Fenofibrate is more effective than gemfibrozil in decreasing LDL-C. Side effects are rare and related mostly to the gastrointestinal tract. These drugs also may increase the risk of gallstones. Therapeutically, they are most useful for disorders of hypertriglyceridemia, especially in patients with diabetes mellitus.

All the above-mentioned drugs have the potential to interact with warfarin (bile acid sequestrants can bind the drug, thus decreasing the INR, and the other hypolipidemic drugs may potentiate warfarin, thus increasing the INR). Therefore, when they are prescribed for patients taking anticoagulants, close monitoring is indicated.

Generally, the following drugs alone or sometimes in combination are recommended:

1. For patients with increased levels of LDL-C: HMG-CoA reductase inhibitors, bile acid sequestrants, and nicotinic acid
2. For patients with increased levels of LDL-C and triglycerides: HMG-CoA reductase inhibitos, nicotinic acid, and fibrates
3. For patients with isolated hypertriglyceridemia: therapeutic lifestyle change and, if drug treatment is indicated, fibrates and nicotinic acid

Drug therapy for hyperlipidemia must be individualized. In general, a positive effect is obtained and fewer side effects are experienced by starting therapy with low doses of medication and increasing the dose slowly, if necessary.

Tobacco Abuse

Case

A 60-year-old woman comes to your office for her annual mammogram, breast examination, and pelvic examination. You note from the preexamination questionnaire that she is a current smoker and has smoked one pack per day for 30 years. Examination of the lungs shows scattered rhonchi and wheezes with a prolonged expiratory phase. You broach the subject of smoking cessation with the patient, but the patient quickly and defensively counters with a number of statements, including "after 30 years of smoking, the damage is done" and "there's no sense quitting." The patient also fears gaining weight after quitting and says that when she did try to quit several years ago, she quickly became so nervous and edgy that she could not sleep and was unpleasant to be around. How might you devise a plan to deal effectively with this patient's tobacco abuse problem?

Discussion

Tobacco use is the leading cause of preventable premature death in the United States. It accounts for about 20% of all-cause mortality in the United States annually. In addition to being the causative factor for nearly 90% of all cases of lung cancer, smoking is associated with cancer of the oral cavity, larynx, esophagus, stomach, pancreas, uterine cervix, and genitourinary tract. However, among ex-smokers abstinent for 15 years or longer, the increase in lung cancer mortality is decreased to rates nearly those of nonsmokers.

Smokers are two to six times as likely to have an MI as nonsmokers, and 20% of all deaths due to cardiovascular disease are attributable to smoking. After several years of abstinence, the cardiovascular risk of ex-smokers is not significantly different from that of those who have never smoked.

Compared with smokers, ex-smokers have less phlegm production and wheezing, greater FEV_1 and vital capacity, better immune function, and lower mortality rates from pulmonary infections, bronchitis, and emphysema. Although some lung damage is irreversible, ex-smokers have marked improvement in their pulmonary function during the first year of cessation. After that, the decline in lung function stabilizes at a nonsmoker's rate. Smokers continue to show a decline in lung function at many times the rate of ex-smokers.

Often, one of the most compelling arguments for a patient to stop smoking is that it harms others. It is estimated that in the United States more than 50,000 people die annually of medical complications of passive smoking. Most of these deaths are from accelerated heart disease, although the number of lung cancer deaths is also substantial. Studies have estimated that nonsmoking spouses of smokers have an all-cancer risk about 1.5 times that of nonsmoking spouses of nonsmokers.

The Public Health Service Clinical Practice Guideline advises physicians to use an easy-to-remember five-step approach in counseling their patients in smoking cessation.

1. **Ask**—Systematically identify all tobacco users at every visit. The physician should question patients about smoking at any new encounter, inquiring not only whether they smoke but how much they smoke. It is also helpful to ask whether they have ever tried to stop smoking, and if so, what happened.
2. **Advise** all smokers to quit. Make this a strong and personalized message. Fewer than two-thirds of physicians report advising their patients to stop smoking, and only two-thirds of patients report receiving smoking cessation advice from their physician. This counsel can often be an influential message to patients. The physician should state the advice clearly; for example, "As your physician, I must advise you to stop smoking now." It helps to personalize the "quit smoking" message by referring to other illnesses the patient has, family history, passive smoking issues, and so forth.
3. **Assess** each person's willingness to make a quit attempt. If a person is willing to make a quit attempt, move on to step 4 ("Assist"). If the patient desires intensive treatment, provide a referral. Some patients are unwilling to make a quit attempt. For them, provide a motivational intervention.
4. **Assist** the patient in stopping to smoke. Set a quit date with the patient. Try to do it within 4 weeks, acknowledging with the patient that the time is never ideal. Provide self-help materials. Recommend or prescribe nicotine gum, nicotine patches, intranasal nicotine spray, nicotine inhaler, or bupropion, especially for any patient who smokes more than 10

cigarettes daily and is motivated to attempt smoking cessation. Consider signing a stop-smoking contract with the patient.

5. **Arrange** follow-up visits. Set up a follow-up visit within 1 or 2 weeks after the quit date. Counseling programs and behavioral therapy programs can be effective in smoking cessation. A transdermal nicotine patch together with behavioral therapy results in significantly higher cessation rates than transdermal nicotine alone. If during follow-up visits you discover that the patient has relapsed, advise him or her that this is not uncommon. Encourage the patient to try again immediately.

Pharmacologic therapy to aid in smoking cessation should be recommended to most patients. In clinical trials, smoking cessation rates at 6 to 12 months are more than doubled among those using active therapy, as compared with placebo treatment. Two categories of pharmacologic smoking cessation treatment are available: nicotine replacement therapy and non-nicotine therapy. Nicotine replacement therapy is available in several forms. A transdermal nicotine patch releases nicotine at a steady rate for 16 to 24 hours and is associated with higher patient compliance because of its once-a-day dosing schedule. Nicotine gum, nicotine nasal spray, and nicotine inhaler are immediate-release forms of nicotine replacement and are effective in smoking cessation treatment but must be used several times each day. They have the advantage of allowing patients to use them in response to smoking urges. Currently, bupropion is the only non-nicotine therapy available that has proven efficacy for smoking cessation. It should not be used if the patient has seizure risk; otherwise, it is appropriate for any smoker who is motivated to stop smoking. Bupropion may have the added advantage of attenuating postcessation weight gain.

Several other important concerns that patients have can be addressed and answered. For those who worry about weight gain with smoking cessation, it is useful to let them know that although the majority of patients do gain weight, the average is about 3 to 5 kg, and this can be anticipated and dealt with effectively. For patients who have noted difficulties with nervousness and poor sleep after smoking cessation, advise them that these symptoms are related to nicotine withdrawal and usually resolve after 2 or 3 weeks. Nicotine replacement therapies can often help control these symptoms. Some patients notice an increase in coughing after they stop smoking. This can be explained as a temporary response caused by an increase in the lung's ability to remove phlegm and, thus, represents recovery of the lung's own defense mechanisms. After cessation has been achieved, the patient should be advised to refrain from having even an occasional cigarette, because nicotine addiction seems to be triggered quickly in most ex-smokers.

Acute Low Back Pain

Case

A 55-year-old man comes to your office with a 3-day history of severe low back pain in the lumbosacral area. The patient does not recall any specific trauma, and the review of systems is negative for fever, weight loss, or other constitutional symptoms. The patient does not complain of numbness, tingling, or weakness in his legs, and he has no bladder or bowel symptoms. The patient works in a factory, and his job requires some minor lifting and bending. Make a diagnostic assessment, therapeutic plan, and suggestions about levels of activity.

Discussion

Acute low back problems are one of the most common reasons for patients to visit a physician's office. Acute low back problems are defined as "activity intolerance due to lower back or back-related leg symptoms of less than 3 months' duration." It is important to know that 90% of patients with acute low back problems have a spontaneous recovery and return to previous levels of activity within 1 month. On the initial assessment of such a patient, a focused medical history and physical examination should be performed so that a potentially dangerous underlying condition is not overlooked. On the basis of this evaluation, low back symptoms can be classified into one of three working categories:

1. *Potentially serious spinal conditions*—This rare category includes tumor, infection, fracture, or major neurologic disorder. One should look for "red flags" in the history or examination that would point to these conditions, that is, a history of trauma (fracture) or cancer (spinal epidural metastases), risk factors for spinal infection or fever/chills (infection), and saddle anesthesia or bladder and bowel dysfunction (cauda equina syndrome).
2. *Sciatica*—This category includes back-related lower limb symptoms suggestive of lumbosacral nerve root compromise. Sciatica would be further suggested by a positive straight leg raise, as defined by pain below the knee at less than 70° of leg elevation, aggravated by dorsiflexion of the ankle. Crossover pain (i.e., eliciting pain in the leg with sciatica by straight raising of the unaffected leg) is an even stronger indication of nerve root compression. Correlative findings on sensory examination, specific muscle strength loss, and reflex changes can be used to further diagnose sciatica and to localize the nerve root suspected to be involved.
3. *Nonspecific back symptoms*—This common category includes low back pain without signs or symptoms of a serious underlying condition or nerve root compression.

The patient in the case example appears to have nonspecific back discomfort. After this diagnosis is made, the physician could educate the patient about this problem, reassuring him that the evaluation results do not suggest a dangerous problem and that rapid recovery can be expected. Should the patient not recover within a month, a more extensive evaluation may be needed, including radiography and special studies.

In the interim, the physician must address the need for symptom control measures. This can include oral medications. The safest effective medication for acute low back problems appears to be acetaminophen, which has a low side-effect profile. Nonsteroidal anti-inflammatory drugs can also be prescribed, but the disadvantages are cost and side-effect profile (gastrointestinal tract irritation and ulceration). Muscle relaxants are reported to be no more effective than nonsteroidal anti-inflammatory drugs in treating low back symptoms, and they can produce marked drowsiness. A combination of relaxants and nonsteroidal anti-inflammatory drugs has not demonstrated an increased benefit. Opioids appear no more effective than safer analgesics and should be avoided if possible. If opioids are

chosen, they should be prescribed for only short periods and the patient must be warned of the potential side effects of drowsiness, cloudy mentation, and constipation and the potential for dependency.

Physical methods are often used in the treatment of acute back problems; however, most of these methods, including traction, massage, ultrasound, and trigger point injections, have not been proved to be more effective than simple analgesics in studies of patients with acute symptoms. Spinal manipulation is safe and as effective as other commonly used treatments for patients who have acute low back symptoms in the absence of a radiculopathy.

Activity alteration is a balance between avoiding undue back irritation and preventing debility due to inactivity. Most patients do not require bed rest. In fact, it has been shown that patients with acute low back pain who continue ordinary activities within the limits permitted by the pain recover more rapidly than those treated with bed rest or back-mobilizing exercises. If bed rest is used, it should be used for only 2 or 3 days, because prolonged bed rest has a potentially debilitating effect and its efficacy in treatment is unproven. Generally, bed rest is reserved for patients with severe limitations caused by sciatica. Certain postures and activities can increase stress on the back and aggravate the symptoms. Patients must be taught to minimize the stress of lifting by keeping the object being lifted close to the body at the level of the navel. Lifting with the legs as opposed to the back must be emphasized. Prolonged sitting may sometimes aggravate problems, and patients should be encouraged to change their position frequently. Until the patient returns to normal activity, aerobic conditioning may be recommended to help avoid debilitation from inactivity. When requested, it may be appropriate for the physician to offer specific instructions about activity at work for patients with acute limitations due to low back symptoms. The physician should make it clear to both the patient and the employer that even moderately heavy unassisted lifting may aggravate back symptoms and that any restrictions are intended to allow for spontaneous recovery or for time to build activity tolerance through exercise.

General Internal Medicine Pharmacy Review

John G. O'Meara, PharmD

Antihyperlipidemic Agents

Drug (trade name)	Dose	No. of doses/d	Side effects	Drug interactions	Comments
Bile acid sequestrants			GI (bloating, constipation, flatulence)	Administer at least 4 h before or 2 h after other drugs	No systemic absorption; may be given to pregnant women; lipid effects: decrease LDL-C, increase or no change in HDL-C, & increase triglycerides
Cholestyramine (Questran, Prevalite, Locholest)	4-16 g	2			
Colestipol (Colestid)	2-16 g (tablets), 5-30 g (powder)	1 or 2			
Colesevelam (Welchol)	3.75 g	1 or 2	Fewer GI side effects than with cholestyramine & colestipol	Fewer drug interactions than with cholestyramine & colestipol	
HMG-CoA reductase inhibitors ("statins")			Headache, myalgia, increased liver enzymes, diarrhea, rhabdomyolysis (rare)		Lipid effects: most potent agents in lowering LDL-C, also decrease triglycerides & modestly increase HDL-C All statins are contraindicated in pregnancy
Lovastatin (Mevacor)	20-80 mg	1 or 2		CYP3A4 inhibitors—increase serum levels of lovastatin, simvastatin, and, to lesser extent, atorvastatin (CYP3A4 inhibitors include azole antifungals [itraconazole, ketoconazole, voriconazole], macrolide antibiotics [erythromycin, clarithromycin], diltiazem, verapamil, cyclosporine,nefazodone, fluvoxamine, grapefruit juice, amprenavir, ritonavir, nelfinavir, and indinavir) Fibrates (increased risk of myopathy)	Lovastatin should be taken with evening meal

General Internal Medicine Pharmacy Review (continued)

Antihyperlipidemic Agents (continued)

Drug (trade name)	Dose	No. of doses/d	Side effects	Drug interactions	Comments
HMG-CoA reductase inhibitors ("statins") (continued)					
Pravastatin (Pravachol)	40-80 mg	1		Cholestyramine, colestipol (decreased pravastatin absorption), amprenavir & cyclosporine (increased pravastatin serum levels), fibrates (increased risk of myopathy)	Not metabolized extensively by cytochrome system; therefore, reduced potential for drug interactions; administer at bedtime
Simvastatin (Zocor)	20-80 mg	1		Same as lovastatin, plus amiodarone	Administer at bedtime
Atorvastatin (Lipitor)	10-80 mg	1		Same as lovastatin	May take any time during day ($t_{1/2}$ ~ 14 h)
Fluvastatin (Lescol, Lescol XL)	20-80 mg	1		Potent inhibitor of CYP2C9; warfarin (increased hypoprothrombinemic effect via inhibition of warfarin metabolism)	Administer at bedtime; least potent of statins
Rosuvastatin (Crestor)	10-40 mg	1	Proteinuria & hematuria with higher doses	Minimal (~10%) hepatic metabolism (primarily CYP2C9 & CYP2C19), decreased potential for drug interactions	May take any time during day Most potent statin, but increased risk of myopathy due to higher potency (myopathy is dose dependent)
Fibric acid derivatives			Dyspepsia, diarrhea, myopathy, hepatotoxicity, cholelithiasis		Lipid effects: most potent agents for decreasing triglycerides; also increase HDL-C
Gemfibrozil (Lopid)	1,200 mg	2		Warfarin (increased risk of bleeding), statins (increased risk of myopathy), sulfonylureas (increased risk of hypoglycemia)	Administer 30 min before morning & evening meals
Fenofibrate (Tricor)	54-160 mg	1		Same as gemfibrozil, but with less risk of myopathy than with statins, cholestyramine, & colestipol (decreased fenofibrate absorption)	Give with a meal

General Internal Medicine Pharmacy Review (continued)

Antihyperlipidemic Agents (continued)

Drug (trade name)	Dose	No. of doses/d	Side effects	Drug interactions	Comments
Nicotinic acid (niacin)					Most effective agent in increasing HDL-C
Immediate-release (Niacor)	2-6 g	2 or 3	GI distress, skin flushing, tingling & warmth, headache, hypotension; hepatotoxicity (>2 g/d, increased risk with sustained-release formulation), hyperglycemia, hyperuricemia	Statins (increased risk of myopathy), cholestyramine, & colestipol (decreased niacin absorption)	Aspirin 325 mg 30 min before niacin may decrease flushing reaction (prostaglandin mediated)
Extended-release (Niaspan)	1-2 g	1 at bedtime			Immediate-release niacin: start low & titrate dose upward slowly to minimize side effects
					OTC formulations of immediate-release and extended-release niacin are available
Cholesterol absorption inhibitor					
Ezetimibe (Zetia)	10 mg	1	Similar to placebo in clinical trials	Cholestyramine (decreased absorption of ezetimibe Administer ezetimibe at least 2 h before or 4 h after a bile acid sequestrant Cyclosporine (increased ezetimibe levels)	Not recommended for patients with moderate or severe hepatic insufficiency No increase in myopathy or rhabdomyolysis when given with statins
Combination agents					
Extended-release niacin/lovastatin (Advicor)	Starting dose: 500/20 mg	1 at bedtime, maximum daily	See nicotinic acid and lovastatin	See nicotinic acid and lovastatin	See nicotinic acid and lovastatin
Ezetimibe/simvastatin (Vytorin)	Starting dose: 10/20 mg	1 in the evening	See ezetimibe and simvastatin	See ezetimibe and simvastatin	See ezetimibe and simvastatin
Omega-3 fatty acids					
Eicosapentaenoic acid (EPA) + docosahexaenoic acid (DHA)	CAD: ~1 g Increased triglycerides: 2-4 g	1 or 2	GI upset, fishy aftertaste	No increase in myopathy or rhabdomyolysis when given with statins	Give with a meal Decreases triglyceride levels by 20%-50% but also increases LDL-C Higher doses may interfere with platelet function & possibly cause bleeding

CAD, coronary artery disease; GI, gastrointestinal; HDL-C, high-density lipoprotein cholesterol; LDL-C, low-density lipoprotein cholesterol; OTC, over-the-counter.

Summary of Drugs for Smoking Cessation

Drug	Side effects	Drug interactions	Comments
Nicotine replacement		Drug metabolism may be altered by use/nonuse of nicotine Monitor clinical outcomes	Do not smoke while taking nicotine replacement
Nicotine gum	Taste alteration, mouth/throat irritation, cough, headache		2-mg dose (NTE 30 pieces/d) 4-mg dose (NTE 20 pieces/d)
Nicotine inhaler	Taste alteration, mouth/throat irritation, cough, headache		Usual dose is 6-16 cartridges/d; do not use >6 mo
Nicotine lozenge	Taste alteration, nausea, heartburn, hiccups, cough, headache		Start with 2-mg lozenge if first cigarette is >30 min after waking Start with 4-mg lozenge if first cigarette is within 30 min of waking NTE 20 lozenges daily of either strength
Nicotine nasal spray	Nasal/throat irritation, runny nose, watery eyes, sneezing, congestion, taste alteration, headache	Nasal vasoconstrictors	Dose is 1 mg (2 sprays, 1/nostril), NTE 40 mg (80 sprays daily) Irritation decreases with use
Nicotine patch	Redness, itching, & burning at application site; nervousness, headache		Apply to clean, healthy, nonhairy skin; rotate sites of application every 24 h
Nonnicotine replacement			
Bupropion (Zyban)*	Dry mouth, insomnia, headache, nausea, hypertension	MAOIs, TCAs, SSRIs, levodopa	Contraindicated in patients with previous seizure history May be taken with/without nicotine replacement Pregnancy category B

MAOI, monoamine oxidase inhibitor; NTE, not to exceed; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant.

*Zyban is the only nonnicotine drug approved by the Food and Drug Administration for smoking cessation; other compounds are under invstigation.

Summary of Anticoagulants

Drug	Side effects	Drug interactions	Comments
Warfarin (Coumadin) PO	Hemorrhage, bruising, skin lesions/necrosis	Many interactions (cytochrome P-450 enzymes), more frequent monitoring advised when new medications started/stopped	Dose based on INR Pregnancy category X Anticoagulant effects reversed by vitamin K
Heparin IV/SQ	Hemorrhage, hypersensitivity, thrombocytopenia	Many interactions; monitor patients closely, especially when receiving other anticoagulants	Monitor APTT, platelet counts Dose usually based on weight
Low-molecular-weight heparin SQ Dalteparin (Fragmin) Enoxaparin (Lovenox) Tinzaparin (Innohep)	Hemorrhage, pain/bruising at injection site	Increased bleeding risk when given with oral anticoagulants, platelet inhibitors, & thrombolytic agents	Use with caution in patients with history of heparin-induced thrombocytopenia Dosed per treatment guidelines

APTT, activated partial thromboplastin time; INR, international normalized ratio; IV, intravenously; PO, orally; SQ, subcutaneously.

9

Genetics

Virginia V. Michels, MD

Genetic factors play a role in the development of many types of human disease. Genetic determinants may be chromosome abnormalities, single gene defects, mitochondrial mutations, or epigenetic or multifactorial factors.

Chromosome Abnormalities

Approximately a sixth of all birth defects and cases of congenitally determined mental retardation are due to chromosome abnormalities. Chromosome abnormalities occur in about 1 in 180 live births. One-third of these abnormalities involve an abnormal number (aneuploidy) of non-sex chromosomes (autosomes). Factors known to result in a higher-than-average risk for having a child with autosomal aneuploidy are maternal age 35 years or older and having previously had an affected child. Prenatal diagnosis by karyotyping of fetal cells obtained by amniocentesis or chorionic villus sampling can be offered to pregnant women who are at increased risk.

- Chromosome abnormalities occur in 1 in 180 live births.
- Risk factors for autosomal aneuploidy: maternal age ≥35 years and having had an affected child.

Down Syndrome

The most common autosomal aneuploidy syndrome in term infants is Down syndrome (incidence, l in 880). The most serious consequence of Down syndrome is mild-to-moderate mental retardation (average IQ, about 50). Forty percent of patients with Down syndrome have a congenital heart defect, most frequently ventricular septal defect or atrioventricular canal defect, although other congenital heart defects may occur. Median duration of survival is approximately 60 years. Thyroid disease, hearing loss, and celiac disease are common. Alzheimer disease develops in more than 40% by age 50 years. A few patients have hypoplasia of the odontoid process, which is important to diagnose before participation in certain sports. Males with Down syndrome are usually sterile, but affected females are fertile and have a very high risk of having an affected child. Most persons with Down syndrome have trisomy 21 as a result of a new mutation nondisjunctional event; in these cases, the risk to the parents of having another affected child is 1% to 2% or higher, depending on maternal age. In 3% of persons with Down syndrome, a translocation chromosome abnormality is present, in which the extra chromosome 21 is attached to another chromosome, most commonly 14 (Fig. 9-1). These translocation chromosomes may be inherited in an *unbalanced* form from a parent carrying a *balanced* form of the translocation; these parents have a 5% to 15% risk of having another affected child. Even if the parents have completed their childbearing, the karyotype of the affected individual should be determined so that other relatives (e.g., adult siblings) can be counseled. The same principles are presumed to be true for other autosomal aneuploidy syndromes.

- The most serious consequence of Down syndrome is mild-to-moderate mental retardation.
- The most frequent heart defect in Down syndrome is ventricular septal defect or atrioventricular canal defect.
- Males with Down syndrome are usually sterile, but females are fertile.
- Most persons with Down syndrome have trisomy 21.
- Early-onset Alzheimer disease is common in adults with Down syndrome.

Sex Chromosome Aneuploidy Syndromes

Approximately 35% of chromosome abnormalities in live-born infants involve sex chromosome aneuploidy. Affected individuals may have an additional X or Y chromosome or be lacking one. Patients with 47,XXX or 47,XYY karyotypes usually have no major birth defects or mental retardation, although the mean IQ may be 90 rather than 100. Patients with a 47,XXY karyotype (Klinefelter syndrome) have a tall, eunuchoid body habitus, small testes, and infertility. However, reproduction sometimes can be achieved through in vitro techniques with intracytoplasmic sperm injection. They are at increased risk for breast cancer, nongonadal germ cell tumors, and leg ulcers.

Patients with a 45,X karyotype (Turner syndrome) or its variants—one structurally abnormal X, such as 46,X,i(X)q (Fig. 9-2)—or mosaicism for an X or Y chromosome—such as 45,X/46,XX—usually are mentally normal. Fluorescent in situ hybridization probes can be

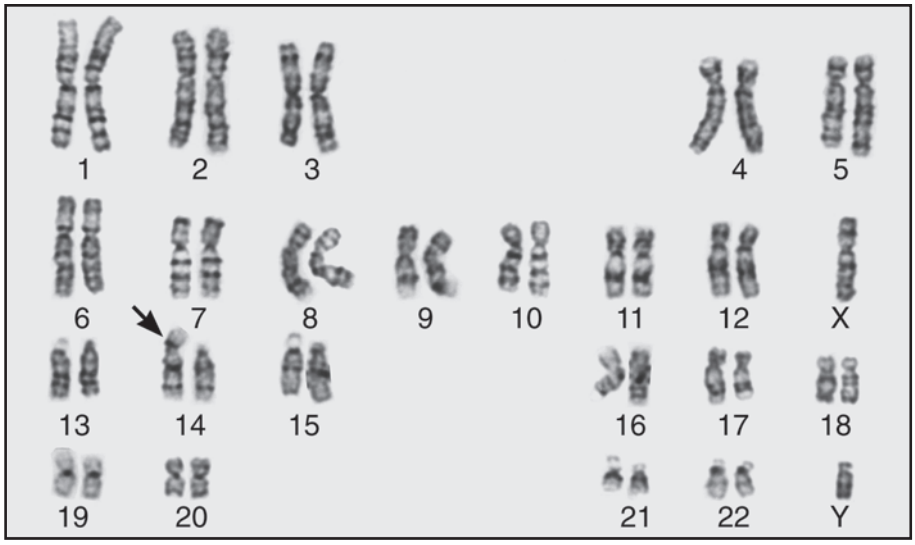

Fig. 9-1. Karyotype 46,XY,-14,+t(14;21)(p11;q11) from patient with Down syndrome. Extra chromosome 21 material is translocated to chromosome 14 (*arrow*). Result is robertsonian translocation. The short arm, at the top of each chromosome, is referred to as the "p" arm; the long arm, at the bottom, is referred to as the "q" arm. (Karyotype courtesy of G. Dewald, Ph.D.)

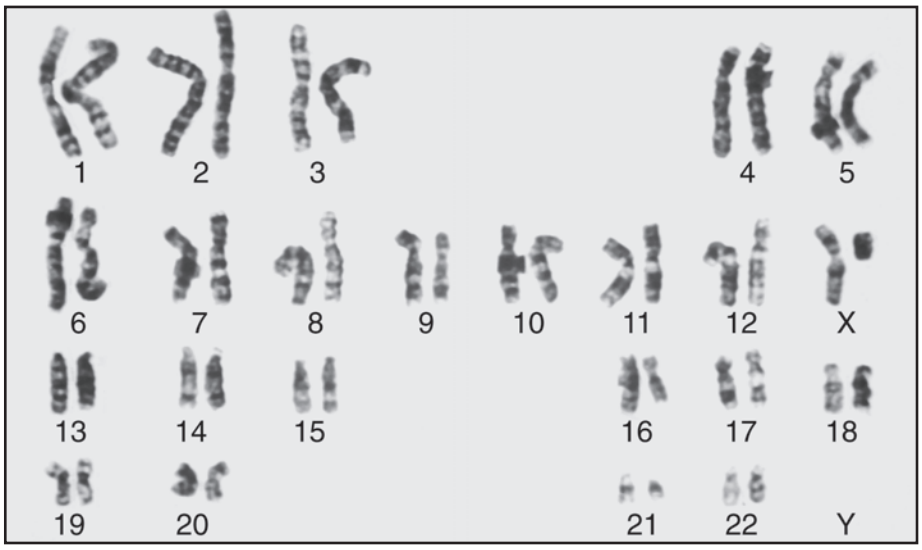

Fig. 9-2. Karyotype 46,X,r(X) from patient with Turner syndrome. "r" is the designation for a ring chromosome. (Karyotype courtesy of G. Dewald, Ph.D.)

used to distinguish a marker X versus Y when it is so small that it cannot be distinguished by karyotype analysis. This distinction is important for determining risk of gonadal malignancy (increased with Y chromosome material) and need for prophylactic gonadectomy. Streak gonads are usually present. Patients have a risk of approximately 30% for a bicuspid aortic valve with or without coarctation of the aorta. Women with Turner syndrome are at increased risk for ascending aortic aneurysm formation, and thus periodic echocardiographic monitoring is recommended. Short stature, webbed neck, increased number of pigmented nevi, failure to develop secondary sexual characteristics, short 4th or 5th metacarpals or metatarsals, renal malformations, and increased risk for thyroid disease are also variably present.

- Typical case of 47,XXY karyotype (Klinefelter syndrome): small testes, infertility, tall, eunuchoid body habitus.
- Typical case of 45,X karyotype (Turner syndrome): short stature, lack of secondary sex characteristics, usually mentally normal, 30% risk of bicuspid aortic valve or aortic coarctation.
- Risk for ascending aortic aneurysm is increased in Turner syndrome.

Other Chromosome Abnormalities

Thirty-four percent of chromosome abnormalities involve structural changes such as deletions, duplications, inversions, or translocations. They may be detected by peripheral blood karyotype or, for more

subtle alterations, by subtelomeric fluorescent in situ hybridization probes (Fig. 9-3). The translocations may be balanced (no net loss or gain of genetic material) or unbalanced. People with balanced translocations are usually phenotypically normal and healthy but may be at increased risk for miscarriages or their children may have birth defects. Patients with net loss or gain of genetic material by any of the mechanisms listed above have phenotypic abnormalities that usually include mental subnormality and frequently other major or minor birth defects. Parents of all patients with a structural chromosome abnormality should have chromosome analyses to determine whether they are carriers of a balanced translocation.

- Parents of all patients with a structural chromosome abnormality should have chromosome analyses.

Fragile X-Linked Mental Retardation

The fragile X-linked mental retardation syndrome occurs in about 1 in 1,000 males. It is characterized by a visible fragile site on the long arm of an X chromosome at band q27 when the lymphocytes are cultured in media deficient in folic acid. The fragile site is never observed in all cells, and the frequency may be as low as 4%. Some carrier females do not express the fragile site cytogenetically. Molecular analysis for this disorder is more sensitive than cytogenetic analysis. Affected and carrier individuals have trinucleotide repeat (CGG) expansions within the *FMR1* gene. There are more than 200 repeats in mentally retarded males, and females with more than 200 repeats have a risk of mental subnormality of 50%. Patients with smaller repeat expansions of 55 to 200 are referred to as premutation carriers, and these men are at risk of a neurologic degenerative disorder even though they do not have mental retardation. Variable combinations of ataxia, intention tremor, dementia, parkinsonism, and peripheral or autonomic neuropathy may develop. These men, also referred to as transmitting males, have obligate carrier daughters who rarely show signs of the disease, who in turn may have mentally retarded sons, because the CGG repeat is more likely to expand when transmitted through a female. Affected males may be physically normal or have a long, thin face with prominent jaw, large simplified ears, and enlarged testes. Carrier females are phenotypically normal or mildly retarded and dysmorphic. The degree of mental retardation ranges from mild to profound.

- Males with fragile X may be physically normal or have a long, thin face, prominent jaw, large ears, enlarged testes, mild to profound mental retardation.
- Molecular DNA analysis is the appropriate clinical test for fragile X.
- Premutation carriers are at risk for a neurodegenerative disorder.

Single Gene Defects

Autosomal Dominant

In autosomal dominant inheritance, the responsible gene is located on one of the autosomes and one copy of the gene is sufficient for the trait to be expressed or for the disease to be present (i.e., heterozygotes have the disease). There is a 50% chance that any child born to an affected person will inherit the abnormal gene.

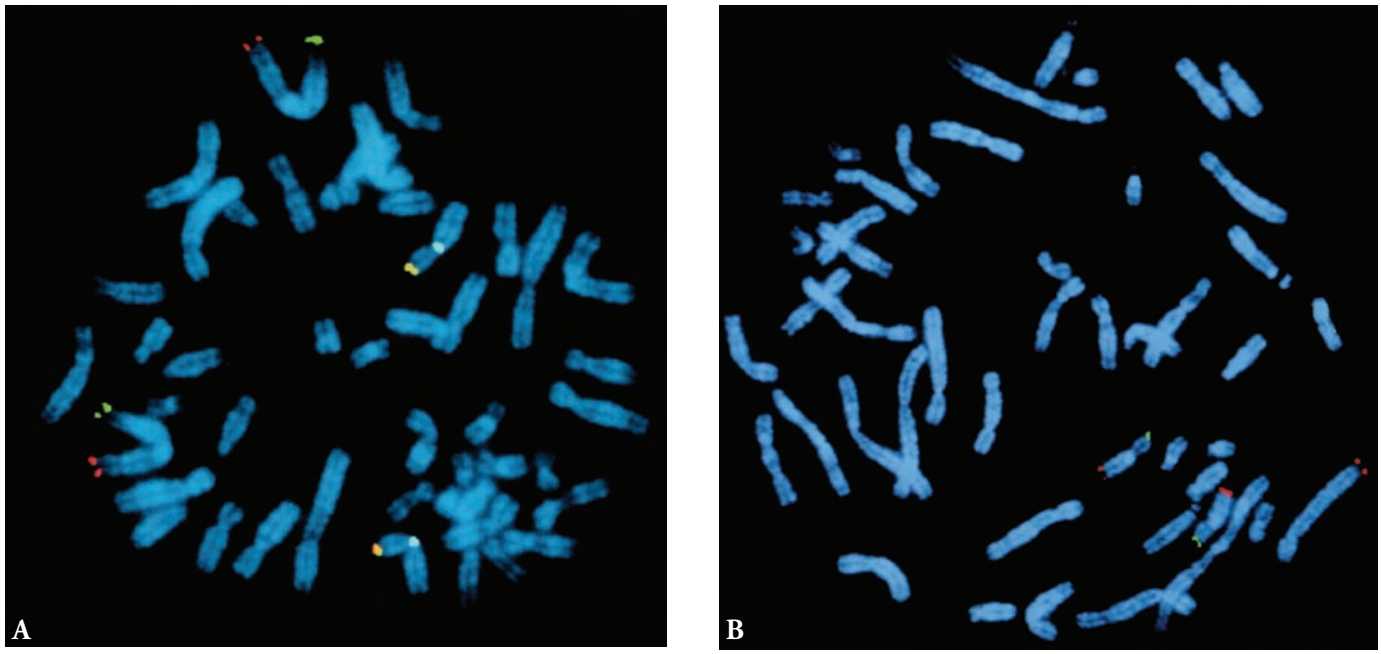

Fig. 9-3. Fluorescent DNA probes for subtelomeres of each p and q arm of all chromosomes, except acrocentric p arms, are used to analyze a complete set of subtelomere regions. *A*, A normal pattern of 1 p in green, 1 q in orange, and Xp in yellow (fusion of green and orange) and X centromere in aqua (used as control). *B*, Chromosomes 16p in green and 16q in orange have a normal pattern but, in addition, 16q probe is present on 4q. Thus, this chromosome 4 is derivative so that 4p probe is deleted (not shown) and 16q subtelomere region is duplicated. (Photograph courtesy of S. Jalal, Ph.D.)

- Autosomal dominant inheritance: responsible gene is located on autosome.
- There is a 50% chance that a child of an affected person will inherit the abnormal gene.

The severity of the disease caused by the abnormal gene may be uniform for some conditions, such as achondroplasia, but the severity may be variable for other conditions, such as neurofibromatosis and Marfan syndrome. This difference of severity is referred to as "variable expression." In contrast, "incomplete penetrance" means that some persons who have inherited the gene show no signs of it. Obviously, the clinical decision regarding whether a person has signs of the gene defect depends on the thoroughness of the examination and on the sensitivity of the investigative techniques. For example, many families with hypertrophic cardiomyopathy were thought to include members with incomplete penetrance until asymptomatic relatives were examined with echocardiography.

Although transmission of a disease through members of either sex through multiple generations of a family strongly suggests autosomal dominant inheritance, it is important to remember that autosomal dominant diseases can occur without a positive family history. This can occur because of incomplete penetrance, new mutation, somatic mosaicism, or incorrect assignment of paternity. New mutation events represent changes in the genetic material of the individual egg or sperm that give rise to the fetus. Although the risk for siblings of a person whose disease arose by new mutation is not increased over that of the general population, the risk for children still is 50%. Somatic mosaicism refers to the possibility that one of the parents has the gene defect in only some cells, including the reproductive cells (germinal mosaicism), such that the person has no or few signs of the disease but potentially can transmit the disease to one or more children.

- In autosomal dominant inheritance, disease severity may be uniform or variable.
- Incomplete penetrance: no signs of abnormal gene in a person who has inherited it.
- Somatic mosaicism: person has gene defect in only some cells.

Some of the diseases with autosomal dominant inheritance are listed in Table 9-1 and summarized on the following pages.

Imprinting is an epigenetic phenomenon that can influence the observed pattern of disease occurrence within families with single gene defects. For imprinted genes, the gene's activity (i.e., expression) in an individual differs depending on which parent (mother or father) transmitted the gene. At the molecular level, these differences may result from methylation status and possibly other factors. An example of imprinting occurs in autosomal dominant familial paragangliomas due to *SDHD* gene mutations. Paragangliomas can develop in a person who inherits the defective gene from his or her father, but they do not develop in a person who inherits the defective gene from his or her mother. Regardless of whether or not a paraganglioma develops, the defective gene can be transmitted to the next generation.

Dilated Cardiomyopathy

The incidence of idiopathic dilated cardiomyopathy is approximately 6 in 100,000 and the prevalence 36 in 100,000. It is familial in at least 30% of cases, but the familial nature of the disease is often not apparent unless relatives undergo echocardiography. Penetrance is decreased and increases with advancing age, although children and young adults can be affected. Severity and mode of presentation, for example with heart failure or arrhythmia, can vary even within families. However, some families have a stronger predisposition to arrhythmias than others. In adults, the inheritance pattern is usually autosomal dominant, although X-linked inheritance also can occur. Mutations in more than nine genes can cause dilated cardiomyopathy, including those that encode α-tropomyosin, α-actin, desmin, titin, δ-sarcoglycan, β-myosin heavy chain, troponin T, metavinculin, and cardiac sodium channel. The last is of interest because it also results in a strong likelihood of atrial fibrillation. Note that some of these genes also can be associated with hypertrophic cardiomyopathy, depending on where in the gene the mutation occurs. X-linked genes that can be involved in dilated cardiomyopathy include those encoding dystrophin, tafazzin and emerin (sometimes also associated with skeletal myopathy). Early diagnosis is important for treatment before refractory heart failure or undetected arrhythmia results in major morbidity or mortality.

Table 9-1 Examples of Diseases With Autosomal Dominant Inheritance

Achondroplasia
Amyloidosis (many types)
Dilated cardiomyopathy
Ehlers-Danlos syndrome, types I, II, III, IV, and some type VII
Hereditary spherocytosis, some types
Huntington disease
Hypertrophic cardiomyopathy
LEOPARD* syndrome
Low-density lipoprotein receptor deficiency (hypercholesterolemia)
Marfan syndrome
Multiple endocrine neoplasia, types 1, 2A, and 2B
Myotonic dystrophy
Neurofibromatosis, types 1 and 2
Noonan syndrome
Osler-Weber-Rendu disease (hereditary hemorrhagic telangiectasia)
Osteogenesis imperfecta, types I and IV, most type II
Polycystic kidney disease (some forms are autosomal recessive)
Porphyria (several types)
Pseudoxanthoma elasticum (some forms are autosomal recessive)
Tuberous sclerosis
Von Hippel-Lindau disease
Von Willebrand disease

*Lentigenes (multiple), electrocardiographic conduction abnormalities, ocular hypertelorism, pulmonary stenosis, abnormalities of genitalia, retardation of growth, deafness.

Ehlers-Danlos Syndromes

There are at least seven forms of Ehlers-Danlos syndrome. Type I, or gravis type, serves as a prototype for discussion of this group of genetically heterogeneous disorders. The syndrome is inherited as an autosomal dominant condition. The basic defect in type I disease has been defined for some cases as a defect in the α-1 or α-2 chain of type V collagen. The disorder is characterized by velvety textured, hyperextensible, fragile skin that bruises and splits easily and heals poorly, resulting in wide, thin scars. Many tissues are friable, which is an important consideration when surgical procedures are needed. Even fetal membranes are affected and frequently rupture before term, resulting in premature birth. Wrinkled, redundant skin may develop over the knee and elbow joints. Small fat- or mucin-containing spherules may be present in the subcutaneous tissue and may be calcified. The joints are hyperextensible and prone to dislocations. Pes planus, scoliosis, degenerative arthritis, visceral diverticulosis, and spontaneous pneumothorax may occur. Mitral valve prolapse may occur in 50% of patients. Dilatation of the aortic root or pulmonary artery and prolapse of the tricuspid valve may occur. Vascular rupture is relatively rare. Type II Ehlers-Danlos syndrome is a milder form of type I. Type III Ehlers-Danlos syndrome is of unknown cause in most cases and is characterized by joint hyperextensibility with minimal skin involvement. Type IV Ehlers-Danlos syndrome is the most severe and is due to deficiency of type III collagen that results in tendency for arterial aneurysms and visceral organ rupture.

- Type I Ehlers-Danlos syndrome is an autosomal dominant condition.
- Features: velvety textured, hyperextensible, fragile skin.
- Joints are hyperextensible and prone to dislocation.
- Associated conditions: pes planus, scoliosis, degenerative arthritis, visceral diverticulosis, spontaneous pneumothorax.
- Mitral valve prolapse occurs in 50% of patients.
- Vascular rupture is relatively rare in types I and II.

Hypertrophic Cardiomyopathy

Hypertrophic cardiomyopathy frequently is inherited as an autosomal dominant disorder. The incidence is estimated to be 1 in 500, and it is one of the most common causes of sudden death in adolescents and young adults. Penetrance ranges from more than 60% to 100% in different families when relatives are studied with electrocardiography and echocardiography. Investigation of first-degree relatives is necessary. Even if parents are normal by echocardiography, the possibility of new mutation cannot be excluded; thus, children born to an affected parent must be considered at risk and should be evaluated to facilitate early diagnosis and treatment.

- Hypertrophic cardiomyopathy is autosomal dominant.
- Investigation of first-degree relatives is necessary.
- Children of affected parents are at risk.

The course of the disease may be variable, even within a family; therefore, the age at onset cannot be predicted precisely.

- The course of hypertrophic cardiomyopathy is variable.
- The age at onset cannot be predicted.

Molecular defects in more than 10 different genes can cause hypertrophic cardiomyopathy. These genes include the β cardiac myosin heavy-chain gene, cardiac troponin T, troponin I, α-tropomyosin, myosin-binding protein C, ventricular myosin essential light chain, ventricular myosin-regulating light chain, α-actin, titin, and α-myosin heavy chain. In addition, genes that encode the γ_2 regulatory subunit of adenosine monophosphate-activated kinase and the X-linked lysosome-associated membrane protein 2 can cause a glycogen storage disease of the heart that can mimic hypertrophic cardiomyopathy.

Marfan Syndrome

The Marfan syndrome has an incidence of 1 in 10,000. It is an autosomal dominant disorder with variable expression, and approximately 20% of cases arise by new mutation. There are no well-documented instances of nonpenetrance.

- Marfan syndrome is relatively common—1 in 10,000.
- It is an autosomal dominant disorder.
- About 20% of cases arise by new mutation.

Marfan syndrome involves the musculoskeletal, ocular, and cardiovascular systems. Skeletal abnormalities include tall stature, a low upper:lower segment ratio (limbs are relatively long compared with the trunk), scoliosis or kyphosis, and pectus deformities. Increased joint laxity and hyperextensibility are common, but occasionally patients have limited extension of fingers and elbows. The face may be long and the palate highly arched. This marfanoid habitus may be present in patients with other disorders such as other connective tissue dysplasias, multiple endocrine neoplasia type 2B, Stickler syndrome, congenital contractural arachnodactyly, and homocystinuria. The characteristic body habitus is never sufficient evidence for making the diagnosis of Marfan syndrome in the absence of other criteria.

- Marfan syndrome involves the musculoskeletal, ocular, and cardiovascular systems.
- Typical case: tall stature, low upper:lower segment ratio, scoliosis or kyphosis, pectus deformities.

The ocular abnormalities associated with Marfan syndrome may include subluxation of the lenses, myopia, and retinal detachment. Dislocation of the lenses occurs in 50% to 80% of patients; the lens frequently is displaced upward. Gross dislocations may be evident without the aid of special equipment, but lesser degrees of dislocation may be evident only by slit-lamp examination. Therefore, all patients suspected of having Marfan syndrome must have a complete ophthalmologic evaluation. Patients with Marfan syndrome should have frequent ophthalmologic examinations to permit early detection of complications such as retinal detachment or glaucoma.

- Ocular abnormalities of Marfan syndrome: subluxation of lenses, myopia, retinal detachment.

- Dislocations of the lenses occur in 50%-80% of cases.
- All patients must have ophthalmologic evaluation.

The life expectancy of patients with Marfan syndrome is shortened because of cardiovascular disease. The most common manifestation is mitral valve prolapse with or without mitral regurgitation. Mitral valve prolapse in Marfan syndrome is progressive. Prophylactic antibiotic therapy for bacterial endocarditis is warranted. Acute onset of severe mitral regurgitation due to rupture of chordae tendineae may occur even in childhood. Mitral valve prolapse in a patient with a marfanoid body habitus is not a sufficient basis for the diagnosis of Marfan syndrome in the absence of a positive family history of Marfan syndrome or other characteristic findings. Patients with some forms of Ehlers-Danlos syndrome and nonspecific connective tissue dysplasias can have a similar body habitus, joint laxity, and mitral valve prolapse.

- Life expectancy in Marfan syndrome is shortened by cardiovascular disease.
- Mitral valve prolapse in Marfan syndrome is progressive.
- Prophylactic antibiotic for bacterial endocarditis is warranted.

Dilatation of the ascending aorta is the next most common cardiovascular disorder; it may lead to aortic regurgitation, aortic rupture, or dissecting aneurysm. More than 80% of patients have abnormalities found on echocardiography. Many patients have no evidence of cardiovascular disease on physical examination. The maximal aortic root diameter involves the region of the sinuses of Valsalva and sinotubular ridge. β-Adrenergic blockers appear to delay progressive dilatation.

- Most common cardiovascular manifestations are mitral valve prolapse and dilatation of ascending aorta.
- More than 80% of patients have abnormalities found on echocardiography.
- β-Adrenergic blockers might delay progressive dilatation.

Although surgical risks are increased in patients with Marfan syndrome because of tissue friability, surgical treatment frequently is successful for mitral and aortic regurgitation and for aortic dissection.

- Surgical risks are increased in Marfan syndrome.
- Surgical treatment is often successful for mitral and aortic regurgitation and aortic dissection.

Additional features sometimes associated with Marfan syndrome include decreased amounts of subcutaneous tissue, skin striae, inguinal hernias, pneumothorax, and degenerative joint disease.

Patients with Marfan syndrome are susceptible to traumatic aortic rupture; therefore, contact sports, strenuous physical exertion, and weight lifting should be restricted. Pregnancy poses significant risks for women with a dilated aorta.

The basic cause of Marfan syndrome is a defect in fibrillin; the gene encoding fibrillin is on chromosome 15q21. Mutations in the gene encoding transforming growth factor-β receptor 2 also can cause a marfan-like condition. Presymptomatic and prenatal diagnosis are possible in some families. However, because of limitations in molecular genetic testing, clinical criteria remain the appropriate basis for diagnosis. All first-degree relatives should be evaluated for signs of Marfan syndrome, including echocardiography and ophthalmologic examination.

- The cause of Marfan syndrome is a defect in fibrillin.
- Mutations in the gene encoding transforming growth factor-β receptor 2 also can cause a marfan-like condition.

Myotonic Dystrophy

Myotonic dystrophy, the most common form of muscular dystrophy in adults, has an incidence of approximately 1 per 8,000 to 20,000. The inheritance pattern is autosomal dominant with extremely variable expression. Although the average age at onset is in the second to third decade of life, the disease may be evident at birth or may first be noticed in the seventh decade. The disease is characterized by myotonia, muscle atrophy and weakness, ptosis of the eyelids, and expressionless facies resulting from particularly severe involvement of facial and temporal muscles. The rate of progression of the disease is variable, but disability is usually severe within 15 to 20 years after onset. Associated abnormalities may include premature frontal baldness, testicular atrophy or menstrual irregularities, gastrointestinal symptoms related to smooth muscle involvement, and cardiac disease. Distinctive refractile posterior subcapsular cataracts often are evident by slit-lamp examination. Although glucose intolerance is common, overt diabetes mellitus occurs in only about 6% of patients.

- Myotonic dystrophy is the most common form of muscular dystrophy in adults.
- The incidence is 1 in 8,000-20,000.
- The inheritance pattern is autosomal dominant with extremely variable expression.
- The age at onset is usually the second to third decade of life.
- Typical case: myotonia, muscle atrophy and weakness, ptosis of eyelids, expressionless facies, and premature frontal baldness.
- Disability is severe within 15-20 years after onset.
- Associated abnormalities: testicular atrophy or menstrual irregularities, gastrointestinal symptoms.
- Diabetes mellitus occurs in 6% of patients.

The diagnosis is based on clinical findings and a typical electromyographic pattern characterized by prolonged rhythmic discharges. The gene for myotonic dystrophy type 1 (*DMPK*) is located on chromosome 19q13, and genetic counseling is warranted for the patient and family. The molecular basis of most cases of myotonic dystrophy is expansion of a CTG trinucleotide repeat sequence affecting a gene encoding myotonin-protein kinase. Thus, direct DNA-based diagnosis of the disease is possible in most cases. The size of the trinucleotide repeat tends to increase as the genetic material is passed from one generation to the next. Increased repeat size tends to correlate with earlier onset and more severe disease, a

phenomenon referred to as "anticipation." First-degree relatives should be investigated. The risk for children born to an affected parent is 50%.

- The diagnosis of myotonic dystrophy is based on clinical and electromyographic findings or DNA analysis.
- Genetic counseling is warranted for patients and family members with myotonic dystrophy.
- First-degree relatives should be investigated.

Cardiac disease is present in approximately two-thirds of patients with myotonic dystrophy, and sudden death may occur as a result of conduction defects. Implantation of a pacemaker may be necessary. Central and alveolar hypoventilation is common and is a particular risk during recovery from anesthesia. Respiratory failure is a common cause of death.

- Cardiac disease occurs in two-thirds of patients with myotonic dystrophy, and sudden death may occur.
- Hypoventilation could complicate recovery from anesthesia.

Myotonic dystrophy type 2, sometimes referred to as proximal myotonic myopathy, is less common and is due to gene defects of zinc finger protein 9 on chromosome 3.

Neurofibromatosis

Type 1

Neurofibromatosis 1 is an autosomal dominant disorder with an incidence of 1 in 3,500. Approximately 50% of patients have the disease because of a new mutation. The disorder has markedly variable expression but very high penetrance. The diagnosis is based on two or more of the following clinical criteria: six or more café au lait macules of 1.5 cm or more in diameter, axillary or inguinal freckling, two or more Lisch nodules of the iris, two or more neurofibromas or one plexiform neurofibroma, a definitely positive family history, or one of these and one of the uncommon characteristic manifestations such as orbital or sphenoid wing dysplasia, optic or other central nervous system glioma, renal artery dysplasia with or without abdominal aortic coarctation, or tibial pseudofracture. Less specific signs of the disease may include pheochromocytoma and scoliosis. Malignancy, often neurofibrosarcoma, develops in fewer than 10% of patients. Patients should have, at minimum, an annual physical examination, including blood pressure check and thorough neurologic assessment. The gene has been identified and is a GTPase-activating protein involved in the ras signaling process. The gene is very large, and multiple different mutations have been identified. Therefore, DNA-based testing for direct diagnosis is difficult and usually not necessary unless prenatal diagnosis is desired.

- Neurofibromatosis 1 is autosomal dominant.
- The incidence is 1 in 3,500.
- The disorder has markedly variable expression but very high penetrance.
- Malignancy (often neurofibrosarcoma) develops in fewer than 10% of patients.
- Multiple different mutations have been identified.

Type 2

Neurofibromatosis 2 is an autosomal dominant disorder that is genetically distinct from neurofibromatosis 1. It is characterized by bilateral vestibular schwannomas (commonly referred to as "acoustic neuroma" in the past) or a family history of neurofibromatosis 2 with a unilateral vestibular schwannoma, or two of the following: meningioma, glioma, neurofibroma, schwannoma, or posterior subcapsular lenticular opacities. Spinal tumors occur in more than 60% of patients. Café au lait macules may or may not be present. The gene, referred to as "merlin," is localized to chromosome 22q12. In addition to occurring in the germline of patients with neurofibromatosis 2, acquired mutations in this gene occur in some sporadic meningiomas and schwannomas. DNA-based diagnosis is available by direct mutation analysis in many patients. Patients should have an annual physical examination with thorough neurologic assessment, monitoring of hearing, and magnetic resonance imaging of the head with gadolinium. Magnetic resonance imaging of the spine should be done in patients with newly diagnosed disease or patients with symptoms referable to the spinal cord.

- Neurofibromatosis 2 is autosomal dominant.
- Characteristics: vestibular schwannomas, sometimes nervous system gliomas, subcapsular cataracts.

Osteogenesis Imperfecta

Osteogenesis imperfecta is characterized by multiple bone fractures. Multiple types exist, with defects in the α_1 or α_2 chains of type I collagen. The most common form is due to an autosomal dominant disorder with mild to moderate severity. Some patients have opalescent teeth, blue sclerae, hearing loss, and increased bruisability.

Tuberous Sclerosis

Tuberous sclerosis is an autosomal dominant disorder with variable expression and high penetrance. Approximately 50% of cases arise by new mutation. Tuberous sclerosis is characterized by subependymal nodules of the brain, cortical or retinal tubers, seizures, mental retardation in less than 50%, depigmented "ash leaf" or "confetti" macules, facial angiofibromas, dental pits, subungual or periungual fibromas, shagreen patches, and renal cysts or angiomyolipomas. Cardiac rhabdomyomas are more frequent in the fetus and infant and often resolve with age. Pulmonary fibrosis resulting in a "honeycomb" appearance on radiography or computed tomography is more frequent in young women and tends to progress rapidly. Central nervous system astrocytomas may occur. One gene defect that causes tuberous sclerosis is located on chromosome 9 (hamartin), and another is located on chromosome 16 (tuberin).

- Tuberous sclerosis is autosomal dominant and has high penetrance.
- About 50% of cases arise by new mutation.
- Typical case: cortical or retinal tubers, seizures, mental retardation

in <50%, "ash leaf" macules, angiofibromas, subungual or periungual fibromas, shagreen patches, and renal cysts or angiomyolipomas.

Von Hippel-Lindau Disease

Von Hippel-Lindau disease is characterized by retinal, spinal cord, and cerebellar hemangioblastomas; cysts of the kidneys, pancreas, and epididymis; and renal cancers. Other manifestations include hemangioblastomas of the medulla oblongata, endolymphatic sac tumors, cysts and hemangiomas of other visceral organs, pancreatic cancer, and pheochromocytomas. Retinal hemangioblastomas may be the earliest manifestation. Annual ophthalmologic examination is important.

- Typical case: retinal, spinal cord, and cerebellar hemangioblastomas; cysts of kidneys, pancreas, and epididymis.
- Retinal hemangioblastomas may be the earliest manifestation of von Hippel-Lindau disease.

Hemangioblastomas of the central nervous system in von Hippel-Lindau disease are benign, and associated morbidity is due to space-occupying effects. They occur most frequently in the cerebellum and spinal cord but also can be in the medulla oblongata and rarely in the cerebrum. Periodic magnetic resonance imaging with gadolinium is recommended.

Renal cysts, hemangiomas, and benign adenomas are usually asymptomatic but occasionally are extensive and mimic polycystic kidney disease. Renal clear cell cancers can develop within the cysts and are bilateral or multiple in 40% to 87% of cases. They are the leading cause of death, which occurs at a mean age of 44 years. Annual imaging of the kidneys is important. Solid tumors of 3 cm or larger should be removed with nephron-sparing and partial nephrectomy whenever possible.

- Renal cysts, hemangiomas, and benign adenomas are usually asymptomatic in von Hippel-Lindau disease.
- Renal cancer is a major cause of death.

Inheritance is autosomal dominant, and the risk for any child born to an affected person is 50%. Expression is variable, and penetrance is high in thoroughly evaluated families. Males and females are affected equally.

- Von Hippel-Lindau disease is autosomal dominant.

The gene that causes von Hippel-Lindau disease (*VHL*) is localized to chromosome 3p25-26. The normal gene has a key role in cellular response to hypoxia and acts as a tumor suppressor. Presymptomatic and prenatal diagnosis by direct mutation analysis is possible for most patients.

Autosomal Recessive

Autosomal recessive disease occurs because of abnormal genes that are located on the autosomes. However, one copy of the abnormal gene is not sufficient to cause disease, and heterozygotes (carriers) are not clinically different from the general population. When two persons who are heterozygotes for a given gene defect mate, the children are at 25% risk of inheriting the abnormal gene from both parents and, thus, of having the disease.

- Autosomal recessive inheritance: abnormal genes are located on autosomes, but one copy of the abnormal gene is not sufficient to cause disease.
- Heterozygotes (carriers) are not clinically different from the general population.

Because the heterozygous state may be transmitted silently through many generations before the chance mating of two heterozygotes occurs, it is not surprising that there rarely is a family history of the disease in previous generations. The occurrence of multiple affected siblings within a family suggests autosomal recessive inheritance; however, because of the small average family size in the United States, many autosomal recessive diseases seem to occur as isolated cases.

The risk for the children of a person who has an autosomal recessive disease depends on the frequency of the abnormal gene in the population. Except for common diseases such as cystic fibrosis or sickle cell anemia, the risk is usually small, provided that the person does not marry a relative or a person who has a family history of the same disease.

Many diseases that are caused by an identified metabolic defect, such as homocystinuria, are autosomal recessive diseases due to an enzyme deficiency. When the enzymatic defect is established, carrier testing and prenatal diagnosis sometimes are possible.

Some of the diseases with autosomal recessive inheritance are listed in Table 9-2 and summarized on the following pages.

Friedreich Ataxia

This is an autosomal recessive disorder. The first sign of the disease is ataxic gait. The mean age at onset is approximately 12 years. Dysarthria, hypotonic muscle weakness, loss of vibration and position senses, and loss of deep tendon reflexes develop subsequently. In some patients, diabetes mellitus, nystagmus, optic atrophy, dementia, respiratory dysfunction due to kyphoscoliosis, and decreased sensory nerve conduction velocities also develop. The major cause of death is cardiomyopathy. Since detection of the gene defect, many atypical cases have been recognized, such as older age at onset or preservation of deep tendon reflexes.

- Friedreich ataxia is autosomal recessive.
- Typical clinical scenario: A 12-year-old child presents with an ataxic gait, dysarthria, hypotonic muscle weakness, loss of vibration and position senses, and loss of deep tendon reflexes develop subsequently.
- The major cause of death is cardiomyopathy.

In one series, 60 of 82 patients with Friedreich ataxia had clinical evidence of cardiac dysfunction 4 months to 4 years before death, and 56% died of heart failure. The mean age at death was 36.6 years. Cardiac arrhythmias, particularly atrial fibrillation, were common and occurred in 50% of fatal cases.

Table 9-2 Examples of Diseases With Autosomal Recessive Inheritance

Alkaptonuria
α_1-Antitrypsin deficiency
Cystic fibrosis
Familial Mediterranean fever
Friedreich ataxia
Gaucher disease
Glycogen storage disease, types I, II, III, IV, V, VII
Hemochromatosis
Homocystinuria
Oculocutaneous albinism
Phenylketonuria
Pseudoxanthoma elasticum (some forms are autosomal dominant)
Refsum disease
Sickle cell disease
Tay-Sachs disease
α- and β-Thalassemia (severe forms)
Wilson disease

- Cardiac arrhythmias occur in 50% of fatal cases of Friedreich ataxia.

The risk for a sibling being affected is 25%. The gene involved, *FXN*, is localized to chromosome 9q13. The most frequent mechanism of mutation is expansion of a GAA trinucleotide repeat that results in abnormal accumulation of intramitochondrial iron.

- The risk of Friedreich ataxia in a sibling of an affected person is 25%.

Gaucher Disease

Gaucher disease is an autosomal recessive disorder due to deficiency of the enzyme glucocerebrosidase, which results in lipid storage in the spleen, liver, bone marrow, and other organs. Type 1 (nonneuronopathic) disease is most frequent in Ashkenazi Jews (carrier frequency, 1 in 10). The disease may be asymptomatic at any age or present in childhood or adulthood with splenomegaly, hepatosplenomegaly, thrombocytopenia, anemia, degenerative bone disease, osteoporosis, or pulmonary disease. Type 2 (infantile, neuronopathic) has no ethnic predisposition, and type 3 (juvenile form) has intermediate clinical signs. The first sign of neurologic involvement in types 2 and 3 is supranuclear ophthalmoplegia. Enzyme replacement therapy is effective for nonneuronopathic Gaucher disease.

- Gaucher disease is autosomal recessive.
- The disease is due to deficiency of the enzyme glucocerebrosidase.
- Type 1 is most frequent in Ashkenazi Jews.
- Type 2 has no ethnic predisposition.
- The first sign of neurologic involvement in types 2 and 3 is supranuclear ophthalmoplegia.
- Enzyme replacement therapy is effective for nonneuronopathic Gaucher disease.

Glycogen Storage Diseases

Glycogen storage disease type I is due to deficiency of the enzyme glucose-6-phosphatase. It is characterized by hypoglycemia, hypercholesterolemia, hyperuricemia, lactic acidosis, short stature, hepatomegaly, and delayed onset of puberty. In adults with this disease, malignant hepatomas, premature coronary disease, pancreatitis, gout, and renal disease may develop.

- Glycogen storage disease type I is due to deficiency of the enzyme glucose-6-phosphatase.
- Characteristics: hypoglycemia, hypercholesterolemia, hyperuricemia, lactic acidosis, short stature, hepatomegaly, delayed puberty.

Glycogen storage disease type II (Pompe disease) is an autosomal recessive disorder due to deficiency of the lysosomal enzyme α-1,4-glucosidase (acid maltase). The infantile form is characterized by hypotonia, macroglossia, and progressive cardiomyopathy resulting in death within the first year of life. Enzyme replacement therapy is available.

- Glycogen storage disease type II is autosomal recessive.
- The disease is due to deficiency of the enzyme α-1,4-glucosidase.
- Characteristics of infantile form: hypotonia, macroglossia, progressive cardiomyopathy.

Juvenile and adult forms of glycogen storage disease type II also exist. The presenting characteristic is skeletal muscle weakness, and cardiac involvement usually is absent or minimal.

- Characteristics of juvenile and adult forms of glycogen storage disease: skeletal muscle weakness, minimal or absent cardiac involvement.

Glycogen storage disease type III is due to an autosomal recessively inherited deficiency of amylo-1,6-glucosidase (debrancher) activity. The enzyme is deficient in the liver, and in some patients also in skeletal muscle, cultured skin fibroblasts, and leukocytes. Clinically, the disorder is characterized by hepatomegaly and growth retardation that resolves at puberty. There may be hypoglycemia and hyperlipidemia. Skeletal muscle weakness may develop in adult life. Cardiomyopathy, when present, may be life-threatening and mimic hypertrophic cardiomyopathy. However, histologic evaluation of cardiac tissue reveals increased intracellular glycogen with no disarray of myofibers or myofibrils. Deficiency of the enzyme has been documented in cardiac muscle.

- Glycogen storage disease type III is autosomal recessive.
- The disease is due to deficiency of amylo-1,6-glucosidase activity.
- Characteristics: hepatomegaly and growth retardation that resolves at puberty.

Homocystinuria

The classic form of homocystinuria is due to an autosomal recessively inherited deficiency of cystathionine β-synthase. The incidence of the disease is approximately 1 per 200,000. Clinically, it is characterized by tall stature with a low upper segment:lower segment ratio, pectus deformities, scoliosis, genu valgum, pes planus, and a highly arched palate. Lens dislocation is progressive, and the direction of displacement is usually, but not always, downward. Myopia, retinal detachment, secondary glaucoma, fair hair and skin, cutaneous flushing, and hernias may be present. Only 50% of affected persons have mental subnormality.

- The incidence of homocystinuria is about 1 per 200,000.
- Typical case: tall stature, pectus deformities, scoliosis, genu valgum, pes planus, highly arched palate, lens dislocation.
- Lens dislocation is progressive.

Cardiovascular abnormalities include arterial or venous thrombosis, coronary occlusions at a young age, renal artery narrowing resulting in hypertension and renal atrophy, cerebrovascular accidents, thrombophlebitis, and pulmonary emboli. Dilatation of the pulmonary artery and left atrial endocardial fibroelastosis have been reported. Thrombi are particularly likely to occur after operation, venipuncture, or catheterization, and they are more common in persons who also have factor V Leiden deficiency.

- Cardiovascular abnormalities of homocystinuria: arterial or venous thrombosis and coronary occlusions at a young age.
- Thrombi are likely after operation, venipuncture, or catheterization.

Histologic examination of the arteries shows marked fibrous thickening of the intima. Aortic intimal fibrosis may be severe enough to mimic coarctation. Medial changes consist of thrombosis and dilatation with widely spaced, frayed muscle fibers. The elastic fibers of the large arteries may be fragmented, and dilatation of the ascending aorta has been observed.

The disease sometimes may be diagnosed from positive results of urinary nitroprusside test and confirmed by quantitative urinary homocystine determination. Levels of plasma homocysteine and its precursor, methionine, are increased. Testing of the plasma homocysteine level is the most sensitive, with levels of 50 to 200 μmol/L. This should not be confused with the lesser increases that occur in hyperhomocysteinemia. The goal of treatment is to lower the plasma homocysteine level, which seems to result in slower progression and fewer symptoms of the disease; 50% of patients respond to pyridoxine therapy (25-1,000 mg/day). Supplemental folate also should be given because patients who are potentially capable of responding to pyridoxine may not do so in the presence of folate deficiency. A low-protein, low-methionine diet can be useful, but adults find it difficult to comply with this. For infants, a low-methionine formula is available. Betaine is of benefit for decreasing plasma homocysteine levels.

- In homocystinuria, levels of plasma homocysteine and its precursor, methionine, are increased.
- The goal of treatment is to lower the plasma homocysteine level.

Mild hyperhomocysteinemia, sometimes associated with polymorphisms in methylenetetrahydrofolate reductase, is believed to be a risk factor for atherosclerosis but is a different condition.

Pseudoxanthoma Elasticum

There are two hereditary forms of pseudoxanthoma elasticum: autosomal dominant and autosomal recessive. Both forms are characterized by yellowish skin papules, especially on the neck and flexural areas, angioid streaks and choroiditis of the retina, and vascular complications, including angina pectoris, claudication, calcification of peripheral arteries, and renal vascular hypertension. The defective gene is *ABCC6* located on chromosome 16p13.1.

- Two hereditary forms of pseudoxanthoma elasticum: autosomal dominant and autosomal recessive.
- Characteristics: yellowish skin papules, angioid streaks and choroiditis of retina, and vascular complications.

Refsum Disease

Refsum disease is an autosomal recessive neurodegenerative disease characterized by cerebellar ataxia, hypertrophic polyneuropathy, and retinitis pigmentosa. Deafness, ichthyosis, and cardiac conduction defects are frequently present.

- Refsum disease is autosomal recessive.
- Typical case: cerebellar ataxia, hypertrophic polyneuropathy, retinitis pigmentosa.
- Frequently present: deafness, ichthyosis, cardiac conduction defects.

Phytanic acid is a fatty acid present in dairy products and fat from grazing animals. Patients with Refsum disease are deficient in the catabolic enzyme phytanic acid α-hydroxylase, which results in accumulation of ingested phytanic acid in fatty deposits in the involved organ systems.

- Patients with Refsum disease are deficient in phytanic acid α-hydroxylase.

Dietary restriction of phytanic acid results in clinical improvement and stabilization of the disease. Electrocardiographic changes sometimes resolve after treatment. Plasmapheresis removes phytanic acid from the body and may allow liberalization of the diet; it can be extremely valuable in the management of acutely ill patients.

Tay-Sachs Disease

Tay-Sachs disease is an autosomal recessive disease due to deficiency of hexosaminidase A. The classic infantile form of the disease is rapidly fatal and is due to storage of ganglioside GM_2 in neural tissue. It is particularly common in people of Ashkenazi Jewish ancestry; the carrier frequency is 1 in 30. Therefore, screening for carriers by determination of enzyme activity in serum (or leukocytes, particularly in pregnant women, in whom the serum level is unreliable) is

recommended in this population. Prenatal diagnosis is available when both the mother and the father are carriers.

In late-onset disease, the mean age at onset is 18 years, and loss of balance is the most frequent chief complaint. Cerebellar atrophy is almost always present. Anterior motor neuron involvement and psychotic episodes are also common.

- Tay-Sachs disease is autosomal recessive.
- The disease is due to deficiency of hexosaminidase A.

X-Linked Recessive

X-linked recessive diseases are caused by abnormal genes located on the X chromosome. Female heterozygotes who have one abnormal gene on one X chromosome and one normal gene on the other X chromosome usually are clinically normal. Exceptions may occur because of the phenomenon of lyonization, in which one X chromosome is inactivated at random early in fetal life; if the normal gene is inactivated in a critical number of cells, the woman may have symptoms or clinical signs of the disease. However, the disease usually is less severe than in males. The likelihood of clinical signs of the disease developing in a female varies by disease. For example, it is rare for female carriers of hemophilia A (factor VIII deficiency) to have severe bleeding problems, but it is relatively common for carriers of ornithine carbamoyltransferase (ornithine transcarbamoylase) deficiency to have intermittent symptoms.

- X-linked recessive diseases are caused by abnormal genes on the X chromosome.
- The development of clinical signs of the disease in a female varies by disease.

Males who inherit the abnormal gene have no corresponding genetic loci on the Y chromosome and therefore are referred to as "hemizygotes." Any male child born to a heterozygous female is at 50% risk for having the disease; female children are at 50% risk for inheriting the gene and being carriers. All the daughters of affected males are carriers, and all the sons are unaffected (i.e., male-to-male transmission cannot occur).

- Males with the abnormal gene are called "hemizygotes."
- A male child of a heterozygous female has a 50% risk of having the disease.
- A female child is at 50% risk of inheriting the gene.

X-linked recessive diseases also may arise by new mutation affecting either the mother or the afflicted son. Genetic counseling is difficult in these situations because if the mother represents the new mutation the risk for her future male children is 50%. However, if the child represents the new mutation, there is no significant risk for siblings of that child. DNA-based diagnosis allows for carrier detection for many diseases, which circumvents problems created by lyonization.

Some of the conditions with X-linked recessive inheritance are listed in Table 9-3 and summarized on the following pages.

Duchenne and Becker Muscular Dystrophies

Duchenne muscular dystrophy is one of the most common types of muscular dystrophy; its incidence is approximately 1 in 3,500 newborn males. Approximately a third of the cases arise by new mutation. Progressive skeletal weakness beginning at 2 to 5 years of age, with death in the late teens or 20s, is characteristic. The diagnosis is made on the basis of clinical findings and a markedly increased creatine kinase level. The muscle biopsy findings are relatively nonspecific. Becker muscular dystrophy has later onset.

- The incidence of Duchenne muscular dystrophy is 1 in 3,500 newborn males.
- Duchenne muscular dystrophy is X-linked recessive.
- Skeletal weakness at 2-5 years of age is characteristic.

The genetic defect that results in both Duchenne and Becker muscular dystrophies involves the dystrophin gene located on chromosome X at band p21. Approximately two-thirds of patients have a submicroscopic partial gene deletion, and the rest have undetected deletions, duplications, or other abnormalities. The dystrophin gene is very large, consisting of at least 60 exons and 1,800 kilobases. The protein product of this gene, dystrophin, is a rod-shaped cytoskeletal protein that is predominantly localized to the surface membrane of striated muscle cells. Identification of the molecular defect has resulted in improved ability to determine carrier status in female relatives by DNA analysis. This is a considerable improvement over carrier testing by measurement of creatine kinase levels, because levels are increased in only 70% of obligate carriers. DNA analysis also can be used for prenatal diagnosis. All males with Becker muscular dystrophy and the first-degree relatives of patients with Duchenne or Becker muscular dystrophy should have genetic counseling.

- Families in which Duchenne or Becker muscular dystrophy is present need genetic counseling.

The heart disease in patients with Duchenne or Becker muscular dystrophy is characterized by extensive changes in systolic time intervals, suggestive of compromised left ventricular function. There are

Table 9-3 Examples of Diseases With X-Linked Recessive Inheritance

Adrenoleukodystrophy ("X-linked" form)
Chronic granulomatous disease (many cases; autosomal recessive forms are less common)
Color blindness
Duchenne and Becker muscular dystrophies
Fabry disease
Glucose-6-phosphate dehydrogenase deficiency
Hemophilia A and B
Ocular albinism
Rickets, hypophosphatemic
Testicular feminization

histologic changes characterized by multifocal dystrophic areas with fibrosis and loss of myofilaments. These changes are most marked in the posterobasal segment and contiguous lateral and inferior walls of the left ventricle. Some families with dystrophin defects have dilated cardiomyopathy with or without serious skeletal muscle weakness.

- The heart disease in Duchenne muscular dystrophy involves changes in systolic time intervals and dilated cardiomyopathy.

Fabry Disease

Fabry disease is a lysosomal storage disease due to deficiency of α-galactosidase A. Females may have less severe signs of the disease than males. Glycosphingolipids accumulate in the endothelium, perithelium (layers of connective tissue that surround the capillaries and small blood vessels), and smooth muscle of blood vessels. There is also accumulation in ganglion cells, myocardial cells, reticuloendothelial cells, and connective tissue cells.

- Fabry disease is due to deficiency of α-galactosidase A.
- The disease is X-linked recessive.
- Females may have less severe signs of the disease than males.

Acroparesthesias and episodes of severe burning pain in the palms and soles with proximal radiation may occur in childhood and adolescence. The first signs of the disease may be telangiectatic angiokeratomas of the skin and mucous membranes. Sweating is impaired and patients may have recurrent abdominal pain with fevers. Whorl-shaped corneal opacities and cataracts develop. In adulthood, cardiovascular and renal diseases are the major causes of morbidity and mortality. Enzyme replacement therapy is available.

- The first signs of Fabry disease may be telangiectatic angiokeratomas of skin and mucous membranes.
- Acroparesthesias may occur in childhood and adolescence.
- Whorl-shaped corneal opacities and cataracts develop.
- In adults, cardiovascular and renal diseases develop.

Mitochondrial Mutations

Mitochondria each contain several circular copies of their own genetic material, mitochondrial DNA. This mitochondrial DNA is approximately 16,000 base pairs in length and encodes for transfer RNAs and 13 protein subunits of the mitochondrial respiratory chain. Many mitochondrial enzymes, including most others of the respiratory chain complex, are encoded by nuclear DNA and transported into the mitochondria. Mitochondrial DNA mutations cause Leber optic atrophy and the multisystem syndromes of mitochondrial myopathy, encephalopathy, episodes of lactic acidosis, and stroke (MELAS), myoclonic epilepsy with ragged red fibers (MERRF), and neuropathy, ataxia, and retinitis pigmentosa (NARP). Many cases of Kearns-Sayre syndrome (cardiomyopathy and ophthalmoplegia) are due to mitochondrial deletions. Clinically, they are very diverse and do not always conform to these well-delineated syndromes. For example, diabetes mellitus type 2 with sensorineural hearing loss or cardiomyopathy also may occur with the classic MERRF mutation. Lactic acidosis in peripheral blood or cerebrospinal fluid and ragged red fibers may or may not be present in the mitochondrial disorders. Mitochondrial disorders can arise as new mutations or be maternally inherited; in most cases, only the egg contributes mitochondria that persist in the zygote, and the sperm usually does not. Mitochondrial mutations may be homoplasmic (present in all mitochondrial DNA) or heteroplasmic (present in only some of the mitochondrial DNA).

- Mitochondrial DNA mutations cause Leber optic atrophy and multisystem syndromes.
- Many cases of Kearns-Sayre syndrome are due to mitochondrial deletions.
- Usually, only the egg contributes mitochondria that persist in the zygote.

Multifactorial Causation

Multifactorial means that the disease or trait is determined by the interaction of environmental influences and a polygenic (many gene) predisposition. Human conditions that may have multifactorial causation include many common birth defects—such as congenital heart defects, cleft lip and palate, and neural tube defects—and many common diseases—such as diabetes mellitus, asthma, hypertension, and coronary artery atherosclerosis.

- Multifactorial causation: disease or trait is due to environmental influences and a polygenic predisposition.
- Birth defects that may have multifactorial causation: congenital heart defects, cleft lip and palate, neural tube defects.
- Diseases that may have multifactorial causation: diabetes mellitus, asthma, hypertension, coronary artery atherosclerosis.

The multifactorial model predicts that there will be a tendency for familial aggregation of the condition but without a strict mendelian pattern of inheritance. Familial aggregation also can be due to common environmental factors; thus, familial aggregation by itself is not sufficient to prove multifactorial causation.

Because familial aggregation exists for multifactorial disorders, it is implicit that the occurrence risk will be increased for members of an affected family over that of the general population. As expected, the risk is highest for first-degree relatives (parents, siblings, children), who have half of their genes in common. The risk is less for second-degree relatives (grandparents, aunts, uncles, grandchildren, nephews, nieces), who share one-quarter of their genes. The risk decreases exponentially thereafter; third-degree relatives (great-grandparents, cousins, great-grandchildren) share only one-eighth of their genes. Empiric (observed) risk figures for some well-studied multifactorial disorders fit well with the predicted risks.

The genetic liability in multifactorial causation is due to the cumulative effect of many genes, each having a small effect, rather than to the effect of one major gene. These genes create a liability that presumably is continuously distributed within the population. If the genetic liability is strong enough, under an unfortunate set of environmental circumstances the disorder will occur.

- Genetic liability in multifactorial causation is due to cumulative effect of many genes.

For many multifactorial conditions, there is a difference in predilection between males and females which could result directly from genetic differences or from different internal (e.g., hormonal) or external environmental factors. Furthermore, if a member of the less commonly affected sex has the condition, his or her genetic liability was probably greater and therefore the risk for his or her relatives is greater. Similarly, if a person has a more severe form of the disease, the risk for relatives is higher. For disorders in which disease frequency increases with age, earlier onset sometimes implies a greater risk for relatives. Finally, the greater the number of affected individuals within the family, the higher the risk for other relatives. There also are racial differences in the frequency of many disorders of multifactorial causation.

Premature coronary atherosclerosis provides a well-known example of these concepts and thus makes them easy to remember. Multiple genetic and environmental risk factors, such as high level of low-density lipoprotein cholesterol, low level of high-density lipoprotein cholesterol, obesity, diabetes, and smoking, predispose to atherosclerosis. The risk for coronary disease in the siblings of an affected 50-year-old woman is greater than that for a similarly affected man of the same age, particularly if the disease is severe in the 50-year-old woman. A positive family history, regardless of cholesterol levels, is also a risk factor, such that multiple affected relatives indicate a higher risk.

When the inheritance pattern of any disease is being determined, the possibility of genetic heterogeneity always must be considered. For example, there are both autosomal dominant and multifactorial causes of atrial septal defect which may be indistinguishable clinically. Failure to recognize that different genetic diseases can cause the same or similar clinical entities can result in confusion when determining risks.

Table 9-4 lists some conditions of multifactorial causation.

Diagnosis of Genetic Disease by DNA Analysis

Diagnosis of genetic diseases with peripheral blood specimens or specimens obtained by amniocentesis or chorionic villus sampling has become a routine part of clinical practice because of the identification of the basic genetic defect underlying numerous mendelian conditions and the capability for direct DNA diagnosis. In addition, even when the causative genetic defect has not yet been identified, knowledge of the involved gene may allow for diagnosis by linkage analysis. Because individual genes are too small to be seen microscopically, standard chromosome analysis generally is not helpful even when the gene has been localized to a specific chromosome region.

Importance of an Accurate Clinical Diagnosis and Family History

The importance of a correct diagnosis in the index patient when diagnosis by DNA analysis is being contemplated cannot be overemphasized. This criterion is in contrast to many instances of genetic diagnosis by chromosome analysis in which the cytogeneticist usually can be relied on to note most abnormalities (fragile X and subtle deletions are examples of exceptions) regardless of the exact indication for the study. This approach is possible because the procedure of chromosome analysis involves examination of all 46 chromosomes in a given cell to look for gross structural changes. In contrast, it is impossible to systematically examine each of a person's 30,000 or more genes to detect all abnormalities.

- It is impossible to systematically examine each of a person's 30,000 genes.

The laboratory's process of detection of even one abnormal gene must be directed by the precise clinical diagnosis. The DNA-based assays are specific for the disease being studied, and abnormalities elsewhere in the genome will not be detected. Thus, if the incorrect assay is chosen because of an incorrect clinical diagnosis, the disease-causing mutation will not be detected. For example, if a patient is at risk for hypertrophic cardiomyopathy on the basis of a positive family history, it is important to know the exact molecular defect in an affected family member before molecular testing of the asymptomatic patient. Defects in at least 10 genes can cause hypertrophic cardiomyopathy, and others remain undiscovered. A normal result in an asymptomatic patient, at risk without the exact molecular diagnosis in the family, could mean either that the patient did not inherit the gene defect or that the gene defect in this particular family is not detectable with available tests.

In sporadic cases, the molecular diagnosis often can be established only for diseases for which direct DNA diagnosis is possible. In contrast, in families with multiple affected members, direct DNA diagnosis is the first choice when possible, followed by linkage analysis if the mutation cannot be directly identified. In these cases, an accurate family pedigree is essential. Diagnosis by linkage can be used only when there is no significant locus heterogeneity. For example, most patients with autosomal dominant polycystic kidney disease have a gene defect in *PKD1* on chromosome 16. However, up to 10% of families have a phenotypically similar disease due to a different, nonallelic genetic mutation. Thus, if a person who has a parent with polycystic kidney disease wants to know if he or she has inherited the gene defect, it should first be established whether the exact mutation can be found in the affected parent. There are numerous other

Table 9-4 Conditions of Multifactorial Causation

Cancer
Cardiac malformations
Cleft lip and palate
Diabetes mellitus
Hypertension
Neural tube defects
Schizophrenia

examples of this type of genetic heterogeneity, including retinitis pigmentosa, spinocerebellar ataxias, and Charcot-Marie-Tooth disease.

It is anticipated that the rapid advances made in molecular genetics in the past several years will accelerate as the genetic bases of additional diseases are identified and newer techniques for molecular diagnosis become available.

- Genetic heterogeneity can confound DNA studies.
- DNA-based diagnoses cannot be used for all families, even when DNA tests for a specific disease are available.

Linkage Analysis

Linkage analysis is based on the biologic fact that individual units of genetic material (genes) are situated in linear order on one of the 24 types of chromosomes (22 autosomes plus the X and Y chromosomes). Alleles are the different forms of genetic material at the same gene locus, for example, the A and B alleles at the ABO blood group locus. Genes located on different chromosomes segregate independently; there is a 50% chance that an individual egg or sperm will contain the same or different alleles encoded within these two chromosomal loci (Fig. 9-4).

- Alleles are different forms of genetic material at the same gene locus.

Genes located on the same chromosome are syntenic. During the pairing of homologous chromosomes during meiosis, crossovers can occur between genes even if they are located on the same chromosome. The average number of crossovers per chromosome per meiosis is two. Genes located far apart on the same chromosome are more likely to be separated by crossovers than are genes located close together. If the genes are so far apart that they are separated by crossovers at least 50% of the time, then these genes are not linked even though they are syntenic, and they exhibit random segregation (Fig. 9-5).

- Genes located on the same chromosome are syntenic.

Of course, linkage is not an all-or-none phenomenon. There is the potential for crossover to occur between any two gene loci, and this could happen in 20% of meioses, 2% of meioses, or 0.2% of meioses, for example, depending on the "distance" between them. Although physical distance is correlated with the likelihood of crossover, other factors such as location of the genes adjacent to the chromosome centromere and sex of the individual also influence the likelihood of crossover. Therefore, a measure of the functional likelihood of crossover, a centimorgan (cM), is used to describe the observed recombination rate. Thus, if crossovers occur in 10% of meioses, the loci are said to be 10 cM apart. On average, 1 cM corresponds to approximately 1,000 kilobases of DNA. The degree of linkage of specific genes must be generated from clinical observations in numerous families.

For tests used in clinical practice, it is important to know the frequency of crossovers occurring between the disease gene and the marker gene, because this is one factor that limits the accuracy of

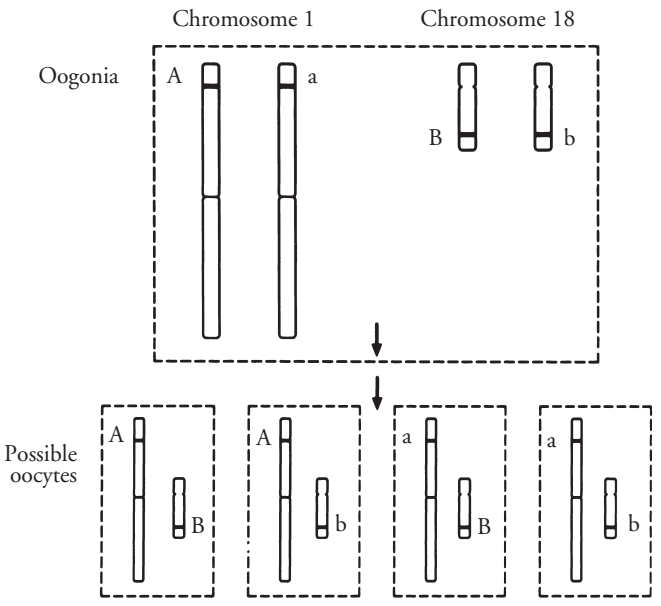

Fig. 9-4. Random segregation of gene locus on chromosome 1 in relation to gene locus on chromosome 18. There is a 50% chance that allele A will segregate with allele B or allele b. These loci are not syntenic and do not demonstrate linkage.

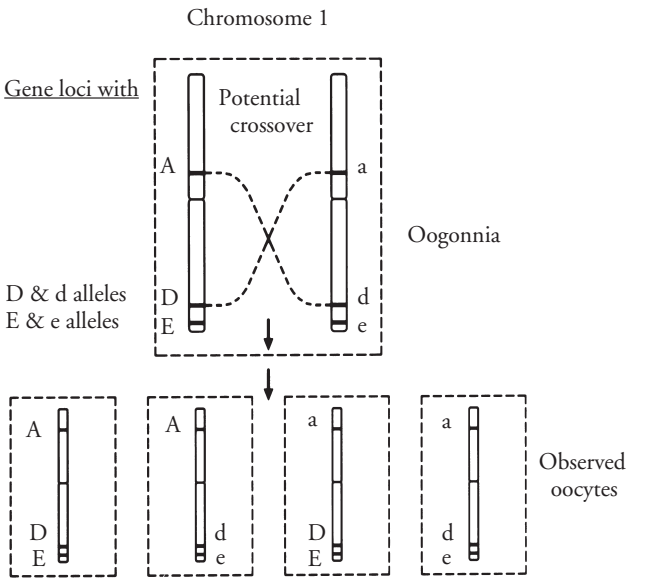

Fig. 9-5. Three gene loci on chromosome 1. Locus with allele A and allele a is located at sufficient distance from loci with alleles D/d and E/e that random segregation occurs. However, loci with alleles D/d and E/e always show D and E together or d and e together (not drawn to scale). Loci for D/d and E/e do not show random segregation and thus are linked.

the test. If the disease gene and the marker gene are 2 cM apart, it is important for the patient to know that the accuracy will be less than 98%. The use of flanking markers, that is, markers on both sides of the gene, if available, can help circumvent the problem of undetected crossovers. Although known genes sometimes are used for markers, more commonly DNA segments of unknown function are used for markers. These "anonymous" DNA segments, like genes themselves, can be highly variable in their nucleotide sequence. These normal variations are located extensively throughout the genome and can be recognized by one of many different kinds of bacterial enzymes that cut DNA at specified sites or by polymerase chain reaction. DNA polymorphisms located within the gene of interest are less likely to show recombination with the mutation site than those located adjacent to the gene (Fig. 9-6).

- The accuracy of linkage-based diagnosis is variable from one disease to another, depending on how tightly the disease gene and marker DNA are linked.

The size of the DNA fragments generated by these cutting enzymes varies among individuals because of normal variations in our DNA sequences. These different-sized fragments are referred to as restriction fragment length polymorphisms. These can be separated by size by electrophoresis on a gel. Once separated by size, the DNA fragments can be transferred to a nylon membrane as part of the procedure known as Southern blot analysis.

Southern Blot Procedure

After a patient's DNA has been extracted from peripheral blood lymphocytes, subjected to enzyme cutting, and electrophoresed to separate different sizes of DNA fragments, a radioactive probe for the disease gene or for the marker DNA segments is applied and hybridizes to the complementary DNA sequences of interest. The fragments then can be visualized on x-ray film. An example of linkage analysis by Southern blotting in a family with Duchenne muscular dystrophy is shown in Figure 9-7.

In addition to linkage analysis, Southern blotting can be used in some cases for direct detection of deletion or duplication types of mutations, or for single-base mutations if the enzyme restriction site is directly altered by the mutation. An example of direct detection of a deletion in a patient with Duchenne muscular dystrophy is shown in Figure 9-8.

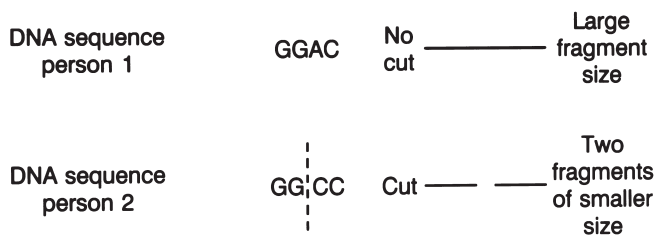

Fig. 9-6. Bacterial restriction enzyme *Hae* III. There are hundreds of types of bacterial enzymes that recognize and cleave specific DNA sequences. An appropriate enzyme that provides the most information for DNA markers near the disease gene of interest will be selected by the laboratory performing the test. Resulting fragments of differing sizes in different persons are restriction fragment length polymorphisms.

Polymerase Chain Reaction

Polymerase chain reaction (PCR) has had great impact on clinical practice and involves replication of a specific, relatively small segment of DNA in an exponential fashion, so that up to a billion copies are produced. One uses known DNA sequences from within the area of interest, and these known DNA sequences allow creation of synthetic oligonucleotides that serve as primers to hybridize with the patient's DNA sequence to initiate the amplification process (Fig. 9-9).

The multiple copies of the DNA segment that are produced by PCR then can be identified by various techniques, including direct visualization after gel electrophoresis. This allows detection of mutations in the patient's DNA. For example, PCR can be used for detection of mutations in specific regions of the dystrophin gene for the diagnosis of Duchenne muscular dystrophy and other diseases.

Diseases Amenable to DNA Diagnosis

The number of diseases that can be diagnosed with DNA analysis is increasing as additional disease genes are localized or identified and

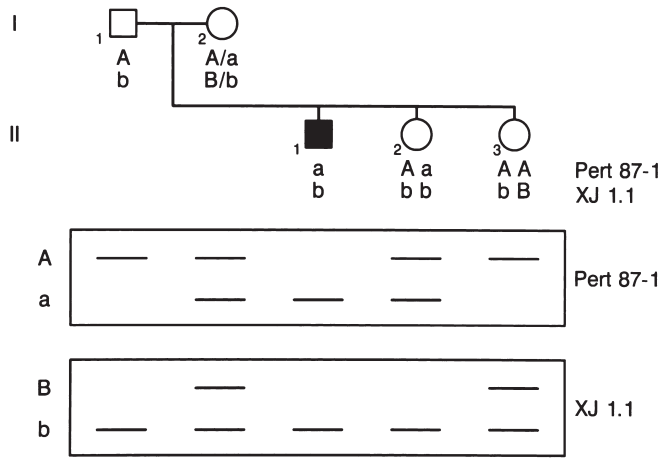

Fig. 9-7. Representation of a family segregating for Duchenne muscular dystrophy and data for two probes that detect restriction fragment length polymorphism, Pert 87-1 and XJ 1.1. Bottom half of figure represents Southern blot analysis of these two probes with arbitrary designation of alleles A/a for Pert 87-1 and B/b for XJ 1.1. Square, normal male; circle, female; shaded symbol, affected individual. Sister II.3 of affected male II.1 inherited Ab haplotype from her father and AB haplotype from her mother. Because her brother has ab haplotype, it can be predicted that she is not a carrier and her fetus is not at increased risk. Although sister II.2 did inherit the ab haplotype, it cannot be determined with certainty that she is a carrier because it is not known whether the mutation arose in the brother or whether the mother is a carrier. Sister II.2 could elect prenatal diagnosis, with the realization that males who inherit the ab haplotype might be affected or unaffected, whereas those who inherit the Ab haplotype would most likely be unaffected.

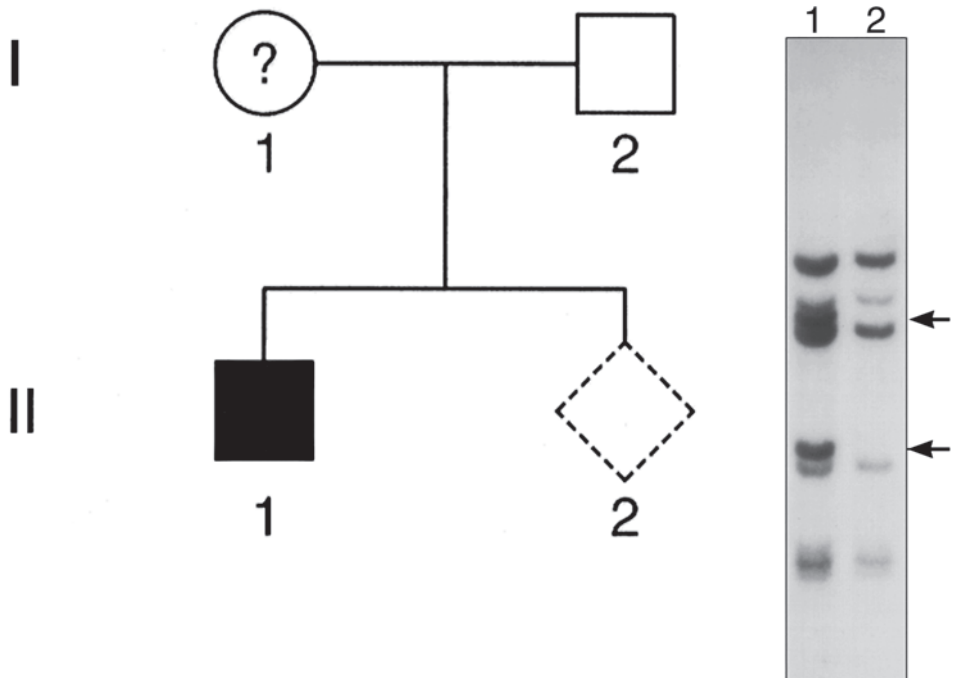

Fig. 9-8. Mother (I.1) of this patient (II.1) with sporadic Duchenne muscular dystrophy wanted to know whether she was a carrier or whether a new mutation had occurred in her son because of her concern for the risk for future children. Southern blot analysis detected a deletion in her son (II.1) (lane 2 as compared with control in lane 1). By densitometry, the mother seemed to have less than the expected amount of DNA (not shown) corresponding to her son's deletion. Thus, she was determined to be a carrier for the dystrophy and can be offered specific prenatal diagnosis. If no deletion had been detectable (by various methods), then her carrier status could not have been determined.

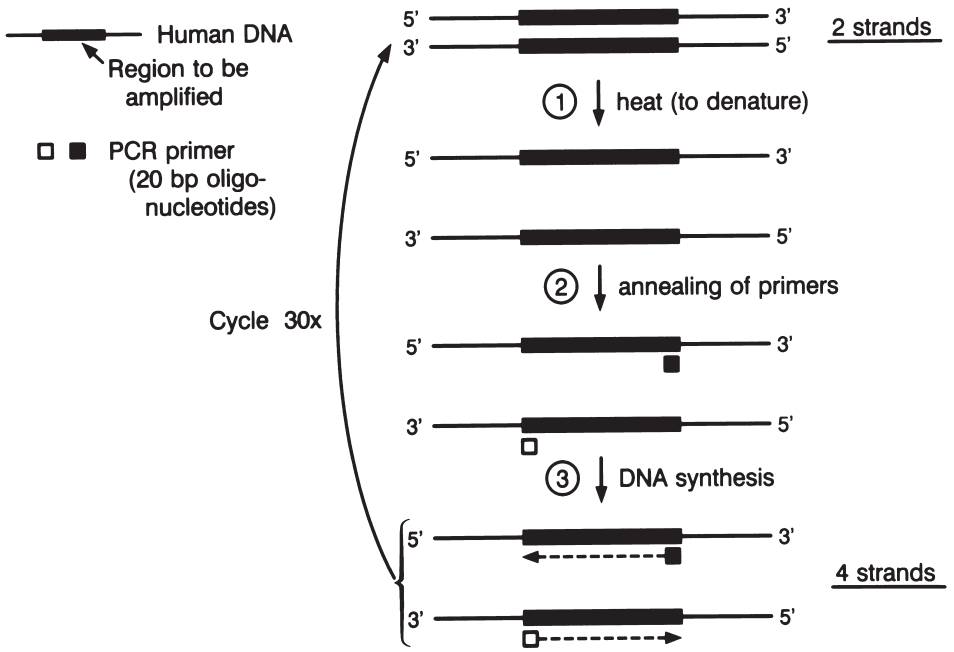

Fig. 9-9. Polymerase chain reaction (PCR) is used to make multiple copies of a short segment of the DNA of interest. DNA from the patient is denatured to single-stranded DNA in the presence of oligonucleotide primers. DNA sequences of these primers are made to specification to anneal with DNA sequences on both sides of the DNA segment of interest. DNA between these primers is then synthesized, and the entire process can be repeated automatically.

cloned. The physician who encounters a clinical situation for the first time which may be amenable to DNA-based diagnosis should discuss the testing procedure and its limitations with the laboratory personnel or a geneticist familiar with the details of the specific disease testing before a detailed discussion of the presymptomatic or prenatal diagnosis with the patient. Ideally, these discussions should take place before a woman becomes pregnant.

Diagnosis by Fluorescent In Situ Hybridization

Fluorescent in situ hybridization (FISH) is a cytogenetic technique that is being used with increasing frequency for diagnosis of certain congenital and malignant disorders. The technique uses DNA probes homologous to the DNA area of interest within the chromosome so the probe binds the DNA segment of interest. The DNA probe is labeled with a fluorophore so it can be visualized under the microscope. The probe can be designed to bind to a discrete region of a chromosome, as in the case of Sphrintzen velocardiofacial syndrome. This syndrome is caused by a microdeletion (i.e., a deletion otherwise too small to be seen under the microscope) (see Fig. 9-3). It is relatively common; the estimated frequency is approximately 1 in 4,000. This syndrome is characterized by a variable combination of subaverage intellect, a characteristic facial appearance, velopharyngeal incompetence resulting in nasal speech, cleft palate, mild-to-moderate hearing loss, predisposition to dental caries, congenital heart defect (especially tetralogy of Fallot), and increased risk for hypocalcemia. Many patients are so mildly affected that the syndrome is not diagnosed until they have a more severely affected child.

DNA probes also can be designed to "paint" an entire chromosome (whole chromosome paints) and are helpful for defining complex chromosome rearrangements, as can occur in some malignancies. Less commonly, DNA FISH probes can be used to identify single gene defects such as hereditary neuropathy with liability to pressure palsies due to deletion of peripheral myelin protein 22 on chromosome 17p11.2, or Charcot-Marie-Tooth disease type I due to a duplication of this gene.

Glossary

Autosome: A chromosome other than a sex chromosome.

Chromosome: Long strands of double-stranded DNA that encode genes and that are associated with a protein framework. A normal human has 46 chromosomes per cell.

Deletion: Structural abnormality in which part of a chromosome is missing.

Duplication: Structural abnormality in which an extra copy of part of a chromosome is present.

Epigenetic: Effect on the phenotype or gene expression that does not involve the DNA sequence.

Gene: A portion of DNA molecule that codes for a specific RNA or protein product.

Hemizygote: A person who has a gene form on one chromosome but no homologous chromosome with a corresponding gene site. The term usually refers to males because they have only one X chromosome.

Heterozygote: A person who has different gene forms at a given site on two homologous chromosomes.

Homozygote: A person who has the same gene forms at a given site on two homologous chromosomes.

Inversion: Structural abnormality characterized by reversal of a segment within the chromosome.

Karyotype: The chromosome complement of an individual person.

Linkage (genetic linkage): Physical proximity of two gene loci on the same chromosome such that segregation is nonrandom.

Phenotype: The observable biochemical or physical characteristics of an individual as determined by genetic material and environment.

Proband: The index patient.

Recurrence: Occurrence of another case of a specific condition in the same family.

Translocation: Structural abnormality characterized by transfer of a piece of one chromosome to another chromosome.

Geriatrics

Darryl S. Chutka, MD

Geriatric Assessment

The assessment of elderly patients should differ from that of the general examination of younger adults. The overall function of elderly patients is influenced by factors other than their medical diagnoses. When assessing the medical problems of elderly patients, it is important to assess additional factors: functional status, cognitive capacity, financial resources, and the safety and appropriateness of their domicile. It also is wise to address advance directives with all geriatric patients. Appropriate preventive screening should be a part of the assessment of the elderly who are in good health.

In addition to evaluating for conditions common to the geriatric population, such as heart disease, hypertension, diabetes mellitus, arthritis, and renal insufficiency, it is important to assess for conditions that can have a negative effect on function, such as impairment of vision or hearing (or both), mobility status, urinary incontinence, risk of falling, nutrition, and cognitive status. A thorough review of medications taken (prescription, herbal, and over-the-counter) is important.

- The overall function of elderly patients is influenced by factors other than medical problems.
- For elderly patients, it is important to assess functional status, cognitive capacity, financial resources, and the safety and appropriateness of their domicile.

Because the assessment of geriatric patients includes additional spheres of evaluation, the physician needs to become more efficient in the evaluation process. Previous medical records, paraprofessional interviews, screening tests, and patient questionnaires become valuable tools to expedite the history taking, thus allowing more time to focus on examining the patient and educating the patient on maintaining and improving function. These tools can decrease substantially the time required by the physician to obtain a thorough history, thus allowing the physician to concentrate on the physical examination and patient education about maintaining and improving function. A thorough geriatric assessment should include the following areas: vision, hearing, nutrition, continence, mobility and balance, medications, cognitive status, affect, functional status, social support, and advance directives.

Vision

Essentially all elderly patients have presbyopia, and the physician should determine whether the patient has access to proper assistive devices (reading glasses, magnifiers, and adequate light) to read. Assessment for other major eye diseases should be performed, including glaucoma, macular degeneration, and cataracts, because all these conditions increase in frequency with age and can markedly impair functional status.

Hearing

Impaired hearing is common among the elderly. In addition to periodic audiometric testing, it is important to ask the spouse or other family members if they are aware of the patient having any marked hearing loss. Patients often deny or minimize the symptoms of hearing impairment. Hearing impairment in the elderly is associated with decreased physical, social, and cognitive function. Improved hearing through the use of amplification devices improves the functional status of elderly persons.

Nutrition

Both undernutrition and obesity are common nutritional problems among the elderly and increase the risk of morbidity, mortality, and reduced functional status. Elderly patients should be asked about any weight changes during the past 3 months, and they should be weighed at every physician visit. Height should be checked annually. These measurements allow calculation of body mass index (weight in kilograms/height in meters squared). Laboratory markers that reflect undernutrition and have been correlated with increased mortality among the elderly include hypoalbuminemia and low serum levels of cholesterol.

Continence

Urinary incontinence is common among the elderly, especially older women. Incontinence impairs social function and is a common reason for nursing home placement. Most elderly will not bring up

the issue of urinary incontinence with their physician and assume that it is an expected result of aging. Therefore, it is important for physicians to ask patients about urinary incontinence.

Mobility and Balance

Impaired balance and mobility can reduce functional independence and are major risks for falls. Falls may also signify cardiac or neurologic dysfunction and may have serious sequelae. The patient should be asked about any recent falls and the circumstances surrounding them. The physician can perform simple tests of balance and gait. Lower extremity range of motion and strength should be assessed.

Medications

Polypharmacy is common among the elderly and can lead to serious drug-drug interactions and complications from adverse drug reactions. Patients should be asked about the medications they take, including prescription and nonprescription drugs and herbal products. Patients should be instructed to bring with them to the office all the medications they currently are taking or have taken recently so the physician can review them. The need for the medication, its dosage frequency, and potential to cause harm or to interact with other medications should be assessed. Also, consideration should be given to whether one medication may be substituted for two or more drugs.

Cognitive Status

Although cognitive impairment is obvious in some elderly, it may be difficult to diagnose in others, especially when mild. Cognitive impairment is more common with advancing age, and the screening yield is highest among those older than 85 years, among whom the prevalence of Alzheimer disease can exceed 40%. Several screening tests are available. Most commonly used is the Mini-Mental State Examination, a 30-point assessment of several components of cognitive function. Other screening tests include clock drawing and making change. Because these are screening tests, a normal result does not definitively rule out the possibility of dementia (but makes it less likely that the patient has marked cognitive impairment). If cognitive impairment is suspected but the results of mental status testing are normal, the patient should have formal psychometric cognitive testing, which is more sensitive.

Affect

Depression is common among the elderly and potentially can reduce functional status. It also may result in considerable morbidity and mortality. Several effective screening tests, such as the Geriatric Depression Scale, are available. Unexplained weight loss may be a clue to depression.

Functional Status

How an elderly person functions in the environment is an important component of the assessment. Functional status represents a combination of the person's medical condition and his or her interactions with the social environment. It is important to remember that an elderly person's functional state may change quickly, and various illnesses or prolonged hospitalization may cause a dramatic decline in functional status. The functional state is evaluated in three tiers: The basic activities of daily living are the most simple activities required to remain independent, such as eating, bathing, dressing, transferring, and toileting. The instrumental activities of daily living are the more complex activities required to maintain a household, such as shopping, driving, managing finances, and performing routine household chores. The advanced activities of daily living are the ability to function in the community and include the ability to hold a job or to participate in recreational activities. The environment of the patient should be assessed to determine whether the patient's functional state allows him or her to live safely in that environment.

Support Assessment

If an elderly patient has a compromised functional state, the degree of social support available for him or her should be determined. The physician needs to ascertain who is available to help with various tasks to keep the individual safe in an independent environment. Support usually includes family (most often an adult daughter), friends, and community services. A financial assessment should be made to determine whether the patient can afford treatments recommended by the physician or whether he or she qualifies for financial assistance from the government. A referral to social services may be needed to determine whether the patient meets the criteria for the benefits or services available.

Advance Directives

Advance directives should be discussed early with each elderly patient. It is important for the caregiver to know the patient's preferences should the patient become unable to make independent decisions because of an incapacitating illness. Living wills and a durable power of attorney for health care should be discussed and the directives reviewed periodically to determine whether the patient thinks they continue to reflect his or her wishes. These directives also should be reviewed any time a major change occurs in the medical or functional status of the patient.

- A thorough geriatric assessment should include an assessment of vision, hearing, nutrition, continence, mobility and balance, medications, cognitive status, affect, functional status, social support, and advance directives.

Falls

Falls are a common cause of morbidity and an important contribution to mortality among the elderly. Because falls increase in frequency with advancing age, the likelihood of injury from falls also increases. It is estimated that three-fourths of all deaths related to falls occur in persons older than 65 years. The increased frequency of falls among the elderly reflects multiple age-related changes, including decreased strength from loss of muscle mass, decreased visual and hearing acuity, decreased proprioception, and slowed reaction time. These changes can produce an alteration of gait and decreased balance in an elderly person.

Most falls (70%) occur in the person's home. An accident, usually related to hazards in the environment (throw rugs, slippery

floors, lack of grab bars in bathtubs, and inadequate lighting), is the most common cause of falls among the elderly who live independently. Most accidental falls occur while the person is performing typical daily activities such as walking or changing position (e.g., sitting to standing). An important percentage (10%) occur on stairs, more commonly while the person is descending the stairs. Falls that occur in nursing homes are more likely related to medical problems such as gait abnormalities, impaired balance, weakness, and confusion and are less likely to be caused by an environmental hazard. The common risk factors for falls include weakness of the legs (stroke or neuropathy), gait instability (Parkinson disease), balance disorder (vertigo or orthostatism), cognitive impairment (dementia), and the use of multiple medications. Medications that may contribute to falls include antihypertensive agents, diuretics, tricyclic antidepressants (which may produce orthostatic hypotension), sedative-hypnotics, ethanol, and neuroleptics (which may impair balance).

- Falls among the elderly usually reflect decreased strength from loss of muscle mass, decreased visual and hearing acuity, decreased proprioception, and slowed reaction time.
- Most falls (70%) occur in the person's home.
- Falls that occur in nursing homes are more likely related to medical problems.

Evaluation of Falls

A thorough medical history is the most important component of the assessment of a fall. If the reason for the fall is not known after the patient's history has been taken, it is unlikely that the cause will be found on physical examination or laboratory testing. The history should include the patient's perception of the cause of the fall, any warning symptoms the patient experienced before the fall, and any associated symptoms that occurred with the fall. The patient also should be questioned about how he or she felt immediately after the fall. Loss of consciousness may suggest a cardiac or neurologic event (arrhythmia, seizure, or cerebrovascular event).

The physical examination should include a neurologic examination that tests gait, balance, reflexes, sensory impairment, and extremity strength. Any sensory impairment should be noted. Because falls may be associated with acute illnesses, patients should be assessed for infections, myocardial infarction, and gastrointestinal tract hemorrhage. Orthostatic hypotension, although common among the elderly, also may indicate a medication effect or hypovolemia from hemorrhage or dehydration.

- A thorough medical history is the most important component of the assessment.
- The physical examination should include a neurologic examination that tests gait, balance, sensory impairment, and extremity strength.

Prevention and Treatment of Falls

The goal of the assessment of a fall is to decrease the likelihood of subsequent falls. The treatment plan is based on the findings of the assessment. However, more than one factor is often identified as contributing to falls. Potential interventions for the prevention of falls may include the following:

- Reduction in environmental hazards—provide adequate lighting, remove obstacles from floors, eliminate slippery floors, use appropriate footwear, eliminate bed side rails.
- Physical therapy—improve gait, balance, and strength, especially in the lower extremities.
- Assistive devices—improve gait and balance.
- Review of the medication program—avoid drug-drug interactions and eliminate potentially offending drugs.
- Treatment of medical problems that may contribute to falls (cataracts, postural hypotension, postprandial hypotension, Parkinson disease).

Syncope

Syncope is defined as a transient loss of consciousness with loss of postural tone. It becomes more common with advancing age and has many causes. Although the cause of the syncopal spell itself is usually benign, several serious consequences can result from the fall, including bone fracture and subdural hematoma. Regardless of the cause of syncope, the underlying mechanism is inadequate cerebral blood perfusion. It has been estimated that as many as one-third of syncope cases have a cardiac cause. These include valvular heart disease (aortic stenosis, mitral regurgitation, and mitral stenosis), hypertrophic cardiomyopathy, myocardial infarction, or cardiac arrhythmias (tachyarrhythmias or bradyarrhythmias). An orthostatic decrease in blood pressure is also common in the elderly because of changes in baroreceptor function. In addition, several disease states can be associated with orthostatic hypotension, including peripheral neuropathy, Parkinson disease, and Shy-Drager syndrome. Also, various medications can produce hypotension, including antihypertensive agents, tricyclic antidepressants, neuroleptics, and diuretics. Although vasovagal syncope is more common in younger persons, it can occur in the elderly. Carotid sinus hypersensitivity, an exaggerated hypotensive reflex that occurs in response to carotid sinus massage, also can cause syncope. Other exaggerated cardiovascular reflexes that can result in syncope include micturition, defecation, and coughing. Seizures, hypoxemia (pulmonary embolism or respiratory failure), severe hypoglycemia, and anemia also can produce syncope.

The medical history is the most important part of the evaluation of syncope; the physical examination should focus on the signs related to cardiovascular or neurologic disease. Orthostatic blood pressure should be measured. Findings from the history and physical examination should guide the selection of tests to be performed. Tests that may be of value are electrocardiography and, occasionally, ambulatory cardiac monitoring when a cardiac arrhythmia is suspected. Rarely, electrophysiologic studies should be considered. When neurologic abnormalities are found on examination, an imaging study (computed tomography or magnetic resonance imaging) of the head may yield important information. Electroencephalography is useful when a seizure disorder is thought to cause syncope. Laboratory blood tests do not commonly reveal the cause of syncope; however, several of these tests may be helpful in certain

circumstances. Blood count and electrolyte and creatinine determinations can give information about volume status. Measurement of cardiac enzymes may be useful if a recent myocardial infarction is suspected. Echocardiography should be performed if there is evidence of structural cardiac disease.

- It has been estimated that as many as one-third of the cases of syncope have a cardiac cause.
- Changes in baroreceptor function can result in an orthostatic decrease in blood pressure.
- The medical history is the most important part of the evaluation of syncope.

Vision Changes

A combination of anatomical and physiologic changes related to aging and various disease states common in the elderly frequently cause decreased vision. Vision loss increases with advancing age, and more than one-quarter of those older than 85 years report marked visual impairment. More than 90% of the elderly wear eyeglasses. It has been estimated that at least 25% of nursing home residents are legally blind. The most common eye problem in the elderly is presbyopia, difficulty with close focus. Presbyopia is the result of decreased lens flexibility, which occurs with aging. Cataracts are also more common with advancing age; they begin forming early in life, but the progression varies from person to person. The prevalence of cataracts is approximately 50% in those between 65 and 74 years old and up to 70% in those older than 75. Typically, cataracts produce a gradual reduction in visual acuity and represent opacities of the crystalline lens. In persons with early cataracts, near vision may actually improve; however, distant vision becomes blurred. This change occurs because of an increase in the convexity of the lens. Although cataracts are usually bilateral, one eye may be affected more than the other. Cataract surgery with intraocular lens implantation is effective for restoring visual acuity. The decision about the surgical treatment of cataracts should be individualized and based on the patient's disability.

Glaucoma is the most common cause of blindness worldwide and is characterized by increased intraocular pressure and associated optic nerve damage, manifested by cupping of the optic disk, atrophy of the optic nerve, and an associated reduction in the visual field. The two major types of glaucoma are chronic open-angle and angle-closure. Open-angle glaucoma is more common and occurs in up to 70% of adults with glaucoma. Chronic open-angle glaucoma produces a slow, progressive loss of peripheral vision that often is not appreciated by the patient until a considerable amount of vision is lost. Glaucoma is more common among African Americans than whites and is the most common cause of blindness in African Americans. In persons with the disease, a positive family history of glaucoma is very common. Open-angle glaucoma is associated with partial obstruction of aqueous humor flow through the trabecular meshwork. Funduscopic examination shows atrophy and cupping of the optic disk. Visual field testing documents typical peripheral field defects. A small number of patients with funduscopic or visual field changes of glaucoma have normal intraocular tension. If the physician routinely checks for glaucoma, it can be diagnosed and treated effectively before pronounced loss of vision occurs. The decision to treat glaucoma is not based only on the degree of increased ocular tension. Treatment is started when there is evidence of loss of vision or physical evidence of ocular damage.

Several options are available for the treatment of glaucoma, including surgery and medication. Medications are effective for decreasing the production of aqueous humor or for increasing its outflow. Pilocarpine causes pupillary constriction and opens the trabecular meshwork, resulting in increased flow of aqueous humor. β-Adrenergic blockers such as timolol decrease the production of aqueous humor, as do carbonic anhydrase inhibitors. Epinephrine decreases the production of aqueous humor and increases its flow. The goal of surgical treatment is to increase the flow of aqueous humor. Laser trabeculectomy is performed occasionally for open-angle glaucoma and usually is successful for increasing the outflow of aqueous humor.

Acute angle-closure glaucoma is much less common than chronic open-angle glaucoma and represents about 5% of glaucoma cases. It often presents after pupillary dilatation. It results from the obstruction of aqueous humor as it flows from the anterior chamber of the eye through the canal of Schlemm. This obstruction abruptly increases intraocular pressure. Patients with acute angle-closure glaucoma present with symptoms of intense eye pain, blurred vision with halos around lights, headache, and nausea. Physical examination reveals a slightly dilated pupil unresponsive to light. Urgent treatment is necessary to prevent permanent loss of vision.

Macular degeneration is the most important disease of the retina in the elderly. It is the leading cause of blindness in those older than 50. Macular degeneration is associated with the gradual and progressive loss of central vision, with sparing of peripheral vision. In addition to advanced age, macular degeneration has several risk factors, including a family history of macular degeneration, hyperopia, a light color of the iris, and chronic tobacco use. Although it initially tends to develop in one eye, it eventually becomes bilateral in many patients. It results in atrophy of the pigmented retinal epithelium. Impaired function of the photoreceptors eventually occurs, resulting in the characteristic loss of central vision and sparing of peripheral vision. The breakdown of the epithelium causes the deposition of drusen. The pathologic changes of macular degeneration generally can be seen on funduscopic examination. Laser treatment can be beneficial in some types of macular degeneration; however, the management of most patients with macular degeneration consists of devices used to assist vision, such as increased lighting and magnifying lenses.

- The most common eye problem in the elderly is presbyopia.
- Glaucoma is the most common cause of blindness worldwide. It is characterized by increased intraocular pressure and associated optic nerve damage.
- Chronic open-angle glaucoma is the most common form of glaucoma and produces a slow, progressive loss of peripheral vision.
- Macular degeneration is associated with the gradual and progressive loss of central vision and the sparing of peripheral vision.

Hearing Changes

Notable hearing loss in the elderly is common and usually due to a central auditory processing disorder, which causes difficulty with speech perception. The ability to discriminate speech is worse than predicted for the amount of pure tone lost. The prevalence of hearing loss, especially of high frequencies (presbycusis), increases markedly among persons older than 65 years and approaches 50% in those older than 80. Presbycusis is typically bilateral and associated with a high-frequency hearing loss. The cause is not known. Noise-induced hearing loss produces a similar high-frequency hearing loss. Elderly patients with a high-frequency hearing loss usually have the most difficulty with appreciating consonant sounds. A pronounced hearing impairment is thought to be present when there is a loss of 25 decibels or more at 500, 1,000, or 2,000 Hz. Speech typically occurs between 1,000 and 3,000 Hz.

Causes of conductive hearing loss include cerumen impaction, perforation of the tympanic membrane, cholesteatoma, Paget disease, and otosclerosis. Hearing aids may be beneficial, and many improvements have been made in these devices. Some models of hearing aids are able to select the optimal frequency amplification for the specific environment, and others can be programmed to amplify the specific frequencies that the patient has lost. A less complex version amplifies the higher frequencies, the frequencies most commonly lost with aging. Hearing aids are most beneficial when used in an environment with minimal background noise, for example, a one-on-one conversation in a quiet room. They are least helpful when used in crowds with extensive background noise.

- The prevalence of hearing loss, especially of high frequencies (presbycusis), increases markedly in the elderly.
- Causes of conductive hearing loss include cerumen impaction, perforation of the tympanic membrane, cholesteatoma, Paget disease, and otosclerosis.

Rheumatologic Problems

Rheumatologic problems are among the commonest complaints of the elderly. These diseases tend to be chronic and often accumulate with time. Although most of these diseases are not life-threatening, they commonly cause an alteration in lifestyle and lead to substantial disability.

Osteoarthritis

Osteoarthritis is extremely common among the elderly and is present to some degree in more than 80%. It produces joint symptoms that vary with time and degree of activity. Osteoarthritis usually can be differentiated from rheumatoid arthritis by the medical history and physical examination findings (Table 10-1). Osteoarthritis tends not to produce systemic symptoms, which are common in rheumatoid arthritis. Joint inflammation can occur in osteoarthritis, but it is more pronounced in rheumatoid arthritis. Although disease activity varies, acute worsening of a specific joint should make one suspicious of a superimposed crystalline arthritis (gout or pseudogout) or septic arthritis, which occasionally is found in patients with underlying chronic joint disease.

Osteoarthritis has a predilection for the hands (distal and proximal interphalangeal joints and first carpometacarpal joint of the thumb), knees, hips, and feet (first tarsometatarsal joint), with relative sparing of the elbow, wrist, metacarpophalangeal joints, and ankle. It has a typical radiographic appearance that includes asymmetrical narrowing of the joint space, presence of osteophytes, subchondral sclerosis, and cystic changes in the bone. Systemic symptoms do not occur. Joint pain is common with joint use and weight-bearing activity. Rest usually provides relief from the pain. The treatment of osteoarthritis includes adequate rest, local heat, and exercise to strengthen periarticular muscles, occasionally the injection of corticosteroids into the joint space when inflammation is present, and analgesics. Because joint inflammation is rarely marked in osteoarthritis, an analgesic such as acetaminophen should be tried initially for

Table 10-1 Comparison of Osteoarthritis and Rheumatoid Arthritis in the Elderly

Type of arthritis	Systemic symptoms	Joints involved	Joint findings	Radiographic appearance	Initial treatment
Osteoarthritis	No	Hands (DIPs > PIPs/MCPs), knees, feet	Marked joint inflammation uncommon	Asymmetrical joint space narrowing, osteophytes, subchondral sclerosis, cystic changes	Rest, heat, exercise to strengthen periarticular muscles, occasional intra-articular corticosteroids, analgesics
Rheumatoid arthritis	Yes, plus extra-articular manifestations	Symmetrical distal joints Hands (MCPs > DIPs/PIPs	Inflammation common	Symmetrical joint space narrowing	Nonsteroidal anti-inflammatory drugs

DIP, distal interphalangeal; MCP, metacarpophalangeal; PIP, proximal interphalangeal.

pain relief. Once this has been tried and thought to be ineffective for managing the pain, more aggressive treatment should be used. Nonsteroidal anti-inflammatory drugs can be effective; however, they carry a risk of important adverse effects, especially when taken chronically. If nonsteroidal anti-inflammatory drugs are not tolerated or are ineffective, alternative treatment may include tramadol or codeine. Combinations of these drugs with low doses of acetaminophen may be helpful. Occasionally, corticosteroid may be injected into individual joints for temporary relief of pain. Some patients with knee osteoarthritis receive relief with injections of hyaluronic acid.

- Osteoarthritis usually can be differentiated from rheumatoid arthritis by the medical history and physical examination findings.
- Marked joint inflammation in osteoarthritis is uncommon.
- Radiographic findings in osteoarthritis include asymmetrical narrowing of the joint space, osteophytes, subchondral sclerosis, and cystic bone changes.

Rheumatoid Arthritis

Rheumatoid arthritis is often found in elderly patients, most commonly as a chronic disease that was acquired earlier in life. It also can develop later in life and has two presentations. As in younger persons, it may present with symmetrical distal joint inflammation, positive rheumatoid factor, and a tendency to progress with time. The second presentation is common in the elderly and consists of the acute onset of proximal joint pain and stiffness, which can be very similar to polymyalgia rheumatica. Testing for rheumatoid factor often gives negative results, and rheumatoid nodules are often absent. In contrast to osteoarthritis, patients with rheumatoid arthritis have systemic symptoms. Extra-articular manifestations are occasionally present with rheumatoid arthritis and include potential involvement of the skin (rheumatoid nodules), lung (fibrosis, rheumatoid nodules, and pleural effusions), blood vessels (vasculitis), nervous system (mononeuritis multiplex), and hematologic system (Felty syndrome). Sjögren syndrome (splenomegaly and leukopenia) also occasionally accompanies rheumatoid arthritis. Radiographs of joints involved by rheumatoid arthritis characteristically show symmetrical narrowing of the joint space. Demonstrating inflammatory, symmetrical arthritis on physical examination usually confirms the diagnosis. Laboratory test results often can be misleading in the elderly. Testing for rheumatoid factor is often negative in many elderly patients with rheumatoid arthritis. The test result can be false-positive in many elderly patients who do not have the disease, although the rheumatoid factor usually is of low titer. Elderly patients with rheumatoid arthritis receive the same therapeutic agents as younger patients: nonsteroidal anti-inflammatory drugs, chloroquine, methotrexate, gold, and low doses (5-7.5 mg daily) of corticosteroids.

- Patients with rheumatoid arthritis often have systemic symptoms.
- Extra-articular manifestations are occasionally present.
- Radiographically, rheumatoid arthritis characteristically shows symmetrical narrowing of the joint space.
- The elderly with rheumatoid arthritis receive the same therapeutic agents as younger patients.

Crystalline Arthropathy

Crystalline arthropathy is common among the elderly (Table 10-2). Whereas gout tends to be more common in men and to involve more distal joints (especially the great toe), pseudogout is more common in women and tends to involve more proximal joints (especially the knee and wrist).

Gout is usually a monoarticular arthritis, although uncommonly presents as a polyarticular disease. It is caused by intra-articular deposition of uric acid crystals. It is associated with hyperuricemia, which may be produced by thiazide diuretics. Gouty attacks may be precipitated by stressful events such as surgery, severe illnesses, or trauma. Although gout usually is diagnosed on the basis of the medical history and physical examination, the diagnosis is confirmed by microscopic evaluation of the synovial fluid from an affected joint. Urate crystals are long and needle-shaped and negatively birefringent with polarizing microscopy. Treatment for an acute attack of gout includes nonsteroidal anti-inflammatory drugs. Colchicine, orally or intravenously, may be given to patients who should not receive nonsteroidal anti-inflammatory drugs. In some circumstances, intra-articular or systemic corticosteroids may be necessary. This

Table 10-2 Crystalline Arthritis

Crystalline arthritis	Gender distribution	Joint involvement	Crystal	Crystal characteristics	Initial treatment
Gout	Male > female	Distal joints, expecially great toe	Uric acid	Long, needle-shaped, negative birefringence	NSAIDs ± intra-articular or systemic corticosteroids, colchicine
Calcium pyrophosphate deposition disease (pseudogout)	Female > male	Proximal joints, especially knee and wrist	Calcium pyrophosphate	Rectangular, positive birefringence	NSAIDs or intra-articular corticosteroids

NSAID, nonsteroidal anti-inflammatory drug.

may be preferred for some elderly patients because of the high incidence of gastrointestinal or renal adverse effects. Long-term suppressive therapy usually is not initiated until several acute episodes of gout have occurred. Suppressive therapy may include allopurinol or probenecid daily or low doses of oral colchicine. Treatment of asymptomatic hyperuricemia is rarely necessary, although it is initiated in patients with uric acid renal stones or, occasionally, when starting chemotherapy for various hematologic malignancies.

- Gout tends to be more common in men and to involve more distal joints.
- Urate crystals are needle-shaped and negatively birefringent with polarizing microscopy.
- Treatment for an acute attack of gout includes nonsteroidal anti-inflammatory drugs, colchicine, or, in some cases, intra-articular or systemic corticosteroids.

Pseudogout (calcium pyrophosphate deposition disease) is usually a monoarticular arthritis that most frequently involves the knee or wrist. As with gout, an acute attack can occur with a stressful event such as surgery, trauma, or illness. Radiographs of joints with pseudogout often show linear articular calcification, although approximately 25% of the elderly have articular calcification with no clinical evidence of the disease. Calcium pyrophosphate crystals are rectangular and exhibit positive birefringence with polarizing microscopy. An acute attack is treated with nonsteroidal anti-inflammatory drugs or corticosteroids injected into the affected joints. Daily therapy with a low dose of colchicine may decrease the frequency of acute attacks.

- Pseudogout is usually a monoarticular arthritis, most commonly involving the knee or wrist.
- Calcium pyrophosphate crystals are rectangular and exhibit positive birefringence with polarizing microscopy.
- An acute attack is treated with nonsteroidal anti-inflammatory drugs or corticosteroids injected into the affected joints.

Polymyalgia Rheumatica and Temporal Arteritis

Polymyalgia rheumatica and temporal arteritis occur more commonly in women than in men and in persons older than 50 years. Patients with polymyalgia rheumatica describe stiffness, aching, and weakness of proximal muscles (shoulders and hips), especially in the morning. This is thought to be due to synovitis of the shoulder or hip joint (or both). The clinical presentation of polymyalgia rheumatica may be very similar to that of rheumatoid arthritis in the elderly. Patients also may complain of nonspecific malaise, fatigue, low-grade fever, and anorexia with weight loss. Although patients commonly describe weakness, muscle strength is normal when tested. The diagnosis usually is suspected from the classic history obtained from the patient; no specific laboratory test is diagnostic for the disease. Patients usually have an increased erythrocyte sedimentation rate and, occasionally, mild anemia. The levels of muscle enzymes (creatine kinase and aspartate aminotransferase) are not increased. The response to treatment is very characteristic and often can be used to support the diagnosis. Treatment with low doses of oral corticosteroids (prednisone, 15-20 mg daily) produces dramatic improvement in symptoms, often within 24 hours. After treatment has been initiated, the corticosteroid dose can be tapered gradually, using the patient's clinical response and erythrocyte sedimentation rate as indicators of disease activity.

- Patients with polymyalgia rheumatica describe stiffness, aching, and weakness of proximal muscles.
- Patients usually have an increased erythrocyte sedimentation rate and, occasionally, mild anemia.
- Treatment with low doses of oral corticosteroids produces dramatic improvement in symptoms.

Temporal arteritis develops in about 15% of patients with polymyalgia rheumatica. Pathologically, there is inflammation of medium-sized arteries, which arise from the aortic arch. Systemic symptoms include low-grade fever and fatigue; anorexia with weight loss is also common. A majority of patients have a unilateral or bilateral headache, usually in the temporal area. Many also have scalp tenderness and jaw claudication due to facial artery involvement with disease. Loss of vision, including unilateral or bilateral visual blurring, visual field loss, diplopia, or blindness caused by ischemic optic neuritis, may occur and is the most worrisome symptom. As with polymyalgia rheumatica, temporal arteritis usually is suspected on the basis of the patient's description of the symptoms. Few findings are documented on physical examination. Some patients have tender, swollen, or pulseless temporal arteries. Rarely, bruits may be heard over medium-sized arteries involved by the disease. Although no diagnostic laboratory test is specific for temporal arteritis, almost all patients have a markedly increased erythrocyte sedimentation rate, often greater than 100 mm/h. Mild anemia also may be present. After temporal arteritis is suspected, the diagnosis should be confirmed with temporal artery biopsy. A 4- to 5-cm piece of temporal artery should be obtained, initially on the side of the patient's symptoms. If the pathologic findings are negative, a similar biopsy should be performed on the opposite side. The inflammatory changes in the artery may be spotty or confined to a small portion of the artery, occasionally causing difficulty in confirming the diagnosis pathologically. Temporal artery biopsy should not be performed routinely in those with polymyalgia rheumatica without symptoms of temporal arteritis. Treatment consists of prednisone, 60 mg daily, and may be started before the biopsy sample is obtained, assuming the biopsy is to be performed within 48 hours. The prednisone dose should be tapered on the basis of an assessment of the patient's clinical response to treatment as well as the response of the erythrocyte sedimentation rate.

- Temporal arteritis develops in about 15% of patients with polymyalgia rheumatica.
- Symptoms include low-grade fever, fatigue, anorexia with weight loss, unilateral or bilateral headache, scalp tenderness, and jaw claudication.
- The diagnosis should be confirmed with temporal artery biopsy.
- Treatment consists of high doses of corticosteroids.

Thyroid Disease

Thyroid disease becomes more common with advancing age. Most elderly patients with hyperthyroidism present with typical findings. A small but important percentage have atypical symptoms. Some elderly persons have anorexia with weight loss, altered stool frequency (either diarrhea or constipation), or cardiovascular abnormalities, including hypertension, increased angina, myocardial ischemia, congestive heart failure, and atrial fibrillation. Other symptoms that may develop include apathy, depression, tremor, and myopathy. Decrease in bone density is accelerated with hyperthyroidism. Ophthalmopathy, lid lag, tachycardia, and increased perspiration are relatively more uncommon in the elderly than in younger patients. The development of a goiter with hyperthyroidism is noted in about 60% of the elderly. The commonest cause of hyperthyroidism in the elderly is Graves disease. Radioiodine is the treatment of choice for hyperthyroidism in elderly patients.

- Most elderly patients with hyperthyroidism present with the typical findings, although they may develop apathy, depression, tremor, and myopathy.
- The commonest cause of hyperthyroidism in the elderly is Graves disease.
- Radioiodine is the treatment of choice for hyperthyroidism.

The diagnosis of hypothyroidism in elderly patients is usually made by finding an increased level of sensitive thyroid-stimulating hormone (sTSH) on laboratory testing of asymptomatic patients. The common symptoms of hypothyroidism are vague (constipation, cold intolerance, and dry skin) and often attributed to the many "symptoms of aging." Almost all these cases of hypothyroidism are due to primary thyroid failure rather than to pituitary or hypothalamic insufficiency. The commonest cause of hypothyroidism in the elderly is Hashimoto thyroiditis. Treatment should begin with a low dose of thyroid supplement (25-50 µg daily) that is increased by 25 µg every 3 to 4 weeks. Patients with coronary artery disease should receive an even lower starting dose and more gradual dose increments because thyroid replacement that is too rapid can precipitate cardiac ischemia. It takes 6 to 8 weeks for a given dose of thyroid supplement to equilibrate; therefore, the sTSH values should not be checked before this time to assess whether the dose of thyroid supplement is correct. Thyroid hormone requirements decrease with advancing age, and most elderly require 75 to 100 µg daily; however, some require as little as 50 µg daily. Subclinical hypothyroidism can be found in approximately 15% of the elderly. These patients are clinically euthyroid and have a low-normal total (serum) thyroxine (T_4) level and a slightly increased sTSH level. Whether to treat these patients is a matter of controversy. Patients with an sTSH value less than 6 mIU/L and negative microsomal antibodies rarely have progression to clinical hypothyroidism. Most physicians choose to observe patients who have modest increases in sTSH (<10 mIU/L) unless symptoms of hypothyroidism develop or the sTSH level continues to increase.

- The common symptoms of hypothyroidism are vague and often attributed to symptoms of aging.
- The commonest cause of hypothyroidism in the elderly is Hashimoto thyroiditis.
- Treatment of hypothyroidism should begin with a low dose of thyroid supplement (25-50 µg daily) that is increased by 25 µg every 3 to 4 weeks.

Euthyroid sick syndrome is common in elderly hospitalized patients. Patients are clinically euthyroid but have low serum levels of triiodothyronine (T_3) and T_4 and a low-normal level of sTSH. Laboratory values tend to return to normal after the patient has recovered from the illness. The syndrome may be caused by a decreased amount of thyroid-binding protein and a substance that inhibits T_4 binding.

- Patients with euthyroid sick syndrome are clinically euthyroid but have low serum levels of T_3 and T_4 and a low-normal level of sTSH.

Sexual Function and Sexuality

Multiple physical and social changes occur with aging that can result in changes in the desire and capacity of an older person for sexual activity. Although there is evidence that interest in sexuality is retained well into older age, for several reasons the frequency of sexual activity tends to be reduced with aging. Whereas this is true for the elderly population in general, there is great variability in sexual interest and activity from one elderly person to another. One of the most important factors that may determine whether a person is sexually active is the availability of a partner who is capable of sexual activity. The setting in which the elderly live may also have a role in whether a person is sexually active. Many elderly live in an environment in which sexual activity is difficult or not condoned (e.g., in a nursing home or in the home of their children). Because privacy may not be possible in these settings, intimacy is unlikely to occur.

Little is known about the influence of sex hormones on libido for either the male or the female. Although it is not thought that the presence of estrogen or progestin is primarily responsible for sexual desire in females, evidence suggests that androgens increase sexual interest. Lack of estrogen can produce reduced vaginal lubrication and mucosal atrophy, which can cause dyspareunia. Painful conditions such as osteoarthritis also may contribute to diminishing desire for sexual activity.

Erectile dysfunction increases in frequency with advancing age and is the most common reason for a man to reduce his degree of sexual activity. It may be related to psychosocial as well as to physical factors. An erection is the result of a combination of neurologic and vascular activity, which may be impaired with aging.

With age, testosterone levels tend to decrease in males. This age-related change does not seem to be related to erectile dysfunction; however, it may decrease interest in sexual activity. Many cases of erectile dysfunction are associated with complications of atherosclerotic disease such as coronary artery disease, peripheral arterial disease, and stroke. Hypertension and antihypertensive medications also have been associated with erectile dysfunction. Diabetes mellitus is associated with a high incidence of erectile dysfunction, which

may be due to the vascular or neurologic complications (or both) of diabetes.

The evaluation of a patient with erectile dysfunction begins with a medical history. The patient's libido should be assessed, as should the frequency and quality of erections. Hypogonadism should be suspected when a marked reduction in libido has occurred. This also may be caused by depression. Critical to the evaluation of sexual dysfunction is a careful assessment of medications, alcohol intake, and a history of diseases that can cause erectile dysfunction. Medications that have been associated with erectile dysfunction include antihypertensive agents, phenothiazines, antidepressants, histamine$_2$-receptor antagonists, digoxin, and clofibrate. Symptoms of medical problems such as diabetes mellitus, peripheral neuropathy, peripheral arterial disease, hypertension, thyroid disease (both hypothyroidism and hyperthyroidism), and uremia should be sought. The physical examination should concentrate on findings that suggest the presence of hypogonadism, peripheral arterial disease, or peripheral neuropathy. Appropriate laboratory tests should include determination of sTSH, fasting blood glucose, and total and bioavailable testosterone levels. When hypogonadism is suspected, luteinizing hormone and prolactin levels should be determined. Nocturnal penile tumescence testing is considered unreliable and does not reliably distinguish between psychogenic and organic causes. A duplex scan of the penile arteries can be useful to assess blood flow to the penis. This test can be performed before and after vasodilator therapy and can predict the response to this therapy.

Treatment for erectile dysfunction includes both mechanical and pharmacologic therapies. Appropriate treatment for specific medical disorders that can be associated with erectile dysfunction should be started. Patients with hypogonadism should be given androgens. Androgens alone should not be expected to reverse erectile dysfunction. Vacuum devices are safe and relatively effective for any cause of erectile dysfunction. Intracorporeal injection of prostaglandin E_1 is also effective for producing a sustained erection. Patients tend to lose their enthusiasm for injections with time, probably because of the relatively invasive nature of the treatment. Sildenafil was the first oral medication approved for the treatment of erectile dysfunction. Currently, vardenafil and tadalafil are also available. They are effective in a majority of patients regardless of the underlying cause. They inhibit the breakdown of cyclic guanosine monophosphate and improve blood flow to the penis. Because of the potential for hypotension, they are contraindicated in persons receiving nitrate therapy. Vardenafil and tadalafil should not be used in individuals taking α-adrenergic antagonists because of a potential for hypotension. The risk of adverse effects associated with these medications may be increased in patients with coronary artery disease.

- One of the most important factors that may determine whether a person is sexually active is the availability of a partner.
- With age, testosterone levels tend to decrease in males and do not appear to be related to erectile dysfunction.
- Treatment for erectile dysfunction includes both mechanical and pharmacologic therapies.

Dementia

Dementia is an acquired cognitive impairment that affects all spheres of the intellect. It is a gradually progressive disorder and becomes more common with increasing age. Approximately 10% of the population older than 65 years has some degree of dementia. The number increases with age and has been reported to be as high as 50% among those older than 90 years. Dementia involves considerably more than the loss of memory. Other cognitive functions that are affected include judgment, abstract thinking, attention, ability to learn new material, and, eventually, the recognition and production of speech. Personality changes frequently accompany dementia. The commonest form of irreversible dementia is Alzheimer disease (50%-70% of cases), followed by vascular dementia (15%-25%). In the recent past, the prevalence of reversible dementias was thought to be as high as 30%. Currently, it is believed that in most patients with some reversibility in cognitive impairment, the improvement is only transient and in most of the patients irreversible dementia eventually develops. The prevalence of truly reversible dementia is low, from 1% to 2%. The most common causes of potentially reversible dementia include the following: depression, selected drugs, metabolic disorders (hypothyroidism, hyperthyroidism, hyperparathyroidism), toxic agents (heavy metals, pesticides, alcohol, various organic solvents), nutritional deficiencies (vitamin B_{12}, niacin, thiamine), normal-pressure hydrocephalus, subdural hematoma, central nervous system (CNS) tumors, and CNS infections (neurosyphilis, chronic fungal or bacterial meningitis, and human immunodeficiency virus [HIV] infection).

Alzheimer Disease

The diagnosis of Alzheimer disease cannot be confirmed until postmortem examination: no laboratory test or radiologic evaluation, including computed tomography or magnetic resonance imaging of the head, is specific for diagnosis of the disease. The diagnosis is made primarily on the basis of the history, usually from family members, and a determination of the cognitive status of the patient. The accuracy of clinicians for diagnosing Alzheimer disease is as high as 95%. The disease is a gradually progressive impairment of cognition. It is characterized by gradually progressive difficulty learning new tasks and information. Loss of memory begins with recent events and eventually includes memory of distant events. Both receptive and expressive language difficulty develop in which the patient has difficulty naming familiar objects and understanding language. Patients may easily become lost, even in familiar surroundings. Calculation skills decline, and patients may no longer be capable of such tasks as balancing a checkbook. Eventually behavioral problems develop in many patients, including the tendency to wander and to develop paranoia, agitation, delusions, or hallucinations (or a combination of these). Typically, patients with Alzheimer disease have little insight into the disease process and are often brought to the physician by a family member. Driving safety is often impaired in persons with dementia, and the physician should play a prominent role in discussing this with the patient and his or her family. At times the physician may need to take steps to prevent the patient from driving if safety is an issue.

Pathologically, the CNS findings include neuronal plaques, which represent extracellular deposits of protein containing amyloid, and neurofibrillary tangles, which are intracellular protein bound to microtubules. Neuronal plaques and neurofibrillary tangles are also found in nondemented persons but in much smaller amounts. Alzheimer disease is associated with a decreased amount of CNS neurotransmitters such as acetylcholine, norepinephrine, and serotonin. Acetylcholine deficiency is especially prominent, as is a decrease in choline acetyltransferase activity.

The evaluation of a demented patient establishes the existence and degree of cognitive impairment, ruling out reversible dementias. Screening mental status examinations (such as the Mini-Mental State Examination) often identify those who may not have obvious cognitive impairment. If cognitive impairment is suspected but the mental status examination findings are normal, formal psychometric studies should be conducted. Normal findings on mental status examinations do not rule out dementia. The Mini-Mental State Examination is also used to follow future deterioration. The medical evaluation consists of a medical history and physical examination (including neurologic examination) and general laboratory tests. Accepted laboratory tests include a complete blood count; electrolyte panel; liver function tests; blood urea nitrogen; serum levels of creatinine, calcium, glucose, and vitamin B_{12}; thyroid function; syphilis serology; chest radiography; and electrocardiography. Although some form of brain imaging study (computed tomography or magnetic resonance imaging) is usually performed, there are arguments for and against this practice. An imaging study is performed to rule out various types of potentially reversible CNS lesions such as mass lesions, normal-pressure hydrocephalus, or previous strokes and not to examine for cerebral atrophy. If the patient has had dementia for an extended period, has no focal findings on neurologic examination, has no history of head trauma, and has no headache, an imaging study may not be cost-effective. Electroencephalography, HIV testing, and lumbar puncture are performed only in unusual circumstances and are rarely necessary.

Until recently, the treatment of Alzheimer disease has been limited to controlling abnormal behavior (agitation, delusions, hallucinations, and paranoia) with various neuroleptic drugs (sedative-hypnotics and major tranquilizers). None of the neuroleptic medications commonly used improve cognitive function, and very often, they worsen memory and orientation. Major tranquilizers also may cause movement disorders (tardive dyskinesia) and can contribute to falls. The recent availability of acetylcholinesterase inhibitors (tacrine, donepezil, rivastigmine, and galantamine) has given clinicians the first real options for treating Alzheimer disease. Although acetylcholinesterase inhibitors are not considered disease-modifying drugs, they may transiently delay cognitive decline and should be considered for patients who have mild to moderate dementia. The major benefit of these drugs is their potential to delay institutionalization, although there have been reports of improvement in abnormal behaviors associated with dementia with the use of these drugs. The high prevalence of liver toxicity associated with tacrine has not been found with the other acetylcholinesterase inhibitors.

Memantine is a new and novel treatment for Alzheimer disease. It is neuroprotective and considered a disease-modifying agent. It can slow the progression of cognitive decline. This drug blocks the effect of glutamate, an excitatory neurotransmitter in CNS neurons. Glutamate stimulates *N*-methyl-D-aspartate receptors, which are commonly involved in memory and learning. Excessive receptor stimulation can result in damage to the receptor. Memantine inhibits the activity of glutamate, protecting the *N*-methyl-D-aspartate receptors from damage. Patients with Alzheimer disease can be given a combination of an anticholinesterase medication and memantine.

Evidence suggests that vitamin E and selegiline also may slow the progression of Alzheimer disease through their antioxidant activity. Nonsteroidal anti-inflammatory drugs may protect against the development of Alzheimer disease by suppressing the inflammation and immune response present in the brains of patients with Alzheimer disease. These agents are not given routinely for prevention because of the risk of adverse effects. Estrogen therapy has not been consistently shown to be of benefit in the prevention or treatment of Alzheimer disease. In the Women's Health Initiative Study, estrogen plus progestin did not improve cognitive function when compared with placebo, and a small increased risk of clinically meaningful cognitive decline occurred in the estrogen plus progestin group.

- The diagnosis of Alzheimer disease is established on the basis of the history, usually from family members, and a determination of the cognitive status of the patient.
- Screening mental status examinations often identify patients who may not have obvious cognitive impairment.
- Accepted laboratory tests include a complete blood count; electrolyte panel; liver function tests; blood urea nitrogen; serum levels of creatinine, calcium, glucose, and vitamin B_{12}; thyroid function; syphilis serology; chest radiography; and electrocardiography. A brain imaging study (computed tomography or magnetic resonance imaging) is usually performed.
- Acetylcholinesterase inhibitors may transiently delay cognitive decline.

Diseases other than Alzheimer disease may cause dementia. At times, it may be difficult to differentiate one from the other, although subtle differences often are present clinically.

Vascular Dementia

Vascular dementia tends to affect older persons and is due to repeated cerebral infarcts. It is the second most common cause of dementia and can be difficult to differentiate from Alzheimer disease. The patient usually demonstrates a stepwise progression of cognitive impairment consistent with the multiple ischemic infarcts, often with focal neurologic deficits also produced by the ischemic CNS events. Several types of vascular dementias are possible, including cortical multi-infarcts, subcortical multi-infarcts due to small-vessel thrombosis (lacunar strokes), and deep white matter small-vessel ischemia with demyelination (Binswanger disease). Amyloid angiopathy may cause cognitive impairment and is associated with cerebral hemorrhages. The presentation depends on which portion of the brain is affected by the ischemic insults. CNS imaging usually shows

evidence of multiple strokes or white matter ischemia. Treatment consists of management of risk factors for cerebrovascular disease such as hypertension, diabetes mellitus, and hyperlipidemia. Also, antiplatelet therapy is usually given.

- Patients with vascular dementia usually demonstrate a stepwise progression of cognitive impairment.

Dementia With Lewy Bodies

Patients with this cortical dementia have cognitive impairments similar to those of Alzheimer disease. Pathologically, Lewy bodies are cytoplasmic inclusion bodies, and they can be found in subcortical brain tissue. Patients have findings of parkinsonism with bradykinesia, extremity rigidity, and postural instability. Absence of a resting tremor is common (unlike Parkinson disease). The ability of patients to maintain attention is poor. Also, they show marked day-to-day changes in cognitive status and may have hallucinations (visual and auditory). Patients are very sensitive to the effects of antipsychotic medications and frequently have adverse extrapyramidal reactions, which may be life-threatening.

- Dementia with Lewy bodies is associated with cognitive impairment and findings of parkinsonism.
- Patients typically show marked day-to-day changes.

Dementia With Parkinson Disease

Up to 40% of patients with Parkinson disease have development of dementia, and many are indistinguishable from those with Alzheimer disease. These patients have the features typical of Parkinson disease, including resting tremor, rigidity, and bradykinesia, in addition to the intellectual impairments of dementia, which tend to be very slowly progressive. For some patients, effective treatment of Parkinson disease with dopamine improves cognitive status, but not for those with more severe dementia.

- Up to 40% of patients with Parkinson disease have development of dementia.

Frontotemporal Dementia

Frontotemporal dementia is characterized by changes in personality and behavior due to prominent frontal lobe involvement. It has less effect on cognitive status and memory impairment. Onset of the disease tends to be somewhat earlier than for Alzheimer disease, often in the 50s and 60s. Patients frequently have poor personal hygiene and disinhibition and may demonstrate hypersexual behavior. Urinary incontinence is also common. Physical examination usually shows prominent frontal reflexes. CNS imaging shows the typical frontal and temporal lobe involvement. One type of frontotemporal dementia is Pick disease, characterized pathologically by intraneuronal inclusion bodies known as "Pick bodies." Management of the behavioral disturbance is the most challenging aspect of the treatment of this condition.

- Pick disease is characterized by prominent changes in personality and behavior.

Creutzfeldt-Jakob Disease

Creutzfeldt-Jakob disease is an uncommon cause of dementia. It has an earlier onset than Alzheimer disease, usually in the sixth decade. The progression of the disease is rapid, eventually producing a vegetative state and the development of myoclonic jerks and seizures. Most patients die within 1 year after disease onset. The cause is thought to be infectious and due to prions.

- Creutzfeldt-Jakob disease is a rapidly progressive dementia associated with myoclonic jerks and seizures.

Other Dementias

Huntington disease is an autosomal dominant disorder with early onset of symptoms (usually in the fourth or fifth decade). Eventually, choreiform movements develop. Cognitive impairment is severe and progressive. Acquired immunodeficiency syndrome (AIDS) dementia affects up to 50% of persons with AIDS. It can produce a subcortical dementia, and it is gradually progressive. Currently, AIDS dementia is uncommon among the elderly. Also, dementia can occur as a chronic complication of Lyme disease years after onset of the infection.

Delirium

Delirium is an acute confusional disorder frequently mistaken for dementia. It is associated with a decreased level of consciousness, hallucinations, and delusions. Its several causes are listed in Table 10-3. It is important to differentiate delirium from dementia because of the potential for reversibility of cognitive impairment associated with delirium. Patients with delirium frequently have a preexisting mild (often unrecognized) dementia.

- Delirium is a reversible cause of cognitive impairment and may be related to medications or acute medical conditions.

Table 10-3 Causes of Delirium

Drugs
Sedative-hypnotics
Anticholinergic agents
NSAIDs
β-Adrenergic blockers
Antipsychotic agents
Metabolic disturbances
Hyperglycemia
Hypoglycemia
Hypercalcemia
Hypoxia
Hypotension
Common medical illnesses in patients with limited organ reserve function or organ failure
Urinary tract infection
Sepsis
Pneumonia

NSAID, nonsteroidal anti-inflammatory drug.

Preoperative Assessment of the Elderly

Elderly patients commonly undergo anesthesia and surgery, and age alone should not be a contraindication for a surgical procedure. Most elderly persons have some increased risk of perioperative complications because of a combination of normal physiologic changes of aging and, more importantly, various disease states. Most perioperative deaths result from cardiac or respiratory complications. It can be difficult to determine preoperatively if an elderly patient has marked cardiac or respiratory disease. The high prevalence of inactivity among the elderly commonly masks the presence of coronary or pulmonary disease because symptoms may be present only with exercise. Usually, an older patient who is active, without symptoms, at low risk for cardiorespiratory disease, and scheduled for a nonvascular operation does not require further testing. However, asymptomatic patients who are inactive and have several risk factors for cardiorespiratory disease may benefit from noninvasive cardiac or pulmonary testing (or both).

The patient's medications should be reviewed preoperatively. Because of the increased risk of postoperative bleeding, aspirin should be discontinued at least 1 week before the operation. Nonsteroidal anti-inflammatory drugs also can increase the risk of bleeding and their use should be discontinued preoperatively. Because of a shorter antiplatelet effect, nonsteroidal anti-inflammatory drugs may be taken up to 48 hours before the operation. Oral hypoglycemic medications should not be given the morning of the operation because of the risk of hypoglycemia. The blood glucose level can be managed by the administration of regular insulin if needed. Other medications that the patient takes daily should be given the morning of the operation. The use of cardiovascular medications, especially β-adrenergic blockers and clonidine, should not be discontinued abruptly. If corticosteroids have been taken recently in doses capable of suppressing adrenal function, they should be given preoperatively.

In addition to the questions typically asked of younger patients during a preoperative assessment, functional ability and cognitive status should be assessed in the elderly. The Mini-Mental State Examination is an adequate screening test for cognitive impairment. Patients with cognitive impairment preoperatively are at increased risk for postoperative delirium. They also may have difficulty completing a physical therapy program. It is not unusual for the functional status of an elderly person to deteriorate markedly after an operation, especially with a prolonged hospital stay. It is wise to prepare for assistance in the home or to consider temporary nursing home placement for possible strength rehabilitation to prevent even longer hospitalization.

- Most elderly persons have some increased risk of perioperative complications because of both normal physiologic changes of aging and various disease states.
- Most perioperative deaths result from cardiac or respiratory complications.

Preventive Geriatrics

For many disease states, there is evidence to recommend continuing screening tests with advancing age. In other areas, data are not sufficient about whether screening is beneficial for the elderly. In these situations, clinical judgment (taking into account the patient's functional status and estimated life expectancy) is important for deciding whether certain screening tests should be performed. Before a screening test is indicated, several basic principles must be considered, including the following: 1) the incidence of the disease is high enough to warrant performing screening tests, 2) there must be a period during which the disease is present but the patient is asymptomatic and the disease can be diagnosed with a screening test, 3) effective treatment is available for the disease, 4) early treatment of the disease has a better outcome than it would if the diagnosis is made after symptoms develop, and 5) the screening test has a reasonable sensitivity and specificity and is relatively inexpensive and safe.

Cardiovascular Disease

- High low-density lipoprotein cholesterol and low high-density lipoprotein cholesterol have predictive value in the elderly for coronary artery disease. Many organizations now recommend checking for hyperlipidemia in persons older than 65 years, especially those who have an established diagnosis of coronary artery disease or multiple risk factors.
- The risks of hypertension and the benefits of treatment extend to the elderly, and it is recommended that screening for hypertension be performed in the elderly.
- Routine screening for carotid artery disease in the elderly is not recommended.
- Routine screening with resting or exercise electrocardiography is not recommended for the elderly.

Malignancy

- Because breast cancer continues to increase in incidence with age, continued annual screening with mammography is recommended. For patients older than 75 years, clinical judgment should be used. If appropriate, it is reasonable to continue mammography as long as the patient's life expectancy exceeds 5 years.
- Although colon cancer is common among the elderly, screening recommendations require clinical judgment. Tests with an acceptable sensitivity and specificity (e.g., colonoscopy) are difficult for many elderly and have some associated risks. Simple tests such as digital rectal examination or fecal occult blood tests have a low sensitivity and specificity. The American Cancer Society recommends several options for colon cancer screening. According to these recommendations, annual fecal occult blood testing, with flexible sigmoidoscopy every 5 years, is preferable. Colonoscopy should be performed if the results of either test are abnormal. For those at increased risk for colorectal cancer, such as a history of colorectal adenomatous polyps, screening with colonoscopy should be performed. The Preventive Health Services Task Force recommends screening with fecal occult blood testing or sigmoidoscopy or both. Another option now available is computed tomography colography. This may be especially useful for persons receiving long-term anticoagulation with warfarin or those who have had difficulties or complications in the past with colonoscopy or flexible sigmoidoscopy.

- If cervical Papanicolau smears have been performed appropriately at younger ages and the results have been negative, the U.S. Preventive Services Task Force recommends discontinuing Papanicolau smears at age 65 years. For the elderly who did not have regular screening with cervical Papanicolau smears, the incidence of cervical cancer is notable. Screening is recommended for older women who have not previously had a screening test or if information about previous screening is unavailable or if screening is unlikely to have occurred in the past. Women who have had a hysterectomy with removal of the cervix for benign reasons and with no history of abnormal cancerous growth may discontinue routine cytologic testing. Women who have had a hysterectomy but who have a history of abnormal cell growth (cervical intraepithelial neoplasia, grade 2 or 3) should be screened annually until they have three consecutive negative vaginal cytologic tests. They may then discontinue routine cytologic surveillance.
- Although prostate cancer is common in males, screening tests are controversial. The U.S. Preventive Services Task Force considers the evidence inadequate to recommend for or against screening for prostate cancer with the prostate-specific antigen test or digital rectal examination. The American Cancer Society recommends that a digital rectal examination and prostate-specific antigen test be offered annually to men older than 50 if they have a life expectancy of at least 10 years.
- Screening tests for lung cancer, including chest radiography, chest computed tomography, or sputum cytology, are not recommended for either smokers or nonsmokers.
- No screening test has been recommended for the early detection of ovarian cancer.

Pulmonary Changes

Pulmonary function decreases with advancing age, likely because of a combination of normal anatomical and physiologic changes, injury from exposure to various environmental toxins (tobacco and air pollution), and disease states that affect the lung. Changes in the shape of the thorax also contribute to changes in pulmonary physiology. The apical-to-base length of the lungs decreases as the anterior-to-posterior length increases with age. The bronchioles and alveolar ducts increase in diameter, decreasing alveolar surface area. The aging lungs also have reduced compliance because of decreased lung elasticity. These anatomical and physiologic changes result in reduced airflow rates, decreased efficiency of air exchange, and alterations in lung volumes. Changes that occur with aging in pulmonary physiology include a decrease in mucociliary clearance, vital capacity, 1-second forced expiratory volume (FEV_1), maximal breathing capacity, and diffusing capacity (DLCO). The lung residual volume and alveolar-arterial oxygen gradient (AaO_2) increase with age. Aging has no effect on total lung capacity.

- Pulmonary function decreases with advancing age because of a combination of anatomical and physiologic changes, exposure to environmental toxins, and disease states that affect the lung.

Respiratory Disease

Pneumonia is one of the top 10 causes of death among the elderly and is the cause of death of 15% of nursing home residents. The bacterial organisms that cause pneumonia change with advancing age. The elderly have an increased number of gram-negative bacteria as part of their normal oral flora. They also have an increased likelihood of aspirating oral secretions, which contributes to the increased incidence of pneumonia caused by gram-negative and anaerobic bacteria. The likely cause of pneumonia depends on the setting in which the elderly patient acquired the infection. Overall, *Streptococcus pneumoniae* is the most common etiologic organism. *Haemophilus influenzae*, other gram-negative bacteria, and anaerobes are common among the elderly in nursing homes and hospitals. Infections with anaerobe organisms must be considered if the patient is suspected of having an aspiration pneumonia. Organisms such as *Legionella*, *Chlamydia*, and *Moraxella catarrhalis* are also found occasionally in the elderly. Treatment for pneumonia should reflect the most likely etiologic agent (Table 10-4). Recently, a large percentage of *S. pneumoniae* organisms have become penicillin-resistant. Nursing home-acquired pneumonia can be serious; however, if the patient's condition is not toxic and appears stable and the patient is able to take adequate oral fluids, the pneumonia can be treated in the nursing home if the patient is observed closely.

- The elderly have an increased number of gram-negative bacteria as part of their normal oral flora and an increased likelihood of aspirating oral secretions.
- *Streptococcus pneumoniae* is the most common etiologic organism of pneumonia.
- Pneumonia due to *Haemophilus influenzae*, other gram-negative bacteria, or anaerobes is common in nursing homes and hospitals.
- Infections with anaerobe organisms must be considered if the patient is suspected of having an aspiration pneumonia.

Tuberculosis, after decreasing in frequency for many years, is increasing in frequency. The number of reported cases has increased 20% during the past 10 years. Tuberculosis is more common with advancing age, with the elderly having two to four times the case rate of those younger than 65 years. Persons residing in nursing homes have from two to six times the case rate of the general population. Most cases of tuberculosis in the elderly are due to reactivation of a previous infection rather than to a newly acquired infection. It is thought that about 10% of patients with a positive tuberculin skin test (PPD) eventually develop active tuberculosis (4% in the first 2 years). Tuberculosis is suspected on the basis of clinical findings, which can be subtle and include fatigue, anorexia with weight loss, and cough. Chest radiographic findings may be helpful in assessing whether disease is present. Confirmation of the disease requires evaluation of sputum and gastric washings for the presence of the acid-fast organisms. Although culture results usually are available within 2 weeks, cultures may take up to 8 weeks to become positive. An increasing number of multidrug-resistant *Mycobacterium tuberculosis* organisms are being detected; however, these organisms are not common in the elderly because most cases are due to reactivation of the disease

Table 10-4 Empiric Management of Pneumonia in the Elderly

Patient profile	Recommended antibiotics
Community-acquired, treated as outpatient	PO quinolone with respiratory coverage (levofloxacin, moxifloxacin, gatifloxacin, gemifloxacin) or PO macrolide (azithromycin, clarithromycin) or PO doxycycline
Community-acquired, treated in hospital	IV quinolone with respiratory coverage (levofloxacin, moxifloxacin, gatifloxacin, gemifloxacin) or β-lactam (IV ceftriaxone, IV ampicillin-sulbactam) plus IV azithromycin
Nursing home-acquired, treated in nursing home	IV or PO quinolone with respiratory coverage (levofloxacin, moxifloxacin, gatifloxacin, gemifloxacin) or Macrolide (IV or PO azithromycin, PO clarithromycin) plus β-lactam (IV cefotaxime, IV or IM ceftriaxone, PO amoxicillin-clavulanate, IV ampicillin-sulbactam)
Nursing home-acquired, treated in hospital	IV quinolone with respiratory coverage (levofloxacin, moxifloxacin, gatifloxacin, gemifloxacin) or Macrolide (IV azithromycin) plus β-lactam (IV cefotaxime, IV ceftriaxone, IV ampicillin-sulbactam)

IM, intramuscular; IV, intravenous; PO, oral.
Modified from Mandell LA, Bartlett JG, Dowell SF, File TM Jr, Musher DM, Whitney C. Update of practice guidelines for the management of community-acquired pneumonia in immunocompetent adults. Clin Infect Dis. 2003;37:1405-33. Used with permission.

acquired many years ago when there were fewer drug-resistant organisms.

Without symptoms, the PPD is the best test available to determine the possibility of tuberculosis. Intermediate-strength tuberculin (5 TU) is administered intradermally, and the degree of induration (not erythema) is determined.

On admission to a nursing home, the patient should have a two-stage PPD. The second test is administered on the seventh day if the patient has less than 10 mm of induration. The second test is interpreted 2 days after it is applied. Up to 15% of additional patients can be identified with this method. If the PPD is positive, chest radiography should be performed. If the findings are negative and the patient is asymptomatic, no treatment should be initiated unless it can be shown that the patient has had conversion to a positive PPD within the past 2 years. If the chest radiographic findings are abnormal, sputum and gastric washings should be obtained and cultured.

Up to one-third of all new patients admitted to a nursing home may have a positive PPD. Chemoprophylaxis is not recommended for all elderly patients with a positive PPD. Toxicity from isoniazid, especially hepatotoxicity, is very common in the elderly. Evidence of active tuberculosis should be excluded before chemoprophylaxis is given. Elderly patients receiving isoniazid treatment should have close follow-up for symptoms of hepatotoxicity. Isoniazid-induced hepatotoxicity is common with advancing age and develops in up to 5% of those older than 65 years. The baseline level of aspartate aminotransferase should be determined and checked periodically in elderly patients taking isoniazid. These patients also should receive vitamin B_6 (pyridoxine) supplements (10-25 mg daily) to prevent peripheral neuropathy.

Immunizations

Pneumococcal pneumonia vaccine is effective against 23 strains of *S. pneumoniae*, which accounts for 80% of the strains that commonly cause pneumonia. Because of decreasing effectiveness, revaccination should be considered after 6 years for those who received their initial vaccination before age 65 years. The influenza vaccine is changed on a yearly basis, depending on the prevalent strain. It should be given in late autumn, and it should be given annually to high-risk persons, persons older than 65 years, and those in frequent close contact with the elderly. After the vaccine has been injected, it takes about 2 to 3 weeks before immunity to influenza develops. Any of the elderly who are unvaccinated during an influenza epidemic should be given amantadine or rimantadine.

- Pneumococcal pneumonia vaccine is effective against 80% of the bacterial strains that commonly cause pneumonia.
- Influenza vaccine should be given annually to high-risk persons, persons older than 65, and those in frequent close contact with the elderly.

Osteoporosis

Osteoporosis and its complications are extremely common among the elderly. Osteoporosis results in a loss of bone density, with preservation of a normal bone-to-mineral ratio. Hip, wrist, and vertebral compression fractures are common causes of morbidity and mortality. Peak bone density is achieved at about age 30 years; men have a greater bone density than women at all ages. After age 30 years, bone density gradually decreases. In women, loss of estrogen, either because of surgery (bilateral oophorectomy) or menopause, causes a more rapid decrease in bone density.

- Hip, wrist, and vertebral compression fractures are common causes of morbidity and mortality from osteoporosis.

The diagnosis of osteoporosis is usually made clinically. The World Health Organization uses T scores of bone mineral density. Osteopenia is defined as a T score between –1.0 and –2.5. Osteoporosis is defined as a T score of less than –2.5. The following help in establishing the diagnosis:

1. The presence of multiple risk factors, including advanced age, female sex, white, low calcium intake through much of one's lifetime, thin build, a history of corticosteroid or tobacco use, history of previous fracture (especially vertebral), northern European ancestry, prolonged inactivity, and family history positive for osteoporosis
2. Ruling out secondary causes (glucocorticoid excess, hypogonadism, hyperthyroidism, hyperparathyroidism, osteomalacia, myeloma)
3. Physical examination findings (loss of height, increased thoracic kyphosis)
4. Radiographic findings of osteopenia or vertebral compression fractures

- The diagnosis of osteoporosis is usually made clinically.

Bone density can be measured with several techniques, the most common of which is dual x-ray absorptiometry. Bone density is determined to assess the risk of fracture, to follow the progression of disease, or to evaluate the response to treatment.

- Bone density is determined to assess the risk of fracture, to follow the progression of disease, or to evaluate the response to treatment.

Previously, the treatment of osteoporosis was disappointing and was aimed at prevention. Currently, several options are available that can provide effective treatment for established osteoporosis. The initial treatment for osteoporosis in postmenopausal women should be adequate calcium intake, weight-bearing exercise, and adequate vitamin D (600-800 IU daily). Premenopausal women require 1,000 mg daily of elemental calcium, and postmenopausal women require 1,500 mg daily. Calcium carbonate is adequate for most, and it is the least expensive form of calcium supplementation. Calcium citrate should be used if the patient has a lack of gastric acid. Pharmacologic therapy is effective for increasing bone density as well as decreasing the risk of bone fractures. Although hormonal therapy has been shown to stabilize the decrease in bone density and, in some cases, to increase bone density slightly, it is no longer approved primarily for the prevention of osteoporosis on the basis of the Women's Health Initiative findings. The bisphosphonates alendronate and risedronate increase bone density and decrease the risk of hip and vertebral fractures. Compliance with these medications can be a problem, although both are now available in once-weekly dosing. They are poorly absorbed and bind to food and calcium and, thus, must be taken with tap water before food is ingested. Also, they have been associated with esophagitis. To minimize this, the patient must remain upright for at least 30 minutes after taking the medication.

Calcitonin increases vertebral bone density, but more data are needed to determine whether it decreases the risk of hip fracture. Calcitonin seems to have an analgesic effect and may be helpful in patients with painful osteoporotic vertebral compression fractures. Raloxifene is a selective estrogen receptor modulator that reduces bone resorption. Although it has estrogen-like effects on bone, it acts as an estrogen antagonist in the breast and uterus. It can cause a modest increase in bone mineral density in the hip and spine. Teriparatide is a synthetic polypeptide consisting of the biologically active N-terminal portion of human parathyroid hormone and is approved for the treatment of osteoporosis. Unlike all other treatment options for osteoporosis, parathyroid hormone increases bone formation rather than decreasing bone resorption. It seems to produce a greater increase in bone density than other pharmacologic treatments for osteoporosis; however, its high cost may be prohibitive for many patients. Also, it must be administered daily by subcutaneous injection. Hip protectors have been shown to reduce the risk of hip fractures in the elderly and should be considered for nursing home residents who have an increased risk of falling.

- Initial treatment of osteoporosis in postmenopausal women should be adequate calcium intake, weight-bearing exercise, adequate vitamin D (600-800 IU/d), and hormonal replacement therapy.
- Bisphosphonates increase bone density and decrease the rate of hip and vertebral fractures.
- Calcitonin appears to have an analgesic effect and may be helpful in patients with painful osteoporotic vertebral compression fractures.
- Raloxifene is a selective estrogen receptor modulator that reduces bone resorption and produces a modest increase in bone mineral density in the hip and spine.
- Teriparatide may be an option for a select group of patients with osteoporosis.

Osteomalacia

Osteomalacia is the result of defective bone mineralization and is caused most commonly by a deficiency of vitamin D. It may be due to inadequate intake of vitamin D, lack of exposure to the sun, malabsorption, chronic liver disease, or chronic renal disease. Radiographically, the bone appears osteopenic and can resemble osteoporosis. Unlike osteoporosis, several abnormal laboratory findings are associated with osteomalacia, including decreased levels of calcium, phosphorus, and 1,25-dihydroxyvitamin D and increased levels of alkaline phosphatase. Defective bone mineralization also may be caused by very low levels of phosphate. This can be due to excessive use of aluminum-containing antacids, tumor effect, or renal tubule disorders.

- Osteomalacia is the result of defective bone mineralization and is most commonly caused by a deficiency of vitamin D.
- Osteomalacia is associated with decreased levels of calcium, phosphorus, and 1,25-dihydroxyvitamin D and increased levels of alkaline phosphatase.

Pressure Ulcers

Seventy percent of pressure ulcers occur in persons older than 70 years. Approximately 60% of pressure ulcers develop during

hospitalization, 18% in nursing homes, and the rest at home. They are especially common among the elderly in intensive care units. The most important risk factor for the development of a pressure ulcer is immobility. Nutritional deficiencies, age-related changes in the skin, and urinary incontinence are also contributing risk factors. Most pressure ulcers occur below the waist. The common sites include the sacrum, greater trochanter, ischial tuberosity, calcaneus, and lateral malleolus of the ankle. Four factors are thought to be important in the development of pressure ulcers: pressure, shearing force, friction, and moisture. When the persistent pressure of skin overlying a bony prominence exceeds the capillary pressure, the blood supply to the tissues is impaired. After approximately 2 hours, tissue ischemia can occur and result in skin ulceration. Friction and shearing forces are contributing factors when the patient is dragged across a bed or chair. This has the effect of causing angulation and occlusion of subcutaneous blood vessels and producing ischemia of the underlying tissue. Chronic skin moisture produces tissue maceration and promotes skin breakdown. This tends to magnify skin damage.

- Risk factors for the development of pressure ulcers are immobility, nutritional deficiencies, age-related changes in the skin, and urinary incontinence.

The most important component of pressure ulcer care is prevention. Preventive strategies include:

- Repositioning patients at least every 2 hours
- Use of pressure-reducing mattresses
- Minimizing head elevation
- Lifting instead of dragging the patient
- Keeping the patient as dry as possible when incontinent
- Keeping the skin moisturized to help maintain skin integrity

After a pressure ulcer has developed, the basic strategy for its treatment includes the following:

- Relieving pressure over the ulcer
- Debridement of nonviable tissue
- Optimizing the wound environment (preventing wound maceration and avoiding friction and shearing forces) to promote the formation of granulation tissue
- Management of other conditions (malnutrition or infection when present) that may delay wound healing

Pressure ulcers can be classified into one of four stages (I-IV). They tend to be understaged because often the underlying tissue damage is not immediately apparent.

Stage I: Nonblanchable erythema of intact skin. There may be associated edema.

Stage II: Partial-thickness skin loss involving the epidermis or dermis or both. The ulcer is superficial and may present as an abrasion, a blister, or a shallow crater.

Stage III: Full-thickness skin loss with damage or necrosis of subcutaneous tissue. The damage may extend to the fascia. The ulcer is a deep crater.

Stage IV: Full-thickness skin loss with extensive destruction, tissue necrosis, or involvement of muscle, bone, or tendons. Sinus tracts may be present.

Stages II, III, and IV pressure ulcers should be debrided of necrotic tissue when present. Stage II ulcers can be debrided mechanically with wet-to-wet (saline) gauze dressings changed every 6 hours. Also, several enzymatic debriding agents are available and effective. Surgical debridement may be useful, especially for deeper ulcers (stages III and IV). This should be done with caution in patients with lower extremity ulcers and arterial disease. Water debridement (whirlpool) is useful for larger ulcers. A moist wound environment is optimal for wound healing. Heat lamps dry the ulcer and should not be used. Several products are available to help maintain a moist wound environment, including semipermeable polyurethane films and foams, hydrocolloid dressings, and hydrophilic polymer gels. Topical iodine-povidone, hydrogen peroxide, and acetic acid compounds can impair wound healing and should not be used on pressure ulcers. Infection commonly complicates the healing of pressure ulcers. Infected ulcers require treatment with systemic antibiotics. Topical antibiotics have little penetration into deeper tissue and can promote the development of resistant bacteria. Culturing the surface of an ulcer does not represent accurately the bacteria involved in an infected ulcer; all skin ulcers develop surface bacterial colonization. An accurate determination of the bacteria involved requires deep tissue cultures.

An ulcer that does not heal should alert the physician to the presence of osteomyelitis. Bone radiography and bone scanning are often performed in patients with suspected osteomyelitis, but they have a rather high incidence of false-negative and false-positive results. Magnetic resonance imaging is an effective diagnostic test when osteomyelitis is suspected; however, bone biopsy with culture is the best confirmatory test.

Platelet-derived growth factor is occasionally useful for stimulating the healing of pressure ulcers. For large or very deep ulcers, surgical treatment may be necessary. The use of skin grafts or rotation flaps using neighboring subcutaneous tissue and muscle may be the best option in these cases. Hyperbaric chamber pressure therapy may be useful in selected patients.

- Stages II, III, and IV pressure ulcers should be debrided of necrotic tissue.
- A moist wound environment is optimal for wound healing.
- Infected ulcers require treatment with systemic antibiotics.
- Bone biopsy with culture is the best confirmatory test for osteomyelitis.

Urinary Incontinence

Urinary incontinence is common among the elderly, affecting at least 15% of those living independently and about 50% of those in institutions. It is much more common in females than in males. It causes numerous medical, social, and economic complications and is a common reason for nursing home placement. The complications include urinary tract infection, skin breakdown, social isolation, and depression. Urinary incontinence also has been associated with an increased

risk for falls in the elderly. Understanding urinary incontinence requires knowledge of the anatomy of the urinary tract and the physiology of normal micturition. Failure to appreciate this information can result in inaccurate diagnosis and ineffective treatment.

Anatomy

The detrusor muscle of the bladder consists of three muscular layers. Both sympathetic and parasympathetic nerves innervate the detrusor muscle. The internal sphincter is a smooth muscle under involuntary (sympathetic innervation) control. Stimulation of the sympathetic nerves results in contraction of the internal urinary sphincter and detrusor relaxation, promoting urine storage. Stimulation of the parasympathetic nerves produces contraction of the detrusor muscle and internal spincter relaxation, promoting bladder emptying. The external sphincter is striated muscle and under voluntary (pudendal innervation) control. It contracts in response to transient increases in intra-abdominal pressure (e.g., cough or sneeze) to prevent urine loss, but it fatigues rapidly.

Stretch receptors in the wall of the detrusor muscle send information to the brain. The spinal cord carries sensory signals to the brain and motor signals to the bladder. The brain produces stimulation of the sympathetic nerves and inhibition of the parasympathetic nerves when urine storage is desired (relaxation of the detrusor muscle and contraction of the internal sphincter) and stimulation of the parasympathetic nerves and inhibition of the sympathetic nerves when bladder emptying is desired (contraction of the detrusor muscle and relaxation of the internal sphincter).

- Both sympathetic and parasympathetic nerves innervate the detrusor muscle.

Stimulation of the sympathetic nerves results in relaxation of the detrusor muscle, and stimulation of the parasympathetic nerves produces contraction of the detrusor muscle.

Effects of Age

Changes occur in the urinary system with aging, but these changes do not result in urinary incontinence. Incontinence is not a normal result of aging. However, the changes that occur can contribute to the problem of incontinence. These changes include smaller bladder capacity, early contractions of the detrusor muscle, decreased ability to suppress contractions of the detrusor muscle and to postpone urination, and increased nocturnal production of urine.

Medications Affecting Urination and Continence

Many medications can have an effect on urinary continence. They may alter the ability of the brain to appreciate bladder fullness or the ability of the internal sphincter to contract and relax, or they may interfere with the function of the bladder. These medications include potent diuretics that cause brisk filling of the bladder, anticholinergic agents, calcium channel antagonists or narcotics that can impair contraction of the detrusor muscle, sedative-hypnotics that may cause confusion, α-adrenergic agonists that increase internal sphincter tone, and α-adrenergic antagonists that decrease internal sphincter tone.

Established Incontinence

Patients are more likely to have reversible incontinence if the incontinence is of recent onset. Although established incontinence is more difficult to treat, it can be managed with substantial benefit to the patient. The four types of established incontinence are overactive bladder (urge incontinence), outlet incompetence (stress incontinence), and overflow incontinence (Table 10-5). Functional or iatrogenic incontinence can occur in persons with mobility problems or as an adverse effect of medication.

Overactivity of the detrusor muscle (overactive bladder) is a common cause of established incontinence, accounting for 40% to 70% of cases. When overactive bladder results in incontinence, it is known as urge incontinence. Overactive bladder tends to be most common in middle-aged and older women and men. Although overactive bladder is equally common in men and women, urge incontinence is much more common in women. Overactive bladder causes early detrusor contractions at low bladder volumes. Symptoms include urinary frequency and urgency, with losses of small-to-moderate urine volumes. Nocturia often occurs. At times, detrusor overactivity occurs with CNS disease (mass lesions, Parkinson disease, stroke) or bladder irritation (urinary tract infection, benign prostatic hyperplasia, fecal impaction, atrophic urethritis). There is no association between chronic asymptomatic bacteriuria and urinary incontinence.

- Overactivity of the detrusor muscle is a common cause of established incontinence.
- Symptoms include urinary frequency and urgency, with losses of small-to-moderate urine volumes and nocturia.

Outlet incompetence (stress incontinence) is common in middle-aged women and rare in men (unless internal sphincter damage has occurred). It is caused by inadequate resistance of urinary outflow and worsened by laxity of pelvic floor musculature and lack of bladder support. This may be caused by hypermobility of the urethra or intrinsic urinary sphincter insufficiency. The symptoms include losses of small amounts of urine with transient increases in intra-abdominal pressure (e.g., cough, sneeze, laugh, or change in position). Some patients describe a combination of urge incontinence and stress incontinence. This is known as "mixed urinary incontinence." In these patients, the history can be confusing because the patients describe symptoms of both urge incontinence and stress incontinence.

- Outlet incompetence (stress incontinence) is common in women.
- Symptoms include losses of small amounts of urine with transient increases in intra-abdominal pressure.

Overflow incontinence is uncommon. It occurs with urinary outflow obstruction (benign prostatic hyperplasia, prostate cancer, or pelvic tumor) or detrusor underactivity-hypotonic bladder (autonomic neuropathy). This often occurs transiently in the elderly after surgery. Symptoms include difficulty emptying the bladder, low urine flow, and frequent dribbling. Patients give a history of difficulty starting urination and a weak urinary stream, with stream hesitancy.

Functional incontinence is the inability of normally continent patients to reach toilet facilities in time. Often, it is due to various

Table 10-5 Types of Established Urinary Incontinence

Type	Cause	Symptoms	Treatment options
Urge incontinence	Detrusor overactivity	Urgency, frequency, nocturia. Loss of small to moderate volumes of urine	Behavioral: urge suppression, elimination of bladder irritants, timed voiding Pharmacologic: antimuscarinic medications (oxybutynin, tolterodine, trospium, darifenacin, folifenacin)
Stress incontinence	Urinary outlet incompetence from intrinsic urethral sphincter insufficiency or hypermobility of the bladder	Losses of small amounts of urine associated with transient increases in intra-abdominal pressure (e.g., cough, sneeze, laugh)	Behavioral: continence tampons, vaginal cones, urethral plugs, continence pessaries, pelvic floor exercises. Surgical: urethral sling, tension-free vaginal tape, bladder suspension, injection of periurethral bulking agents, artificial urinary sphincter
Overflow incontinence	Urinary outlet obstruction or detrusor underactivity	Difficulty emptying bladder, low urine flow, straining to void, urinary dribbling	Relief of bladder outlet obstruction (TURP), α-adrenergic antagonists, indwelling or intermittent bladder catheterization

TURP, transurethral resection of prostate.

medications (e.g., potent diuretics and α-adrenergic antagonists) and some limitation of mobility (restraint use, arthritis, or hemiparesis).

- Overflow incontinence is uncommon and due to urinary outflow obstruction or detrusor underactivity-hypotonic bladder.
- An atonic or hypotonic bladder often occurs transiently postoperatively.

Evaluation of Incontinence

The evaluation of urinary incontinence includes a thorough medical history, physical examination, and several simple selected laboratory tests. The history is most important and should include the amount of urine lost, duration of symptoms, precipitating factors, whether symptoms of obstruction exist, and the patient's functional status. Also, symptoms of neurologic disease, associated disease states, menstrual status and parity, and medications taken should be documented.

Physical examination of the abdomen should evaluate bladder distention and possible abdominal masses. Examination of the pelvis should include assessment for uterine, bladder, or rectal prolapse; atrophic vaginitis; and pelvic masses. The rectal examination should document any masses, fecal impaction, sphincter tone, and prostate enlargement or nodules. A neurologic examination should be performed to search for disease of the brain or spinal cord, autonomic nerves, or peripheral nerves. Patients should complete a voiding diary that records fluid intake, types of fluids ingested, and voidings (both continent and incontinent).

Laboratory tests commonly ordered in the investigation of urinary incontinence include urinalysis and urine culture to check for infection, pyuria, and hematuria; blood urea nitrogen and creatinine determination to assess renal function; and calcium and glucose measurements to assess polyuric states. Occasionally, intravenous pyelography or renal ultrasonography (or both) may be necessary to check for hydronephrosis, which may occur with chronic bladder outlet obstruction. A postvoid residual bladder volume test should be performed to determine the degree of bladder emptying when a patient describes symptoms of urinary outlet obstruction.

Urodynamic studies are occasionally necessary to establish the diagnosis of incontinence, but the results are not always consistent with the clinical picture and, thus, can be misleading. Urodynamic studies are indicated when patients have medically confusing histories or more than one type of urinary incontinence (mixed incontinence). Cystometry measures bladder volume and pressure and can be used to detect uninhibited detrusor muscle contractions, lack of bladder contractions, and bladder sensation. Voiding cystourethrography measures the urethrovesical angle and residual urine volume. Uroflow measures urinary flow rate, and electromyography evaluates the external sphincter and detects detrusor-sphincter dyssynergia.

- The medical history is the most important part of the incontinence evaluation.
- Urodynamic studies are occasionally necessary to establish the diagnosis of incontinence, but the results can be misleading in some patients.

Treatment of Incontinence

The treatment of urinary incontinence is usually successful to some degree. All patients should be encouraged to drink an adequate volume of fluid, 40 to 60 oz daily. The treatment of detrusor overactivity is aimed at suppressing the early contractions of the detrusor muscle. Behavioral training should be the initial treatment attempted. Often, it is successful for decreasing incontinent episodes. It includes eliminating bladder irritants (especially caffeine), urge suppression techniques (pelvic floor muscle contraction), scheduled toileting, and prompted voiding. When behavioral training is ineffective, pharmacologic therapy may be added. Medications that inhibit parasympathetic stimulation of the bladder muscle (antimuscarinics) are often effective. Drugs with antimuscarinic activity that are most commonly used include oxybutynin and tolterodine. Trospium, darifenacin, and solifenacin are also antimuscarinic medications that may have fewer peripheral anticholinergic adverse effects (dry mouth, constipation, blurred vision). Tricyclic antidepressants also have been used, but they have a higher risk of anticholinergic adverse effects. Topical estrogen therapy also may be effective in some women when atrophic urethritis is the cause of early contractions of the detrusor muscle.

- The treatment of detrusor overactivity is aimed at suppressing early detrusor contractions.
- Nonpharmacologic therapy should be attempted initially.
- Medications that inhibit parasympathetic stimulation of the bladder muscle (antimuscarinics) are often effective.
- Topical estrogen therapy may be effective in some women.

The treatment of outlet incompetence should also begin with behavioral therapy. Patients should be instructed in pelvic floor exercises (Kegel exercises). In some patients, this is more effective with the assistance of biofeedback. Although pelvic floor exercises are useful, they must be performed for several months before any benefit is recognized. Increasing the tone of the internal sphincter with α-adrenergic agonists (pseudoephedrine or imipramine) may be of limited short-term benefit. Tolerance to these medications develops quickly, and the beneficial effect disappears. Hormonal therapy (topical estrogen) has been used for outlet incompetence in an attempt to restore the mucosa of the urethra, increasing its resistance, but the results have been disappointing. Pessaries and continence tampons are occasionally used for outlet incompetence, but chronic use is difficult because of potential vaginal irritation. Urethral plugs are available and can provide temporary relief of symptoms. However, they potentially can produce urethral irritation.

For selected patients, surgical therapy may be effective. Internal sphincter bulking agents such as collagen may provide substantial benefit for up to 2 years. Occasionally a surgical procedure to provide an artificial urinary sphincter may be considered. For patients who have more severe symptoms of outlet incompetence, surgical suspension of the bladder and bladder neck sling therapy can restore continence. Tension-free vaginal tape is a relatively new procedure that provides a urethral sling and can be performed on an outpatient basis with the patient under local or regional anesthesia.

- Patients with outlet incompetence should be instructed in pelvic floor exercises.
- Pharmacologic treatment has limited short-term benefit.
- For selected patients, surgical therapy may be effective.

The treatment of overflow incontinence is aimed at providing complete drainage from a bladder that either is not contracting adequately or has marked outflow obstruction. For a hypotonic bladder, treatment can be tried with medications that increase the tone of the detrusor muscle, including the cholinergic agonist bethanechol. This may be effective for short-term use, for example, for a transient hypotonic bladder postoperatively; however, adverse effects are common in the elderly and limit its long-term use. Treatment of obstruction includes operation (transurethral resection of the prostate) and use of α-adrenergic antagonists (terazosin, doxazosin, or tamsulosin), which decrease the tone of the internal sphincter. An external (condom) urinary catheter is of little benefit because it does not provide adequate drainage of the bladder. Occasionally, an indwelling catheter or intermittent catheterization is necessary. When a patient is expected to regain contractile function of the bladder, intermittent catheterization is performed at a frequency determined by the residual urine volume. If outflow obstruction is a chronic condition and not expected to improve, indefinite self-catheterization or an indwelling catheter is usually necessary.

- Medications that increase the tone of the detrusor muscle can be tried for transient hypotonic bladder.
- Surgery is often necessary to relieve bladder outlet obstruction from benign prostatic hypertrophy.
- An indwelling catheter or indefinite catheterization is occasionally necessary.

Urologic Consultation

In most elderly patients, the diagnosis of urinary incontinence can be established without the need for evaluation by a urologist. The following conditions indicate the need for urologic evaluation: high postvoid residual urine volume, symptoms of urinary outflow obstruction, marked uterine or bladder prolapse, abnormal findings on prostate examination, recurrent urinary tract infection, hematuria, unknown diagnosis, or failure to improve with treatment.

Use of Urinary Catheters

External (condom) catheters have a slight risk of infection, and problems with penile skin breakdown limit long-term use. They also have minimal benefit in overflow incontinence. Intermittent catheterization has a small risk of infection with each catheter insertion (from 1% in persons who are ambulatory and otherwise healthy to 20% in those who are frail and have multiple chronic illnesses). It is useful for temporary incontinence, as in postoperative transient hypotonic bladder. Postvoid residual volumes should be used as a guide for determining the frequency of catheterization. Intermittent catheterization is of limited use in the management of chronic incontinence in nursing home patients because of catheter expense and in those living independently if they have limited manual dexterity or poor vision.

Essentially all patients with indwelling catheters eventually have development of marked bacteriuria, and the bacterial organisms typically change with time. Other than maintaining a closed urinary collection system, nothing has been found to prevent or even substantially delay the onset of bacteriuria. Neither urethral cleansing nor bladder irrigation has been shown to be effective. Routine surveillance cultures should not be performed, and the chronic use of suppressive antibiotics is not recommended. Antibiotic therapy does not prevent long-term colonization by bacteria and eventually results in infections caused by resistant organisms. Antibiotic treatment should be reserved for symptomatic infections only, although it may be difficult to determine when a symptomatic urinary tract infection is present in a catheterized elderly patient. In patients who have had urinary catheters removed, bacteriuria should be treated if the urine remains bacteriuric for more than 48 hours. In many cases, the bacteriuria will resolve with removal of the urinary catheter alone.

- Essentially all patients with indwelling catheters eventually have development of marked bacteriuria.
- Surveillance cultures should not be performed, and the bacteriuria should be treated only when it is symptomatic.
- Chronic use of suppressive antibiotics is not recommended.

Urinary Tract Infection

Urinary tract infection becomes more common with advancing age and causes a wide spectrum of disease. The prevalence in the elderly is much higher than in younger individuals. It is the most common infection in nursing home residents and the most common cause of sepsis in the elderly. Urosepsis is also a very common cause of delirium in the elderly. It also may produce the syndrome of asymptomatic bacteriuria. Incomplete emptying of the bladder, which is common in the elderly (cystocele, benign prostatic hyperplasia, or hypotonic bladder), urinary instrumentation, and chronic catheterization all predispose the elderly to urinary tract infection. The clinical presentation of bacteriuria in the elderly can vary tremendously. Many have no symptoms, and vague symptoms such as confusion, decreased appetite, and urinary incontinence commonly result in a delayed diagnosis. Pyuria is not a reliable indicator of bacteriuria in the elderly population, although the absence of pyuria is a reasonably good indicator of the absence of bacteriuria.

The elderly have various bacterial organisms that typically produce urinary tract infections, and these differ from younger patients. *Escherichia coli*, the most common organism to cause urinary tract infections in the younger population, causes about half to three-fourths of these infections in the elderly. Other gram-negative organisms such as *Enterococcus* sp, *Proteus* sp, *Klebsiella* sp, *Enterobacter* sp, *Serratia* sp, and *Pseudomonas* sp are frequent in the elderly. Polymicrobial infections and resistant organisms are also common. Because of the variety of organisms, the urine usually should be cultured when evaluating an elderly patient who has a urinary tract infection.

Asymptomatic bacteriuria becomes more common with age and has been associated with increased mortality; however, the mortality seems to be unrelated to the bacteriuria and is likely a marker for increased severity of illness, frailty, and debility. Asymptomatic bacteriuria should not be treated unless there is a history of chronic urinary obstruction or if bladder instrumentation is planned. Treatment is also advised prior to performing a transurethral resection of the prostate.

- Urinary tract infection is the most common infection in nursing home residents and the most common cause of sepsis in the elderly.
- Because of the variety of organisms, the urine should be cultured when evaluating an elderly patient who has a urinary tract infection.
- Asymptomatic bacteriuria should not be treated unless there is a history of chronic urinary obstruction, bladder instrumentation is planned, or a transurethral resection of the prostate is to be performed.

Use of Medications in the Elderly

More than 30% of all prescriptions are written for persons older than 65 years. Medications are a common cause of iatrogenic disease in the elderly and are handled differently in the elderly because of various changes in pharmacokinetics and pharmacodynamics. Overall, the activity of many drugs has a longer duration, lower doses often achieve desired therapeutic effects, adverse drug effects are more frequent, drug-drug interactions are more frequent, and the likelihood of drug toxicity is greater in the elderly.

Pharmacokinetics includes drug absorption, distribution, metabolism, and elimination. Age-related changes have an effect on each of these variables, affecting some more than others. Age-related changes that affect drug absorption include decreased blood supply to the small bowel (the site of most drug absorption), villous atrophy resulting in decreased surface area for the absorption of drugs, and decreased gastric acidity. Little evidence supports any marked reduction in drug absorption with increasing age. Drug absorption is the least important of the pharmacokinetic changes associated with aging. Drug distribution has a major role in altered pharmacokinetics and changes significantly with age. This is due to age-related alterations in the various volumes of distribution in the elderly. These changes include an increase in adipose tissue, a decrease in total body water and lean body mass, and, for many, a change in levels of plasma protein. The result of increased adipose tissue is an increase in the volume of distribution for lipid-soluble drugs, which can result in an increase in drug half-life (e.g., highly lipid-soluble benzodiazepines). The decrease in body water creates a smaller volume of distribution for water-soluble drugs, potentially leading to a higher than expected drug concentration (e.g., ethanol). A decrease in plasma protein (e.g., albumin) results in less protein-bound (inactive) acidic drugs and a greater amount of free (active) drug. This can produce a greater than anticipated drug effect. α_1-Acid glycoproteins are acute-phase reactants that are increased in patients with inflammatory conditions. This can cause an increase in basic drug (lidocaine, propranolol) protein binding, thereby reducing the amount of bioavailable drug and possibly attenuating the drug effect.

Drug metabolism occurs primarily in the liver. With advanced age, the ability of the liver to metabolize drugs decreases because of

various factors, including a decrease in the number of functioning hepatocytes, reduced hepatic blood flow, and reduced hepatic enzymatic activity. Phase I metabolism involves the oxidation or reduction of a drug by the cytochrome P-450 system. This type of metabolism produces active metabolites and slows with age. Phase II metabolism involves acetylation and produces inactive metabolites. It shows no changes with advancing age. A patient's ability to metabolize a specific drug is extremely difficult to predict because no simple test is available that provides this information.

Drug elimination refers primarily to the ability of the renal system to excrete drugs from the circulation. Generally, renal function decreases with age, with both decreased renal plasma flow and glomerular filtration rate (up to 30%), although the variability among elderly persons is great. The serum level of creatinine is not a good measure of renal function in the elderly and tends to underestimate the degree of renal insufficiency. Creatinine is a product of muscle breakdown. Because lean body mass decreases with advancing age, less creatinine is produced. Thus, an elderly patient who has as much as a 30% reduction in renal function may have a normal serum level of creatinine. A more accurate estimate of renal function is the following:

$$\text{Creatinine clearance} = \frac{140 - \text{age} \times \text{weight (kg)}}{72 \times \text{creatinine}} = (\times 0.85 \text{ for women})$$

Age-related changes occur in pharmacokinetics involving drug absorption, distribution, metabolism, and elimination.

- Drug distribution has a major role in altered pharmacokinetics.
- The ability of the liver to metabolize drugs decreases in most elderly patients.
- Because of decreased renal function with age, elimination of many drugs is delayed in the elderly.
- Serum creatinine level may underestimate the degree of renal insufficiency.

Pharmacodynamic changes also occur with aging and have an effect on the action of medications. The term "pharmacodynamics" refers to drug sensitivity, which can change with age. These changes may reflect an alteration of receptor number or receptor sensitivity to a drug or an altered receptor response to a drug. Less is known about age-related altered pharmacodynamics than about pharmacokinetics; however, the pharmacodynamic changes for several drugs have been identified. There is a reduced responsiveness to β-adrenergic drugs (e.g., less tachycardia with isoproterenol, less bradycardia with β-blockers), increased sedation with benzodiazepines, greater analgesia with opiates, and greater anticoagulant activity with warfarin.

Adverse drug effects are common in the elderly and frequently cause serious complications. Elderly patients often have limited organ reserve function and are unable to respond as younger persons can to an adverse effect. Drug-drug effects tend to occur more commonly in the elderly and tend to be more serious. The likelihood of a drug-drug effect is related to the number of medications taken.

- Pharmacodynamic changes result in an alteration in a given drug effect with age.
- Adverse drug effects tend to occur more often and are often more severe in the elderly, primarily because of reduced organ reserve capacity with age.

As a result of altered pharmacokinetics and pharmacodynamics with aging, medications need to be prescribed carefully for the elderly, avoiding polypharmacy whenever possible and watching for evidence of adverse drug effects and drug-drug interactions, both of which increase in frequency with age. Medications have been identified that have potentially greater risks in the elderly. These drugs should be prescribed with great caution for older patients. Some of these medications are discussed in the following paragraphs. See the Geriatrics Pharmacy Review for a more complete list of pharmacologic considerations in the elderly.

Long-acting benzodiazepines (diazepam, chlordiazepoxide, and flurazepam) are highly lipid-soluble and, thus, have a very long half-life in elderly patients. They also have active metabolites. These drugs can easily accumulate in the elderly and possibly produce drug toxicity. Barbiturates also are highly lipid-soluble and have very long half-lives in the elderly. Drug accumulation may occur; also, tolerance develops quickly to their sedating activity. Diphenhydramine is available over-the-counter and is often used to induce sleep. It potentially can cause cognitive impairment in the elderly. Propoxyphene is a weak analgesic with little therapeutic advantage over acetaminophen; yet, it has all the risks and adverse effects of narcotics. Pentazocine is a mixed agonist and antagonist oral narcotic that has significant potential for adverse effects on the CNS, including confusion and hallucinations.

Meperidine is a weak analgesic with an unpredictable rate of oral absorption. Its metabolites can accumulate in patients with renal insufficiency; seizures or respiratory depression may occur. Tricyclic antidepressants have the potential for various adverse effects because of their nonselective neurochemical blockade. α-Adrenergic antagonist activity can produce orthostatic hypotension, antihistamine activity can lead to sedation, and anticholinergic effects can cause urinary obstruction in men and delirium, constipation, and blurred vision. Monoamine oxidase inhibitors and antidepressants have marked potential for serious adverse effects, such as hypertension, when they interact with tyramine-containing products. Chlorpropamide, an oral hypoglycemic agent, is a first-generation sulfonylurea and has an extremely long half-life; thus, it has a substantial risk of causing prolonged hypoglycemia.

Geriatrics Pharmacy Review

Robert W. Hoel, RPh, PharmD

Drug	Toxic/adverse effects	Considerations in the elderly
Anticoagulants		
Warfarin	Monitor INR (PT) and for bleeding. Review changes in entire drug regimen for interactions	Elderly who are prone to fall may have risks of bleeding but show highest therapeutic benefit
Antihypertensive agents (see Cardiovascular agents)	Additive orthostatic hypotension occurs with many common drugs	Orthostasis increases likelihood of falls
Cardiovascular agents		
ACE inhibitors (or angiotensin receptor blocker)	Worsen renal function in artery stenosis. Cough. Substitute ARB if ACE not tolerated	ACE inhibitors have proven long-term benefits in CHF. Proven renal benefit in diabetes
α-Adrenergic blockers	Syncope and orthostatic hypotension	Particular susceptibility to falls. Slower hepatic clearance
β-Adrenergic blockers	Bronchoconstriction with agents having B-2 effect or in high doses of all agents, depression, orthostasis, glucose intolerance, blocks hypoglycemia warning signs	Proven long-term benefits in CHF, MI
Calcium channel blockers	See Cardiology chapter	
Digoxin	Dysrhythmias, confusion, visual disturbances, anorexia, nausea, vomiting, diarrhea at toxic levels	Many drugs decrease clearance (NSAIDs, etc). Monitor K^+ and toxicity. Decrease dose
Nitrates	Hypotension and orthostasis, dizziness, syncope, headache	Tolerance to beneficial effects alleviated with 8-12 h nitrate-free interval
Cognitive agents	Nausea, insomnia, fatigue	Dose adjustments indicated later in treatment
Tacrine, donepezil	Donepezil is better tolerated	
Diuretics (see Cardiovascular agents)	Electrolyte imbalances, dehydration, orthostasis	Especially prone to orthostasis but low-dose thiazide is still first-line therapy
Endocrine agents		
Insulin, hypoglycemic, oral	Monitor for excess hypoglycemia, which can result from medication interactions	Administer judiciously in anorexia, avoid first-generation sulfonylureas (chlorpropamide)
Thyroid agents	Adjustment to results of thyroid laboratory tests	Bioequivalence problems switching between different products. Stay with same brand
Levothyroxine (Synthroid, Levothyroid)	Excess worsens CHF, tachycardia, weight loss, palpitations, insomnia, sweating	
Erectile dysfunction agents		
Sildenafil, vardenafil	Headache, flushing, dyspepsia, hypotension, QTc prolongation (vardenafil), and many drug-drug interactions	Contraindicated in patients receiving nitrate therapy, those with reduced renal and hepatic clearance (decrease doses) Increased susceptibility to hypotension
Gastrointestinal drugs		
H_2 antagonists	Confusion occasionally	Dose adjust to clearance. Do not necessarily prevent NSAID-induced GI ulcers
Proton pump inhibitors	No more side effects than in younger adults	Do not necessarily prevent NSAID-induced GI ulcers
Glaucoma agents	Burning, itching eyes	Many OTC agents, ophthalmics exacerbate narrow-angle glaucoma (decongestants, antihistamines)

Geriatrics Pharmacy Review (continued)

Drug	Toxic/adverse effects	Considerations in the elderly
Incontinence agents		
Oxybutynin, flavoxate, imipramine, tolterodine	Drowsiness, anticholinergic effects; inhibit early detrusor contractions, hesitancy	Poorly tolerated side effects lead to confusion, falls, retention
Iron products	Constipation, nausea, weight loss	Anorexia, weight loss, patients rarely tolerate more than once-daily dosing
Osteoporosis agents*		
Calcitonin (salmon)	200 units nasal spray	Efficacy data are weaker than with bisphosphonate or hormone replacement therapy
Calcium (Ca) salts	Constipation. H_2 antagonists and proton pump inhibitors impair absorption of Ca salts except calcium citrate	1,200-1,500 mg elemental Ca daily intake for all elderly, postmenopausal women. Add smoking cessation, weight-bearing exercise
Hormone replacement therapy	Abnormal vaginal bleeding, thromboembolism, DVT	Estrogen with progestin to prevent endometrial cancer
Oral bisphosphonates: alendronate, risedronate	Erosive esophagitis	Take 30 min before meals and other medications with full glass of water and remain upright for 30 min
Raloxifene	Thromboembolism, DVT, hot flashes	Effective osteoporosis prevention, but not menopausal symptoms
Vitamin D	Many multivitamins have 400 units/dose	400-800 IU daily with Ca
Psychotropic agents†		
Antidepressants‡		
Tricyclic agents (imipramine, amitriptyline)	Severe anticholinergic, dysrrhythmias, drowsiness	Avoid except nortriptyline or desipramine, which have favorable side-effect profiles
SSRI antidepressants	Fewer severe side effects than with TCAs, but no more effective	Decrease in clearance (renal and hepatic); titrate dose gradually. Use with NSAIDs may increase incidence of GI bleeding
Paroxetine, sertraline	Nausea, weight changes (loss), mental status changes, especially sedation, sexual dysfunction	Watch for weight loss
Fluoxetine	Hallucinations, anxiety	Often worsens anxious behavior
Nafazodone, trazodone	Sedation, anticholinergic, orthostasis, less sexual dysfunction, agitation or weight changes	Trazodone – Sedation (with low dose), but weak antidepressant effect
Mirtazapine	Sedation, weight gain	Decrease in clearance (renal and hepatic); titrate dose gradually
Antipsychotic agents§		
Haloperidol	Tardive dyskinesia high in elderly, extrapyramidal or Parkinson-like symptoms, sedation	Less orthostasis and cardiovascular and anticholinergic effects
Phenothiazines (chlorpromazine, thioridazine, etc.)	Sedation, orthostatic hypotension, dizziness, increased falls, anticholinergic and extrapyramidal effects. Dose-related Q-Tc interval prolongation	Consider atypical agents (less hypotension and anticholinergic and extrapyramidal side effects)
Risperidone, olanzapine, quetiapine, ziprasidone	Weight gain, worsens hyperglycemia. Ziprasidone may prolong Q-Tc interval	Reduce doses because of renal and hepatic clearance decreases. Risperidone showed higher incidence of stroke and TIAs in trials of patients with dementia

Geriatrics Pharmacy Review (continued)

Drug	Toxic/adverse effects	Considerations in the elderly
Psychotropic agents (continued)		
Sedatives and hypnotics		
Benzodiazepines	Sedation, confusion	Use short half-life agents. Lorazepam, oxazepam, & temazepam are preferred because no phase I active metabolites
Zolpidem, zaleplon	Sedation	Higher sensitivity (lower dose indicated). Indicated only for short-term (7 days) treatment of insomnia
Diphenhydramine	Sedation, anticholinergic effects, urinary retention	Worsens narrow-angle glaucoma, susceptible to excess sedation, anticholinergic effects, delirium, confusion. Avoid
Respiratory agents		
Metered-dose inhalers		Frequent inability to coordinate administration. Extended inhalation tube required
Theophylline	Tachycardia, insomnia, anxiety. Narrow therapeutic index necessitates monitor drug levels	Overall side effects not tolerated well. Most respiratory disease can be controlled with other agents (i.e., inhaler therapy)
Zafirlukast	Approved indication is asthma	Prolonged metabolism, indicating dose reduction
Rheumatologic agents		
Colchicine	Nausea, myelosuppression	Increase toxicity in renal dysfunction
Corticosteroids	Nausea, ulcers, weight gain, blood sugar fluctuations, osteoporosis, adrenal suppression	*Taper* to lowest effective dose that decreases symptoms. Consider osteoporosis, PCP prophylaxis
COX-2 inhibitors	Nephrotoxicity, fluid retention, hypertension	Potential fewer GI bleeds. GI bleeding occurs with other pro-ulcer agents (i.e., aspirin, warfarin)
Hydroxychloroquine	Muscle weakness, retinal damage, visual disturbances, nausea	Long time to benefit; if no benefit in 6 mo, stop use. Eye exam needed twice yearly.
Methotrexate	Myelosuppression, nausea, hypotension	Start with lowest possible dose and increase as tolerated
NSAIDs	Nausea, GI ulcers, fluid retention, nephrotoxicity	Use lowest dose possible. Avoid in kidney disease

ACE, angiotensin-converting enzyme; ARB, angiotensin receptor blocker; CHF, congestive heart failure; COX, cyclooxygenase; DVT, deep venous thrombosis; GI, gastrointestinal; INR, international normalized ratio; MI, myocardial infarction; NSAID, nonsteroidal anti-inflammatory drug; OTC, over-the-counter; PCP, *Pneumocystis carinii* pneumonia; PT, prothrombin time; Q-Tc, Q-T interval corrected for heart rate; SSRI, selective serotonin reuptake inhibitor; TCAs, tricyclic antidepressants.

*Osteoporosis is often undertreated in the elderly.

†Use of antipsychotics, sedatives and hypnotics, and anxiolytics in a nursing facility for treating behaviors associated with dementia is regulated and surveyed and requires specific supporting documentation in the patient's chart.

‡Depression is the most common psychiatric diagnosis in the elderly.

§Use of antipsychotic agents for dementia is not a labeled indication. They do not improve dementia but modify behavioral responses. In elderly, start with one-fourth to one-third of usual starting dose.

Hematology

Thomas M. Habermann, MD

Anemias

Evaluation of Anemias

The causes of anemia are complex. The World Health Organization (WHO) defined the lower limit of normal for venous hemoglobin concentration as 13 g/dL in males older than 14 years living at sea level and as 12 g/dL in nonpregnant females. However, accurate interpretation requires the use of an appropriate age-, sex-, and race-adjusted reference range. An organized approach to the anemias is essential. After the history and physical examination, the initial evaluation of anemia begins with a complete blood cell count (CBC). With those results, anemias can be classified on the basis of mean corpuscular volume (MCV) as microcytic, macrocytic, or normocytic.

The CBC is the most commonly ordered blood test. The measured values of the CBC include the total counts for red blood cells (RBCs), platelets, and white blood cells (WBCs) and the volumes of RBCs, platelets, WBCs, and hemoglobin. The calculated values include the hematocrit, MCV, mean corpuscular hemoglobin, mean corpuscular hemoglobin concentration, and red cell distribution width.

The most common anemias are microcytic anemias (Tables 11-1 and 11-2). The differential diagnosis of hypochromic microcytic anemias includes iron deficiency, thalassemic syndromes, anemia of chronic disease, sideroblastic anemias, hemoglobin E, unstable hemoglobins, and lead poisoning. Vitamin B_6 deficiency may cause a microcytic anemia. The causes of iron deficiency include blood loss, increased requirements (as in pregnancy), and decreased absorption (partial gastrectomy and malabsorption syndromes). The following are associated with blood loss: gastrointestinal disorders (ulcers, malignancy, telangiectasia, arteriovenous malformations, hiatal hernia, and long-distance runner's anemia), respiratory disorders (malignancy and pulmonary hemosiderosis), menstruation, phlebotomy (blood donor, diagnostic phlebotomy, polycythemia rubra vera, and self-inflicted), trauma, and surgery.

Iron deficiency is the most common cause of anemia in the world. In the United States, iron deficiency occurs in 11% of adolescent females and women of childbearing age and iron deficiency anemia in 3% to 5%. In a nonreferral practice, iron deficiency may be the cause of up to 90% of all hypochromic microcytic anemias (Fig. 11-1). Of the remaining 10%, thalassemic syndromes are more common than the other rare forms of hypochromic microcytic anemias. However, the incidence and prevalence of anemia of chronic disease vary, depending on whether the setting is inpatient or outpatient and whether the practice is community-based or referral. The CBC and other laboratory values provide additional information for differentiating these entities (Table 11-2). These laboratory studies often provide the major clues to the type of anemia. Blood loss should be considered in the differential diagnosis of any patient with anemia. The evaluation of stool for blood loss is essential in the initial work-up and may also provide clues to a combined anemia. A laboratory approach to microcytic anemias is outlined in Figures 11-2 and 11-3. The serum ferritin test is the most useful initial test for documenting iron deficiency, but the values obtained may be increased in the presence of iron deficiency and coexistent inflammatory states (rheumatoid arthritis), liver disease, hepatocellular carcinoma, and malignancy.

Confusing problems in iron deficiency include patient compliance with iron treatment, incorrect dosage schedules, treatment with enteric-coated iron preparations, diminished absorption (previous operation or mucosal disease of the small bowel), competitive interference with antacids, blood loss in excess of treatment, other causes of anemia, and physician impatience with response. Oral replacement therapy is the treatment of choice for iron deficiency. The

Table 11-1 Differentiation of Microcytic Anemias (Decreased MCV) on the Basis of Blood Values

Variable	Type of anemia	
	Thalassemia	Iron deficiency
RBC count, × 10^{12}/L	>5.0	<5.0
RBC distribution width, %	<16	>16

Hb, hemoglobin; MCV, mean corpuscular volume; RBC, red blood cell.

Table 11-2 Comparison of Hypochromic Microcytic Anemias

Disease state	MCV	Red blood cells	TIBC, µg/dL	% Transferrin saturation	Ferritin, µg/L	Marrow iron
Iron deficiency anemia	Decreased	Decreased	>300	<9	Low	Absent
Anemia of chronic disease	Normal or decreased	Decreased	<300	>15 or normal	Normal or increased	Normal or increased
Thalassemia minor	Decreased	Usually increased	<300	Normal	Normal or increased	Normal

MCV, mean corpuscular volume; TIBC, total iron-binding capacity.
Modified from Savage RA. Cost-effective laboratory diagnosis of microcytic anemias of complex origin. ASCP check sample H84-10(H-153). Used with permission.

initial treatment is ferrous sulfate three times daily at a dose of 325 mg orally 1 hour before or 2 hours after meals. A CBC should be performed again 4 weeks after the initiation of iron therapy. Correction of the anemia would be expected in 6 weeks. Treatment for another 6 months is necessary to replenish bone marrow reserves. Indications for intravenous iron therapy include patients on renal dialysis, bloodless medical treatment, and bloodless surgery for patients who decline blood transfusions because of religious beliefs. Treatment is with iron dextran (InFeD), with the risk of anaphylactoid reactions, or ferric gluconate for renal dialysis patients.

- Typical clinical scenario: An elderly patient with a history of abdominal pain and weakness was found to have a microcytic hypochromic anemia. The serum level of ferritin is low. The RBC count is low. The RBC distribution width index is increased. The diagnosis is iron deficiency anemia. A likely cause is colon cancer producing chronic blood loss. Upper and lower gastrointestinal endoscopy is indicated.

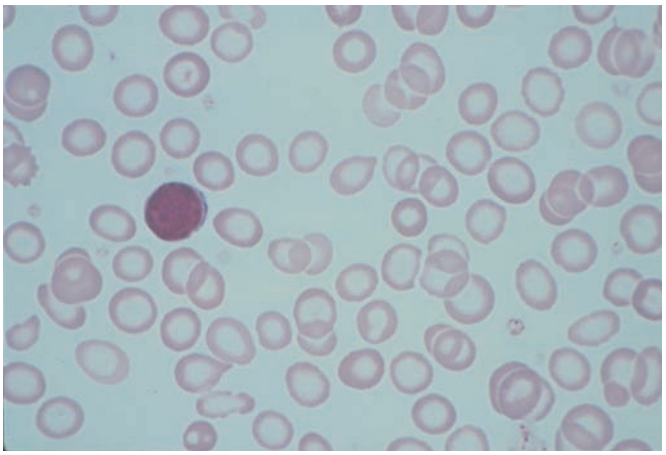

Fig. 11-1. Hypochromic microcytic anemia. Small cells, <6 µm in diameter, with increased central pallor and assorted aberrations in size (anisocytosis) and shape (poikilocytosis). (Courtesy of Curtis A. Hanson, MD, Mayo Clinic.)

Thalassemia is the most common single-gene disorder in the world. β-Thalassemia results when β-globulin chains are decreased (heterozygous) or absent (homozygous), resulting in an excess of α-globulin chains in the RBCs. Patients with the β-thalassemia trait have a mild anemia and marked microcytosis. β-Thalassemia can be identified with simple screening methods (Tables 11-1 and 11-2 and Fig. 11-3). However, if iron deficiency coexists, the hemoglobin A_2 level may be normal. The risks of β-thalassemia include having offspring with thalassemia major or heterozygous hemoglobinopathies and iatrogenic iron overload when the disorder is misdiagnosed as iron deficiency.

The normal population has two α-chain loci but only one β-chain locus per haploid genome. Thus, the absence of one or two of four α-globin genes does not cause symptomatic abnormality (α-thalassemia silent carrier, α-thalassemia minor). Patients with α-thalassemia minor characteristically have a low-normal MCV, with a normal concentration of hemoglobin. The α-thalassemia trait may be confirmed with a polymerase chain reaction–based assay. However, most cases may be managed without laboratory confirmation. Genetic counseling is indicated after the diagnosis of α- or β-thalassemia has been established.

- Typical clinical scenario: An African American person (or person of Mediterranean or Southeast Asian ancestry) has mild anemia and is asymptomatic. The RBC count is disproportionately normal or increased compared with the hemoglobin level. The RBC distribution width index is normal. The concentration of hemoglobin A_2 is increased (β-thalassemia) or normal (α-thalassemia).

The differential diagnosis of macrocytic anemias includes vitamin B_{12} deficiency, folate deficiency, drugs, myelodysplasia, liver disease, alcohol abuse, hypothyroidism, cold agglutinin disease, tobacco, and hemolysis. A laboratory approach to macrocytic anemias is outlined in Figure 11-4. The pathophysiology of drug-induced macrocytosis includes marrow toxicity from interference with folate metabolism (alcohol) and from other drugs (zidovudine) and altered folate metabolism from anticonvulsants (phenytoin, primidone,

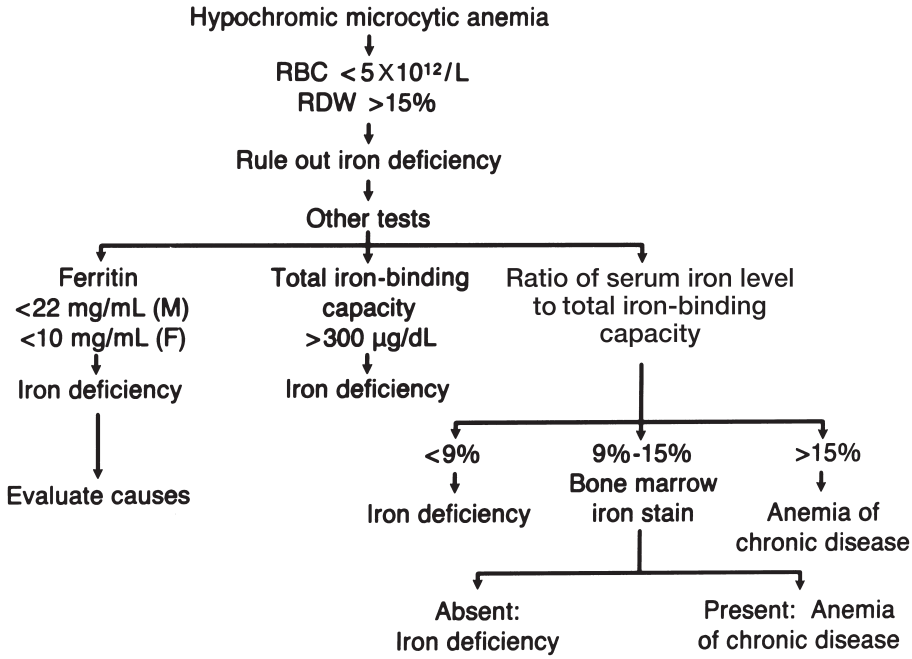

Fig. 11-2. Algorithm for approach to diagnosis of hypochromic microcytic anemias with normal or decreased red blood cell (RBC) counts. RDW, red blood cell distribution width. (Modified from Savage RA. Cost-effective laboratory diagnosis of microcytic anemias of complex origin. ASCP check sample H84-10[H-153]. Used with permission.)

and phenobarbital) and other drugs (oral contraceptives, triamterene, sulfasalazine, and sulfamethoxazole). Common causes of macrocytosis are chemotherapy drugs that inhibit purine or pyrimidine synthesis (azathioprine and 5-fluorouracil), deoxyribonucleotide synthesis (hydroxyurea and cytarabine [cytosine arabinoside]), and dihydrofolate reductase (methotrexate).

Patients with achlorhydria of any cause do not absorb vitamin B_{12} because hydrochloric acid is required to free vitamin B_{12} from food. A normally functioning pancreas is required. The many causes of vitamin B_{12} deficiency include pernicious anemia, total or partial gastrectomy, ileal resection, bacterial overgrowth syndromes, achlorhydria, and chronic pancreatitis.

The symptoms and signs of vitamin B_{12} deficiency include a beefy and atrophic tongue, diarrhea, and neurologic signs (paresthesias, gait disturbance, mental status changes ["B_{12} madness"], vibratory/position sense impairment [dorsal column "dropout"], and the absence of ankle reflexes and extensor plantar responses).

The MCV is increased, and Howell-Jolly bodies are typically present, as are hypersegmented neutrophils. The serum level of methylmalonic acid is increased. A serum level of vitamin B_{12} less than 200 pg/mL is suggestive of the diagnosis of vitamin B_{12} deficiency, but vitamin B_{12} levels of 100 to 200 pg/mL are not diagnostic of a deficiency state. Urinary methylmalonic acid is increased in vitamin B_{12} deficiency. An abnormal intrinsic factor antibody confirms the diagnosis of pernicious anemia. Of patients with pernicious anemia, 60% have a positive blocking antibody test. The serum level of vitamin B_{12} may rarely be normal in pernicious anemia. Serum gastrin levels are high in pernicious anemia.

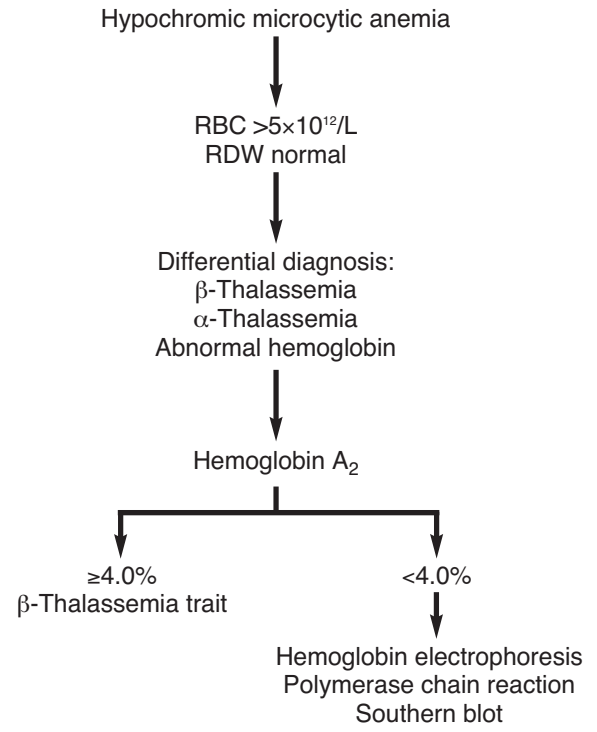

Fig. 11-3. Algorithm for approach to diagnosis of hypochromic microcytic anemias with an increased total red blood cell (RBC) count. RDW, red blood cell distribution width. (Modified from Savage RA. Cost-effective laboratory diagnosis of microcytic anemias of complex origin. ASCP check sample H84-10[H-153]. Used with permission.)

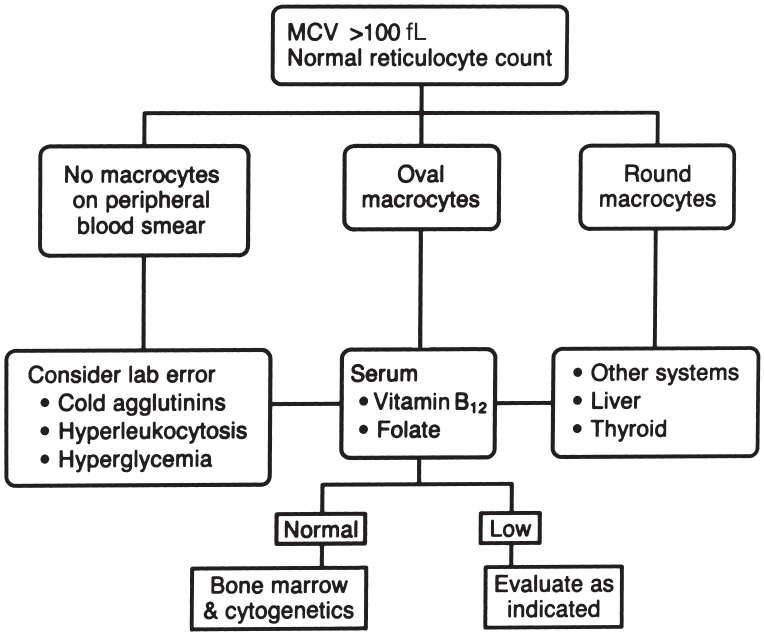

Fig. 11-4. Laboratory approach to macrocytic anemias. MCV, mean corpuscular volume. (Modified from Colon-Otero G, Menke D, Hook CC. A practical approach to the differential diagnosis and evaluation of the adult patient with macrocytic anemia. Med Clin North Am. 1992 May;76:581-97. Used with permission.)

The Schilling test may be required after testing for intrinsic factor blocking antibody. The Schilling test confirms a defect in intestinal absorption (sprue or inflammatory bowel disease). In part I of the test, radiolabeled vitamin B_{12} is administered orally, nonradioactive vitamin B_{12} is administered intramuscularly within 1 to 2 hours, and the urinary and serum levels are measured. Normal urinary excretion rates after a flushing dose of nonradioactive vitamin B_{12} in the first 24 to 72 hours are greater than 7%. Low urine radioactivity with normal renal function means decreased absorption. The differential diagnosis of an abnormal finding in part I includes pernicious anemia, small-bowel disease interfering with absorption, and bacterial competition for vitamin B_{12}. True-negative results in part I of the Schilling test include dietary deficiency and cobalamin-binding protein abnormalities. False-negative results occur in food-bound malabsorption due to achlorhydria. In part II of the test, intrinsic factor is added. Patients with pernicious anemia have normal results. False-positive results occur in cases attributable to mucosal megaloblastosis. Antibiotics are given in part III of the Schilling test, and the differential diagnosis of a positive result includes ileal malabsorption and defective intrinsic factor in the test. A negative test result occurs in the blind loop syndrome secondary to bacterial competition for vitamin B_{12}.

The treatment of pernicious anemia is vitamin B_{12}, 1,000 µg intramuscularly for 5 days, followed by 500 to 1,000 µg intramuscularly every month. Alternatively, vitamin B_{12} may be given orally at a dose of 500 to 1,000 µg daily. Lifelong treatment is required. Vitamin B_{12} levels are spuriously low in pregnancy and in persons receiving oral contraceptive treatment. In the elderly and patients with low WBC counts, the serum levels of methylmelonic acid are increased in vitamin B_{12} deficiency but are normal during pregnancy and when taking oral contraceptives.

- Typical clinical scenario: An elderly diabetic patient has weakness and fatigue, and laboratory evaluation suggests macrocytic anemia. The vitamin B_{12} level is low. The serum level of methylmalonic acid is increased. Anti-intrinsic factor and anti-parietal cell antibody tests are positive.

Megaloblastic anemia caused by folate deficiency develops in 1 to 3 years, in contrast to 3 years for vitamin B_{12} deficiency, because of the low storage levels of folic acid in tissues and the relatively high dietary requirement. This deficiency is less common since fortification of grain products with folic acid was mandated in 1977. Morphologically, this anemia is indistinguishable from vitamin B_{12} deficiency. Folate is absorbed in the proximal small bowel. Deficiency states are associated with increased requirements (pregnancy and hemolytic anemia), poor intake (alcoholics), diseases of the small intestine (sprue), and interference with the recycling of folate from liver stores to tissue (alcohol). The possibility of concomitant vitamin B_{12} and iron deficiency (sprue) should be considered if the response to replacement therapy is not optimal. The serum homocysteine level is increased in folate deficiency because of impaired folate-dependent conversion of homocysteine to methionine.

- Typical clinical scenario: A middle-aged alcoholic person presents with an MCV of 102 fL and normal B_{12} and folate levels.

The normochromic normocytic group of disorders present the greatest challenge in differential diagnosis. Both iron and vitamin B_{12} deficiencies are possible causes and should be excluded. The differential diagnosis includes stem cell dysfunction (aplastic anemia and red cell aplasia), marrow replacement (malignancy and fibrosis),

kidney disease, hemolysis, acute hemorrhage, mixed nutritional deficiency, myelodysplastic syndromes, chemotherapy, anemia of acute disease, anemia of chronic disease characterized by a low total iron-binding capacity (acute infections, chronic infections, neoplasia, rheumatoid arthritis, and polymyalgia rheumatica), and erythropoietin deficiency. The anemia of renal failure and liver disease is important in this differential diagnosis. The anemia of kidney disease may be related to decreased erythropoietin level or shortened RBC survival. It is important to obtain a reticulocyte count to exclude hemolysis early in the evaluation of patients with normochromic normocytic anemia. It is essential to exclude blood loss from the gastrointestinal tract that may be acute and not manifested by features of microcytic blood. No blood test confirms anemia of chronic disease or of acute disease. The soluble transferrin receptor concentration is used to differentiate iron deficiency anemia (the receptor level is usually increased in iron deficiency) from anemia of chronic disease (the receptor level is usually normal).

- Typical clinical scenario for anemia of chronic disease: The patient has renal insufficiency (or human immunodeficiency virus [HIV] infection or other serious medical problem) and microcytic hypochromic anemia. The ferritin level is normal or high. The RBC count is low, and there is no evidence of hemolysis. The erythopoietin level is inappropriately low, given the presence of anemia.

Erythropoietin

Erythropoietin is a glycoprotein that acts through specific receptors on RBC precursors; 90% is produced in the kidneys and a small amount in the liver. There are no preformed stores. Erythropoietin production increases with hypoxia. Hypoxic signals include anemia, hypoxemia, decreased oxygen release (high oxygen-affinity hemoglobinopathies), and decreased renal blood flow (renal artery stenosis). Regulation is linked to an oxygen sensor, not to peripheral catabolism. The serum levels of erythropoietin are not influenced by age or sex. The higher hemoglobin value in men appears to be due to androgenic steroids. The toxicity profile is low. Recombinant human erythropoietin is identical to native erythropoietin. Hypertension may develop or progress in patients receiving renal dialysis.

The serum levels of erythropoietin are low—never absent—in chronic renal failure, polycythemia rubra vera, rheumatoid arthritis, and HIV infection. Zidovudine can increase the serum levels. High erythropoietin levels are present in persons with marrow hypofunction (pure red cell aplasia), deficiency states (iron deficiency), tumor, or autonomous production (hepatocellular carcinoma) or at high altitude.

Approved indications for erythropoietin therapy include anemia of malignancy, anemia caused by neoplastic agents, anemia caused by renal insufficiency, and anemia due to HIV infection in patients who are taking zidovudine. For patients undergoing an operation and donating autologous blood, erythropoietin may increase the amount of blood donated by about 40%. The ferritin concentration should be greater than 100 µg/L or the transferrin saturation greater than 20%. The erythropoietin level should be less than 500 U/L. Recombinant erythropoietin is recommended for chemotherapy patients when the hemoglobin level is less than 10 g/dL. Two preparations are available: epoetin alfa (150 U/kg three times per week or 40,000 U per week) and darbepoetin alfa (2.25 mg/kg per week).

- Erythropoietin: a glycoprotein produced in the kidney; production increases with hypoxia.
- The erythropoietin level is low in renal failure, polycythemia rubra vera, rheumatoid arthritis, and HIV infection.
- Its level is high in persons with pure red cell aplasia, iron deficiency, or tumors or at high altitude.
- Indications for erythropoietin therapy include end-stage renal disease, anemia of HIV infection, anemias of malignancy and neoplastic agents, after bone marrow transplantation, and patients undergoing an operation donating autologous blood.

Patients must have adequate iron stores to respond to erythropoietin. If erythropoietin is given to a healthy person, the hematocrit can increase dramatically. As the hematocrit increases above 60%, the viscosity of the blood rapidly increases. Thus, hypertension, myocardial infarction, or stroke may occur with the misuse of erythropoietin. Doping with erythropoietin for sporting events has been associated with cerebrovascular events due to marked increases in the hematocrit. Patients who have iron deficiency, vitamin B_{12} and folate deficiency, hyperparathyroidism, or aluminum toxicity will not have a response to erythropoietin.

- Typical clinical scenario: A patient receiving chemotherapy presents to a primary care physician with fatigue and a hemoglobin concentration of 8.5 g/dL. Treatment with recombinant erythropoietin is indicated.

Vitamin C Deficiency

Patients with vitamin C deficiency present with anemia and purpura. The purpura may be large. Purpuric lesions are about the hair follicles.

Hemolytic Anemia

In the initial evaluation of suspected hemolysis, it is essential to determine the presence of hemolytic anemia as manifested by laboratory evidence of an increased rate of erythropoiesis and increased RBC destruction. Evidence of increased erythropoiesis includes an increased reticulocyte count, and evidence of increased catabolism and destruction includes an increase in indirect bilirubin and lactate dehydrogenase (LDH) in the initial screening tests. Avoiding this step results in the ordering of unnecessary laboratory tests. If these tests suggest hemolytic anemia, specific causes should be sought. Hemolytic anemias may be Coombs-negative or Coombs-positive. An aplastic crisis may occur in chronic hemolytic anemia secondary to folate deficiency.

The initial evaluation includes a history and physical examination, CBC, RBC morphology, and reticulocyte count. Conditions found during the work-up that can be mistaken for hemolysis include hemorrhage, recovery from deficiency states, metastatic carcinoma,

and myoglobinuria. Studies of a family's hematologic history are important. The differential diagnosis of hemolytic anemia is outlined in Figure 11-5.

Inheritance Patterns

Membrane defects and unstable hemoglobin diseases are autosomal dominant. Most enzymopathies are autosomal recessive. However, the most common enzymopathy, glucose-6-phosphate dehydrogenase (G6PD) deficiency, is sex-linked, as is phosphoglycerate kinase deficiency.

- Membrane defects and unstable hemoglobin diseases are autosomal dominant.
- Most enzymopathies are autosomal recessive.
- G6PD deficiency is sex-linked.

Laboratory Findings

The bilirubin value is usually 1 to 5 mg/dL and almost exclusively unconjugated or indirect. Direct bilirubin should be less than 15% of the total if the bilirubin value is greater than 4 mg/dL. The haptoglobin concentration is usually low, with no compensatory increased rate of synthesis, and the LDH level is increased. CBC abnormalities in autoimmune hemolytic anemia include anemia, thrombocytosis, and thrombocytopenia. The presence of autoimmune hemolytic anemia and autoimmune thrombocytopenia is called *Evans syndrome*. The reticulocyte value usually is persistently increased, reflecting an enhanced bone marrow response.

Peripheral Smear (Differential Diagnosis)

Spherocytes (Fig. 11-6) are associated with hereditary spherocytosis, alcohol, burns, *Clostridium* infections, autoimmune hemolytic anemia, and hypophosphatemia. Basophilic stippling occurs in lead poisoning, β-thalassemia, and arsenic poisoning. Hypochromia occurs in thalassemia and lead poisoning. Target cells are present in thalassemia, hemoglobin C and E, obstructive jaundice, hepatitis, lecithin–cholesterol-acyltransferase deficiency, and the splenectomized state (Fig. 11-7). Agglutination is present in cold agglutinin disease (Fig. 11-8). Stomatocytes are associated with acute alcoholism and also occur as an artifact. Spur cells (acanthocytes) (Fig. 11-9) are present in chronic liver disease, abetalipoproteinemia, malabsorption, and anorexia nervosa. Burr cells (echinocytes) occur in uremia. Heinz bodies are present in G6PD deficiency. Howell-Jolly bodies (the result of fragmentation of the nucleus) indicate hyposplenism and megaloblastic anemia.

Differential Diagnosis of Intravascular Hemolysis

The differential diagnosis of intravascular hemolysis includes transfusion reactions from ABO antibodies, microangiopathic hemolytic anemia, paroxysmal nocturnal hemoglobinuria, paroxysmal cold hemoglobinuria, autoimmune hemolytic anemia (uncommon), cold agglutinin syndrome, immune-complex drug-induced hemolytic anemia, infections (including falciparum malaria and clostridial sepsis), and G6PD deficiency.

- Most hemolysis is extravascular.

In intravascular hemolysis, hemoglobin is released into the plasma, where it combines rapidly with haptoglobin, which transports it to the liver. When haptoglobin is depleted, hemoglobinemia results and the plasma turns pink-red at concentrations of 50 to 100 mg/dL.

Hemoglobinuria occurs when the plasma hemoglobin is less than 25 mg/100 mL. The urine may become pink, red, brown, or

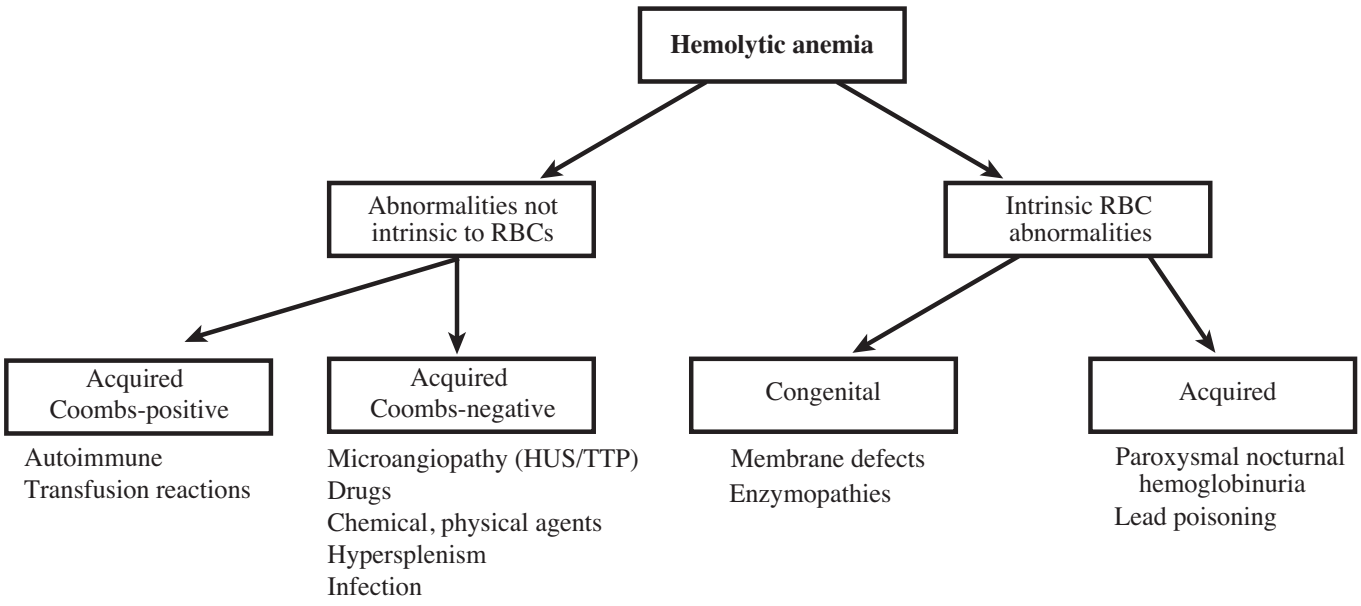

Fig. 11-5. Differential diagnosis of hemolytic anemia. HUS, hemolytic uremic syndrome; RBC, red blood cell; TTP, thrombotic thrombocytopenic purpura.

black. Other causes of red urine include beets, phenazopyridine (Pyridium), porphyrinuria, and myoglobinuria. Hemosiderin is an insoluble form of iron consisting of breakdown products of ferritin. Hemosiderinuria is the result of desquamation of renal tubular cells.

Coombs-Positive Hemolytic Anemia

Positive results with a direct Coombs test indicate the presence of C3 or IgG (or both) on the surface of RBCs. The three most common causes of Coombs-positive hemolytic anemias are idiopathic, drugs, and malignancy, including chronic lymphocytic leukemia, non-Hodgkin lymphoma, and ovarian carcinoma. The Coombs test gives positive results in 8% to 15% of all hospitalized patients, and studies have not demonstrated the cause in 95% of these patients. Hemolytic transfusion and drug-related reactions are important causes of a positive Coombs test.

- Coombs test: detects the presence of C3 or IgG (or both) on RBCs.
- The cause of positive findings on the Coombs test is unknown for 95% of hospitalized patients.
- Transfusion-related and drug-related reactions are important causes of a positive Coombs test.

Drug-Induced Hemolytic Anemia (Mechanisms)

Autoantibody Mechanism

The autoantibody mechanism associated with methyldopa is dose-related, and hemolysis develops in about 0.3% to 0.8% of patients. Hemolysis occurs 18 weeks to 4 years after ingestion of the drug. The direct Coombs test becomes positive in 3 to 6 months, and the IgG titer is high. There is no anamnestic response to rechallenge. Discontinuation of use of the drug usually leads to a rapid reversal

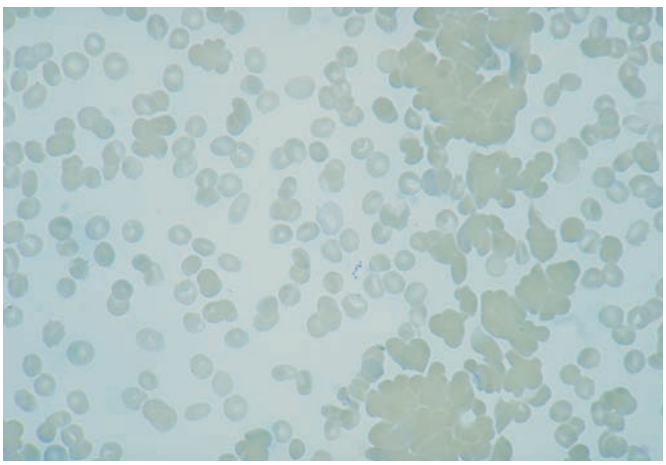

Fig. 11-8. Agglutination. Clumping of red blood cells.

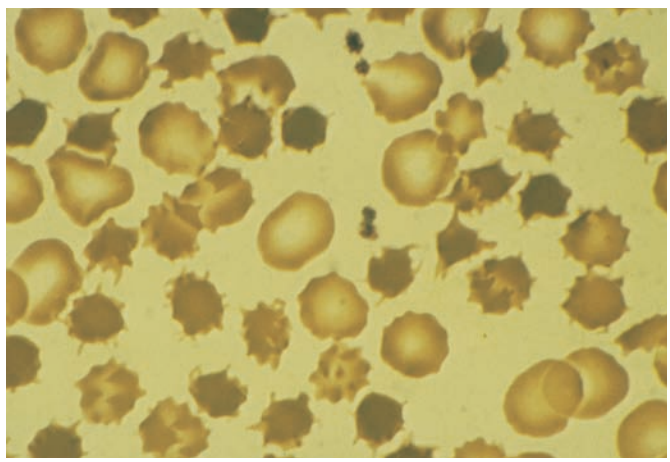

Fig. 11-9. Spur cells (acanthocytes). Note the thin, thorny, or finger-like projections. (Courtesy of Curtis A. Hanson, MD, Mayo Clinic.)

in hemolysis. The mechanism of action is related to an altered cellular immune system, with a block in the activation of suppressor T cells. Methyldopa induces the formation of anti-Rh antibodies. Other drugs with a similar mechanism known to cause autoimmune hemolytic anemia include procainamide, ibuprofen, and cimetidine.

Drug Adsorption Mechanism

In drug adsorption (hapten) immunohemolytic anemia (penicillin or cephalosporin), the drug binds to the RBC membrane and antibody forms against the drug membrane–antigen complex. This complication requires high doses of drug for more than 7 days. The onset is subacute at 7 to 10 days. A high titer of penicillin antibody is always present in the serum. A positive Coombs test develops in 3% of patients, and the response is dose-related in that 30% of patients are positive at 2 million U/d and 100% at 10 million U/d. Penicillin allergy is not necessarily present. Drug-adsorption immunohemolytic anemia may be fatal if not detected early. Other drugs, including cephalosporins, tetracycline, quinidine, tolmetin, and cisplatin, may cause autoimmune hemolytic anemia through the same mechanism.

Immune-Complex Mechanism

In the immune-complex, or "innocent bystander," mechanism (quinine, rifampin, and stibophen), the antidrug antibody forms first and reacts with the drug to form an immune complex. The antidrug–antibody complex is then adsorbed on the RBCs. The cell-bound complex may activate complement, causing intravascular hemolysis. The Coombs test is positive because of the complement on the RBC surface. Clinically, a small quantity of drug is sufficient to cause autoimmune hemolytic anemia if there was previous exposure. Acute intravascular hemolysis with hemoglobinemia and hemoglobinuria is the usual clinical course. Drugs implicated in this type of autoimmune hemolytic anemia include quinidine, quinine, phenacetin, acetaminophen, para-aminosalicylate (PAS), isoniazid (INH), streptomycin, rifampin, methadone, probenecid, insulin, sulfonylureas, hydralazine, hydrochlorothiazide, sulfa drugs, triamterene, and melphalan. Immune hemolytic anemia and renal failure may occur in patients taking captopril, hydrochlorothiazide, rifampin, dipyrone, or mitomycin C.

- Autoantibody mechanism: methyldopa.
- Drug adsorption mechanism: penicillin.
- Immune-complex mechanism: stibophen, quinine, and quinidine.
- Some drugs produce autoimmune hemolytic anemia by more than one mechanism.
- Typical clinical scenario: A patient has evidence of hemolysis (increased reticulocyte count, LDH, and indirect bilirubin), positive Coombs test with or without splenomegaly, and jaundice, with a positive drug history.

The first general principle in the treatment of warm autoimmune hemolytic anemia is to treat the underlying disease and to discontinue the use of drugs that have been implicated in hemolysis. If the patient's condition is stable clinically, do not transfuse blood. Avoid transfusion for patients with autoimmune hemolytic anemia. If the patient is symptomatic and studies show improvement in symptoms if the hemoglobin concentration is greater than 8 g/dL, transfuse packed RBCs only if angina, cardiac decompensation, or neurologic symptoms (e.g., lethargy, weakness, confusion, or obtundation) are present. If transfusion is required, transfuse the most compatible RBCs by crossmatch with type-specific ABO and Rh blood. The major risk of transfusion is the formation of autoantibodies to foreign RBC antigens.

Corticosteroids are indicated for the treatment of idiopathic autoimmune hemolytic anemia and are considered in the treatment of disease-associated autoimmune hemolytic anemia. In drug-related warm autoimmune hemolytic anemia, treatment usually is limited to discontinuing use of the implicated drug. The dosage of prednisone should be 1 mg/kg daily. Most patients have a response in 7 days. Patients should have supplementation with oral folate (1 mg daily). If the patient has a relapse during tapering of the drug, return to the previous dose. Splenectomy is required for about 60% of patients with idiopathic autoimmune hemolytic anemia. Immunosuppressive drugs such as cyclophosphamide, danazol (400-800 mg daily), and high-dose intravenous gamma globulin are the next lines of therapy.

Cold Agglutinin Syndrome (Primary Cold Agglutinin Disease)

Cold agglutinin syndrome is characterized by agglutination, hemolytic anemia, a positive Coombs test, chronic anemia, and a "monotonous" prognosis. Autoantibodies are maximally reactive at low temperatures. The degree of hemolysis depends on the thermal amplitude: the higher the titer, the more likely complement is to bind. The clinical signs and symptoms are related to small-vessel occlusion and include acrocyanosis of the ears, tip of the nose, toes, and fingers. Hepatosplenomegaly is uncommon. The skin is dusky blue and then turns normal or blanches. All digits may be affected equally. This should be differentiated from Raynaud phenomenon, in which the skin of one or two fingers turns white to blue to red.

The peripheral blood smear shows RBC agglutination that disappears if prepared at 37°C (Fig. 11-8). Agglutinated RBCs clump together. In rouleaux, the cells stack up on one another (Fig. 11-10). The anemia is mild to moderate, and the Coombs test is positive. The cold agglutinin titer is greater than 1:1,000. Therapy includes avoidance of the cold. Oral danazol (200 mg twice daily) or subcutaneous interferon alfa may be given as initial therapy. Some patients may respond to immunosuppressive drugs such as cyclophosphamide or chlorambucil. Plasma exchange is not very effective but should be considered if the patient is acutely ill, because IgM is intravascular.

- Cold agglutinin syndrome: agglutination and hemolytic anemia.
- Positive Coombs test response and cold agglutinin titer >1:1,000.
- Typical clinical scenario: The patient has acrocyanosis of the ears, tip of the nose, toes, and fingers. The diagnosis of cold agglutinin syndrome is made by finding, on a peripheral blood smear, RBC agglutination that disappears if the smear is prepared at 37°C. Differentiate from Raynaud phenomenon with Coombs-positive hemolytic anemia.

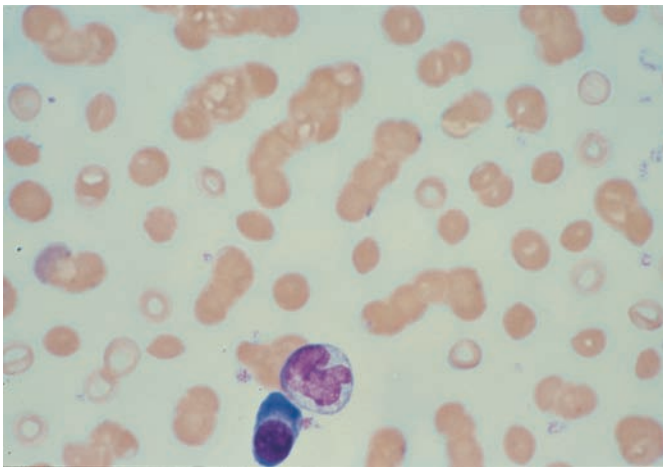

Fig. 11-10. Rouleaux. Stacking of red blood cells. (Courtesy of Curtis A. Hanson, MD, Mayo Clinic.)

Immunology of Cold Agglutinins

An IgM antibody exhibits a reversible thermal-dependent equilibrium reaction with the I or i antigen, which is related to the ABO on RBCs and is favored at lower temperatures. A monoclonal κ protein is found in cold agglutinin syndrome, chronic lymphocytic leukemia, multiple myeloma, lymphoma, and Waldenström macroglobulinemia. In secondary diseases, there is a polyclonal light chain reaction with a high thermal cold agglutinin of anti-I specificity (*Mycoplasma pneumoniae*) or anti-i specificity (infectious mononucleosis, cytomegalovirus, and lymphoma).

Mycoplasma pneumoniae *(anti-I)*

Of the patients with *Mycoplasma pneumoniae*, 50% have cold agglutinins greater than 1:64, most have splenomegaly, and acrocyanosis is unusual. The course of this complication generally resolves in 2 or 3 weeks, but fatalities have been reported. Treatment includes keeping the patient warm and treating the infection with tetracycline or erythromycin.

Infectious Mononucleosis (anti-i)

Of the patients with infectious mononucleosis, 40% to 50% have cold agglutinins and 3% have autoimmune hemolytic anemia. The onset occurs by 13 days in 67% of patients. The duration of hemolysis is less than 1 month in 75% of patients and 1 to 2 months in 25%. Hepatosplenomegaly is present in 71% of patients. Corticosteroids are of distinct value in treating this disorder, as may be splenectomy.

Paroxysmal Cold Hemoglobinuria (Complement-Mediated Lysis)

Paroxysmal cold hemoglobinuria is the least common cause of autoimmune hemolytic anemia. Results of the Donath-Landsteiner test are positive. This condition can be idiopathic or secondary. The secondary causes include syphilis (congenital and late), mononucleosis, mycoplasma, chickenpox, mumps, and measles. Measles is the most common secondary cause. Clinical manifestations include shaking chills, fever, malaise, abdominal pain, back pain, and leg pain. There is rapid and severe anemia. The prognosis is good. This condition resolves after the infection clears. Treatment includes protection from the cold, treatment of the underlying disease, and possibly a short course of corticosteroids.

Coombs-Negative Hemolytic Anemias

The differential diagnosis of Coombs-negative hemolytic anemia includes the enzymopathies (G6PD deficiency and pyruvate kinase deficiency), paroxysmal nocturnal hemoglobinuria, hereditary spherocytosis, Wilson disease, and thrombotic thrombocytopenic purpura.

Glucose-6-Phosphate Dehydrogenase Deficiency

G6PD deficiency is the most common RBC enzyme deficiency. It causes decreased levels of glutathione, which is an antioxidant. It is inherited on the X chromosome and is sex-linked. All enzymopathies are autosomal recessive except G6PD and phosphoglycerate kinase deficiencies, which are sex-linked. It is present in 12% of African Americans (70% G6PD B+, the wild type), and 20% of African American females carry the G6PD A– variant. The variant in people of Mediterranean origin is G6PD B– and is associated with the ingestion of uncooked fava beans and may cause hemolysis. In females, one X chromosome is inactivated, and the gene is present on both, so the activity ranges from 0% to 100%, with a mosaic population. G6PD deficiency confers some protection against falciparum malaria. Protection extends to both males and heterozygous females. This selective advantage has been attributed to the inhibition of parasite growth and replication through the mechanism of increased oxidant stress.

The oxidation of hemoglobin leads to the formation of methemoglobin, and sulfhemoglobin may be a product, with precipitation, condensation, and attachment of the denatured portion to the inside of the membrane-forming Heinz bodies. The normal enzyme has a half-life of 62 days, but reticulocytes have a half-life of 124 days and aged cells have a half-life of 31 days. Therefore, in an acute hemolytic state, the glucose-6-phosphate level may be within normal limits because sensitive old RBCs are destroyed and younger RBCs with higher enzyme activity are resistant. Therefore, in the African American variant, the hemolysis is self-limited. There is individual variability to oxidant stress. It is not possible to stimulate the enzyme with methylene blue or ascorbic acid to counteract the formation of methemoglobin; these drugs may actually exacerbate the anemia.

In the steady state, there is no anemia or RBC defect. There is an increased risk of hemolysis in patients with concurrent kidney or liver disease, viral or bacterial infection, diabetic acidosis, viral hepatitis, and low levels of blood glucose. Even a mild infection can produce hemolytic anemia; this is more common than drug provocation. The organisms commonly associated with this complication are *Salmonella*, *Escherichia coli*, pneumococci, and *Rickettsia*. Favism is found only in whites, not in blacks.

Drugs that commonly cause hemolytic anemia in G6PD deficiency include antimalarial agents (primaquine and chloroquine), dapsone, sulfonamides (sulfanilamide, sulfamethoxazole, sulfapyridine, and sulfasalazine), nitrofurantoin, diazoxide, high-dose aspirin, probenecid, and nitrites (which are derived from nitrates from nitroglycerin, fertilizer-contaminated home wells, and amyl nitrite).

Abnormal laboratory findings include intravascular hemolysis, methemoglobinemia, and methemalbuminemia (highly specific for intravascular hemolysis). Supravital staining for Heinz bodies is a good screening test, but the absence of these bodies does not rule out the diagnosis. Reticulocytosis rarely masks the deficiency in whites, but it may in blacks and heterozygous females. The G6PD assay is the definitive test. Therapy includes treating the underlying infection and withdrawing use of the offending drug.

- G6PD deficiency: the most common RBC enzyme deficiency; it is inherited on the X chromosome.
- G6PD deficiency provides some protection against falciparum malaria.
- Half-life: normal enzyme, 62 days; reticulocytes, 124 days; and aged cells, 31 days.
- No anemia or RBC defect occurs in the steady state.
- Important to look for cause, particularly drugs.
- Infection is more common than drug provocation.
- A good screening test: Heinz bodies seen on supravital staining of the peripheral blood.
- Treat underlying infections and withdraw the use of offending drugs.
- Typical clinical scenario: Acute symptomatic anemia in an African American after infection or drug ingestion. There is evidence of intravascular hemolysis (including an increase in the LDH level), urinary hemoglobinuria, and hemosiderinuria and a decrease in haptoglobin levels. The Heinz body test is positive. The Coombs test is negative.

Other Enzymopathies

The most common deficiency states are G6PD and pyruvate kinase. In a referral population, only 35% of patients who were referred for an enzyme deficiency work-up had an identifiable enzyme deficiency.

Paroxysmal Nocturnal Hemoglobinuria

Paroxysmal nocturnal hemoglobinuria is an acquired clonal chronic hematologic stem cell disorder. Patients with this condition have a median survival of 10 years. It is a clonal disorder in which blood cells are unusually sensitive to activated complement and are lysed. Hemolysis occurs at night because this is when plasma becomes more acidotic. The disorder is characterized by abnormal pluripotent stem cells, reticulocytopenia, leukopenia, or thrombocytopenia due to lysis by complement. Normal and abnormal cells occur simultaneously in most patients.

A distinct class of membrane proteins is selectively deleted from the plasma membranes of maturing cells. The abnormal cells in paroxysmal nocturnal hemoglobinuria have decreased glycosylphosphatidylinositol (GPI)-linked proteins in erythroid, granulocytic, megakaryocytic, and, in some cases, lymphoid cells, which is the result of a somatic mutation in the *PIG-A* gene. Flow cytometric studies can detect the presence or absence of these GPI-linked proteins, which include CD14, CD16, CD24, CD55, and CD59. This disease involves deficiencies in the surface molecules that normally regulate activation of C3B and C5 to C9 in the complement cascade. There is a decreased quantity of a membrane protein (decay-accelerating factor [CD55]) and homologous restriction factor that regulates the alternate complement pathway on normal blood cells. Also, the activity of RBC acetylcholinesterase is decreased.

Clinically, paroxysmal nocturnal hemoglobinuria is characterized by a chronic hemolytic anemia with hemoglobinuria and hemoglobinemia (intravascular hemolysis). Venous thrombosis of the portal system, brain, and extremities is associated with 50% of the deaths in paroxysmal nocturnal hemoglobinuria. Episodes of severe pain may occur in the abdomen and back in conjunction with painful or difficult swallowing.

Complications include acute nonlymphocytic leukemia in 5% to 10% of patients (paroxysmal nocturnal hemoglobinuria clone disappears), aplastic anemia (the association of aplastic anemia, splenomegaly, and relative reticulocytosis suggests the diagnosis), and venous thrombosis (Budd-Chiari syndrome is the main cause of death). Budd-Chiari syndrome is manifested by abdominal pain, tender hepatomegaly, nausea, vomiting, fever, and increased levels of LDH, serum glutamic-oxalacetic transaminase, γ-glutamyl-transferase, and conjugated bilirubin. Liver ultrasonography and venography are important in making the diagnosis. Treatment includes emergent heparinization, a long-term course of anticoagulation, and fibrinolytic therapy.

The most useful assay is flow cytometry to establish the absence of the GPI-linked antigens (this has replaced the sucrose hemolysis test and the Ham test [acid hemolysis test]).

Up to 60% of patients benefit from prednisone treatment. Prednisone (20-40 mg every other day) may inhibit activation of complement by the alternate pathway. Prednisone is of no benefit if the bone marrow is hypoplastic or if there is mild hemolysis. Corticosteroid treatment should be discontinued if no effect occurs in 6 weeks. Danazol may be effective. Transfuse packed RBCs. If hemolysis has occurred, washed or frozen RBCs should be given. A hemolytic crisis may be initiated by infections. Treatment may include corticosteroids, transfusion, and hydration to prevent renal failure. For venous thrombosis, the treatment of choice is heparin, which may activate the alternate pathway of complement. Painful episodes are managed with narcotics and rehydration. Bone marrow transplantation is indicated for severe aplastic anemia. Antithymocyte globulin is effective in the management of paroxysmal nocturnal hemoglobinuria with aplastic anemia.

- Paroxysmal nocturnal hemoglobinuria is a chronic disease.
- Venous thrombosis is associated with 50% of deaths.
- Intravascular hemolysis with hemoglobinuria and hemoglobinemia.
- Leukemia occurs in 5%-10%; aplastic anemia.
- Diagnosis: Ham test, sucrose hemolysis test, and flow cytometry studies.
- Typical clinical scenario: A patient has pancytopenia, Coombs-negative anemia, dark urine, abdominal pain, absence of stainable iron in the marrow, and unusual venous thrombosis.

Hereditary Spherocytosis

Hereditary spherocytosis, in which splenomegaly is invariably present, most commonly is an autosomal dominant disorder (75%), but it

can be autosomal recessive or sporadic. It is caused by an underlying defect in the RBC membrane cytoskeleton owing to a partial deficiency in one or more of the components ankyrin, spectrin and ankyrin, band 3, and protein 4.2. Osmotic fragility of RBCs is increased. The results of the incubated osmotic fragility test—the most reliable diagnostic test—are almost always abnormal. The clinical features include jaundice, splenomegaly, negative results on the Coombs test, spherocytes, and increased osmotic fragility. Gallstones are present in 43% to 85% of patients (55%-75% after the fifth decade). Treatment is splenectomy, which invariably causes a reduction in hemolysis. It should be performed after the first decade of life. Asymptomatic adults may be observed if they have a hemoglobin concentration greater than 11 g/dL and a reticulocyte count less than 6%.

- Hereditary spherocytosis: autosomal dominant (75%), autosomal recessive, or sporadic.
- Splenomegaly is invariably present; cholelithiasis occurs in 55%-75% after the fifth decade.
- Other features: negative results on the Coombs test and increased osmotic fragility.
- Treatment: splenectomy after the first decade of life for patients with moderate or severe hemolysis. Asymptomatic adults with a hemoglobin concentration >11 g/dL and reticulocyte count <6% may be observed.
- Typical clinical scenario: A patient presents with extravascular hemolysis, spherocytosis, splenomegaly, and premature gallstones.

Thrombotic Microangiopathies: Differential Diagnosis

In microangiopathic hemolytic anemia, the RBCs are fragmented and deformed in the peripheral blood (Fig. 11-11). The fragmentation is caused by fibrin deposits in small blood vessels which lead to mechanical hemolysis. The results of the Coombs test are negative. Patients with microangiopathic hemolytic anemia are often thrombocytopenic. The associated disorders are characterized by widespread microvascular thrombosis leading to end-organ injury.

Microangiopathic hemolytic anemia is associated with thrombotic thrombocytopenic purpura, hemolytic uremic syndrome, malignant hypertension, pulmonary hypertension, acute glomerulonephritis, acute renal failure, renal allograft rejection, HELLP syndrome (hemolysis, elevated liver function tests, and low platelet count), pregnancy (last trimester), postpartum state, disseminated intravascular coagulopathy, collagen vascular diseases (scleroderma, systemic lupus erythematosus, Wegener syndrome, and periarteritis nodosa), cardiac valve hemolysis, carcinomatosis, small gastric carcinomas, hemangiomas, Kasabach-Merritt syndrome, viral infections (HIV), bacterial infections (*E. coli* O157:H7), drugs (mitomycin C, quinine, ticlopidine, tacrolimus, cisplatin, and cyclosporine), acute radiation nephropathy, post–bone marrow transplantation (total body irradiation and allogeneic bone marrow transplantation more than autologous marrow transplantation), and post–solid-organ transplantation.

Thrombotic Thrombocytopenic Purpura

Idiopathic thrombotic thrombocytopenic purpura (TTP) is a syndrome rather than a disease. Classically, it is characterized by the pentad of anemia, thrombocytopenia, neurologic signs, fever, and kidney abnormalities. The primary criteria are thrombocytopenia and microangiopathy, and these are sufficient to establish the diagnosis. The anemia is normochromic normocytic, with microangiopathic hemolytic features (Fig. 11-11). The serum LDH levels are increased and often high. The Coombs test gives negative results. The results of coagulation studies are normal or only mildly abnormal, in contrast to disseminated intravascular coagulopathy. The cause of this syndrome is unknown in more than 90% of patients. TTP is related to pregnancy and the use of oral contraceptives.

Clinically, thrombocytopenia is associated with bleeding in 96% of patients and includes petechiae, purpura, retinal bleeding, hematuria, gingival bleeding, melena, menorrhagia, hematemesis, and hemoptysis. Neurologic signs consist of remittent and frequent changes, including headache, coma, mental changes, paresis, seizure/coma, aphasia, syncope, visual symptoms, dysarthria, vertigo, agitation, confusion, and delirium. Kidney abnormalities include a creatinine level greater than 1.5 mg/dL (in less than 20% of patients). Azotemia is an unfavorable prognostic sign. An abnormal urinary sediment with proteinuria, hematuria, pyuria, or casts was present in 82% of patients in one series. Results of coagulation studies, including activated partial thromboplastin time (APTT), prothrombin time (PT), and fibrinogen, are characteristically normal.

The pathologic findings are characterized by widespread intraluminal hyaline vascular occlusions with platelet aggregates and fibrin, with no inflammatory changes in the microvasculature (terminal arterioles or capillaries) in virtually any organ. The preferred biopsy site is the bone marrow. Other sites to consider for biopsy are the gingiva, skin, petechial spot, muscle, and lymph nodes. Systemic endothelial damage is the result of apoptosis in the microvasculature. This causes the release of von Willebrand factor (vWF), which is

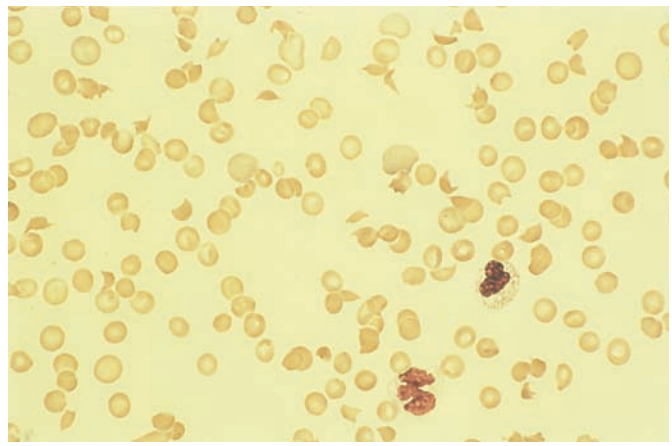

Fig. 11-11. Schistocytes. Fragmented red blood cells shaped like helmets, triangles, or kites. (Courtesy of Curtis A. Hanson, MD, Mayo Clinic.)

believed to participate in platelet agglutination and thrombus formation. Patients with TTP are deficient in the vWF-cleaving protease ADAMTS13 that reduces the size of the large vWF multimers. A severe deficiency of ADAMTS13 is detected in patients with acquired or congenital TTP. Large multimers of vWF appear to be the aggregating agents of TTP. Patients who have had a single acute episode of TTP have little if any plasma vWF-cleaving protease activity, and an IgG antibody accounts for the lack of protease activity in the sporadic form.

Without treatment, more than 90% of patients die of multiorgan failure, but with treatment, 70% to 80% survive the disease and have few or no sequelae. The treatment of choice is plasma exchange (plasmapheresis with infusion of fresh frozen plasma or the supernatant fraction from cryoprecipitate preparations [cryosupernatant]). The deficiency of ADAMTS13 as the cause of TTP explains why plasma infusion or exchange is effective. This is the only treatment at many centers. Other ancillary treatments with unknown value include dipyridamole (400-600 mg daily), aspirin (from 300 mg twice weekly to 600-1,200 mg daily), and prednisone (60 mg/kg daily). The overall response rate to therapy is 80% to 90%. The projected 10-year risk of relapse in the Canadian Apheresis Group Trial is 36%. The management of refractory disease includes intravenous vincristine, splenectomy, and intravenous high-dose gamma globulin. Platelet transfusions should be used only when required for an invasive procedure.

- TTP: the pentad of anemia, fever, thrombocytopenia, neurologic signs, and renal abnormalities.
- Its cause is unknown; exclude oral contraceptives and pregnancy as etiologic factors.
- Features: Coombs test gives negative results, microangiopathy, normal PT, normal APTT, and normal fibrinogen.
- The treatment of choice is plasmapheresis with infusion of fresh frozen plasma.
- Typical clinical scenario: A patient presents with anemia, thrombocytopenia, neurologic signs and symptoms, renal abnormalities, and fever. Peripheral blood smear shows schistocytes. Clotting times (PT and APTT) are normal.

Hemolytic Uremic Syndrome

Hemolytic uremic syndrome is characterized by microangiopathic hemolytic anemia (anemia and thrombocytopenia) and renal microangiopathy, with a creatinine level greater than 3 mg/dL. Fever and neurologic signs are not part of this syndrome. The pathologic findings are similar to those in thrombotic thrombocytopenic purpura but are limited to the kidneys. It is often preceded by an acute infectious process. The morbidity and mortality rates are much higher for adults than for children. A recurrent illness may be caused by defective production of the complement control protein factor H. Adult hemolytic uremic syndrome is best managed with plasma exchange. The syndrome may be associated with *E. coli* O157:H7 diarrhea, as is the classic association in children. Other associations include various *E. coli* serotypes and *Shigella dysenteriae*. Hemolytic uremic syndrome is usually not associated with a decrease in ADAMTS13 activity. The management of the hemolytic-uremic syndrome with this complication is supportive. Dialysis may be necessary. Corticosteroids may be incorporated in the management.

Sickle Cell Disorders

The sickle cell disorders include sickle cell anemia (homozygous sickle gene), sickle cell trait (heterozygous), and other forms of sickle cell disease (sickle cell–hemoglobin C disease, and sickle cell thalassemia).

Sickle cell anemia is the most common heritable hematologic disease affecting humans. The gene for the β chain must be inherited from both parents. It occurs in black Africans and rarely in whites. About 8% of African Americans carry the sickle cell gene, with disease occurring in 1 of 625 individuals. The sickle cell trait offers a selective advantage because in malaria due to *Plasmodium falciparum*, the parasitized cells preferentially sickle. Sickle cell anemia is an example of a balanced polymorphism (a common mutation) that provides a selective advantage but also has the potential to produce a disease state. In the heterozygous state, there is protection against malaria. In the homozygous state, sickle cell anemia is a serious, life-shortening disease. Hemoglobin S is different from hemoglobin A in the substitution of valine for glutamic acid at the sixth position of the β chain. Deoxygenated hemoglobin S aggregates into rigid polymers that essentially fill the cell and distort it into a sickle shape. The end result of the polymerization is a permanently altered membrane protein. Vaso-occlusion is a function of decreased RBC deformability, increased viscosity, and increased RBC adherence to the endothelium. Two-thirds of the RBCs are removed by extravascular mechanisms.

Vaso-occlusion occurs in arterioles and larger arteries, not capillaries. Polymorphonuclear leukocytes release activators.

Sickling is inhibited by hemoglobin F, which is a potent inhibitor of polymerization, the process that leads to sickling. Sickling is promoted by low oxygen tension, low pH, high cellular concentration of hemoglobins, loss of cell water, hemoglobin D, and hemoglobinopathy.

Symptoms are not present until the patient is older than 6 months. Vaso-occlusive disease develops between the ages of 12 months and 6 years. Acute crises result from recurrent obstruction of the microcirculation by intravascular sickling. Laboratory testing is not helpful. Atypical symptoms should suggest pneumonia, pulmonary infarct, acute pyelonephritis, or cholecystitis.

Bone and joint pain crises are characterized by gnawing pain and swelling of the elbows and knees. Pain prevalence is highest between ages 19 and 39 years. The average duration is 10 days. Radiographs may show bone infarcts and periostitis, but these do not appear until symptoms subside. Infarcts and periostitis may be documented with bone scans. Abdominal crises result from small infarcts of the mesentery and abdominal viscera, with symptoms lasting for 4 or 5 days. This is a nonsurgical problem if bowel sounds are present. Associated signs and symptoms include fever, tenderness, hypertension, tachycardia, tachypnea, nausea, and vomiting. Treatment includes bed rest, folate supplementation, heating pads, tub baths, analgesics, intravenous narcotics, opioid medications, antihistamines, intravenous hydration with hypotonic fluids (after correcting the volume depletion; limited to 1 to 1.5 times maintenance

fluid requirements to avoid overhydration), and correction of hypoxia and acidosis.

The Cooperative Study of Sickle Cell Disease reported that the incidence of hemorrhagic stroke was highest among patients 20 to 29 years old, with a mortality rate of 26% in the first 2 weeks and no deaths after infarctive strokes. The frequency of stroke is 10% to 15% among children and young adults. Transient ischemic attack is a strong risk factor for infarctive stroke. Angiographic procedures should not be performed unless the patient has been prepared with RBCs. The management for these crises is immediate exchange transfusion to decrease hemoglobin S levels to less than 30% and maintain the hematocrit at less than 33% to 35%. In a randomized study of chronic transfusion, therapy decreased the risk of recurrence of a cerebrovascular event. Chronic transfusion therapy is indicated for this complication to maintain hemoglobin S higher than 30%, because the risk of recurrent episodes is more than 46% to 90%. Multivariate analysis found that low steady-state hemoglobin concentration and high leukocyte concentration were not factors for hemorrhagic stroke. This complication clusters in families and is associated with a risk of recurrence of up to 90%.

In pulmonary crises, acute chest syndrome accounts for up to 25% of deaths in sickle cell disease and the risk is 25%. Clinical aspects include fever, chest pain, tachypnea, increased WBC count, and pulmonary infiltrates. Age is a factor in cause. In children, infected segments enhance local sickling, so sickling is a secondary phenomenon. The causative organisms include pneumococcus, *Mycoplasma*, *Haemophilus*, *Salmonella*, and *E. coli*. In adults, sickling tends to be a primary event, with no sign of infection. In a cooperative study, 13% of patients required ventilator support, 11% had neurologic events, and the mortality rate was 9%. With multifactorial causes (thromboembolism and fat embolism), chronic lung disease is a long-term complication. Acute management includes supportive measures, which include decreasing the level of hemoglobin S to 20% to 30%.

Aplastic crises usually follow a febrile illness, with the disappearance of reticulocytes and normoblasts. B19 parvovirus infections are more common in adults than in children. Other agents include *Salmonella*, *Streptococcus pneumoniae*, and Epstein-Barr virus. The aplastic crisis lasts 5 to 10 days. Hemolytic crises may occur in patients with concomitant G6PD deficiency, hereditary spherocytosis, and mycoplasmic pneumonia.

Infectious crises are the most frequent cause of death of patients younger than 5 years. The organisms include *Streptococcus pneumoniae* of the blood and cerebrospinal fluid (70% of patients). Normally, 80% of the cases of meningitis in this age group are caused by *Haemophilus influenzae*. In patients older than 5 years, gram-negative bacteria predominate, with osteomyelitis caused by *Salmonella*, *Staphylococcus*, and pneumococci. Bone infarction is more common than osteomyelitis. In contrast to bone infarction, osteomyelitis presents with high fever, a left shift with an increased leukocyte count, an increased erythrocyte sedimentation rate, and positive blood cultures. The causes of infections/infectious crises include decreased IgM, defective alternate pathway, deficiency of the phagocytosis-promoting peptide tuftsin, and impaired splenic function. The challenge with *S. pneumoniae* is not followed by appropriate opsonin production. Supportive care measures include prophylactic penicillin therapy and immunization. High-risk patients should be hospitalized (fever ≥40°C; WBC $<6 \times 10^9$/L or WBC $>30 \times 10^9$/L; or pulmonary infiltrates).

The chronic manifestations of sickle cell anemia are multiple, but anemia is the most common manifestation. There is a progressive lag in growth and development after the first decade of life and a chronic destruction of bone and joints, with ischemia and infarction of the spongiosa. The vertebrae become "fish-mouthed." Avascular necrosis is common in multiple joints, and the incidence of femoral and humeral necrosis increases with advanced age. Ocular manifestations include retinopathy with stasis and occlusion of small vessels that is nonproliferative or proliferative. The small vessels may require laser photocoagulation.

Cardiovascular manifestations include cardiomegaly, flow murmurs, and a pansystolic murmur with a click that mimics mitral regurgitation. Restrictive lung disease may develop. Hepatobiliary manifestations include hepatomegaly (present clinically in 40%-80% of patients; in autopsy series, 80%-100%) with the pathologic features of distended sinusoids, periportal fibrosis, and hemosiderin pigment. Marked hyperbilirubinemia may be due to hepatitis, intrahepatic sickling, choledocholithiasis, or coexistent G6PD deficiency. Hemochromatosis is a complication. There is an increased incidence of pigmented gallstones in 30% to 60% of adults, with symptoms in 10% to 15%. Elective laparoscopy is recommended. Hepatic crises occur and resolve in 1 to 3 weeks. Renal manifestations include papillary necrosis, hyposthenuria by age 6 to 12 months (disruption of the countercurrent multiplier system, nocturia, and enuresis), hematuria (ulcer in renal pelvis and urate stones), nephrotic syndrome caused by focal segmental glomerulonephropathy, tubular damage from small infarcts, and priapism. Chronic renal insufficiency is common (25%-75% of patients). Leg ulcers are painful and may be complicated by infection.

Although disease manifestations do not increase during pregnancy, maternal mortality increases 5% to 8% and fetal mortality, 20%. Early complications of pregnancy include thrombophlebitis, pyelonephritis, and hematuria. Late complications include preeclampsia, toxemia, congestive heart failure, postpartum endometritis, and major infarcts of the lung, kidney, and brain. Prophylactic exchange transfusions are not recommended.

Laboratory findings include anemia (range, 5.5-9.5 g/dL), sickled cells, cigar cells, ovalocytes, target cells, basophilic stippling, polychromatophilia, reticulocytosis (3%-12%), and hyposplenia with Howell-Jolly bodies. A persistent increase in the WBC count of 12 to 15×10^9/L is characteristic. Evidence of chronic hemolysis may be present. Values on liver function tests are often increased. On hemoglobin electrophoresis, hemoglobin S moves more slowly than hemoglobin A. Routine diagnostic tests include the sickle solubility test and cellulose acetate gel electrophoresis.

The primary treatment is prevention. Infection, fever, dehydration, acidosis, hypoxemia, cold, and high altitude should be avoided. Immunizations, penicillin prophylaxis, and education are essential. Acetaminophen is indicated for fever because aspirin contributes to an acid load. A temperature higher than 105°F (40.6°C) means infection (infection is uncommon if the temperature is lower

than 102°F [38.9°C]). Prophylactic use of penicillin is beneficial. Vaccines, including pneumococcal (with revaccination for pneumococcus one time after 5 years), influenza A, meningococcal, hepatitis B, and *H. influenzae* type b, are indicated, as is folate supplementation, especially during pregnancy. Iron chelation is recommended if the transfusion requirement is high. Splenectomy is recommended for children who survive the initial splenic sequestration crisis. This is the only indication for splenectomy.

Blood transfusion and exchange transfusions are the most effective means of treatment available. Hemoglobin S fractions of less than 30% have been recommended for life-threatening complications. Posttransfusion increases in hemoglobin of more than 10 to 11 g/dL should be avoided. Simple blood transfusion to increase the hemoglobin level to 10 g/dL is as effective as exchange transfusion to reduce the hemoglobin S level to 30%. These modalities are indicated especially for the following: history of cerebrovascular accidents, recurrent acute chest syndrome, progressive retinopathy, renal or cardiac decompensation preoperatively, and pregnancy (multiple gestations, history of fetal loss, and severe disease). Short-term transfusion therapy is indicated in acute chest syndrome. Other indications for transfusion are priapism, protracted hematuria, and chronic skin ulcers. High-risk patients should be given transfusion to achieve a hemoglobin concentration greater than 10 g/dL for laparotomy or thoracotomy. In vaso-occlusive crises, the cornerstone of treatment includes fluids and correction of urinary sodium losses. Captopril reduces albuminuria in normotensive patients. Poloxamer 188 shortens the duration of acute painful episodes.

Other important considerations include treatment of infections: penicillin for children and coverage for *Staphylococcus* in adults. Analgesics are essential. Blood transfusions do not modify the course. Prenatal diagnosis may be made by analysis of amniotic fluid or chorionic villi biopsy (to test for an abnormal endonuclease cleavage pattern), which is preferred to fetal blood sampling. New approaches that inhibit potassium and water loss from sickle cell RBCs include low-dose clotrimazole and magnesium. In the Multicenter Study of Hydroxyurea in Sickle Cell Anemia, which was a double-blind, placebo-controlled trial, hydroxyurea decreased the frequency of painful vaso-occlusive crises by about 50%. In patients with severe recurrent episodes, the frequency of the acute chest syndrome was decreased and patients required fewer transfusions and hospitalizations. Hydroxyurea increases fetal hemoglobin. Side effects include readily reversible myelosuppression. In addition, hydroxyurea causes slight neutropenia and decreases the reticulocyte count, which may contribute to the efficacy of the drug.

Hematopoietic stem cell transplantation with marrow or umbilical cord blood from HLA-identical siblings has demonstrated that sickle cell disease can be cured. The present indications are stroke and recurrent chest syndrome. Gene therapy remains unproven at this time. Related cord blood transplantation offers a good probability of success and has a low risk of graft-versus-host disease.

The Cooperative Study of Sickle Cell Disease reported in a prospective analysis that 50% of patients with sickle cell anemia survive beyond the fifth decade. Few patients survive into their 60s. Symptomatic patients had the highest early mortality. A high level of fetal hemoglobin predicted improved survival of young patients. Acute chest syndrome, renal failure, seizures, a baseline WBC count greater than 15×10^9/L, and a low level of fetal hemoglobin were associated with risk of early death in patients 20 years or older. Of adult patients, 78% died during an acute sickle cell crisis. Acute pain and chest syndrome were the most common causes of death, and stroke was the next most common cause. This was followed by infection (*E. coli*, *Staphylococcus aureus*, HIV, tuberculosis, malaria, pneumococci, and hepatitis). In children younger than 5 years, the cause of infection nearly always is pneumococcal sepsis.

Sickle cell trait occurs in 8% of African Americans. There is no anemia, RBC abnormalities, increased risk of infections, or increased mortality; 35% to 45% of hemoglobin is hemoglobin S. Associations with sickle cell trait include hematuria, splenic infarction at high altitude (higher than 10,000 feet), hyposthenuria, bacteriuria, pyelonephritis in pregnancy, pulmonary embolism, glaucoma, and decreased mortality from *P. falciparum* infection.

In sickle cell–hemoglobin C disease, patients have hemoglobin S and C, with an absence of hemoglobin A and normal or increased levels of hemoglobin F. Patients with sickle cell–hemoglobin C survive longer than those with sickle cell anemia. Sickle cell–hemoglobin C disorder is less severe than sickle cell disease, with four exceptions: 1) proliferative retinopathy, 2) retinal detachment, 3) aseptic necrosis of the head of the femur, and 4) acute chest syndrome due to fat emboli in the final months of pregnancy. There is mild anemia; in 10% of patients, the hemoglobin concentration is less than 10 g/dL. Sickle cells are rare on the peripheral blood smear, and 50% of the cells in the peripheral blood are target cells. Splenic hypofunction occurs at an older age.

Hemoglobin S/β-thalassemia is less severe than sickle cell disease. Both affect the β chain. The spleen remains functional, but retinopathy is more common. The protective effect of α-thalassemia largely results from improvement in hemoglobin concentration.

- Hydroxyurea decreases the frequency of painful vaso-occlusive crises by 50%.
- Acute chest syndrome, renal failure, seizures, a baseline WBC count >15×10^9/L, and a low level of fetal hemoglobin are associated with the risk of early death in adults.
- Death is associated with acute pain and chest syndrome, stroke, and infection.
- Patients with sickle cell–hemoglobin C survive longer than those with sickle cell anemia.
- High WBC counts are a risk factor for severe pain, acute chest syndrome, and mortality from a hemorrhagic cerebrovascular event.
- The best method of prenatal diagnosis is to sample either from the amniotic sac or chorionic villi and to test for an abnormal endonuclease cleavage pattern.
- Hemoglobin S levels of <30% are recommended for life-threatening complications.
- A posttransfusion increase in hemoglobin of >10 g/dL should be avoided.
- Typical clinical scenario: An African American patient has pain, fevers, stroke, or infection and evidence of Coombs-negative hemolytic anemia with Howell-Jolly bodies on a peripheral blood smear. The diagnosis is made with hemoglobin electrophoresis.

Malignancies

Chronic Lymphocytic Leukemia

Chronic lymphocytic leukemia is a lymphoproliferative disorder of mature lymphocytes (Fig. 11-12). The clinical diagnosis has classically required an absolute lymphocytosis with more than 5,000 mature-appearing lymphocytes per microliter and more than 30% lymphocytes in the bone marrow. It is the commonest form of leukemia in patients 60 years and older in the Western world (90% of patients are older than 50), and it accounts for 30% of all leukemias at any one time. It is more common in men and is rare in Asia. B-cell chronic lymphocytic leukemia is the only major adult leukemia not associated with exposure to ionizing radiation, drugs, or chemicals. The two staging classifications are outlined in Tables 11-3 and 11-4.

Low-risk patients have a normal hemoglobin level, low lymphocyte count, nondiffuse bone marrow infiltration pattern, and a lymphocyte doubling time of more than 1 year. New prognostic factors for a better prognosis which determine a risk-adapted approach include a normal karyotype, 13q deletion, hypermutated *IGVH* gene, and low expression of ZAP-70. The 2-year survival rate for patients with13q deletion or normal karyotypes is 90% or more.

Poor risk factors include advanced stage, unmutated *IGVH* genes, atypical lymphocyte morphology, trisomy 12, and deletion of q23, 17p, 11q, or 6q. Patients with a 17p deletion have a 2-year survival of 34% and do not respond to chemotherapy.

- Cytogenetic features are predictive of survival: normal karyotype and 13q deletion predict a favorable prognosis, and 17p deletion predicts the most unfavorable outcome.
- Stage is predictive of survival.

The clinical course is chronic in 60% of patients. Complications include recurrent infection; 50% of patients have hypogammaglobulinemia. Fever is due to infection and not to chronic lymphocytic leukemia, except in Richter syndrome. Autoimmune and immunodeficiency complications include autoimmune hemolytic anemia (in 10% of patients), monoclonal gammopathy (in 5%), immune-mediated thrombocytopenia (occurs in 2% and is IgG-mediated and treated with corticosteroids), pure RBC aplasia, hypogammaglobulinemia, impaired delayed-type hypersensitivity, increased susceptibility to microorganisms, and second malignancies. Prophylactic intravenous gamma globulin is indicated for gamma globulin levels <0.3 g/dL with or without previous infection.

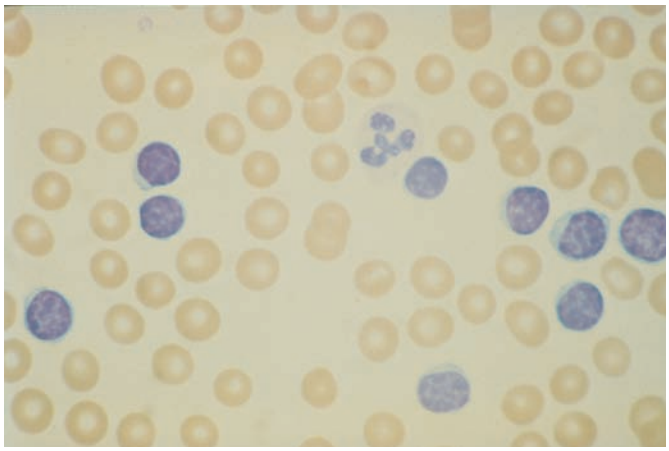

Fig. 11-12. Chronic lymphocytic leukemia. Large number of small and agranular mature lymphocytes with nuclei approximately the same size as red blood cells.

- In chronic lymphocytic leukemia, fever is not related to the disease but to infection, except in Richter syndrome.
- Hypogammaglobulinemia occurs in 50% of patients with recurrent infection.

Table 11-3 Staging: Rai Classification

Stage	Characteristics	No. of patients	Median survival time, mo	No. of patients*	Median survival time, mo*
0	Peripheral lymphocytosis (>15 × 10^9/L), bone marrow lymphocytosis (>40%)	22	>150	79	129
I	Lymphocytosis, lymphadenopathy	29	101	154	74.4
II	Lymphocytosis, splenomegaly	39	71	203	58.2
III	Lymphocytosis, anemia with hemoglobin <11 g/dL excluding AIHA	21	19	127	28.1
IV	Lymphocytosis, thrombocytopenia	14	19	105	19.3

AIHA, autoimmune hemolytic anemia.
*Six combined series.
Data from Rai KR, Sawitsky A, Cronkite EP, Chanana AD, Levy RN, Pasternack BS. Clinical staging of chronic lymphocytic leukemia. Blood. 1975;46:219-34.

Table 11-4 Classification of International Workshop on Chronic Lymphocytic Leukemia

Clinical stage	Features
A	No anemia or thrombocytopenia and fewer than three areas of lymphoid enlargement. (Spleen, liver, and lymph nodes in cervical, axillary, and inguinal regions.) A(0), A(I), or A(II).
B	No anemia or thrombocytopenia with three or more involved areas. B(I) or B(II).
C	Anemia (<10 g/dL) and/or thrombocytopenia regardless of the number of areas of lymphoid enlargement. C(III) or C(IV).

From International Workshop on CLL. Chronic lymphocytic leukaemia: proposals for a revised prognostic staging system. Br J Haematol. 1981;48:365-7. Used with permission.

- Autoimmune hemolytic anemia occurs in 10%.
- Thrombocytopenia occurs in <5%.
- Prophylactic intravenous gamma globulin is indicated for gamma globulin levels <0.3 g/dL with or without previous infection.
- Typical clinical scenario: A middle-aged or older patient has an increased WBC count, lymphocytosis, and lymphadenopathy. Peripheral blood lymphocyte flow cytometry shows the presence of mature CD23+ B lymphocytes that aberrantly express the T-cell marker CD5. The cells are also "dimly" positive for surface immunoglobulin that is "light-chain restricted" (i.e., almost all the cells express one type of light chain, κ or λ).

The major hematologic malignancies associated with chronic lymphocytic leukemia include Richter syndrome, which is chronic lymphocytic leukemia that has transformed into diffuse large cell lymphoma and is characterized by fevers, massive asymmetrical adenopathy, splenomegaly, and a poor outcome. Chronic lymphocytic leukemia is associated with an increased incidence of solid tumors of the lung and skin (basal cell and squamous cell). Patients may develop secondary drug-induced acute nonlymphocytic leukemia. Infectious complications result from *S. aureus*, pneumococci, *Pseudomonas*, *Klebsiella*, *Pneumocystis*, cytomegalovirus, *Candida*, herpes simplex, and herpes zoster.

Findings that establish the diagnosis include blood lymphocytosis greater than 5,000 mature-appearing lymphocytes (<55% prolymphocytes) per microliter, "smudged" cells on the peripheral blood smear, and a characteristic phenotype (CD19+, CD20+, CD23+, coexpression of the T-cell marker CD5+, and faint monoclonal light chain restriction). The neoplastic cells usually express high levels of bcl-2 protein, rendering them resistant to programmed cell death (apoptosis). Chromosomal abnormalities are found in more than 50% of patients.

Risk-adapted therapy is now the treatment of choice. For patients with no adverse prognostic factors (Rai stage 0 or I, low lymphocyte count, and normal or 13q deletion), the standard practice is to withhold treatment until the disease is active or progressive. A French study found no difference in survival between groups receiving treatment or no treatment in early-stage disease. In contrast, survival of patients with advanced-stage disease is better if the disease responds to treatment, with a median response duration of 4 years, compared with 1 year if no response. For patients with adverse prognostic factors (Rai stage III or IV, trisomy 12, or deletion of chromosome 11q and 17p), the FCR chemoimmunotherapy regimen (fludarabine, cyclophosphamide, and rituximab) is now the treatment of choice, with high rates for complete remission and molecular remission. Chlorambucil with or without prednisone was the initial treatment of choice, but it is still a reasonable treatment option in some elderly patients. Bone marrow transplantation is being evaluated in chronic lymphocytic leukemia. Prednisone alone may be indicated for isolated immune-related anemia and thrombocytopenia. The major toxic effects of fludarabine are myelosuppression and immunosuppression, which predispose to opportunistic infections due to a quantitative suppression in T-helper (CD4) lymphocytes.

A large randomized trial has demonstrated the usefulness of recombinant erythropoietin in increasing hemoglobin levels in patients with chronic lymphocytic leukemia who have anemia. Splenectomy may be indicated for patients with refractory immune anemia and thrombocytopenia, massive splenomegaly, and hypersplenism. An alternative is to include systemic chemotherapy with CHOP (cyclophosphamide, hydroxydaunomycin [doxorubicin or Adriamycin], Oncovin [vincristine], and prednisone). With each relapse, the disease becomes more resistant to treatment.

Treatment guidelines based on the Rai classification for staging are as follows:

Stage 0—Provide no treatment.

Stage I and stage II—The National Cancer Institute (NCI) Working Group recommended treatment of active disease and included the presence of disease-related symptoms (weight loss ≥10% in 6 months, fatigue, performance score ≥2, fevers without overt infection, or night sweats), massively enlarged nodes or spleen, progressive or rapid rate of increase (<12 months) in the peripheral blood lymphocyte count, autoimmune anemia or thrombocytopenia, and repeated infections with or without hypogammaglobulinemia.

Stage III and stage IV—Short median life expectancy, invariably symptomatic. Treat all patients to alleviate symptoms and to improve life expectancy.

Treatment guidelines based on the International Workshop classification for staging are as follows:

Stage A—Observe.

Stage B—Some patients will need treatment, as outlined in stages I and II indications above.

Stage C—Treat all patients.

- Observe patients who have stage 0 or stage A disease and normal cytogenetics or 13q deletion.
- Treat all patients who have Rai stage III or IV disease, International Workshop stage C disease, or the cytogenetic abnormalities of trisomy 12 and deletion of chromosome 11q.
- The optimal treatment of choice is FCR (fludarabine, cyclophosphamide, and rituximab).
- Typical clinical scenario: A 60-year-old patient has lymphocytosis and lymphadenopathy. Peripheral blood lymphocyte flow cytometry shows mature $CD23^+$ B lymphocytes that aberrantly express the T-cell marker CD5. The cells are also "dimly" positive for surface immunoglobulin that is "light-chain restricted" (i.e., almost all the cells express one type of light chain, κ or λ).

Patients who have disease relapse may be followed without therapy until they experience disease-related symptoms or progressive disease, with deterioration of blood cell counts, discomfort from lymphadenopathy or hepatosplenomegaly, recurrent infections, or associated autoimmune disorders.

Hairy Cell Leukemia

Hairy cell leukemia is characterized by an insidious onset of cytopenias without constitutional symptoms. At some time during the course of the disease, 90% of patients have splenomegaly. The hairy cell cytoplasmic projections are "hairy," with multiple thin or blunt projections (Fig. 11-13). Most of the cells are B cells in nature and clonal, as demonstrated by light- and heavy-chain immunoglobulin gene rearrangements. Hairy cell leukemia accounts for less than 2% of all cases of leukemia. The male-female ratio is 4:1. The cause is not known.

- Hairy cell leukemia: cytopenias.
- Splenomegaly is common.
- Hairy cells have cytoplasmic projections.
- B cell in nature and clonal.
- Constitutes <2% of all cases of leukemia.

The symptoms are related to cytopenias, infections, and splenomegaly. Laboratory findings demonstrate anemia, thrombocytopenia, neutropenia, and pancytopenia. More than 75% of patients have anemia, thrombocytopenia, and neutropenia. The bone marrow yields a dry tap on bone marrow aspiration; biopsy specimens are hypercellular with diffuse infiltration. Hairy cells may or may not be seen in the peripheral blood.

- Cytopenias in >75% of patients with hairy cell leukemia.
- Bone marrow: dry tap.
- Hairy cells may not be seen in a peripheral blood smear.
- Typical clinical scenario: A patient has cytopenias and splenomegaly. Bone marrow biopsy findings include malignant cells.

Infection is the major cause of death. Infection should be considered when new symptoms develop in a patient who previously had a stable condition. Fever is not a manifestation of the disease but indicates an underlying infection. Localized pyogenic infections are more common, for example, bacterial pneumonia, urinary tract infections, and infections of the skin. Impaired cell-mediated immunity predisposes patients to other infections. The incidence of atypical mycobacterial infections is increased. There is a higher incidence of viral infections, fungal infections, parasitic diseases, toxoplasmosis, histoplasmosis, and coccidiosis. Bleeding and vasculitis (skin, joint, and erythema nodosum) are other complications.

- Hairy cell leukemia: infection is the major cause of death.
- Infection is related to granulocytopenia and impaired cell-mediated immunity.
- Fever denotes infection.
- Atypical mycobacterial infections.

Observation may be indicated only for patients who are asymptomatic with a normal CBC or very mild cytopenias. Indications for intervention include masked cytopenia, serious or recurrent infections associated with neutropenia, bleeding due to thrombocytopenia, splenic infarction, vasculitis, and an increasing number of hairy cells. The treatment of choice is with 2-chlorodeoxyadenosine, which produces durable complete remission rates in 85% to 88% of patients after a single 7-day continuous, intravenous infusion. Other treatments include interferon alfa-2a or alfa-2b recombinant, which produces a 13% complete remission rate after 18 months of subcutaneous treatments and a partial remission rate of 66%. Pentostatin produces complete remission in 75% of patients. Patients now have a survival rate similar to that of the normal population. Splenectomy improves only peripheral blood cell counts and has no effect on the bone marrow. The only indications for splenectomy are a very large spleen and patchy bone marrow involvement in a young patient, splenic infarct, and profound life-threatening bleeding due to thrombocytopenia.

- 2-Chlorodeoxyadenosine is the treatment of choice for hairy cell leukemia.

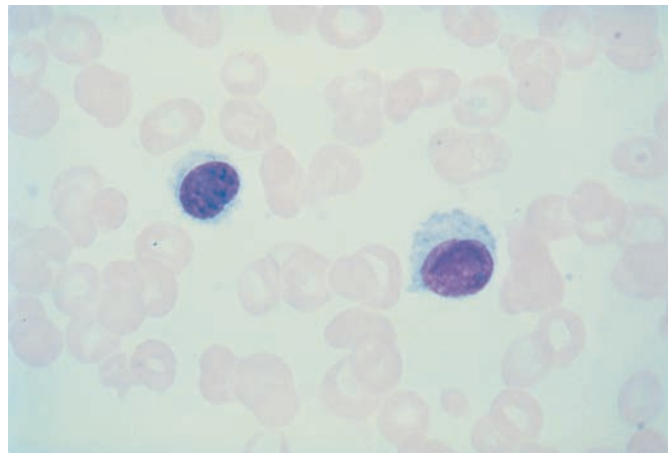

Fig. 11-13. Hairy cell leukemia. These mature lymphocytes have eccentrically placed nuclei, pale cytoplasm, and characteristic projections.

- Other treatments include pentostatin, interferon alfa-2a or alfa-2b recombinant, and splenectomy.
- Typical clinical scenario: A 50-year-old man presents with pancytopenia and cells in the peripheral blood that have projections.

Infectious Mononucleosis

The outcomes of infectious mononucleosis include acute infectious mononucleosis, asymptomatic primary infection, symptomatic chronic infection, chronic infectious mononucleosis syndrome, malignant lymphoproliferative disorders, hypogammaglobulinemia, and death (200 deaths/10 years). Ninety percent of patients have fever of 38°C to 39°C for 10 to 14 days and 70% to 90% develop a sore throat, with an exudative tonsillitis in 30% to 50%. Lymphadenopathy occurs in 80% to 90% of patients, splenomegaly in 50% to 60%, hepatomegaly in 10% to 15%, and rash in 5% to 15%. From 50% to 90% of patients are asymptomatic carriers. Laboratory abnormalities include leukocytosis in 70% of patients, lymphocytosis in 50% (variant lymphocytosis and transient increase in suppressor T cells) (Fig. 11-14), mild thrombocytopenia in 50%, and increased values on liver function tests in 80% to 90%. Complications of infectious mononucleosis include fulminant infections in immunodeficient hosts, severe tonsillar hypertrophy, splenic rupture, upper airway obstruction, neurologic syndromes (Guillain-Barré syndrome), myocarditis, and bleeding due to thrombocytopenia. Malignant diseases associated with Epstein-Barr viral infections include Burkitt lymphoma, nasopharyngeal carcinoma, post-transplantation lymphoproliferative disorders, HIV-related non-Hodgkin lymphoma, and Hodgkin disease. Hematologic complications include autoimmune hemolytic anemia and autoimmune thrombocytopenic purpura.

Hodgkin Lymphoma

With therapy, 75% of patients with Hodgkin lymphoma are cured. Untreated, the 5-year survival rate is less than 5%. Since 1973, Hodgkin lymphoma has ranked second in decreased survival rates among cancer patients in the United States. The age at presentation has a bimodal distribution, with the first peak at a median age of about 25 years. Patients with Hodgkin lymphoma usually present with a locally limited disease that progresses in an orderly manner. The typical finding at presentation is lymph node enlargement, but virtually any organ or tissue may be involved (lung, bone marrow, liver, and bone). Less common presentations include pruritus, cytopenias, abnormal findings on liver function tests, and jaundice (extrahepatic biliary obstruction, autoimmune hemolytic anemia, or, rarely, intrahepatic cholestasis). Patients with Hodgkin lymphoma have impaired cell-mediated immunity and are predisposed to herpes zoster and cytomegalovirus infections. The most important unfavorable prognostic factors are hemoglobin concentration less than 11 g/dL, a serum level of albumin less than 4 g/dL, male gender, age older than 45 years, stage IV disease, total WBC count greater than 15,000/μL, and lymphocytopenia (lymphocyte count <500/μL).

The diagnosis of Hodgkin lymphoma is based on the presence of Reed-Sternberg cells, which typically have two or more nuclei with prominent nucleoli that give the cells the appearance of an owl's eyes (Fig. 11-15). Polymerase chain reaction detects Epstein-Barr virus in 60% to 80% of cases of Hodgkin disease.

Disease stage is the principal factor in selecting treatment (Tables 11-5 and 11-6). The disease is routinely staged by use of computed tomographic (CT) scan of the chest, abdomen, and pelvis. Positron emission tomographic (PET) scans are an effective method of staging and restaging.

Before treatment is started, male patients should be advised to store sperm if they intend to have children and female patients should be advised not to become pregnant for 2 years after therapy because 75% of relapses occur during this period.

Radiotherapy is a consideration in the management of Hodgkin disease emergencies, including acute superior vena cava syndrome, airway obstruction, pericardial tamponade, and epidural spinal cord compression.

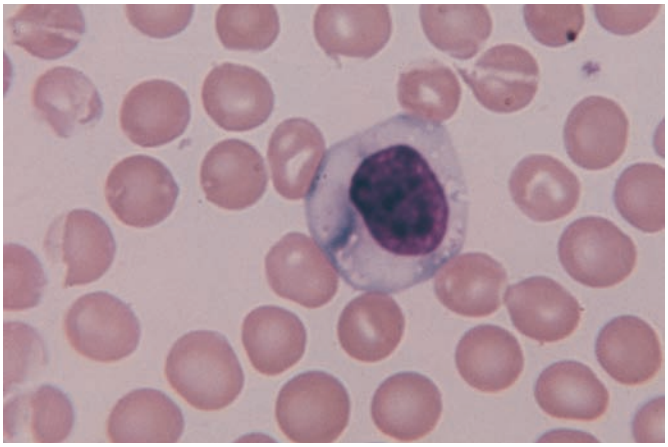

Fig. 11-14. Infectious mononucleosis. Large atypical lymphocyte has a large oblong nucleus and a large amount of pale cytoplasm, which may be vacuolated.

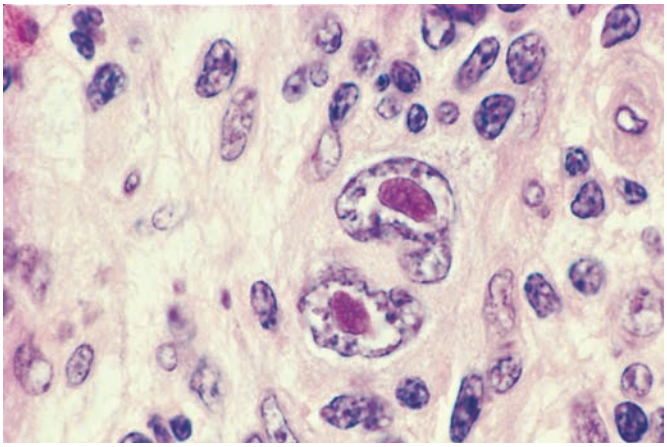

Fig. 11-15. Hodgkin disease. Reed-Sternberg cell, a large binuclear cell. (Courtesy of Curtis A. Hanson, MD, Mayo Clinic.)

Table 11-5 The Cotswolds Staging Classification of Hodgkin Disease

Classification	Description
Stage I	Involvement of a single lymph node region or lymphoid structure
Stage II	Involvement of 2 or more lymph node regions on the same side of the diaphragm (the mediastinum is considered a single site, whereas hilar lymph nodes are considered bilaterally)
Stage III	Involvement of lymph node regions or structures on both sides of the diaphragm
Stage III-1	With or without involvement of splenic, hilar, celiac, or portal nodes
Stage III-2	With involvement of para-aortic, iliac, and mesenteric nodes
Stage IV	Involvement of 1 or more extranodal sites in addition to a site for which the designation "E" has been used
	Designations applicable to any disease stage
A	No symptoms
B	Fever (temperature >38°C), drenching night sweats, unexplained loss of >10% of body weight within the preceding 6 months
X	Bulky disease (a widening of the mediastinum by more than 1/3 or the presence of a nodal mass with a maximal dimension >10 cm)
E	Involvement of a single extranodal site that is contiguous or proximal to the known nodal site
CS	Clinical stage
PS	Pathologic stage (as determined by laparotomy)

From Lister TA, Crowther D. Staging for Hodgkin's disease. Semin Oncol. 1990;17:696-703. Used with permission.

The preferred treatment for pathologic stage I or IIA Hodgkin disease had been radiotherapy, at a dose of 35 to 44 Gy, to a mantle (fields extending to include all nodes above the diaphragm) and upper abdominal field. The corresponding rates of freedom from progression and survival at 14 years are 93% and 83%. Currently, the treatment of choice is a short course of chemotherapy with ABVD (doxorubicin [Adriamycin], bleomycin, vinblastine, and dacarbazine [DTIC]) and lower doses of radiotherapy. ABVD chemotherapy is administered for two cycles beyond a complete remission. The treatment of choice for stages IIIA, IIIB, IVA, and IVB is combination chemotherapy (Table 11-7). Stages IB and IIB are also treated with combination chemotherapy. Chemotherapy is given if the disease is only infradiaphragmatic. The cure rates are up to 65% for patients with advanced disease. There is less sterility and secondary leukemia than with MOPP (mechlorethamine, vincristine [Oncovin], procarbazine, and prednisone) chemotherapy. Stanford V, a 12-week dose-intensive chemotherapy with 36 Gy radiotherapy, is currently being evaluated. Increased-dose BEACOPP (bleomycin, etoposide, doxorubicin [Adriamycin], cyclophosphamide, vincristine [Oncovin], procarbazine, and prednisone) results in improved disease-free survival and overall survival, but longer follow-up is necessary to confirm these results.

Relapse patterns are relatively predictable in Hodgkin disease. After irradiation, relapse occurs in the first 2 years and usually involves nonirradiated sites adjacent to the treated fields. Relapse after chemotherapy occurs at sites of bulky disease. Patients who have relapse after radiotherapy have about a 66% chance of cure with salvage chemotherapy. Those who have relapse after chemotherapy currently are offered autologous stem cell or bone marrow transplantation. In a study that compared autologous bone marrow transplantation with conventional chemotherapy for recurrent or refractory disease, the 3-year event-free survival was 53% for the transplantation group and 10% for the chemotherapy group.

Late complications of Hodgkin disease are substantial. The risks include infertility, amenorrhea, pneumococcal sepsis in 7% of patients following splenectomy, hypothyroidism, thyroid carcinoma, avascular necrosis, cardiomyopathy due to doxorubicin or radiotherapy, radiation pneumonitis, radiation-induced constrictive pericarditis, pulmonary fibrosis, and secondary malignancies. The secondary malignancies include acute nonlymphocytic leukemia, myelodysplastic syndromes, non-Hodgkin lymphoma, and solid tumors. ABVD is less leukemogenic than MOPP. Patients at highest risk are those who have received multiple courses of chemotherapy. The risk

Table 11-6 Staging Procedures for Hodgkin Disease

History and examination: identification of B symptoms (see Table 11-5)
Imaging procedures: plain chest radiography; computed tomography of thorax, abdomen, and pelvis
Hematologic procedures: CBC with differential, determination of erythrocyte sedimentation rate, and bilateral bone marrow aspiration and biopsy in selected cases
Biochemical procedures: tests of liver function; measurement of serum albumin, lactate dehydrogenase, and calcium
Special procedures: PET scan
Staging laparotomies: not performed

CBC, complete blood cell count; PET, positron emission tomographic.

Table 11-7 Suggested Initial Therapy Based on Clinical Stage of Hodgkin Disease

Stage	Treatment—no. of monthly cycles of chemotherapy and dose of radiotherapy (RT)
IA	
Limited high neck (0 or 1 risk factor*)	Involved- or extended-field RT (20-24 Gy)
Nonbulky	ABVD × 3 + involved-field RT (20-24 Gy)
Bulky mediastinal or >2 risk factors*	ABVD × 6-8 + involved-field RT (24-30 Gy)
IB	
Nonbulky and ≤2 risk factors*	ABVD × 6-8
Bulky mediastinal disease or >2 risk factors*	ABVD × 6-8 + involved-field RT (24-30 Gy)
IIA	
Nonbulky and ≤2 risk factors*	ABVD × 4-6 ± involved-field RT (20-24 Gy)
Bulky mediastinal disease or >2 risk factors*	ABVD × 6-8 + involved-field RT (24-30 Gy)
IIB	
Nonbulky	ABVD × 6-8
Bulky mediastinal or other bulky disease plus extranodal disease or >2 risk factors*	ABVD × 6-8 + involved-field RT (24-30 Gy)
IIIA	ABVD × 6-8 or increased-dose BEACOPP
IIIB	ABVD × 6-8 or increased-dose BEACOPP
IVA	ABVD × 6-8 or increased-dose BEACOPP
IVB	ABVD × 6-8 or increased-dose BEACOPP

ABVD, doxorubin (Adriamycin), bleomycin, vinblastine, and DTIC; BEACOPP, bleomycin, etoposide, doxorubicin (Adriamycin), cyclophosphamide, vincristine (Oncovin), procarbazine, and prednisone.

*Risk factors: serum albumin <4 g/dL, hemoglobin <10.5 g/dL, male sex, age ≥45 years, stage IV, leukocyte count ≥15,000/μL, and lymphocytes <8% of total leukocyte count and/or <600/μL (<0.6 × 10^9/L). (Hasenclever D, Diehl V for the International Prognostic Factors Project on Advanced Hodgkin's Disease. N Engl J Med. 1998;339:1506-14.)

From Habermann TM, Colgan JP. Hodgkin's disease. In: Furie B, Cassileth PA, Atkins MB, Mayer RJ, editors. Clinical hematology and oncology: presentation, diagnosis, and treatment. Philadelphia: Churchill Livingstone; 2003. p. 615-35. Used with permission.

of non-Hodgkin lymphoma is 4% at 10 years. Radiotherapy increases the risk of solid tumors. After 15 years, the risk of secondary solid tumors is 13%; these tumors include malignancies of the stomach, breast, lung, thyroid, skin, and head and neck.

- Polymerase chain reaction detects Epstein-Barr virus in 60%-80% of cases of Hodgkin disease.
- Disease stage is the principal factor in selecting treatment for Hodgkin disease.
- Of patients who have relapse after radiotherapy, 66% are in long-term remission after chemotherapy.
- The treatment of choice for patients with pathologic stage IIB, IIIA2, IIIB, or IV disease: ABVD chemotherapy is administered two cycles beyond a complete remission.
- Autologous bone marrow or peripheral blood stem-cell transplantation is indicated after a first relapse from any front-line chemotherapy for Hodgkin disease.
- Complications of survival include acute nonlymphocytic leukemia, solid tumors, and cardiomyopathy.
- Typical clinical scenario: A patient has asymptomatic lymphadenopathy or mediastinal mass. Lymph node biopsy shows the presence of large binucleated or multinucleated cells with prominent nucleoli (Reed-Sternberg cells).

Non-Hodgkin Lymphoma

Non-Hodgkin lymphomas are clinically, pathologically, cytogenetically, and immunologically a diverse group of lymphoproliferative disorders. Mortality from non-Hodgkin lymphoma increased from 1973 to 1994. The prognosis depends on the histologic subtype, stage, and other clinical and laboratory features. The Working Formulation for Clinical Usage, which groups non-Hodgkin lymphomas by natural history and response to therapy, had been the most widely used scheme in the United States. This scheme was based on morphologic patterns only. These morphologic patterns have characteristically associated cytogenetic abnormalities and oncogene associations. The most recent classification is the WHO Classification of Neoplastic Diseases of the Hematopoietic and Lymphoid Tissues (Table 11-8).

The Ann Arbor Staging System has traditionally been used for lymphoma. Low-grade lymphomas may transform into intermediate-grade and high-grade lymphomas. The low-grade non-Hodgkin lymphomas, which include follicular histologic features, are a group of lymphoproliferative disorders that are not curable (unless pathologic stage I disease), are most commonly present with advanced stage III or IV disease, are very treatable with simple programs, occur in older patients, and have long survival (median, 8 years). The paradox of non-Hodgkin lymphomas is that low-grade non-Hodgkin

lymphomas are not curable, but patients live for a long time even after disease relapse. In contrast, the intermediate- and high-grade lymphomas are potentially curable, but the length of survival is short if the patient does not have remission. The disease may progress to a more aggressive lymphoma, with a risk that ranges from 10% to 70% in reported series, depending on the frequency of new biopsies at the time of progression, follow-up duration, and postmortem data. Lymphoblastic lymphoma and Burkitt lymphoma have a higher risk of central nervous system involvement and tumor lysis syndrome.

Because low-grade non-Hodgkin lymphomas are not curable, the most reliable end points are progression-free survival and overall survival. Achievement of complete remission is not a viable end point in low-grade lymphomas. In patients who have been deemed to be in remission, immunoglobulin κ/λ light-chain restriction studies of peripheral blood and bone marrow with flow cytometry demonstrate malignant cells in the peripheral blood after treatment, and polymerase chain reaction studies have demonstrated persistent abnormal cell populations in patients believed to be in complete remission.

Most patients with low-grade non-Hodgkin lymphoma have stage III or IV disease, which is not curable with standard treatment regimens. Observation is the initial treatment of choice for asymptomatic patients with no evidence of bulky disease. The Stanford group reported on 83 patients with advanced disease who were not treated initially and had an actuarially predicted survival of 82% at 5 years and 73% at 10 years. At median follow-up of 50 months, 51 of the 83 patients (61%) required therapy at a median interval of 3 years after diagnosis. Spontaneous regression was observed in 19 patients, partial remission in 13, and complete remission in 6. Treatment with more aggressive regimens has not improved survival.

For patients with symptoms, bulky disease, or progressive disease, options with the goal of achieving complete remission include oral chlorambucil taken daily, intravenous CVP (cyclophosphamide, vincristine, and prednisone) with rituximab concomitantly or as maintenance therapy, and R-CHOP (rituximab with CHOP). CVP or chlorambucil was considered the standard treatment of choice.

Anti–B-cell antibody therapies have been developed. Anti-CD20 antibody therapy, rituximab, was initially approved for patients who have had relapse and is being evaluated as an initial treatment

Table 11-8 Classification of Tumors of Hematopoietic and Lymphoid Tissues

B-cell neoplasms
- Precursor B-cell neoplasm
  - Precursor B lymphoblastic leukemia/lymphoma
- Mature B-cell neoplasms
  - Chronic lymphocytic leukemia/small cell lymphocytic lymphoma
  - B-cell prolymphocytic leukemia
  - Lymphoplasmacytic lymphoma
  - Splenic marginal zone lymphoma
  - Hairy cell leukemia
  - Plasma cell myeloma
  - Solitary plasmacytoma of bone
  - Extraosseous plasmacytoma
  - Extranodal marginal zone B-cell lymphoma of mucosa-associated lymphoid tissue (MALT-lymphoma)
  - Nodal marginal zone B-cell lymphoma
  - Follicular lymphoma
  - Mantle cell lymphoma
  - Diffuse large B-cell lymphoma
  - Mediastinal (thymic) large B-cell lymphoma
  - Intravascular large B-cell lymphoma
  - Primary effusion lymphoma
  - Burkitt lymphoma/leukemia
- B-cell proliferations of uncertain malignant potential
  - Lymphomatoid granulomatosis
  - Posttransplantation lymphoproliferative disorder, polymorphic

T-cell and natural killer (NK)-cell neoplasms
- Precursor T-cell neoplasms
  - Precursor T lymphoblastic leukemia/lymphoma
  - Blastic NK-cell lymphoma
- Mature T-cell and NK-cell neoplasms
  - T-cell prolymphocytic leukemia
  - T-cell large granular lymphocytic leukemia
  - Aggressive NK-cell leukemia
  - Adult T-cell leukemia/lymphoma
  - Extranodal NK/T-cell lymphoma, nasal type
  - Enteropathy-type T-cell lymphoma
  - Hepatosplenic T-cell lymphoma
  - Subcutaneous panniculitis-like T-cell lymphoma
  - Mycosis fungoides
  - Sézary syndrome
  - Primary cutaneous anaplastic large cell lymphoma
  - Peripheral T-cell lymphoma, unspecified
  - Angioimmunoblastic T-cell lymphoma
  - Anaplastic large cell lymphoma
- T-cell proliferation of uncertain malignant potential
  - Lymphomatoid papulosis

Hodgkin lymphoma
- Nodular lymphocyte predominant Hodgkin lymphoma
- Classic Hodgkin lymphoma
  - Nodular sclerosis classic Hodgkin lymphoma
  - Lymphocyte-rich classic Hodgkin lymphoma
  - Mixed cellularity classic Hodgkin lymphoma
  - Lymphocyte-depleted classic Hodgkin lymphoma

Modified from Jaffe ES, Harris NL, Stein H, Vardiman JW, editors. World Health Organization Classification of Tumours. Pathology and genetics of tumours of haematopoietic and lymphoid tissues. Lyon: IARC Press; 2001. p. 120, 190, 238. Used with permission.

regimen. Anti-CD20 conjugated to yttrium 90 (Zevalin) and anti-CD20 conjugated to iodine I 131 tositumomab produce high remission rates in patients with advanced follicular lymphoma who have had multiple relapses and are refractory to chemotherapy (Table 11-9).

Gastric MALT lymphomas have clonal gene rearrangements and are associated with *Helicobacter pylori* infections. This is the first malignant lymphoproliferative disorder to respond to an antimicrobial approach. Up to 70% of patients have a response to a regimen such as amoxicillin, metronidazole, and omeprazole. Subsequent treatment approaches include radiotherapy or oral chlorambucil. Other exceptions to the standard management programs for non-Hodgkin lymphoma include primary bone, isolated gastric, central nervous system, testicular, bowel, orbital, pulmonary, and cutaneous T-cell and B-cell lymphomas. Patients with HIV-related lymphoproliferative disorders with a CD4 count less than 200/mL have a poor response to standard treatment.

In patients with the histologic features of intermediate-grade non-Hodgkin lymphoma or diffuse large cell lymphoma, anthracycline chemotherapy (CHOP) regimens are the hallmark of therapy (40%-50% are cured), with complete remission rates of 60% to 80% for stages II to IV disease and long-term disease-free survival as predicted by the International Prognostic Factor Index. Currently, trials are comparing standard treatment with the incorporation of autologous bone marrow transplantation as primary treatment. R-CHOP is the current reference standard of treatment for intermediate-grade non-Hodgkin lymphoma. In two studies, CHOP with anti-CD20 was superior to CHOP alone. The long-term complete remission rates are 30% to 86%.

In nonrandomized studies of patients with relapsed disease who received high doses of chemotherapy with or without radiotherapy and autologous bone marrow transplantation, the overall cure rates have been reported to be 20%. For patients who had disease relapse after complete remission and who are sensitive to retreatment with standard chemotherapy regimens, the reported cure rates are 35% to 40%. An international study, the PARMA study, randomly assigned patients who were initially in complete remission but subsequently in first or second relapse to receive DHAP (cisplatin, cytosine arabinoside, and dexamethasone) chemotherapy or high-dose therapy, followed by autologous bone marrow transplantation. Autologous bone marrow transplantation increased the event-free survival and overall survival. Autologous bone marrow transplantation is considered the standard treatment for intermediate-grade and high-grade non-Hodgkin lymphoma in sensitive relapse. Currently, the role of autologous bone marrow transplantation as part of the initial management of non-Hodgkin lymphomas is being evaluated in randomized studies.

Prognostic factors are important in lymphoma. The International Prognostic Factor Index is based on clinical pretreatment characteristics and the relative risk of death. Clinical features that were associated with survival included age (≤60 vs. >60 years), LDH (normal vs. greater than normal), performance status (0 or 1 vs. 2-4), stage (I/II vs. III/IV), and extranodal involvement (≤1 site vs. >1 site). Patients were categorized into different risk groups based on the number of risk factors. Predicted 5-year survival in the low-risk group (with 0 or 1 factor) was 73%; in the low-intermediate group (with 2 factors), 51%; in the high-intermediate group (with 3 factors), 43%; and in the high-risk group (with 4 or 5 factors), 26%.

- Non-Hodgkin lymphomas are diverse.
- The WHO classification is now the most commonly used classification scheme.
- The Ann Arbor Staging System has traditionally been used for lymphoma.
- Currently, the most predictive pretreatment characteristics for the risk of death are age, LDH, performance status, stage, and extranodal involvement (the International Prognostic Factor Index).

Table 11-9 **Treatment Strategies for Non-Hodgkin Lymphomas (NHL)**

Treatment	Follicular NHL	Diffuse large B-cell NHL	Gastric MALToma *Helicobacter pylori*–positive
Initial	Observation R-CVP	R-CHOP	Antibiotic therapy (triple therapy)
For first relapse	Anti-CD20 monoclonal antibody *or* Anti-CD20 monoclonal antibody conjugated to yttrium 90 (Zevalin) *or* Anti-CD20 monoclonal antibody conjugated to iodine I 131 tositumomab (Bexxar)	Peripheral blood stem cell transplantation	Radiotherapy Oral chlorambucil

CHOP, cyclophosphamide, doxorubicin (hydroxydaunomycin), vincristine (Oncovin), and prednisone; R-CVP, rituxan with cyclophosphamide, vincristine, and prednisone; R-CHOP, rituxan with CHOP.

- Exceptions to the standard management programs for non-Hodgkin lymphoma include MALT, primary bone, isolated gastric, central nervous system, testicular, bowel, orbital, pulmonary, and cutaneous T- and B-cell lymphomas.
- In most patients, low-grade lymphoma is not curable but survival time is long.
- Of patients with the histologic features of diffuse large cell advanced intermediate-grade non-Hodgkin lymphoma, 40%-50% are cured of disease with anthracycline regimens. CHOP chemotherapy had been the standard treatment of choice. However, R-CHOP with anti-CD20 monoclonal antibody therapy is superior to CHOP.
- Patients with HIV-related lymphoproliferative disorders with a CD4 count <200/mL have a poor response to standard treatment.
- Low-grade lymphomas may transform into intermediate-grade and high-grade lymphomas.
- Lymphoblastic lymphoma and Burkitt lymphoma have a higher risk of central nervous system involvement and tumor lysis syndrome.
- Death rates in non-Hodgkin lymphoma increased from 1973 to 1994.
- Typical clinical scenario for follicular lymphomas: A 65-year-old patient has asymptomatic cervical and axillary lymphadenopathy. Lymph node biopsy findings show involvement with lymphoma, predominantly small cell, with relative preservation of follicular architecture. Bone marrow biopsy findings are also positive. In the absence of symptoms, observation is reasonable.
- Lymphomas are managed with different treatments (Table 11-9).
- Typical clinical scenario for diffuse large B-cell lymphoma: A patient with abdominal pain, fever, and weight loss is found to have bulky retroperitoneal adenopathy. A biopsy specimen demonstrates diffuse replacement of the lymph node with large lymphoma cells. The usual treatment is staging evaluation, followed by chemotherapy such as CHOP.

Monoclonal Gammopathies

The differential diagnosis of monoclonal gammopathies includes monoclonal gammopathies of undetermined significance (MGUS) and malignant monoclonal gammopathies. In the monoclonal gammopathies, there is a monoclonal excess of one of the light chains, resulting in abnormal κ/λ ratios. Serum free light-chain analysis is more sensitive than immunoelectrophoresis in identifying these light chains. The malignant gammopathies include multiple myeloma (IgG, IgA, IgD, IgE, and free light chains), overt multiple myeloma, smoldering multiple myeloma, plasma cell leukemia, nonsecretory myeloma, osteosclerotic myeloma, plasmacytoma (solitary plasmacytoma of bone and extramedullary plasmacytoma), malignant lymphoproliferative diseases (Waldenström [primary] macroglobulinemia and malignant lymphoma), heavy chain diseases, and amyloidosis (primary, with myeloma).

Monoclonal Gammopathies of Undetermined Significance

In MGUS, the most common dysproteinemia, the monoclonal (M)-protein level is less than 3 g/dL in the serum and the percentage of plasma cells in the bone marrow is less than 10%. The serum level of creatinine is normal, and the urine has either no M protein or only a small amount. The serum levels of calcium and hemoglobin are normal. Anemia and osteolytic bone lesions are absent, and patients are asymptomatic. MGUS may be a precursor to multiple myeloma. Twenty-three percent of patients may have progression to a malignant monoclonal gammopathy. Population-based studies have demonstrated that 1% of adults older than 50 years and 3% of those older than 70 have an M protein in the serum. Of monoclonal gammopathies, 60% are IgG, 20% are IgM, 10% are IgA, and 7% are free light chains. In most patients, M-protein measurements are stable, and serum protein electrophoresis should be repeated initially at 6 months and then at 12-month intervals indefinitely if there is no progression or symptoms. Patients with MGUS should be observed. Unnecessary treatment can lead to development of a myelodysplastic syndrome or acute leukemia. Annually, approximately 1% of cases of MGUS progress to multiple myeloma or a related lymphoproliferative disorder. An abnormal κ/λ ratio on free light-chain analysis is a major independent risk factor for progression. MGUS patients with low concentrations in the M-protein spike (<15 g/L) and normal κ/λ ratios had a sevenfold lower risk of progression than patients with a higher concentration in the M-protein spike (>30 g/L) and abnormal κ/λ ratios.

- MGUS is the most common dysproteinemia.
- M protein is <3 g/dL; <10% plasma cells in the bone marrow; normal concentrations of hemoglobin, creatinine, and calcium.
- Asymptomatic.
- Stable M-protein measurements.
- Patients are safely observed, with no chemotherapy.
- Typical clinical scenario: A patient without symptoms has a serum M-protein spike <3 g/dL and bone marrow plasma cells <10%. The CBC, serum creatinine level, and bone radiographs are normal. Observe, with no therapy.

Multiple Myeloma

Multiple myeloma is a result of the insidious accumulation in the marrow of neoplastic plasma cells that produce homogeneous immunoglobulin in the serum or in the urine (or in both); it accounts for 1% of all malignancies. Osteoclast-activating activity due to exaggerated expression of specific cytokine results in osteolytic bone lesions. Interleukin-6 may be involved in the pathogenesis of myeloma. The median age at onset of multiple myeloma is 65 years. It is more common in males and African Americans. Ten percent or more plasma cells are found in the bone marrow (Fig. 11-16). At least one of the following must be present: M protein in the serum greater than 3 g/dL by serum protein electrophoresis (in 80% of patients), M protein in the urine only (light-chain myeloma only in 20%), anemia, hypercalcemia, renal failure, or osteolytic bone lesions. M protein is detected in the serum or urine of 99% of patients with free light-chain analysis.

Clinical features include weakness, fatigue, bone pain (66% of patients), anemia (initially about 66%, eventually all), renal insufficiency (50%), hypercalcemia (20%), and spinal cord compression (5%). Back pain and chest pain are characteristically exacerbated by

movement. Severe back pain may be a manifestation of spinal cord compression, requiring immediate MRI or CT, dexamethasone treatment, irradiation, and possible surgical decompression. Patients are at higher risk of infections with encapsulated gram-positive organisms such as *S. pneumoniae* and *H. influenzae*; vaccination is recommended. The incidence of gram-negative infections and herpes zoster is also increased. The CBC findings are similar to those of normochromic normocytic anemia. Radiographs show punched-out lytic lesions, osteoporosis, and fractures in 75% of patients at diagnosis. Bone scans are rarely helpful. Magnetic resonance imaging (MRI) may be helpful if plain radiographs do not show abnormalities, especially spine lesions.

The median survival has been about 3 years. This is improving with peripheral blood stem cell transplantation and newer treatment regimens. A β_2-microglobulin level greater than 2.7 mg/mL and a bone marrow plasma cell labeling index greater than 0.8% are adverse prognostic factors. If these values are low, the median survival is 6 years. Patients with smoldering myeloma (M protein >3 g/dL, >10% plasma cells in the bone marrow, no lytic bone lesions, and no other manifestations of myeloma) should be observed.

Because multiple myeloma is not curable, treatment may be delayed until evidence of disease progression develops, the patient becomes symptomatic, or treatment is necessary to prevent imminent complications. Two randomized trials have demonstrated that patients with anemia or small osteolytic lesions may be observed. The median overall survival for patients with multiple myeloma was about 36 months. The standard treatment for patients older than 70 years, poor performance status, pronounced renal failure, or other comorbid conditions is melphalan and prednisone given for 7 days every 6 weeks; the objective response rate is 50% to 60%; the median survival is 3 years. Palliative radiotherapy at a dose of 20 to 30 Gy is effective in the management of disabling focal pain unresponsive to analgesic therapy.

Autologous peripheral stem cell transplantation is the initial treatment of choice. Before an autologous peripheral stem cell harvest, treat with high-dose dexamethasone in combination with thalidomide or lenalidomide (Revlimid). This is effective in the management of patients younger than 70 years, and it does not have the toxic effects that melphalan has on stem cells. The overall response rate to thalidomide alone is about 32%. Side effects include sedation, fatigue, constipation, and peripheral neuropathy. High-dose dexamethasone produces a response rate of 50% and does not cause stem cell damage. Use of Lenalidomide has resulted in higher response rates with less severe peripheral neuropathy and less incidence of deep venous thrombosis (DVT). High-dose therapy followed by an autologous stem cell transplantation improves the response rate and survival in patients with multiple myeloma, but it is not curable. The overall response rates are 75% to 90%, and the complete response rate is 20% to 40%. Most patients have disease relapse. Anemia responds to erythropoietin in 50% of patients. Bisphosphonate therapy, such as pamidronate and zoledronic acid, delays the onset of skeletal-related events, reduces bone pain, and modestly extends survival. The proteozome inhibitor bortezomib (PS-341) is effective in pretreated patients with relapsed disease and in patients with refractory multiple myeloma, and the response rates are doubled with the addition of dexamethasone.

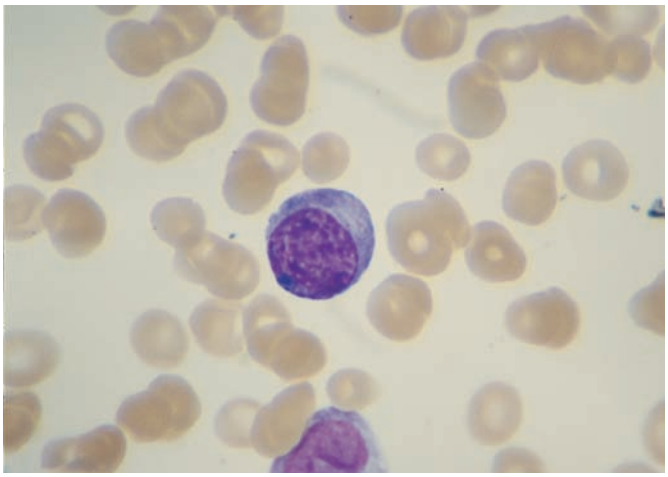

Fig. 11-16. Plasma cell. Note the eccentrically placed round nucleus; the copious, dark blue cytoplasm has a characteristic pale-staining area adjacent to the nucleus.

Renal failure may be caused by hypercalcemia, dehydration, or light chain nephropathy (myeloma kidney). Cast nephropathy may respond to plasmapheresis.

- Plasma cells: <10% in MGUS and >10% in myeloma.
- Serum M protein: <3 g/dL in MGUS and usually >3 g/dL in myeloma.
- Multiple myeloma: usually has M protein in urine.
- Myeloma: bone pain (66% of patients), renal dysfunction (50%), hypercalcemia (20%), and spinal cord compression (5%).
- Severe back pain may be a manifestation of spinal cord compression, requiring immediate MRI or CT, dexamethasone treatment, irradiation, and possible surgical decompression.
- Myeloma: punched-out lytic bone lesions and pneumococcal infection.
- Multiple myeloma patients are at increased risk of infections due to encapsulated organisms, including *S. pneumoniae*.
- Patients with low-risk disease, including a plasma cell labeling index of ≤0.8% or β_2-microglobulin of ≤2.7 mg/mL, have longer overall survival.
- The principal organisms causing infection are *S. pneumoniae* and *H. influenzae*. Vaccination is recommended.
- The initial treatment is now an angiogenesis inhibitor, thalidomide or lenalidomide, with dexamethasone followed by an autologous peripheral blood stem cell transplantation.
- Typical case scenario: A patient presents with back and bone pain that is exacerbated by movement. The patient is discovered to have anemia with or without renal insufficiency and hypercalcemia. A bone survey shows lytic bone lesions, and serum and urine protein electrophoresis demonstrate M protein. Bone marrow biopsy specimens contain >10% plasma cells. Recombinant erythropoietin may improve the anemia.

Solitary Plasmacytomas

Solitary plasmacytomas may occur without other evidence of multiple myeloma. These extramedullary lesions are potentially curable with irradiation.

Waldenström Macroglobulinemia

Waldenström macroglobulinemia is characterized by an increase in the IgM paraprotein which is usually greater than 3.0 g/dL, lymphadenopathy, anemia, or hepatosplenomegaly. Retinal "sausage" formation may be present. The bone marrow is populated with well-differentiated plasmacytoid lymphocytes. Bence Jones proteinuria may be present in 80% of patients, and hyperviscosity syndrome occurs in 15%. Other features include cryoglobulinemia, sensorimotor peripheral neuropathy, cold agglutinin hemolytic anemia, and renal disease (nephrotic syndrome).

Many patients have only an IgM MGUS, with no signs or symptoms, and should be observed without initial treatment.

Hyperviscosity syndrome is characterized by fatigue, dizziness, blurred vision, bleeding from mucous membranes, sausage-shaped retinal veins, and papilledema. The plasma volume is expanded, with an increase in serum viscosity. Because 80% of IgM is intravascular, the initial treatment of choice is plasmapheresis with albumin and saline replacement, followed by chemotherapy. This disorder had been treated most commonly with chlorambucil (6-8 mg daily) and prednisone (40 mg/m^2 for 10 days at 6-week intervals); 60% of patients had a response, with a median survival of 5 years. The treatment of choice is now R-CHOP or rituximab in combination with 2-chlorodeoxyadenosine with cyclophosphamide. Transfusion with packed RBCs should not be given solely on the basis of the hemoglobin concentration, because the increased plasma volume produces spuriously low values.

- IgM paraprotein >3.0 g/dL.
- Hyperviscosity syndrome.
- Treatment of choice is R-CHOP or rituximab in combination with 2-chlorodeoxyadenosine with cyclophosphamide.
- Typical clinical scenario: A 65-year-old patient has fatigue, bleeding from oral and nasal areas, and visual and neurologic symptoms. Serum protein electrophoresis demonstrates an IgM M protein, and bone biopsy shows a lymphoplasmacytic infiltration.

Amyloidosis

Amyloidosis is a group of diseases with extracellular deposition of pathologic insoluble fibrillar proteins, which stain with Congo red, in organs and tissues. The amyloid fibrils in primary amyloidosis are fragments of the variable portions of the immunoglobulin light chains. Patients with amyloidosis present with fatigue, weight loss, hepatomegaly, macroglossia, renal insufficiency, proteinuria, nephrotic syndrome, congestive heart failure, orthostatic hypotension, carpal tunnel syndrome, and peripheral neuropathy. Amyloidosis is classified as primary (light-chain related; 90% of patients in the United States), secondary (chronic infections or autoimmune disease), familial (associated with positive transthyretin) (prealbumin stain), associated with aging (senile), localized (skin, bladder, or other organs), and dialysis (associated with β_2-microglobulin). Serum free light-chain analysis differentiates primary amyloidosis from other amyloid disorders. Most commonly, patients with primary amyloidosis have kidney involvement, followed by congestive heart failure due to an infiltrative cardiomyopathy (25% of patients), carpal tunnel syndrome (20% of patients), peripheral neuropathy, and orthostatic hypotension.

Generally, the diagnosis of primary amyloidosis is first established by finding M protein in the serum or urine. The bone marrow usually has less than 20% plasma cells, and there are no lytic bone lesions. Initial biopsies should include fat aspiration of the abdominal wall (80% positive), rectum (75%), or bone marrow (56%). Nearly 90% of patients with primary systemic amyloidosis have a detectable M protein in the serum or urine, which is λ in two-thirds of patients. This is the most important screening test when the diagnosis is expected. Serum free light-chain assays provide quantification of the circulating fibrils in 90% to 95% of patients and aid in assessing response. The bone marrow usually has plasma cells that have a clonal predominance of a light chain isotype. Four of 10 patients present with nephrotic syndrome, 1 in 6 with right-sided congestive heart failure that worsens with calcium channel blockers, and about 1 in 7 with a sensorimotor peripheral neuropathy. Unexplained hypercholesterolemia may be a manifestation of the nephrotic syndrome. The electrocardiogram may show low voltage or a pattern consistent with myocardial infarction. The echocardiogram is abnormal in 60% of patients with concentrically thickened ventricles. The neuropathy is progressive, painful, symmetrical, and demyelinating. Peripheral neuropathy is often associated with autonomic failure, as manifested by diarrhea, pseudo-obstruction, or orthostatic syncope. About 50% of patients with amyloid neuropathy have carpal tunnel syndrome. Other symptoms and signs include fatigue, weight loss, change in voice, macroglossia, submandibular swelling, and postproctoscopic purpura. Acquired inhibitors for thrombin and factor X deficiency may occur.

The median survival for all patients with primary amyloidosis is 13 months; with overt congestive heart failure, less than 6 months; with nephrotic syndrome, 27 months; and with peripheral neuropathy, 42 months.

Oral chemotherapy produces superior results compared with colchicine. Treatment with melphalan and prednisone is effective. Treatment with 4′-iodo-4′-deoxyrubicin, which binds to amyloid fibrils, is being studied. Treatment with high-dose intravenous melphalan with autologous blood stem cell support results in remission of both the plasma cell dyscrasia and clinical signs and symptoms in 50% to 65% of patients treated; this treatment is being studied.

Patients with amyloidosis are unusually sensitive to digitalis. In congestive heart failure, salt restriction and diuretics are the mainstay of treatment.

The pathologic characteristics are as follows: primary amyloidosis involves the variable region of immunoglobulin light chains; secondary amyloidosis involves protein A.

- Typical clinical scenario: A 64-year-old man with weakness, weight loss, congestive heart failure, carpal tunnel syndrome, peripheral neuropathy, and orthostatic hypotension has a λ light chain M spike detected on serum electrophoresis.

Acute Leukemias

The cause of acute leukemia is unknown in most cases, but there are many associations: idiopathic aplastic anemia, paroxysmal nocturnal hemoglobinuria, myeloproliferative disorders, myelodysplastic syndromes, radiation, benzene, chemotherapy (alkylating agents, type II topoisomerase inhibitors [etoposide]), Down syndrome, Fanconi syndrome, and ataxia-telangiectasia. The classic syndrome of patients who have been exposed to alkylating agents (melphalan, cyclophosphamide, and chlorambucil) is pancytopenia in 10 to 36 months, with the chromosome abnormalities of monosomy 5 and 7. Alkylating agents should not be prescribed for benign diseases because of the risk of acute myelogenous leukemia, non-Hodgkin lymphoma, bladder cancer, and other solid tumors. This condition is refractory to standard treatment regimens.

- Alkylating agents should not be prescribed for benign diseases because of the risk of acute myelogenous leukemia, non-Hodgkin lymphoma, bladder cancer, and other solid tumors.
- Recently described secondary leukemias are related to type II topoisomerase inhibitor agents (etoposide).

Acute Nonlymphocytic Leukemia (Acute Myelogenous Leukemia)

The median age of patients with acute nonlymphocytic leukemia (Fig. 11-17) is 63 years. Fifty percent of patients have symptoms for more than 3 months. Specific cytogenetic abnormalities are the best predictors of outcome. More than half of the acute myelogenous leukemia cases have good prognoses. Good prognostic signs include being younger than 40 years; having chromosomal abnormalities of t(8;21), t(15;17), or inv(16) or normal chromosomes (40%-50%); and achieving complete remission with one cycle of induction chemotherapy. Poor prognostic signs include age older than 40 years; preleukemic phase; chromosomal abnormalities related to therapy with monosomy 5 and monosomy 7, 11q–, and complex cytogenetic patterns; and poor general physical condition or underlying health problems.

For patients who present with extreme leukocytosis (WBC >100 $\times 10^9$/L) with acute leukemia, the initial complication of most concern is cerebral hemorrhage. Emergency treatment includes hydration, alkalinization of urine, allopurinol (600 mg), hydroxyurea (6-8 g orally), cranial irradiation (4-6 Gy), and leukapheresis, followed by the treatment of the specific type of leukemia.

- Acute nonlymphocytic leukemia: median age of patients is 63 years; 50% have symptoms >3 months.
- Good prognosis: patients <40 years old; chromosomal abnormalities t(8;21), t(15;17), or inv(16) or normal chromosomes; and achieving complete remission with one cycle of induction chemotherapy.
- Typical clinical scenario for acute leukemia: A 40-year-old patient has fever, sore throat, bleeding gums (thrombocytopenia), and anemia. The WBC count is 50 $\times 10^9$/L. A peripheral blood smear shows numerous immature WBC precursors ("blasts"). Differentiation between acute myelogenous and acute lymphoblastic leukemia requires evaluation of bone marrow biopsy specimens with special stains and immunophenotyping.
- Typical clinical scenario for acute promyelocytic leukemia (M3): A patient who has acute leukemia presents with disseminated intravascular coagulation. Cytogenetics show t(15;17).
- Typical clinical scenario for secondary acute myelogenous leukemia: Cytopenias are demonstrated in a patient who has received chemotherapeutic agents for a previous malignancy. Cytogenetic studies show monosomy 5 or 7.

Therapeutic interventions include platelet and RBC transfusions, which are required throughout the course of treatment. Early empirical broad-spectrum antibiotic coverage for fever is essential. Treatment is divided into 1) induction therapy to reduce the leukemic burden and 2) consolidation therapy to maintain complete remission.

Induction chemotherapy includes cytarabine (cytosine arabinoside) and an anthracycline agent (daunorubicin or idarubicin). The complete remission rate is about 80% for patients 60 years or younger and 35% to 50% for those older than 60 years, with the potential for cure in 20% of patients. The 5-year survival for patients with good cytogenetics is 60%, but with poor cytogenetics, the 5-year survival is 10%. Intermediate-risk patients have a 5-year survival rate of 40%. Despite substantial recent advances, most patients with acute myelogenous leukemia eventually have relapse, usually within 1 year. Of patients who have relapse after induction and consolidation therapy, 30% to 50% achieve a second remission.

All-*trans*-retinoic acid (ATRA) is the treatment of choice in M3 acute promyelocytic leukemia (promyelocytic acute nonlymphocytic leukemia) (Fig. 11-18) with t(5;17). Induction chemotherapy is with ATRA and an anthracycline-based program with idarubicin. Consolidation includes an anthracycline drug, and maintenance therapy includes ATRA for 1 to 2 years. This is the first malignancy in which a chromosomal alteration has served as the target for induction chemotherapy. ATRA improves the overall survival and treatment at induction, and maintenance therapy may be superior. Disseminated coagulaopathy is associated with this leukemia. Management includes aggressive platelet transfusions to maintain a platelet count of more than 50,000/μL and cryoprecipitate to maintain the fibrinogen at

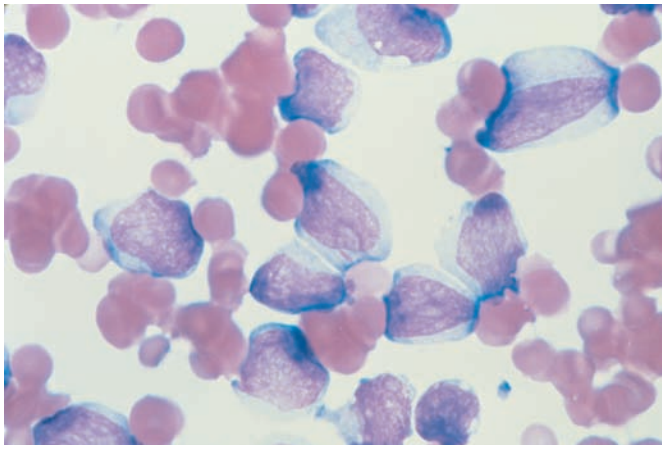

Fig. 11-17. Acute nonlymphocytic leukemia. Large pleomorphic cells with large nuclei and a barely visible nuclear membrane.

a level of 100 mg/dL or greater. Arsenic trioxide (Trisenox) has been approved by the U.S. Food and Drug Administration as second-line treatment for acute promyelocytic leukemia and is the treatment of choice for relapsed M3 acute nonlymphocytic leukemia, followed by transplantation. Gemtuzumab (Mylotarg), an anti-CD33 antibody, is approved for the treatment of $CD33^+$ acute nonlymphocytic leukemia in patients older than 60 years experiencing a first relapse.

The three types of postremission therapy are maintenance, consolidation, and intensification. Maintenance therapy uses low doses of chemotherapy, which avoids severe bone marrow suppression. Consolidation therapy uses regimens similar to those used for induction therapy. Intensification therapy uses more intensive therapy than that used during remission induction. Postremission therapy includes chemotherapy and autologous or allogeneic transplantation. Low-dose combination cytarabine and 6-thioguanine are superior to no additional treatment in prolonging disease-free survival after complete remission has been achieved. High-dose cytarabine improves the duration of remission in patients younger than 60 years, as compared with conventional-dose cytarabine with or without 6-thioguanine.

The following generalizations may be made about allogeneic bone marrow transplantation in acute nonlymphocytic leukemia. Generally, after 2 years of complete remission, the risk of relapse is lower. Transplantation in cases of relapse is age-dependent: patients younger than 30 years have a better prognosis than those 30 or older. Allogeneic bone marrow transplantation in early relapse or in second remission is almost as efficacious as transplantation during the first complete remission. If the patient is younger than 55 years, bone marrow transplantation should be considered for those in first remission if they have an HLA match and poor prognostic factors, which include poor-risk cytogenetic features and antecedent hematologic disease. For patients without poor risk factors and not part of a formal study, transplantation should be considered in early relapse or second remission. Currently, the disease-free survival at 5 years for patients having allogeneic transplantation during the first remission is 50%; during the first relapse, 30%; and during the second remission, 28%. The use of autologous transplantation in first remission is controversial, with 5-year survival rates of 35% to 55%. Early results of autologous transplantation are encouraging. Chemotherapy treatment and autologous transplantation are equivalent in most studies.

Acute Lymphoblastic Leukemia

Acute lymphoblastic leukemia (Fig. 11-19) is most common in children; complete remission rates are greater than 90%, and 60% to 70% of patients have long-term disease-free survival. In adults, this leukemia is less common, with remission rates of up to 75%; however, most patients have disease relapse. Of acute lymphocytic leukemia cases in adults, 80% are B cell in origin, 20% have T-cell markers, and 1% or 2% express surface immunoglobulin. Most B-cell leukemias express CD10, the common ALL antigen (cALLa). Patients with early pre–B-cell type acute lymphocytic leukemia, also called *null acute lymphocytic leukemia*, are cALLa negative.

One-third of patients present with bleeding, and 25% have symptoms for more than 3 months. Bone pain, lymphadenopathy, splenomegaly, and hepatomegaly are more common in acute lymphoblastic leukemia than in acute nonlymphocytic leukemia. Splenomegaly, lymphadenopathy, and hepatomegaly occur in three-fourths of the patients (compared with one-half of those with acute myelogenous leukemia).

The best prognosis is for children 3 to 10 years old. After the age of 20, survival time continues to decrease with increasing age and the duration of complete remissions is shorter. Poor prognostic factors include age, WBC count greater than 30×10^9/L, null cell phenotype, specific chromosomal abnormalities, and achievement of remission after more than 4 weeks of intensive chemotherapy.

From 80% to 90% of adults have chromosomal abnormalities. Those with normal chromosomes have the best prognosis. The poorest prognosis is associated with t(9;22); t(4;11); t(8;14); and t(1;19). These patients have lower complete remission rates, shorter duration

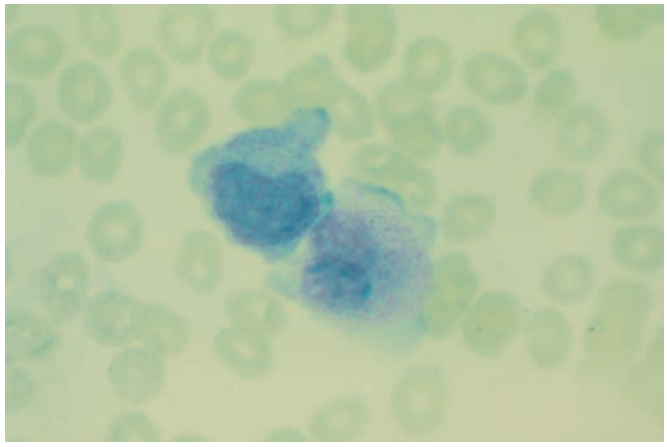

Fig. 11-18. Acute promyelocytic leukemia. Note the large nuclei; more than half of the leukemic cells have large atypical granulations. (Courtesy of Curtis A. Hanson, MD, Mayo Clinic.)

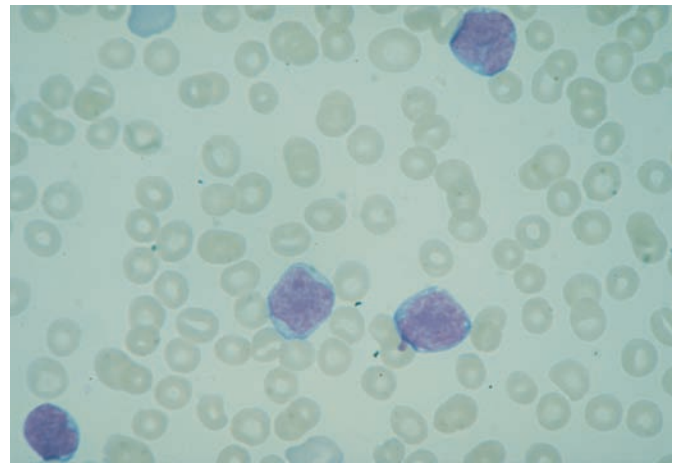

Fig. 11-19. Acute lymphoblastic leukemia. Large, rounded, and indented nuclei with diverse shapes and scant, darker blue cytoplasm.

of remission, and very poor survival. Also, t(9;22) is associated with less than 15% survival at 5 years and is present in 25% of adults but in only 2% to 3% of children. Chromosomal abnormalities are independent of age, WBC count, and immunophenotype.

The three agents commonly used in induction therapy are vincristine, prednisone, and anthracyclines in combination with one or more of the following: L-asparaginase, cytarabine, methotrexate, and cyclophosphamide. The complete remission rate is 70% to 90%. The addition of L-asparaginase, cytarabine, or cyclophosphamide may improve the duration of remission.

Intensification/postinduction therapy is commonly used. The long-term relapse-free survival in adults is 10% to 42%. The use of allogeneic bone marrow transplantation in the first complete remission results in a 21% to 71% disease-free survival at 2 to 10 years, with relapse rates of 10% to 40%. Allogeneic transplantation is recommended for patients with t(9;22) and t(4;11). Trials are under way for evaluating autologous bone marrow transplants and matched unrelated transplants.

In relapse, allogeneic or autologous bone marrow transplants are of benefit in patients who achieve a second complete remission. After a second complete remission and then an allogeneic transplant, the disease-free survival ranges from 26% to 54% for various times. At second complete remission and then autologous transplant, the disease-free survival ranges from 23% to 31% for various times.

Recent results of unrelated allogeneic donor transplants have shown a 45% leukemia-free survival for patients in the first remission, but there are significant logistical and age restrictions. Trials are under way to evaluate autologous transplantation. Indications for bone marrow transplantation include high-risk cytogenetic abnormalities in the first remission and patients in a second or subsequent remission.

In a study that compared bone marrow and peripheral blood allogeneic transplantation in acute leukemia, myelodysplasia, and chronic myeloid leukemia, the use of peripheral blood led to faster hematologic recovery and improved survival.

Chronic Myeloid Disorders

Myelodysplastic Syndromes

Chronic myeloid disorders include myelodysplastic syndromes, chronic myeloid leukemia, chronic myeloproliferative disease, and atypical myeloproliferative disorders.

Myelodysplastic disorders are characterized by dysplastic bone marrow hyperplasia associated with various degrees of peripheral blood cytopenias with or without chromosomal changes. They are typically heterogeneous and biologically diverse. Myelodysplastic syndromes, as classified by the French-American-British Group (with median survival time), are refractory anemia (26 months), refractory anemia with ringed sideroblasts (34 months), refractory anemia with excess blasts (9 months), refractory anemia with excess blasts in transformation (5 months), and chronic myelomonocytic leukemia (12 months). Patients with these disorders present with anemia and other cytopenias. The course of the disease is complicated by hemorrhage in 20% of patients and infection in 40%. Clonal karyotypic abnormalities, predominantly deletions, have been reported in 30% to 70% of patients; by comparison, acute myelogenous leukemia has balanced translocations. Del(5q), del(20q), and −y are the only abnormalities that confer a favorable prognosis, and patients with these abnormalities frequently present with anemia that requires transfusions. The most life-threatening complication is transformation to acute leukemia. This occurs in 12% of patients with refractory anemia, in 8% with refractory anemia with ringed sideroblasts, in 44% with refractory anemia with excess blasts, in 14% with chronic myelomonocytic leukemia, and in 60% with refractory anemia with excess blasts in transition. A large proportion of patients die of cytopenic complications, most commonly leukopenia.

The standard of care for most patients is supportive, with RBC transfusions, erythropoietin, and antibiotics for infection. Low-risk myelodysplastic syndrome patients unresponsive to erythropoietin may respond to lenalidomide. Patients younger than 55 years should be considered for allogeneic bone marrow transplantation if the patient has an HLA match. Antileukemic chemotherapy regimens have a complete remission rate of 47% to 66%, with disease-free survival of 30% to 45%. New treatment approaches include 5-azacytidine, antithymocyte globulin, and amifostine. Granulocyte-colony stimulating factor (G-CSF) increases the absolute neutrophil count in 90% of patients.

- Patients with myelodysplastic disorders present with various degrees of cytopenia of peripheral blood components.

Chronic Myelogenous Leukemia (Chronic Granulocytic Leukemia)

Chronic myelogenous leukemia constitutes 20% of all leukemias and is characterized by an acquired defect of clonal origin at the pluripotential cell level. There is a pool of granulocyte precursors with the capacity for normal maturation (Fig. 11-20). The Philadelphia chromosome, t(9;22), is the hallmark of this disease in 95% of patients and is identified with karyotypic or fluorescent in situ hybridization or polymerase chain reaction of peripheral blood or bone marrow specimens. The translocation results in the fused *bcr-abl* oncogene. The hyperproliferation of the *bcr-abl* clone results in production of an upregulated tyrosine kinase enzyme. The myeloid compartment is expanded and normal hematopoiesis is suppressed. New chromosomal abnormalities appear and reappear. The diseases are preleukemic and terminate in a maturation block or blast crisis. Different cell types can be seen, including myeloblasts (50%-60% of patients), megakaryoblasts (15%), B lymphoblasts, erythroblasts (10%), monoblasts, myelomonocytic blasts, and basophilic blasts.

Before the advent of allogeneic bone marrow transplantation and recombinant interferon alfa-2a or alfa-2b, the median survival was 3.5 years after diagnosis. The presence of chromosomal abnormalities other than t(9;22) is an adverse prognostic factor. The chronic phase is characterized by less than 10% blasts in blood and bone marrow and typically has a median duration of 4 years.

Symptoms include malaise, dyspnea, anorexia, fever, night sweats, weight loss, abdominal fullness, easy bruising, bleeding, gout, priapism, and hypermetabolism. Splenomegaly is present in 85% of patients.

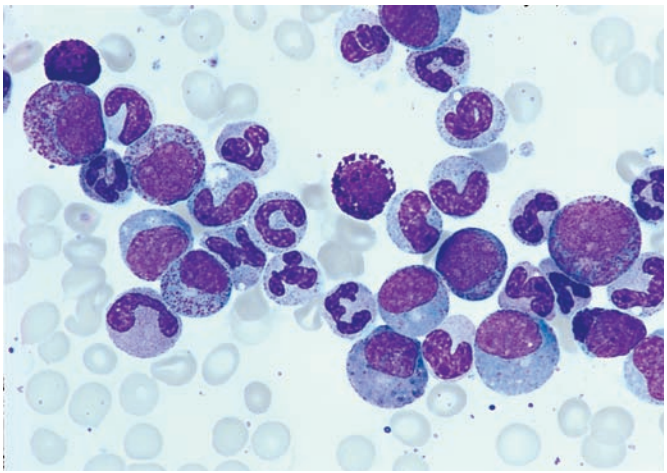

Fig. 11-20. Chronic myelogenous leukemia. Normal-appearing myeloid cells representing all stages of maturation, with a decreased number of erythropoietic cells and one basophil precursor in the center. (Courtesy of Curtis A. Hanson, MD, Mayo Clinic.)

Characteristic laboratory findings include leukocytosis, with less than 10% blasts in the chronic phase of the disease, and WBC counts of 100 × 10^9/L are common. Granulocytes in all stages of maturation are present on peripheral blood smear, with basophilia and eosinophilia and a characteristic myelocyte bulge. The number of platelets is increased, with large bizarre forms found in peripheral blood smears. The hemoglobin concentration ranges from 9 to 12 g/dL. The leukocyte alkaline phosphatase score is low or zero. The differential diagnosis of a low or zero leukocyte alkaline phosphatase score also includes paroxysmal nocturnal hemoglobinuria, infectious mononucleosis, and aplastic anemia. The vitamin B_{12} level is increased because of increased transcobalamin I. Other findings include pseudohyperkalemia, pseudohypoglycemia, and a false-positive increase in the level of acid phosphatase in the serum. The bone marrow is hyperplastic, with myelofibrosis in 10% to 40% of patients.

- Chronic myelogenous leukemia: acquired defect of clonal origin.
- Philadelphia chromosome, t(9;22), is the hallmark of the disease.
- Increased WBC count; granulocytes in all stages of maturation.
- Bone marrow shows hyperplasia; myelofibrosis in 10%-40% of patients.
- The leukocyte alkaline phosphatase score is low or zero in chronic myelogenous leukemia, paroxysmal nocturnal hemoglobinuria, infectious mononucleosis, and aplastic anemia.
- Increased vitamin B_{12}; increased acid phosphatase.
- Typical clinical scenario: A patient without symptoms presents with a high WBC count, myeloid bulge, basophilia, and splenomegaly. Cytogenetic studies show t(9;22).

The initial treatment of chronic myelogenous leukemia is imatinib mesylate. Other treatments include hydroxyurea, interferon alfa, allogeneic bone marrow transplantation, and autologous bone marrow transplantation.

Hydroxyurea had been used more commonly, with response rates of 85% to 90%. One study demonstrated that both overall and posttransplantation survival are inferior for patients treated with busulfan compared with those given hydroxyurea. Hydroxyurea is the treatment of choice for high blast counts and leukostasis lesions, and it is safe in thrombocytopenia. Continued maintenance therapy is necessary. Megaloblastic RBCs appear in the peripheral blood. Hydroxyurea should be considered for patients who are candidates for bone marrow transplantation.

Recombinant interferon alfa-2a or alfa-2b suppresses the Philadelphia chromosome. Hematologic responses are 40% to 80%, with cytogenetic remissions in the range of 10% to 40%. Prospective randomized trials have demonstrated an improvement in survival and duration of remission in patients treated with recombinant interferon alfa-2a or alfa-2b, in comparison with hydroxyurea. The addition of cytarabine to interferon reportedly improves survival and cytogenetic responses.

Imatinib is an oral agent that inhibits the *bcr-abl* protein product. Studies demonstrated high remission rates for those who have had disease relapse after treatment with oral interferon, for accelerated phase disease, and for untreated patients (80% molecular remissions). This is the standard first-line therapy for chronic myelogenous leukemia. In a randomized trial that compared interferon and cytarabine versus imatinib, there were higher hematologic response rates for imatinib. In addition, the cytogenetic response rates were superior (76% vs. 12%). Discontinuation of the drug is usually followed by relapse. New *bcr-abl* inhibitors are being developed for patients who are imatinib resistant.

The chronic phase converts to an accelerated or blast phase (75% of patients), which is characterized by blast counts greater than 20%; increases in anemia, thrombocytopenia, basophilia, and leukocyte alkaline phosphatase score; splenomegaly; lymphadenopathy; bone pain; cerebral hemorrhage; fever; headache; and myelofibrosis. Cytogenetic abnormalities precede the condition by 6 months. Blast transformation occurs in 13% of patients in the first 2 years, and the annual risk is then 25%. The treatment of "blast crisis" includes allopurinol, fluids, hydroxyurea, cranial irradiation, and leukocyte apheresis.

- Accelerated phase; the chronic phase converts to an accelerated or blast phase (75% of patients), which is characterized by blast counts >20%; increases in anemia, thrombocytopenia, basophilia, and leukocyte alkaline phosphatase score; splenomegaly; lymphadenopathy; bone pain; cerebral hemorrhage; fever; headache; and myelofibrosis. Cytogenetic abnormalities precede the condition by 6 months.
- Blast transformation occurs in 13% of patients in the first 2 years, and the annual risk is then 25%.
- Imatinib is the treatment of choice.

Currently, the only curative regimen is high-dose chemotherapy with total body irradiation, followed by transplantation of allogeneic bone marrow from HLA-compatible siblings. However, morbidity and

mortality rates are significant. Hematologic relapse occurs in 10% to 20% of patients receiving a transplant in the chronic phase. The long-term disease-free survival rates approach 80% if the patient has favorable factors (age <30 years, related donor, and HLA-identical match) and transplantation occurs less than 1 year after diagnosis. Otherwise, long-term survival may be less than 30%.

- Currently, the only curative regimen is HLA-compatible allogeneic bone marrow transplantation.
- Mortality and morbidity rates are significant factors.

Because only 15% of all new cases of chronic myelogenous leukemia have an HLA sibling donor, studies are evaluating HLA-matched unrelated volunteer donor bone marrow transplantation protocols and autologous bone marrow transplantation. Autologous bone marrow transplantation can improve survival, but there is no evidence of cure. New oral agents are being developed that overcome imatinib resistance and are the initial treatment of choice.

- Typical clinical scenario: A 45-year-old woman presents with anemia and leukocytosis. The spleen is palpable 3 cm below the costal margin. The leukocyte differential count demonstrates basophilia, myelocytes, and metamyelocytes. The blast count is not increased. The treatment of choice is imatinib.

Myeloproliferative Disorders

Myeloproliferative disorders include polycythemia rubra vera, agnogenic myeloid metaplasia (idiopathic myelofibrosis), essential thrombocythemia, and chronic myelogenous leukemia. These are clonal processes with a multipotent stem cell origin that are characterized clinically by peripheral blood and bone marrow proliferation. Their characteristic features are listed in Table 11-10. These disorders are interrelated: polycythemia rubra vera converts to agnogenic myeloid metaplasia in 10% of patients, and essential thrombocythemia converts to agnogenic myeloid metaplasia in 5%. Acute myelogenous leukemia is a complication of polycythemia rubra vera (10% of patients), essential thrombocythemia (<5%), agnogenic myeloid metaplasia (10%-20%), and chronic myelogenous leukemia (70%-90%). In each of these disorders, overall survival is less than that of age-matched controls. There is also a risk of thrombosis and hemorrhagic complications, especially in polycythemia rubra vera and essential thrombocythemia.

Recent studies have identified a unique activating mutation in *JAK2* in polycythemia rubra vera (65%-97%), idiopathic myelofibrosis (50%), and essential thrombocythemia (30%).

- Myeloproliferative disorders include polycythemia rubra vera, agnogenic myeloid metaplasia, essential thrombocythemia, and chronic myelogenous leukemia.
- Myeloproliferative disorders are interrelated.
- Polycythemia rubra vera may convert to myelofibrosis, and essential thrombocythemia may convert to myelofibrosis.

Myelofibrosis With Myeloid Metaplasia, Agnogenic Myeloid Metaplasia, and Postpolycythemic and Postthrombocytic Myeloid Metaplasia

Splenomegaly occurs in 100% of the patients and is the hallmark of agnogenic myeloid metaplasia. Other features are a leukoerythroblastic peripheral blood smear (96% of patients), dacrocytes (teardrop cells), and hypocellular marrow (85% of patients) (Fig. 11-21). The basic event is the fibroblastic proliferation in bone marrow. Anemia may be caused by expanded plasma volume, ineffective erythropoiesis, blood loss, or hemolysis.

The bone marrow shows panhyperplasia with modest fibrosis to osteosclerosis. The spleen is characterized by extramedullary hematopoiesis in the sinusoids of red pulp. Hepatomegaly may occur in 70% of patients because of engorgement by blood, extramedullary hematopoiesis, or hemosiderosis. The median survival approaches 5 years.

- The median survival approaches 5 years.
- Agnogenic myeloid metaplasia: its hallmark is splenomegaly.
- Leukoerythroblastic peripheral blood smear in 96% of patients.
- Teardrop cells.
- Basic event: fibroblastic proliferation of bone marrow.

Twenty percent of patients are asymptomatic and should be observed; 80% are still asymptomatic at 5 years. Medical therapy for anemia with symptoms includes transfusion with packed RBCs if the RBC mass is low. Androgens (fluoxymesterone, 50 mg twice daily, or

Table 11-10 Characteristic Features of Chronic Myeloproliferative Disorders

Characteristic	Polycythemia rubra vera	Agnogenic myeloid metaplasia	Primary thrombocythemia	Chronic granulocytic leukemia
Increased red cell mass	Yes	No	No	No
Myelofibrosis	Later	Yes	Rare	Later
Thrombocytosis	Variable	Variable	Yes	Variable

danazol) and prednisone, 30 mg daily, improve anemia in one-third to one-half of patients. Corticosteroids may be of benefit in one-third of patients with hemolysis or thrombocytopenia. In the evaluation of anemia, check the stool for occult blood loss from esophageal varices and microinfarcts of the gut, and treat vitamin B_{12} and folate deficiency if indicated.

Pressure symptoms occur in 23% of patients and may be managed with hydroxyurea or splenic irradiation. Hydroxyurea is indicated for symptomatic hepatosplenomegaly, leukocytosis, and thrombocytosis.

Bleeding with or without thrombocytopenia is managed with platelet transfusions.

Treat disseminated intravascular coagulopathy appropriately if present (may be present in up to 40% of patients).

Splenectomy may be of benefit in major hemolysis, pressure symptoms, life-threatening thrombocytopenia, portal hypertension, and refractory thrombocytopenia. Splenectomy is contraindicated in disseminated intravascular coagulopathy.

Bone marrow transplantation may be helpful in some young patients. The prognosis is good if the patient is asymptomatic, the hemoglobin concentration is more than 10 g/dL, the platelet count is greater than 100×10^9/L, and the liver is less than 5 cm below the costal margin.

- Typical clinical scenario: A 58-year-old woman presents with fatigue and anemia. The differential blood cell count included two nucleated RBCs, 4 myelocytes, and 2 metamyelocytes. RBC morphology demonstrates dacrocytes. The bone marrow is fibrotic.

Essential Thrombocythemia (Primary Thrombocythemia)

Essential thrombocythemia is a clonal hematologic disorder in which patients present with asymptomatic thrombocytosis, thrombotic disorders, or hemorrhage. Patients have a near-normal life expectancy. The overall risk of bleeding is 3% and of thrombosis, 20%. The risk factors for these include age older than 60, previous thrombosis, and short remission. Young females have a higher risk of miscarriage. The risk of acute leukemic transformation is less than 2%.

The diagnosis of essential thrombocythemia includes a platelet count greater than 600×10^9/L, megakaryocytic hyperplasia and stainable iron in the bone marrow, splenomegaly, absence of the Philadelphia chromosome or rearrangement of the major breakpoint cluster region (Mbcr) of the *bcr* gene (100% of patients), normal RBC mass (100%), and no collagen fibrosis. Also, there is no reactive thrombocytosis. Clinical findings that suggest reactive thrombocytosis include a recent normal manual platelet count, a clinical condition associated with reactive thrombocytosis, and no clinical features of a myeloproliferative disorder. The secondary causes include acute or chronic inflammatory disease, acute or chronic bleeding, iron deficiency, chronic bone marrow stimulation (e.g., hemolysis), rebound after thrombocytopenia, disseminated malignancy, splenectomy or congenital asplenia or functional hyposplenism, postoperative state, intense exercise, parturition, trauma, and epinephrine. An increased C-reactive protein level in patients with thrombocytosis suggests a reactive process.

Treatment depends on the clinical situation. Platelet apheresis should be used for emergent management of acute bleeding or thrombosis. Treatment of patients younger than 30 years is controversial. They may be observed if there are no hemorrhagic or thrombotic problems, no important trauma, and no emergency or elective surgery. Platelet apheresis is indicated in cases of elective surgery for patients of any age and in pregnant women during the course of delivery. Treatment is recommended for patients with thrombotic symptoms, a previous history of thrombotic events, and cardiovascular risk factors and for those older than 60 years who have a platelet count higher than 600×10^9/L. Currently, hydroxyurea is the treatment of choice for most patients. Anagrelide is a therapeutic alternative for patients who cannot tolerate hydroxyurea or who are younger than 65. Patients who are asymptomatic and have a platelet count less than 600×10^9/L and patients who are asymptomatic and of childbearing age may be observed. Chronic treatments available for the management of essential thrombocythemia include hydroxyurea, anagrelide, antiaggregating agents for mild thrombotic symptoms (including aspirin and dipyridamole), radioactive phosphorus at a dose of 2.7 mCi/m^2, and recombinant interferon alfa-2a or alfa-2b.

Erythrocytosis

An increased hematocrit due to a decreased plasma cell volume and normal RBC mass is "relative polycythemia." Absolute erythrocytosis is almost always present with a hemoglobin concentration in males of 18 g/dL and in females, 16.5 g/dL. The history, physical examination, CBC, arterial blood gases, leukocyte alkaline phosphatase score, and bone marrow examination can indicate the diagnosis of polycythemia in a high percentage of patients (Table 11-11).

The differential diagnosis of erythrocytosis with a normal oxygen saturation value and normal leukocyte alkaline phosphatase score includes the following: hypernephroma, renal adenoma, hydronephrosis, renal cyst, transplantation, Bartter syndrome, cerebellar hemangioblastoma, adrenal cortical adenoma or hyperplasia, ovarian carcinoma, hepatoma, pheochromocytoma, uterine fibroids, and hemoglobinopathies. The administration of erythropoietin or

androgens to healthy persons may cause erythrocytosis. Other causes include exogenous administration of erythropoietic drugs, post–renal transplantation erythropoiesis, and congenital polycythemia. Patients with unexplained erythrocytosis should have intravenous pyelography or CT of the abdomen to exclude hypernephroma.

The cerebral blood flow decreases at a hematocrit greater than 46%. Smoking 1.5 packs of cigarettes a day can increase the hematocrit to 60% (check the carboxyhemoglobin level). The RBC mass returns to normal when the person stops smoking.

Polycythemia Rubra Vera

Polycythemia rubra vera is a myeloproliferative disorder of undetermined cause. Its clinical features include postbathing pruritus, weakness, erythromelalgia (acral dysesthesias and erythema), headache, dizziness, weight loss, joint symptoms, dyspnea, and epigastric distress. More than 50% of patients have leukocytosis and thrombocytosis. Thrombosis is a presenting feature in 12% to 49% of patients and occurs in more than 40% during the course of the disease.

The classification according to the Polycythemia Vera Study Group includes the following:

Category A—increased RBC mass, splenomegaly, normal arterial oxygen saturation.

Category B—platelet count greater than 400 × 10^9/L, WBC count greater than 12 × 10^9/L (no fever or infection), leukocyte alkaline phosphatase score higher than 100, serum level of vitamin B_{12} greater than 900 ng/L.

The presence of all three criteria in category A establishes the diagnosis. If the patient has an increased RBC mass (category A) with either of the other two category A criteria, then two of the four category B criteria are necessary to establish the diagnosis. These criteria from categories A and B are no longer considered prerequisites for the diagnosis of polycythemia rubra vera. Unfavorable prognostic signs are previous thrombotic disease, age older than 60 years, diabetes mellitus, vascular disease, and hypertension.

New approaches to diagnosis include only the use of the serum erythropoietin level and the bone marrow examination in the

Table 11-11 Differential Diagnosis of Erythrocytosis

Feature	Polycythemia rubra vera	Relative or stress polycythemia (Gaisböck syndrome)	Anoxic polycythemia	Tumor

Modified from Dameshek W. Comments on the diagnosis of polycythemia vera. Semin Hematol. 1966;3:214-5. Used with permission.

diagnostic algorithm, rather than the diagnostic criteria from categories A and B, after establishing that the hemoglobin and hematocrit are higher than the 95th percentile and polycythemia vera–related features are present (thrombocytosis, leukocytosis, microcytosis, iron deficiency, splenomegaly, pruritus, erythromelalgia, and unusual thrombosis). The erythropoietin level, which is usually low in polycythemia rubra vera, may be normal, but the estimated specificity is greater than 90%.

Bone marrow findings typically demonstrate trilineage hyperplasia but are normal in up to 10% of patients. From 90% to 95% of bone marrow specimens have an absence of iron stores even if the patient is not phlebotomized. Cytogenetic abnormalities are present in 13% to 18% of patients. The bone marrow is negative for the Philadelphia chromosome. Morphologically, the bone marrow findings may resemble those of chronic myelogenous leukemia in 10% to 40% of patients. The leukocyte alkaline phosphatase score is increased in polycythemia rubra vera (and in leukemoid reactions, agnogenic myeloid metaplasia, idiopathic thrombocytopenic purpura, pregnancy, pyogenic infections, and stress erythrocytosis). Other morphologic abnormalities are present. Laboratory evaluation for polycythemia rubra vera includes previous results to document interval change, low or normal erythropoietin level, and bone marrow evaluation (hypercellularity, atypical megakaryocytic hyperplasia, decrease in iron stores, reduced expression of the thrombopoietin receptor [c-Mpl]). Erythropoietin is increased in secondary erythrocytosis.

- Polycythemia rubra vera: very low erythropoietin.
- The leukocyte alkaline phosphatase score may be increased in polycythemia rubra vera.
- Typical clinical scenario for polycythemia rubra vera: A hemoglobin concentration >18 g/dL in a white male or >2 g/dL that is documented and persistent, microcytosis, absence of iron stores, and splenomegaly. Other features include postbathing pruritus, unusual thrombosis, and erythromelalgia. The erythropoietin level is low.

The mainstay of treatment for all patients with polycythemia rubra vera is phlebotomy. However, there is no consensus about the optimal therapy for this disorder. Phlebotomy improved median survival by more than 10 years by decreasing the risk of thrombosis. Treatment for patients who are asymptomatic is phlebotomy to maintain the hematocrit below 42% in women and 45% in men. Patients are phlebotomized long term every 2 to 4 months, because there is 250 mg of iron in 1 pint of blood. If the normal daily absorption is 4 mg, then phlebotomizing every 2 months will maintain the hematocrit in the appropriate range. A phlebotomy program starts at 500 mL every day if the patient is symptomatic or at 3 to 6 phlebotomies weekly if asymptomatic and at low risk. The goal is to maintain the hematocrit at 42% to 45%. In the elderly, start phlebotomies at 250 mL. The risk of arterial and venous thrombosis is 20%. In older patients who have vascular lesions, the risk of thrombosis is related to the rate and volume of phlebotomy. Also, there is a risk of recurrent thrombosis in patients with a history of thrombosis. Low-dose aspirin therapy is indicated for all patients who do not have a contraindication to this therapy.

For patients who are symptomatic or at risk of thrombosis, the treatments are hydroxyurea, interferon alfa, anagrelide, and phosphorus 32. Hydroxyurea is the treatment of choice for older patients. Anagrelide and interferon alfa are alternative therapies and the treatment of choice for younger patients. Interferon alfa is the treatment of choice for younger patients and women of childbearing age. Erythromelalgia in polycythemia rubra vera is managed with aspirin and by normalizing the platelet count. Interferon alfa may reduce the pruritus in polycythemia rubra vera in up to 81% of patients. All patients 60 years or younger with cardiovascular risk factors or a previous history of thrombosis should be considered for treatment. With phosphorus 32, the number of platelets decreases in 2 weeks and the number of RBCs decreases in 1 month. This treatment is an alternative for patients older than 60. Treatment of younger patients with phosphorus 32 increases the risk of acute nonlymphocytic leukemia 2.3-fold. Chlorambucil is not indicated because of a 5.3-fold risk of the development of acute nonlymphocytic leukemia when compared with phlebotomy.

The management of thrombosis and bleeding includes heparin, warfarin, hydroxyurea, platelet apheresis if the platelet count is greater than 800×10^9/L, phlebotomy, and allopurinol.

The sequence of tests in erythrocytosis is as follows: If the hematocrit is greater than 58% in males or greater than 52% in females, proceed with an erythrocytosis evaluation. If the arterial oxygen saturation is greater than 92%, check carboxyhemoglobin concentration (smoker's polycythemia). If the arterial blood gases are normal, measure the erythropoietin level. The *JAK2* mutation status should be assessed.

- Sequence of ordering tests in erythrocytosis: If the hematocrit is >58% in males or >52% in females, proceed with an erythrocytosis evaluation. If the arterial oxygen saturation is >92%, check carboxyhemoglobin concentration (smoker's polycythemia). If the arterial blood gases are normal, measure the erythropoietin level. The *JAK2* mutation status should be assessed.
- For polycythemia rubra vera, phlebotomy is the cornerstone of treatment.
- For patients older than 60 years with or without a history of thrombosis, add hydroxyurea.

Oncogenesis

The hallmark of neoplastic disease is clonal proliferation of cells. Balanced reciprocal translocations affect specific sites on the genome (Table 11-12). Viral associations include HTLV-I in adult T-cell leukemia and Epstein-Barr virus in Burkitt lymphoma, Hodgkin disease, and posttransplantation lymphoproliferative disorders.

- Viral associations with hematologic malignancies: HTLV-I in adult T-cell leukemia; Epstein-Barr virus in Burkitt lymphoma, Hodgkin disease, and posttransplantation lymphoproliferative disorders.

Coagulation

The Coagulation System

The coagulation scheme is complex. Classically, the extrinsic pathway is assessed clinically with the PT and the intrinsic pathway with the

Table 11-12 Chromosomal Rearrangement and Increase of Specific Oncogenes

Disease	Rearrangement	Oncogene	Gene product
Burkitt lymphoma	t(8,14) t(8,22)	c-*myc*	Cell cycle progression Translocation into transcriptionally active immunoglobulin heavy or light chain loci

APTT. However, coagulation is more complex. Coagulation in vivo is regulated by plasma inhibitors (proteins C and S, antithrombin III, etc.) and coagulation reactions to cell surfaces.

The process of hemostasis is initiated when tissue factor–bearing cells are exposed to blood at the site of injury, resulting in the activation of factor VII and then the activation of factors IX and X. The main components of coagulation are platelets and factor VIII bound to vWF, which come into contact with the extravascular space with vessel wall injury. Coagulation is initiated when thrombin is generated near tissue factor–bearing cells, resulting in platelet activation, factor V activation, factor VIII activation, the dissociation of factor VIII from vWF, and factor XI activation. Platelets adhere and aggregate at the site of injury. The fibrin/platelet clot is formed at the site of injury and is controlled by the endothelial cell, protein C, protein S, and plasmin protease inhibitors. The fibrinolytic system is activated.

Prolonged Bleeding Time

The coagulation mechanism does not participate in bleeding time. An abnormal bleeding time reflects vascular defects, quantitative disorders of platelets (including thrombocytopenia and thrombocytosis), functional disorders of platelets, or operator error. Qualitative platelet defects result in abnormal bleeding time but normal partial thromboplastin time (PTT), PT, thrombin time, and platelet count (except in von Willebrand disease and disseminated intravascular coagulopathy). In patients with a uremia-induced platelet defect, the treatment of choice is desmopressin (DDAVP) and platelet transfusions. For prolonged bleeding time, the differential diagnosis includes Glanzmann thrombasthenia, von Willebrand disease, Bernard-Soulier syndrome, disseminated intravascular coagulopathy, thrombocytopenia, storage pool disease, drugs (aspirin and others), and uremia.

- Differential diagnosis for prolonged bleeding time: Glanzmann thrombasthenia, von Willebrand disease, Bernard-Soulier syndrome, disseminated intravascular coagulopathy, thrombocytopenia, storage pool disease, drugs (aspirin and others), and uremia.

von Willebrand Disease

von Willebrand disease is the most common inherited bleeding disorder. Different subtypes have been described. In most subtypes, the inheritance pattern is autosomal dominant with incomplete penetrance (parent of either sex). The bleeding usually is mucocutaneous. The most common bleeding symptoms are epistaxis, skin ecchymoses, cutaneous hematomas, prolonged bleeding from trivial wounds, oral cavity bleeding, bleeding from tooth extractions, and menorrhagia. Bleeding may be exacerbated by aspirin. Hemarthroses are rare.

To understand von Willebrand disease, it is helpful to review endothelial interactions. The steps are platelet adhesion and then platelet aggregation. Collagen and vWF antigen are involved in both steps. vWF is a multimeric protein that circulates in blood plasma and is stored in endothelial cells and platelets. It is found in plasma, platelets, and endothelial regions and is detected functionally by its ability to cause aggregation of washed platelets when ristocetin is administered. Aggregation requires adenosine diphosphate (ADP) and thromboxane A_2. The activation of the clotting mechanism and generation of thrombin seem to result from the activation of the platelet membrane during adhesion and aggregation. Platelets make available platelet factor III phospholipid and catalyze the activation of other coagulation factors. The vWF/factor VIII complex is composed of the following:

1. Factor VIII:C—The coagulant activity that is missing in hemophiliac plasma; this is decreased in hemophilia and von Willebrand disease and circulates in the plasma with vWF.
2. Factor VIII vWF antigen (vWF:Ag)—vWF is a carrier protein for factor VIII, protecting it from rapid proteolytic destruction, and is the mediator of the initial adhesion of platelets to the blood vessel wall. The adhesive function is contained mainly within large multimers.
3. vWF activity (ristocetin cofactor activity)—The activity necessary for ristocetin-induced platelet aggregation that is not present in von Willebrand disease. Measurement of the ristocetin cofactor is the closest measurement of vWF activity. This is decreased in von Willebrand disease and is normal in

hemophilia. vWF has an essential role in the adhesion of platelets to the subendothelium. Factor VIII coagulant activity and vWF activity reside in two separate molecules that are noncovalently bound in the plasma. Therefore, von Willebrand disease represents a defect in hemostasis involving the interaction of the platelet membrane glycoprotein, subendothelial tissues, and vWF. There is decreased synthesis, decreased release, or abnormal production of vWF. Defects in vWF may cause bleeding because platelets cannot adhere to sites of vascular injury. vWF has three functions: platelet adhesion, platelet-to-platelet aggregation, and serving as a carrier for factor VIII.

The many distinct variants of von Willebrand disease can be divided into three subtypes. This classification is intended to reflect differences in the pathophysiology of the von Willebrand disease phenotypes. Type 1 is characterized by a partial *quantitative* abnormality in vWF. It is the most common type (75% of patients) and is autosomal dominant. The total amount of circulating vWF multimers is 50% or less. The distribution and function of vWF are normal. The definitive diagnosis of type 1 von Willebrand disease requires documentation of bleeding, low levels of qualitatively normal vWF, and inheritance. Patients who do not meet all three criteria may have "possible" von Willebrand type 1 disease. The broad normal ranges for vWF levels and the variation in levels over time may complicate the diagnosis of vWF type 1. Type 2 disease (A, B, M, and N) is characterized by a *qualitative* dysfunctional abnormality in vWF. In type 3 von Willebrand disease, there is virtually no detectable von Willebrand protein. Heterozygous von Willebrand disease (1% of the population) is characterized clinically by mild to moderate bleeding. Its inheritance pattern is autosomal dominant. The laboratory diagnosis of von Willebrand disease includes normal or abnormal APTT and normal PT; prolonged bleeding time; decrease in factor VIII, vWF antigen (vWF:Ag), and vWF activity (ristocetin cofactor activity); normal platelet aggregation except in the presence of ristocetin; and mildly prolonged PTT. A normal APTT does not exclude the diagnosis of von Willebrand disease.

- vWF has three functions in hemostasis: adhesion and aggregation of platelets and the transportation and stabilization of factor VIII in the plasma.
- The tests for the diagnosis and exclusion of von Willebrand disease are vWF antigen and ristocetin cofactor activity (vWF:Rco).
- Supplementary tests that may be needed for the type of von Willebrand disease include APTT, bleeding time, platelet count, vWF multimer analysis, and ristocetin-induced platelet aggregation response.
- Typical clinical scenario: A patient with recurrent mucosal bleeding has a prolonged APTT.

The goal of treatment is to correct the coagulant defect, the result of subnormal vWF levels. Restoration of vWF levels results in control of hemorrhage in the absence of a consistent correction of the bleeding time. Mild and moderate cases of von Willebrand disease require treatment only at the time of an operation or bleeding. For menorrhagia, birth control pills are effective (estrogen use may increase vWF and mask mild von Willebrand disease). For dental extractions, local hemostasis and local fibrinolytic agents with or without DDAVP are effective. In pregnancy, there is no need to transfuse in mild to moderate cases of the disease because the levels of vWF increase with the duration of pregnancy. The mainstays of treatment are DDAVP and factor VIII concentrates rich in vWF. DDAVP causes the release of preformed vWF multimers from the subendothelium and is useful in type 1 von Willebrand disease. Side effects include facial flushing, headache, mild decrease in blood pressure, mild tachycardia, and hyponatremia. Repeated doses at intervals shorter than 24 hours may result in a decrease or loss of response (tachyphylaxis). DDAVP may be delivered intranasally, subcutaneously, or intravenously. A trial should be conducted before it is used as primary therapy. The levels increase for 4 to 8 hours. This agent usually is effective only in type 1 von Willebrand disease. For patients with type 2B or 3 von Willebrand disease or for those with type 1 disease that has become transiently unresponsive to DDAVP, viral-inactivated factor VIII preparations rich in high-molecular-weight multimer vWF are recommended. Humate-P (antihemophilic factor [human], pasteurized) has been approved by the U.S. Food and Drug Administration. Cryoprecipitate from carefully selected and repeatedly tested donors is more desirable than cryoprecipitate from random donors, but the risk of transmission of viral diseases is higher.

- DDAVP is the treatment of choice for mild disease.
- Preparations rich in high-molecular-weight multimer vWF are recommended for types 2B and 3 disease and for type 1 disease transiently unresponsive to DDAVP.

Glanzmann Thrombasthenia

Glanzmann thrombasthenia results from a defect in the first phase of platelet aggregation because of a marked decrease in or absence of platelet glycoproteins IIb/IIIa. Its inheritance pattern is autosomal recessive. Early hemorrhagic complications occur in the neonatal period, and epistaxis, purpura, petechiae, and ecchymoses persist throughout life. Laboratory findings include no clumping of platelets on the peripheral blood smear, normal platelet number and morphology, and no aggregation with ADP, epinephrine, thrombin, or collagen. Aggregation does occur with ristocetin. Treatment consists of nasal packing, local measures, and cryoprecipitate, with or without platelets, when local measures are not successful. Leukocyte-depleted, single-donor platelet concentrates are preferable to reduce the risk of alloimmunization.

Bernard-Soulier Syndrome

Bernard-Soulier syndrome is the result of the absence of glycoprotein Ib/IX complexes on the surface of human platelets that mediate ristocetin-induced vWF-dependent platelet aggregation. Glycoprotein Ib/IX is the platelet receptor for vWF. These platelets are unable to react with subendothelial vWF. It is more common in whites and blacks, and its inheritance pattern is autosomal recessive. This disorder is characterized by moderate or severe bleeding with surgery and menstruation. Bleeding typically is from mucous membranes, the gums, and the gastrointestinal tract. Bleeding time is markedly

prolonged. Characteristically, there is thrombocytopenia with giant platelets. The aggregation pattern is the opposite of that of Glanzmann thrombasthenia, with normal platelet aggregation with ADP, collagen, epinephrine, and thrombin but no aggregation with ristocetin. No specific treatment is available for Bernard-Soulier syndrome other than local measures and platelets.

Storage Pool Disease

Normally, adenosine triphosphate (ATP), ADP, serotonin, and calcium are stored by platelets and released from them. In storage pool disease, there is a marked decrease in platelet ADP and a lesser decrease in ATP. Because of the profound decrease in ADP, the amount released from the platelets is insufficient to bring uninvolved platelets into larger aggregates.

Disseminated Intravascular Coagulopathy

Disseminated intravascular coagulopathy is characterized by a dynamic process caused by many diseases with microvascular clotting due to thrombin deposition. The laboratory findings vary. No single laboratory test can confirm or exclude the diagnosis, which depends on the clinical setting and laboratory findings. The manifestations vary from patient to patient and from time to time in the same patient. These may be of little clinical significance or cause life-threatening bleeding or clotting. The mortality rates of severe disseminated coagulopathy range from 50% to 85%.

The pathophysiologic mechanism of disseminated intravascular coagulopathy is complex. Thrombin is formed in the vascular system and alters platelets. The platelets aggregate, agglutinate, and secrete many products, resulting in thrombocytopenia and platelets that do not function well. As plasmin circulates, it systematically degrades fibrin and fibrinogen, creating the D-dimer and X, Y, D, and E fragments known as *D-fibrinogen degradation products*. Thrombin cleaves fibrinopeptides A and B from fibrinogen to form fibrin monomers. The complex of fibrin degradation products and fibrin monomers is called *soluble fibrin monomer*. Fibrin degradation products interfere with fibrin monomer polymerization. Fibrin degradation products and D-dimer induce interleukin-1 and interleukin-6. Thrombin induces the release of other factors, including proinflammatory cytokines. These monomers may complex with fibrinogen (polymerization) to form insoluble fibrin, which is deposited in capillaries and small blood vessels, resulting in microangiopathy. Activated factor XIII cross-links fibrin to make it more resistant to fibrinolysis. Thrombin increases the activity of factors V and VIII. Therefore, thrombin accounts for the decrease in fibrinogen, platelets, and factors II, V, VIII, and XIII. Secondary fibrinolysis may occur. Bleeding occurs because the coagulation factors are depleted or fibrinolysis with vessel damage results in a decrease in control proteins, such as antithrombin III and protein C. Activated factor XII leads to kallikrein production, resulting in the conversion of plasminogen to plasmin (the global proteolytic enzyme), which is capable of digesting fibrinogen, clotting factors, and complement. The clinical picture depends on a balance: if thrombin activity is greater than plasmin activity, thrombosis occurs; if plasmin activity is greater than thrombin activity, hemorrhage occurs.

The following occur in acute disseminated intravascular coagulopathy: bleeding from wounds and perivenipuncture sites, ecchymoses, petechiae, hematomas, hematuria, intracranial hemorrhage, intrapleural hemorrhage, intraperitoneal hemorrhage, hemoptysis, vaginal bleeding, melena, and hematemesis. Thromboembolic complications, as manifested by necrotic skin lesions, pulmonary emboli, acute arterial occlusions, ischemia, stroke, and myocardial infarction, may occur in 8% of patients. Thrombosis is more common than bleeding in chronic disseminated intravascular coagulopathy.

Disseminated intravascular coagulopathy has many causes. Malignancy is the most common cause: prostate, breast, lung, leukemia (acute progranulocytic [M3]), pancreas, or lymphoma. Infection is the second most common cause (gram-negative [30%-50% of patients] and gram-positive bacteria and other agents, e.g., *Staphylococcus*, *Streptococcus*, pneumococcus, typhoid, *Rickettsia*, viral, fungal, *Histoplasma*, and *Aspergillus*), and surgery or trauma is the third. Other causes are liver disease, obstetrical (amniotic fluid, embolism, and abruptio placenta), acute renal failure associated with cardiogenic shock, gunshot wounds, endothelial injury (giant hemangiomas [Kasabach-Merritt syndrome], aortic aneurysms, and angiography), hemolytic transfusion reactions, burns, crush injuries, acidosis, alkalosis, reactions to toxins (snake venom), and transfusion reactions.

The optimal screening study results are thrombocytopenia in 90% of patients, increased PT in 50% to 75%, and hypofibrinogenemia in 70% of those with severe disease. The best available confirmatory test is the fibrin D-dimer assay, a test that is specific for fibrin degradation products and detects fibrinogen fragments formed by the lysis of cross-linked fibrin. More sensitive techniques include detection of products of fibrinolysis or fibrin degradation products (D-dimer products) and coagulation activation (soluble fibrin monomers). The values obtained with these two tests may be increased in the postoperative state and in patients with recent thrombi because of fibrinolysis that may not reflect a pathologic state.

- Screening test results for disseminated intravascular coagulopathy: thrombocytopenia (90% of patients), increased PT (50% to 75% of patients), and hypofibrinogenemia (70% of patients with severe disease).

The first goal is to treat the underlying disease. Next, the approach depends on the clinical situation. If the patient has a low level of fibrinogen, low platelet count, or low levels of clotting factor and is not bleeding or undergoing a surgical procedure, no treatment is necessary. If the patient is bleeding or undergoing a surgical procedure, treat with cryoprecipitate, fresh frozen plasma, and platelets. Monitoring the effect of replacement therapy with platelet and fibrinogen levels 30 minutes to 1 hour after transfusion and every 4 to 6 hours thereafter provides a guide to further replacement therapy. If the patient continues to bleed and the above measures do not cause an increase in coagulation factors, it may be necessary to continue factor and platelet replacement therapy and to start a continuous infusion of heparin. Heparin is contraindicated if there is a central nervous system lesion. If there is evidence of fibrin deposition or thrombosis (such as dermal necrosis in purpura fulminans, acral ischemia, livedo reticularis, or venous thromboembolism), heparin therapy is

indicated. Full-dose therapy (a loading dose of 5,000 U, followed by 1,000 U/h), low-dose continuous infusion heparin (300 to 500 U/h), and subcutaneous heparin have been advocated. Monitoring is a problem. The initial approach is to monitor the PT, fibrinogen level, and platelet count. A heparin assay to achieve a level of 0.2 to 0.4 m/mL is an alternative approach that is not advocated as routine practice. The thrombotic events of disseminated intravascular coagulopathy in solid tumor malignancy can be treated effectively with heparin, but warfarin anticoagulation may not be as effective. Other instances in which heparin is indicated are retained dead fetus with hypofibrinogenemia before induction of labor, excessive bleeding associated with giant hemangioma, promyelocytic leukemia, and mucinous adenocarcinoma. For more than 95% of patients, heparin is not indicated. Antithrombin III is a supportive therapeutic option in severe disseminated intravascular coagulopathy.

Chronic disseminated intravascular coagulopathy is common. Routine tests of hypercoagulability are abnormal in a substantial number of patients with cancer. Increased levels of fibrinogen are common. The syndrome of coexisting cancer and thrombotic disease is called *Trousseau syndrome*, which is associated with mucin-producing neoplasms.

Coagulation and Liver Disease

The most important factor is the condition of the blood vessels. There is no tendency to bleed until blood vessels are damaged, such as by a needle, a surgical procedure, or gastric acid. The three main causes of coagulation problems are 1) portal hypertension, which is characterized by thrombocytopenia and normal coagulation factor synthesis; 2) cholestasis, which results in impaired absorption of fat-soluble vitamins, with vitamin K deficiency and an increase in PT and APTT; and 3) acute and chronic hepatocellular disease, which is characterized by a normal fibrinogen level (until late in the course of the disease), thrombocytopenia, and an increase in PT and APTT because of multiple factor deficiencies. Liver disease is compared with disseminated intravascular coagulopathy and vitamin K deficiency in Table 11-13.

Factor-Deficiency States

The causes of an isolated elevated APTT include factor deficiencies (XII, XI, IX, and VIII) and antiphospholipid antibodies (lupus anticoagulant and anticardiolipin antibodies). Mixing studies result in correction in factor deficiencies and no correction on initial mixing at 2 hours in the case of antiphospholipid antibodies.

Factor XIII Deficiency

Factor XIII deficiency is characterized by normal blood test results but marked bleeding. There is a history of umbilical cord bleeding, ecchymoses, and prolonged hemorrhage from cuts. Its inheritance pattern is autosomal recessive. All routine clotting tests, including bleeding time, may give normal results. Treatment is with cryoprecipitate. The causes of an isolated elevated APTT include factor deficiencies (XII, XI, IX, and VIII) and antiphospholipid antibodies (lupus anticoagulant and anticardiolipin antibodies). Mixing studies result in correction of factor deficiencies and no correction on initial mixing at 2 hours in antiphospholipid antibody syndrome.

Factor XII Deficiency

Factor XII deficiency is an autosomal recessive disorder in which thromboembolic complications occur. It is often associated with a very high APTT; PT is normal.

Factor XI Deficiency (Hemophilia C)

Factor XI deficiency is a rare autosomal recessive disorder that occurs predominantly in Ashkenazi Jews. This is a mild bleeding disorder that usually becomes manifest after surgery or trauma or with the initiation of treatment with antiplatelet agents or anticoagulants. The indications for replacement therapy depend on several variables. Treatment options include fresh frozen plasma and virally inactivated factor XI concentrate.

Factor IX Deficiency (Christmas Disease or Hemophilia B)

This X-linked disorder accounts for 15% of all cases of hemophilia. It is clinically indistinguishable from factor VIII deficiency. The laboratory abnormalities include an abnormal PTT. Patients who undergo a surgical procedure or who have major bleeding could receive purified factor IX concentrates. Recombinant factor IX products (nonacog alfa [BeneFix]) developed from a monoclonal antibody-purifying process are available. They are safe from contamination with the acquired immunodeficiency syndrome (AIDS)

Table 11-13 **Differences in Laboratory Findings in Liver Disease, Disseminated Intravascular Coagulopathy, and Vitamin K Deficiency**

Tests	Liver disease	Disseminated intravascular coagulopathy	Vitamin K deficiency
Thrombocytopenia	Mild, 50% of patients, $<50 \times 10^9$/L platelets uncommon	90% of patients	No
Increased prothrombin time	Common	90% of patients	Common
Decreased fibrinogen	Late in disease	70% of patients	No
Factor V	Decreased	Regularly decreased	Normal
Factor VIII	Normal	Regularly decreased	Normal
Factors VII, X	Decreased	Normal	Decreased

virus, and the risk of hepatitis is markedly decreased. Rare thrombotic episodes have been reported with recombinant factor IX.

Factor VIII Deficiency (Hemophilia A)

Factor VIII deficiency results from a defect in factor VIII:C, its inheritance pattern is X-linked recessive, and it accounts for 85% of cases of hemophilia. If a hemophiliac male has children from a nonhemophiliac female, all daughters are obligatory carriers and all sons are nonhemophiliac. If a nonhemophiliac male marries a carrier, each daughter has a 50% chance of being a carrier and each son has a 50% chance of having hemophilia. At birth, there are no bleeding manifestations; however, 50% of males bleed at the time of circumcision. Bleeding occurs in 75% of severely affected infants by age 18 months. The severity of hemophilia runs true in families. Persons with severe hemophilia have less than 1% factor VIII and clinically have hemarthroses, atrophied muscles, subcutaneous hematomas in the tongue and neck, and hematomas in the genitourinary and gastrointestinal tracts. Those with mild hemophilia have factor VIII levels of 5% to 25% and may bleed heavily, even fatally, postoperatively or after dental extractions unless the factor is adequately replaced.

Laboratory studies show an abnormal PTT, abnormal factor VIII, normal PT, normal bleeding time, and normal thrombin time.

Treatment options include DDAVP, plasma-derived clotting factor concentrates, and recombinant clotting factor concentrates. DDAVP may establish adequate hemostatic levels in mild hemophilia.

Factor VIII concentrate has a half-life of 8 to 12 hours. Current factor VIII concentrates are considered to be safe from HIV transmission. However, three highly purified products, all produced by monoclonal antibodies, are available and no cases of AIDS or hepatitis B or C have been reported with their use. No seroconversions to HIV have been reported with any of the products in the United States, including products that have been heated in aqueous solution, solvent-detergent treated, or immunoaffinity purified. Heat- and solvent-detergent–treated concentrates appear to be free from transmission of hepatitis B, hepatitis C, and HIV. Hepatitis A and parvovirus are not inactivated by these techniques. Recombinant factor VIII products (Recombinate, Kogenate, Helixate FS [albumin-free]) are available and appear to be free from human virus transmission and are the standard treatment of choice. A recombinant factor VIII manufactured without human or antiviral protein is now available (Refacto).

The management of patients with factor VIII inhibitors is complex. Porcine factor VIII should be considered in the initial management if the patient does not have an inhibitor to this factor. When porcine factor VIII cannot be used, prothrombin complex concentrates (I, VII, IX, and X) may be administered to bypass the need for factor VIII. These agents have a risk of thrombotic complications. Recently, recombinant factor VIIa has become available. Always check the Bethesda unit assay before any general surgical procedure is performed in a patient with hemophilia. From 5% to 20% of persons with hemophilia develop inhibitors (IgG antibodies) that inactivate factor VIII:C (Bethesda units). If the inhibitor is less than 3 Bethesda units/mL, treat with higher doses or replacement therapy. If the value is higher (>10 Bethesda units), one can attempt to use prothrombin complex concentrates (II, VII, IX, and X) to "bypass." Hemophilia A is compared with von Willebrand disease in Table 11-14.

- Factor VIII and factor IX deficiencies are X-linked.
- Management of hemophilia A: a trial of DDAVP should be undertaken in cases of mild to moderate hemophilia A.
- For other patients, use factor VIII products that are heat-treated, solvent-detergent–treated, immunoaffinity purified, or produced by recombinant techniques.
- Recombinant techniques appear to be free from human virus transmission and are the treatment of choice.
- Typical clinical scenario: A male patient has bleeding into the joints and a prolonged APTT. PT and bleeding time are normal.

Acquired factor VIII deficiency states may occur and have the following causes: idiopathic, postpartum, collagen vascular diseases (rheumatoid arthritis, systemic lupus erythematosus, and temporal arteritis), drug hypersensitivity (penicillin and sulfonamides), malignancies (lymphoproliferative and solid tumors), and old age. Clinically, bleeding is intramuscular, retropharyngeal, retroperitoneal, and cerebral. Also, hematuria occurs. Treatment is difficult and requires the combination of corticosteroids, cyclophosphamide, plasmapheresis, prothrombin-complex concentrate, activated prothrombin-complex concentrate, and porcine factor VIII. The combination of cyclophosphamide and prednisone may be effective in an outpatient setting for patients with an acquired factor VIII inhibitor.

Factor VII Deficiency

Factor VII deficiency is characterized clinically by epistaxis, gingival bleeding, bleeding after trauma, menorrhagia, and hemarthroses. The APTT is normal, and PT is abnormal.

Factor X Deficiency

Factor X deficiency is characterized by bleeding that is the same as that in factor VII deficiency. An acquired factor X deficiency state may occur in amyloidosis. The APTT and PT are abnormal.

Table 11-14 Differences Between Hemophilia A and von Willebrand Disease

Feature	Hemophilia A	von Willebrand disease
Inheritance	Sex-linked	Autosomal
Bleeding time	Normal	Prolonged
Factor VIII:C	Decreased	Decreased
vWF	Normal	Decreased
Ristocetin cofactor	Normal	Decreased

vWF, von Willebrand factor.

Factor V Deficiency

Factor V deficiency may be acquired in myeloproliferative disorders. Bruising occurs with severe bleeding postoperatively and at the onset of menstruation. Treatment consists of administering platelets and fresh frozen plasma.

Causes of an increased thrombin time include heparin, heparin-like anticoagulants, increase in fibrin degradation products, and decreased or defective fibrinogen.

The hemorrhagic disorders are summarized in Table 11-15.

Treatment of Factor-Deficiency States

Circulatory overload problems must be taken into consideration when patients receive transfusion with materials used to treat deficiency states. To control major bleeding or to prepare patients for a surgical procedure, it is advised that the plasma level of factor VIII be increased to 60% in patients with factor VIII deficiency. The number of factor VIII units is calculated by multiplying the patient's weight in pounds by 12 (e.g., 160 lb×12 = 1,920 units of factor VIII).

Fresh frozen plasma is a good source of all factors. It has been used in treating congenital deficiencies in factors II, V, VII, IX, X, XI, and XIII and multiple coagulation deficiencies, including oral anticoagulant overdose, liver disease, massive transfusion, disseminated intravascular coagulopathy, plasmapheresis, and vitamin K deficiency. Multiple coagulation factor deficiencies should be suspected in patients with prolonged PT and partial thromboplastin times greater than 1.5 times normal if not due to known coagulation factor deficiency or circulating lupus-like anticoagulant. In dosing fresh frozen plasma, 1 or 2 units usually is not sufficient to replace coagulation factors, as in patients with liver disease, which requires 3 to 9 units. The maximal effect declines 2 to 4 hours after transfusion. Purified antihemophilic concentrates are derived from fresh frozen plasma of paid donors and are lyophilized or freeze-dried in form. Complications include hepatitis and factor VIII inhibitors.

Cryoprecipitate is a good source of factors VIII and XIII and fibrinogen. The activity per gram of protein is 12 to 60 times that of fresh frozen plasma. One bag increases the factor VIII level 2.5% or one bag per 6 kg of body weight twice a day in factor VIII deficiency. Cryoprecipitate is the treatment of choice for fibrinogen and factor XIII deficiencies.

Factor IX complex contains factors II, VII, IX, and X. Activated factor IX–complex products include Konyne and anti-inhibitor coagulant complex, heat treated (Autoplex T). This is indicated for severe factor IX deficiency and in the management of factor VIII inhibitors. Complications include hepatitis, disseminated intravascular coagulopathy, and thrombosis.

Nonplasma hemostatic agents include antifibrinolytic agents (aminocaproic acid and aprotonin) and DDAVP. The antifibrinolytic agents bind to plasminogen, preventing fibrinolysis-enhancing clot stability. Aprotonin is used in cardiac bypass surgery and liver transplantation. DDAVP increases factor VIII and vWF through release from endothelial cells.

Thrombophilia: The Hypercoagulable States

Thrombophilia refers to the hereditary or acquired tendency to have recurrent venous or arterial thromboembolism. Clinical indications of hypercoagulable states include a family history of thrombosis, recurrent thrombosis without other precipitating risk factors, thrombosis at unusual sites, and postpartum thrombosis. The clinical features of familial thrombophilia include venous or arterial thrombosis at an early age, family history of venous thromboembolism, recurrent venous thromboembolism, unusual sites of thromboembolism (cerebral, mesenteric, and renal), thrombosis during pregnancy, and idiopathic venous or arterial thromboembolism. With the congenital states, the initial episode of venous thromboembolism is rare before the age of 18 years and uncommon after the age of 50 and occurs in high-risk situations.

Table 11-15 **Summary of Test Results in Hemorrhagic Disorders and Anticoagulant Therapy**

Disorder or therapy	Prothrombin time	APTT	Thrombin time	Fibrinogen	Bleeding time
Classic hemophilia A	Normal	Abnormal	Normal	Normal	Normal
von Willebrand disease	Normal	Normal or abnormal	Normal	Normal	Abnormal
Afibrinogenemia	Abnormal	Abnormal	Abnormal	Absent	Normal
Hypofibrinogenemia	Normal	Normal	Normal	Low	Normal
Dysfibrinogenemia	Normal or abnormal	Normal or abnormal	Abnormal	Normal	Normal
Factor XIII deficiency	Normal	Normal	Normal	Normal	Normal
Heparin	Slightly abnormal	Abnormal	Abnormal	Normal	Normal or abnormal
Warfarin (Coumadin)	Abnormal	Normal or abnormal	Normal	Normal	Normal

APTT, activated partial thromboplastin time.

Venous thromboembolism, deep venous thrombosis, and pulmonary embolism are major causes of morbidity, affecting more than 2 million patients annually in the United States. The annual mortality rate is 50,000, higher than that for breast cancer. Deep venous thrombosis and pulmonary embolism affect otherwise healthy patients as a major complication of surgery and hospitalization. Risk factors for thrombosis are noncongenital, congenital, and acquired. Noncongenital risk factors include age, trauma, obesity, immobilization, pregnancy, diabetes mellitus, and oral contraceptive pills. Mutations or polymorphisms in antithrombotic and prothrombotic factors, the thrombophilias, are the genetic factors. Congenital risk factors include the deficiency states of protein S, protein C, prothrombin 20210A gene abnormality (factor II G20210A), hyperhomocystinemia, plasminogen deficiency, antithrombin III deficiency, and congenital resistance to activated protein C (APC). Of all cases of APC resistance, 90% are caused by heterozygosity or homozygosity for a single point mutation in the factor V gene, factor V Leiden. Acquired conditions include lupus anticoagulant, disseminated intravascular coagulopathy, paroxysmal nocturnal hemoglobinuria, pregnancy, malignancy, inflammatory bowel disease, myeloproliferative disorders, cryoglobulinemia, and aberrant blood flow.

Resistance to APC is an autosomal dominant disorder resulting from a point mutation in the gene encoding coagulation factor V, commonly known as the *factor V Leiden mutation*. Normally, protein C inactivates factor Va. An alteration interferes and increases the risk of venous thrombosis. This mutation renders factor V resistant to proteolytic down-regulation by APC, and so the clotting mechanism continues to generate the clotting enzyme thrombin. The heterozygous mutation has a prevalence of 5% to 7% in the white population. There is approximately a tenfold increased prevalence (20%-50%) among persons with familial or recurrent venous thromboembolism and a 20% increased prevalence among those with deep venous thrombosis. Homozygotes have an 80-fold increased risk of venous thromboembolism. The risk of venous thromboembolism is increased 30-fold among heterozygotes receiving oral contraceptive therapy. The diagnosis is established by an APTT-based APC resistance ratio or DNA-based testing. DNA-based testing is recommended for patients with an abnormal APTT-based APC resistance ratio, for patients with an abnormally prolonged APTT (lupus-like anticoagulant), and for those taking anticoagulants. Of patients with hereditary APC resistance, 90% have a single nucleotide mutation of the coagulation factor V gene, the R506Q gene. Asymptomatic patients with APC resistance should have prophylactic intervention when clinical thrombosis risk factors are present. An initial deep venous thrombosis in an APC-resistant person is managed in a standard fashion. Those who are homozygotes or heterozygotes with additional thrombophilic predispositions should be considered for lifelong anticoagulation prophylaxis. The international normalized ratio (INR) for these patients does not need to be higher than required.

- Typical case scenario for protein S or C deficiency: A 40-year-old person has venous thrombosis.

Protein S deficiency is more common than protein C or antithrombin III deficiency. The use of routine coagulation assays fails to detect these patients. A 50% decrease in either protein S or C increases thrombotic tendencies. Family studies are required. Assays are available for all three deficiency states. Protein S is a vitamin K–dependent factor that is required for expression of APC anticoagulant activity. There is an increased incidence of thrombosis, with venous complications greater than arterial. APC destroys activated factors V and VIII and, thus, is a potent plasma anticoagulant. APC requires a second vitamin K-dependent factor, or cofactor, protein S. Antithrombin III deficiency is an uncommon cause of venous thromboembolism. The management of protein S deficiency, protein C deficiency, and antithrombin III deficiency requires heparin and oral anticoagulant agents. There is an increased incidence of warfarin necrosis that is a rare complication in nonhospitalized patients and occurs 2 to 10 days after treatment with warfarin is initiated. Other causes of protein S and protein C deficiency include liver disease, oral anticoagulation, and oral contraceptives.

The antiphospholipid antibodies, which are identified by immunoassays instead of functional testing, include anticardiolipin antibodies, lupus anticoagulants, protein-phospholipid reactivity, and anti-reagin antibodies. Antiphospholipid antibodies are immunoglobulins (IgG or IgM) that interfere with in vitro phospholipid steps of coagulation, causing a prolonged clotting time in the APTT, dilute Russell viper venom time, or plasma clot time. Antiphospholipid antibodies are heterogeneous. Some prolong phospholipid-dependent clotting reactions (lupus anticoagulant detected by increased APTT and prolonged dilute Russell viper venom time) and others bind to cardiolipin or β_2-glycoprotein 1 bound to phospholipids (anticardiolipin antibodies detected by IgG and IgM serum anticardiolipin antibodies).

Activation of protein C is phospholipid-dependent. Therefore, interference with this reaction may create a prothrombotic state. Patients with antiphospholipid antibodies are at higher risk of thrombosis. This is an interfering inhibitor of APTT that does not correct with equal volumes of normal plasma. The screening test is prolonged APTT. Clinically, venous thrombosis of the lower extremities is more common than arterial thrombosis. The clinical approach to lupus anticoagulant and antiphospholipid antibody syndrome is as follows: The APTT does not correct with a 1:1 mixture of normal plasma, so the best confirmatory test is the dilute Russell viper venom time (addition of exogenous phospholipid) or the platelet neutralization procedure (addition of phospholipid to the APTT system in the form of platelets). The dilute Russell viper venom time is also abnormal in patients receiving heparin.

Other assays for antiphospholipid antibody include β_2-glycoprotein 1 antibodies and antithrombin antibodies. If there is no history of thrombotic disease, check the APC-resistant factor Va, antithrombin III, protein C, and protein S. If normal, observe. Prophylactic anticoagulant therapy is indicated for times of increased risk, such as postoperative state and long-bone fracture. Alternatives to oral contraceptives should be considered. If the patient develops thrombosis and is receiving heparin, follow heparin levels or the anti-Xa test. Alternatively, low-molecular-weight heparin obviates the need for monitoring. If the patient requires oral warfarin, regulate with an arbitrary INR of 2.5 to 3.5 or with the prothrombin-proconvertin test. After thrombotic events, long-term warfarin is indicated.

The clinical syndromes of the antiphospholipid antibody include major (venous and arterial thromboses, spontaneous abortions, and thrombocytopenia) and minor (livedo reticularis, multistroke dementia, and chorea) components. The thrombotic manifestations are venous (deep venous thrombosis, cutaneous thrombosis, renal vein thrombosis, and Budd-Chiari syndrome) or arterial (central nervous system, coronary thrombosis, and renal artery or vein thrombosis). Hematologic associations include thrombocytopenia, hemolysis, and hypocomplementemia. Obstetrical associations are maternal (deep venous thrombosis, chorea, eclampsia, and pulmonary embolus) and fetal (spontaneous abortion, fetal death, and second and third trimester premature birth).

There is no indication for the treatment of asymptomatic patients without a history of associated conditions. For thrombosis, initially treat with heparin, followed by anticoagulation with warfarin, with an INR greater than 3.0. Low doses of aspirin and heparin are recommended for the management of pregnant women. Pregnant women with a previous history of venous thromboembolism may be followed with active clinical surveillance or active prophylaxis with heparin treatment.

Who should be tested? Patients who should be considered for further testing include persons younger than 40 years with thrombotic events and those with a strong family history of thrombosis, recurrent thromboses at different sites, skin necrosis, recurrent fetal loss, and thrombosis at unusual sites (sagittal sinus thrombosis, mesenteric thrombosis). Pregnancy increases the risk of venous thromboembolism about fivefold that of the general population and if a patient has had venous thromboembolism in the past, there is a transient, approximately threefold increase in the risk. Pulmonary embolism is the most common medical cause of maternal deaths associated with live births.

Asymptomatic carriers do not need treatment. Asymptomatic family members do not need treatment. Patients with their first venous thromboembolism who have persistent clinical risk factors and reduced coronary reserve and patients with recurrent venous thromboembolism who are homozygotes or compound/double heterozygotes are candidates for long-term anticoagulation.

- Typical clinical scenario for antiphospholipid antibody syndrome: A patient with recurrent events in the same vascular location has an abnormal APTT. Laboratory testing shows that the prolonged APTT is corrected by the addition of platelet-rich plasma.

Anticoagulants

There are different anticoagulation targets. Procoagulant proteins may be depleted (warfarin). Procoagulant proteins may be inhibited indirectly (unfractionated heparin and low-molecular-weight heparin [LMWH], e.g., fondaparinux, ardeparin, dalteparin, danaparoid, enoxaparin, and tinzaparin). Procoagulant proteins may be inhibited directly (hirudin, lepirudin, bivalirudin, and argatroban). The fibrinolytic system may be enhanced (thrombolytic therapy).

Warfarin

Warfarin is a vitamin K antagonist, which limits the gamma-carboxylation of the vitamin K-dependent coagulation proteins II, VII, IX, and X and anticoagulant proteins C and S, impairing their biologic function in blood coagulation. Warfarin derivatives, direct thrombin inhibitors, and hirudin cross the placenta and are contraindicated in pregnancy. Unfractionated heparin, LMWH, and danaparoid do not cross the placenta. Complications include embryopathy. Other relative contraindications for warfarin include a hemorrhagic tendency such as thrombocytopenia or coagulation factor abnormalities, diastolic blood pressure greater than 110 mm Hg, gastrointestinal tract lesions liable to bleed, severe liver disease, severe renal disease, malabsorption, subacute bacterial endocarditis, diverticulosis, or colitis. It is also contraindicated if a surgical procedure was performed recently on the central nervous system or eye.

In venous thromboembolism (VTE), warfarin treatment should be started within 24 hours after the initiation of heparin. The appropriate dose of warfarin for preventing systemic embolism and myocardial infarction, for prophylaxis for venous thrombosis, and for treating venous thrombosis and pulmonary embolism is that which maintains PT at an INR of 2 to 3 for conventional intensity treatment. A loading dose of 5 mg avoids the development of a potential hypercoagulable state caused by a precipitous decrease in the levels of protein C. Patients should receive 3 months of warfarin treatment if in a select group of low-risk patients (trauma or surgery). However, for patients with unproven VTE and persistent risk factors, the duration of anticoagulation is controversial. Patients with metastatic cancer, neurologic disease associated with extremity paresis, thrombophilia, increased body mass index, increased age, inflammatory bowel disease, or idiopathic venous thromboembolism are candidates for long-term therapy, as are patients with a previous VTE. Warfarin has been demonstrated to be efficacious in atrial fibrillation. A target range for the INR of 2.5 to 3.5 is recommended for tilting disk valves, bileaflet aortic valves in the mitral position, bileaflet aortic valves, atrial fibrillation, caged ball valves, and disk valves.

The average annual risk of bleeding is 3% to 9%. In patients with a prolonged PT with or without bleeding, use of the drug should be stopped for 24 to 72 hours. Available information suggests that patients taking warfarin with an INR greater than 8 are at a substantially increased risk of bleeding. In patients who have taken a suicidal dose or have a suspected cerebral hemorrhage and who need no further anticoagulation, vitamin K given intravenously at a dose of 20 to 30 mg may be administered with fresh frozen plasma. Fresh frozen plasma alone may be administered to patients taking warfarin who require continued anticoagulation but who have life-threatening bleeding by the National Institutes of Health consensus. Drugs that potentiate warfarin include those that prolong PT, such as phenylbutazone, metronidazole, sulfinpyrazone, trimethoprim-sulfamethoxazole, and disulfiram. Gingko may increase the risk of hemorrhage for a person taking warfarin. Drugs that inhibit platelet function, such as aspirin, also may potentiate the toxic effects of warfarin. Some drugs antagonize warfarin; for example, cholestyramine decreases its absorption. Other drugs, such as barbiturates, carbamazepine, and rifampin, increase the clearance of warfarin. Acetaminophen may be a cause of overanticoagulation in the outpatient setting. Warfarin skin necrosis is a rare complication and is associated with a protein C deficiency.

Unfractionated Heparin

Heparin inhibits thrombin by binding to antithrombin III and forming a heparin-antithrombin III complex, which interrupts the clotting cascade by inhibition of thrombin (factor IIa), inhibition of and increased release of tissue factor pathway inhibitor, and inhibition of factor Xa. The heparin is then reused. In the initial treatment of deep venous thrombosis or pulmonary embolism, the goal is to prolong APTT at a level of 1.5 to 2.5 times normal within the first 24 hours of treatment. A plasma level of heparin of 1.2 to 0.4 IU/mL is necessary. If this is not accomplished, the risk of recurrent thromboembolism is 15-fold, and the risk persists for weeks. Heparin and warfarin may be given simultaneously and be overlapped for 5 days, after which treatment should be warfarin alone. Heparin should be administered for a minimum of 4 days (range, 5-7 days) and not be discontinued until the INR has been in the therapeutic range for 2 consecutive days, because of the half-lives of the vitamin K-dependent factors. Warfarin treatment should be maintained for 3 months if there are no risk factors. Prolonged treatment may be indicated when risk factors such as prolonged immobilization, hypercoagulable state, and recurrent deep venous thrombosis exist.

Heparin is indicated for the treatment of venous thrombosis and pulmonary embolism. It also is given to *prevent* venous thrombosis and pulmonary embolism (prophylactic doses of 5,000 units given subcutaneously every 8 to 12 hours in cases of abdominal surgery or for medical patients with a history of thrombosis, prolonged bed rest, congestive heart failure, or cancer). The common duration for the postoperative period is 7 days or ending at hospital dismissal. A dose of 12,000 units is administered subcutaneously twice daily for the prevention of mural thrombosis after myocardial infarction. Heparin is indicated for the prevention of coronary artery rethrombosis after thrombolysis, and it is the treatment of choice for venous thrombosis and pulmonary embolism in pregnancy (17,500 units subcutaneously twice daily). Impedance plethysmography, ultrasonography, or venography may document this complication of pregnancy. (Warfarin is contraindicated in pregnancy because of the risks of embryopathy, including nasal hypoplasia and central nervous system abnormalities.) Heparin is indicated after thrombolytic therapy. The normal dose is a 5,000-U bolus (or loading dose of 80 U/kg), followed by 12,000 U/h (18 U/kg per hour) by continuous infusion, with the goal of achieving a therapeutic APTT of 1.5 times control. Side effects include hemorrhage (which occurs in 6.8% of patients receiving continuous infusion), osteoporosis, and skin necrosis. A hypersensitivity reaction may convert antithrombin III from a slow inhibitor to a very rapid inhibitor.

Resistance to heparin is defined as the need for more than 40,000 U daily. The thrombotic process may be reactivated when heparin therapy is discontinued. Heparin resistance is due to increased plasma concentrations of factor VIII and heparin-binding proteins. Approaches include monitoring the plasma heparin concentration or LMWH.

Low-Molecular-Weight Heparin

LMWH has several advantages over unfractionated heparin. It has a more predictable dose response, which allows fixed doses without laboratory monitoring. The risk of heparin-induced thrombocytopenia is lower because nonspecific binding of heparin to other proteins and cells causes variability. It is safe in pregnancy. There is a lower incidence of compression fractures. Furthermore, 50% of all patients with venous thrombosis can be treated with LMWH without hospitalization. LMWH does not cause a marked change in the measured APTT because of the propensity toward factor Xa inhibition over thrombin inhibition. In most circumstances, blood monitoring is not required. If monitoring is necessary, the heparin assay (anti–factor Xa) may be performed 4 hours after the dose. Levels should be measured. Indications for monitoring include prolonged use (pregnancy, extremes of body weight, i.e., <46 kg or >100 kg), and renal insufficiency. Generally, a twice-daily dosage gives better coverage for prophylaxis and treatment, although a once-daily dosage for prophylaxis is adequate for dalteparin and enoxaparin. Subcutaneous dosages for prophylaxis are available for LMWHs, including ardeparin, enoxaparin, dalteparin, tinzaparin, and danaparoid. LMWH can be used as an effective alternative to warfarin therapy. The dosage of LMWH may vary with the indication (prophylaxis vs. therapeutic) and the type of preparation. Certain situations present a high risk of bleeding (obesity, long duration of therapy, and renal insufficiency [creatinine >2.0 mg/dL or creatinine clearance ≤30 mL/min]). Protamine is partially effective in reversing LMWH. Contraindications for LMWH include a previous heparin-induced thrombocytopenia and severe renal dysfunction. Clinical trials have demonstrated that LMWH is at least as effective as unfractionated heparin for venous thromboembolism and recurrent venous thromboembolism and for the prevention of venous thromboembolism. LMWH is more effective than placebo, unfractionated heparin, warfarin, or aspirin for thromboprophylaxis for orthopedic surgery. LMWH is contraindicated in heparin-associated thrombocytopenia. LMWH therapy is safe during pregnancy because it does not cross the placenta.

Direct Thrombin Inhibitors

The direct thrombin inhibitors are hirudin, lepirudin, bivalirudin, and argatroban. Lepirudin is a recombinant form of hirudin. An APTT ratio of 1.5 to 2.5 has been associated with highest efficacy. The thrombin-specific inhibitors prolong the PT as well as APTT, with APTT as the recommended test. However, at higher doses and concentrations, APTT is not reliable and is associated with an increased risk of bleeding. Direct thrombin inhibitors are indicated in type II heparin-induced thrombocytopenia.

Thrombolytic Therapy

The thrombolytic agents are streptokinase, urokinase, recombinant tissue plasminogen activator (t-PA), alteplase (Activase), and reteplase (Retevase), a small t-PA molecule. Fibrin is the major target of thrombolytic therapy. Anticoagulation does not dissolve or prevent the growth of thrombi (even at recommended doses), eliminate the source of subsequent emboli in the deep veins during an acute attack, alleviate hemodynamic problems, prevent valvular damage, prevent persistent venous hypertension, or prevent persistent pulmonary hypertension. The primary role of anticoagulation is prophylaxis against further propagation of the clot.

Thrombolytic therapy lyses thrombi and emboli and restores circulation to normal, normalizes hemodynamic disturbances, reduces

morbidity, decreases systemic and mean pulmonary artery pressures at 72 hours, prevents venous vascular damage and subsequent venous hypertension in the lower extremities, and prevents permanent damage to the pulmonary vascular bed, decreasing the likelihood of persistent pulmonary hypertension. Residual emboli usually persist with heparin therapy alone. Although t-PA, tenecteplase, and reteplase have a relative fibrin specificity, considerable fibrinolysis and bleeding may occur. The initial fibrinolysis of the plug is followed by proteolysis of fibrinogen and factors V and VIII. Venous thrombi generally are rich in fibrin and are potentially more suitable than platelet thrombi for fibrinolytic therapy. The age of the thrombus is also important because it is essential to start treatment with these agents within 48 hours in cases of pulmonary emboli and in less than 7 days in cases of deep venous thrombosis. In cases of pulmonary emboli, thrombolytic therapy improves hemodynamics and pulmonary perfusion; it may be indicated with the involvement of more lobar pulmonary arteries or an equivalent amount of emboli in other vessels with or without shock or submassive emboli accompanied by shock, impending shock, or persistent hypotension. In deep venous thrombosis, these agents may minimize valvular dysfunction and decrease the risk of recurrent and postphlebitic syndrome. Currently, thrombolytic agents are not recommended for routine use in managing pulmonary emboli and deep venous thrombosis. Thrombolytic treatment should be restricted to use in patients with extensive iliofemoral venous thrombosis with a low risk of bleeding and in patients with hemodynamic compromise due to pulmonary embolism.

If the timing is appropriate, thrombolytic agents may be administered in thrombosis of the hepatic, renal, mesenteric, cerebrovenous, sinus, and central retinal veins. Of arterial disorders, acute myocardial infarction has been studied most extensively. The SCAT 1 trial demonstrated that mortality was significantly lower among patients randomly assigned to heparin after thrombolytic therapy for acute myocardial infarction. The GUSTO-1 trial showed that rapid infusion of t-PA with intravenously given heparin was slightly more beneficial than streptokinase. The GUSTO-3 trial compared t-PA and reteplase, and there was no significant difference. Reteplase is easier to administer. In ongoing trials studying acute myocardial infarction, the thrombotic occlusion is a fibrin-based plug attached to a fissured atherosclerotic plaque. Other fibrin-specific agents under evaluation include tenecteplase and staphylokinase.

Thrombolytic therapy is monitored with fibrinogen levels. The absolute contraindications to this therapy include active internal bleeding and a cerebrovascular accident within the preceding 2 weeks and surgery within less than 1 month. Relatively major contraindications include the following if they have occurred within less than 10 days: major surgical procedure, obstetrical delivery, pregnancy, the first 10 days post partum, organ biopsy, burns, skin grafts, previous puncture of noncompressive vessels, thoracentesis, paracentesis, gastrointestinal tract bleeding, ulcerative colitis, diverticulosis, serious trauma, systolic blood pressure greater than 180 mm Hg, diastolic pressure greater than 100 mm Hg, intracranial neoplasms, and thrombocytopenia. Relatively minor contraindications include a high likelihood of left-sided heart thrombus such as mitral stenosis with atrial fibrillation, subacute bacterial endocarditis, severe liver or kidney disease, age older than 75 years, diabetic hemorrhagic retinopathy, active and progressive cavitating lung lesions, ulcerative cutaneous and mucous membrane lesions, and a recent intra-arterial diagnostic procedure except measurement of arterial blood gases. Bleeding may be superficial or internal; it occurs because of the indiscriminate lysis of fibrin. Because thrombolytic agents are not substitutes for heparin and warfarin, the morbidity is additive. Approaches to hemorrhage control include volume replacement, manual techniques, and RBC transfusions. If bleeding is massive, replace with cryoprecipitate and fresh frozen plasma and discontinue treatment with heparin. With central nervous system bleeding, discontinue fibrinolytic therapy, administer cryoprecipitate and fresh frozen plasma, and avoid anticoagulants and antiplatelet agents.

Glycoprotein IIb/IIIa Inhibitors

The glycoprotein IIb/IIIa inhibitors are indicated in non–ST-segment elevation acute coronary syndromes. Abciximab is a Fab fragment that permanently binds to platelet glycoprotein IIb/IIIa receptors inhibiting aggregation. Eptifibatide and tirofiban are competitive inhibitors of the glycoprotein IIb/IIIa receptor so that aggregation returns to normal in 4 hours. There is a risk of bleeding with these agents.

Oral Antiplatelet Therapy

Platelets are pivotal to the initiation and prolongation in thrombus formation. Antiplatelet agents have emerged as key treatment in the prevention of recurrent ischemic events. Aspirin, ticlopidine, clopidogrel, aspirin combined with clopidogrel, and aspirin combined with dipyridamole are effective. Aspirin inhibits platelets by irreversibly acetylating cyclooxygenase 1, inhibiting thromboxane A_2, a potent mediator of platelet aggregation. These agents are used in patients with a history of arterial disease such as myocardial infarction, stroke, transient ischemic attack, and coronary artery disease.

Aplastic Anemia

Aplastic anemia is most often acquired and may develop as a consequence of a defect in the stem cell population, defective marrow microenvironment, or immunologic factors, including antibody-mediated bone marrow suppression, cellular cytolytic suppressive T-cell mechanisms, and bone marrow suppression by cytokines. This group of disorders of failure of hematopoiesis is characterized by peripheral pancytopenia, bone marrow hypocellularity, and the absence of malignant or myeloproliferative diseases at the time of diagnosis. The pathogenesis is heterogeneous and mostly undefined. The differential diagnosis of pancytopenia and hypercellular bone marrow includes aplastic anemia, myelodysplastic syndrome, T-cell clonal disorders, paroxysmal nocturnal hemoglobinuria, and Fanconi anemia. The criteria for the diagnosis of aplastic anemia include less than 25% marrow cellularity and two of the following: 1) neutrophil count less than 0.5×10^9/L, 2) platelet count less than 20×10^9/L, 3) a corrected reticulocyte count less than 1%, and 4) normal cytogenetic findings.

Before the use of allogeneic bone marrow transplantation and antithymocyte globulin, 80% of patients with severe aplastic anemia were not alive at 1 or 2 years and 20% had partial recovery. The only

curative treatment available for aplastic anemia is allogeneic stem cell transplantation.

- Aplastic anemia: pancytopenia, hypocellular bone marrow, and absence of primary disease of hematopoietic tissue (myelodysplastic syndrome).
- Full recovery is uncommon without allogeneic bone marrow transplantation or antithymocyte globulin.

The clinical features of aplastic anemia include weakness, fatigue, easy bruising or bleeding, fever, and infections. Lymphadenopathy and splenomegaly are uncommon. In 40% to 70% of patients, the cause of aplastic anemia is idiopathic. An idiopathic cause is more frequent in adults. Drugs are the second most common cause of aplastic anemia. These include chloramphenicol, phenylbutazone, methylphenylethylhydantoin, trimethadione, sulfonamides, gold, and benzene. Paroxysmal nocturnal hemoglobinuria (positive CD59 and CD58 cell surface markers on flow cytometry studies of bone marrow) and infections are the third and fourth most common causes, respectively. Infectious hepatitis is the most common infection to cause aplastic anemia. Non-A, non-B, and non-C hepatitis and hepatitis A are the most common types of hepatitis to cause aplastic anemia. Hepatitis B is the type of hepatitis that least often causes aplastic anemia. Other infectious agents that cause aplastic anemia include Epstein-Barr virus, influenza virus, HIV, parvovirus, and mycobacteria. Ionizing radiation may also be a cause.

Patients with aplastic anemia should undergo HLA typing. If transfusion is needed, select nonrelated donors and use cytomegalovirus-negative, leukocyte-poor RBC transfusions and single-donor platelet transfusions to maintain the platelet count greater than 10×10^9/L. Transfusions to maintain the hemoglobin concentration greater than 7 g/dL should be given with considerable care and concern. Family members should not be donors because they are more likely to sensitize the patient to minor histocompatibility antigens present in the donor but absent in the patient. Outcomes of patients undergoing allogeneic bone marrow transplantation for aplastic anemia are significantly adversely affected by previous transfusion. A search for unrelated HLA-matched donors should be considered for patients younger than 30 years without an HLA match.

Immunosuppression is the treatment of choice for patients older than 40 years and includes antithymocyte globulin and corticosteroids and cyclosporine. These agents are not curative. In a trial with patients who had moderate or severe aplastic anemia, 11 of the 21 treated with antithymocyte globulin alone had sustained improvement, compared with none of the 21 patients in the control group. For patients not eligible for bone marrow transplantation, treatment with antithymocyte globulin, methylprednisolone, and cyclosporine has been reported to result in 65% to 70% partial recovery of the peripheral blood counts, with overall long-term responses of 30% to 75%. Blood count recovery usually is not complete; however, transfusions are not required, and the absolute neutrophil count is at a level to protect against infectious complications. About 30% of patients have relapse, and clonal myeloid disorders develop in 25% of patients. Toxic effects of antithymocyte globulin include anaphylaxis, fever, urticaria, thrombocytopenia, and serum sickness. Side effects of long-term cyclosporine therapy include hypertension, renal insufficiency, seizures, and hypomagnesemia. In contrast to patients with stem cell transplantation, patients with aplastic anemia are not cured.

The success rate is 40% to 90% for young patients who have allogeneic HLA-matched bone marrow transplantation with cyclophosphamide alone or cyclophosphamide plus irradiation as preconditioning for patients who previously had transfusion. This is the therapy of choice for all patients with a homozygous twin and should be considered immediately for all patients younger than 20 years. It also should be considered for high-risk patients between the ages of 20 and 40 with an HLA match. A trial of immunosuppressive therapy is indicated for patients older than 40 years, including those with moderate disease. Graft failure rates are about 10%, and chronic graft-versus-host disease complicates 40% of cases.

Cyclosporine or corticosteroids, at a dosage of 0.2 to 1.0 mg/kg daily, and androgens are other treatments. Androgens are not effective in severe aplastic anemia. The toxic effects include virilization and liver toxicity. The 17-alpha derivative is responsible for hepatic adenomas and hepatocellular carcinoma. Mismatched family and unrelated donors have survival rates ranging from 0% to 54%. Long-term survival of patients with severe disease has increased from less than 25% for those given androgens to 75% for those given intensive immunosuppressive therapy and to 66% for those who had bone marrow transplantation.

- With severe aplastic anemia, transfuse judiciously.
- If the patient is younger than 40 years and has an HLA-matched donor or identical twin, consider bone marrow transplantation with cyclophosphamide alone or cyclophosphamide plus irradiation as preconditioning for patients who previously had transfusion. If the patient is older and has no HLA match, treat with a combination of antithymocyte globulin and methylprednisolone with or without cyclosporine.
- Long-term survival of patients with severe disease has increased from <25% for those given androgens to 75% for those given intensive immunosuppressive therapy and to 66% for those who had bone marrow transplantation.

Neutropenia

The differential diagnosis of nonmalignant acute neutropenia includes decreased production, ineffective granulopoiesis (vitamin B_{12} deficiency and folate deficiency), drugs, infections (HIV, parvovirus, and hepatitis), hematologic disorders (cyclic neutropenia and aplastic anemia), increased destruction, autoimmune neutropenia (Felty syndrome, rheumatoid arthritis, systemic lupus erythematosus, and Sjögren syndrome), hypersplenism, ulcerative colitis, hemodilution, benign neutropenia, and hematologic disorders (cyclic neutropenia and aplastic anemia). Drug-induced neutropenia is associated with sulfonamides, semisynthetic penicillins (nafcillin and ampicillin), phenothiazines, nonsteroidal anti-inflammatory drugs (indomethacin and phenylbutazone), antithyroid medications (propylthiouracil and methimazole), allopurinol, anticonvulsants, and diuretics (chlorothiazide). Drug-induced neutropenia becomes manifest 1 to 2 weeks

after initial drug exposure or sooner following a recent repeat exposure. The treatment of choice is to discontinue the drug. Corticosteroids characteristically are not efficacious.

The differential diagnosis of chronic neutropenia includes cyclic neutropenia and chronic idiopathic neutropenia. Cyclic neutropenia, characterized by oscillations in the neutrophil counts every 19 to 23 days, is a disorder of neutrophil production at a regulation phase. The typical clinical syndrome is manifested as furuncles, cellulitis, chronic gingivitis, and abscesses. Patients can predict the timing of successive episodes. Treatment involves timely antibiotics, avoidance of dental and surgical work at nadirs, oral hygiene, and dental care. G-CSF (filgrastim) may be effective in increasing the neutrophil count in cyclic neutropenia and chronic idiopathic neutropenia.

In the adult population, the recommended dosage of G-CSF is 5 µg/kg daily subcutaneously. A single 6-mg dose of pegylated G-CSF 24 hours after chemotherapy is now the treatment of choice in most situations following chemotherapy outside of the transplant setting.

The 1999 American Society of Clinical Oncology colony-stimulating factor guidelines emphasized the following: primary prophylaxis is recommended when the incidence of febrile neutropenia is greater than 40% of the control group. Therefore, in general, for previously untreated patients receiving most chemotherapy regimens, primary administration of colony-stimulating factors should not be used routinely. Special circumstances for patients who might benefit from these agents include preexisting neutropenia due to disease, extensive previous chemotherapy, previous irradiation to the pelvis, a history of recurrent febrile neutropenia while receiving earlier chemotherapy, and conditions that potentially enhance the risk of infection (poor performance status, decreased immune function, open wounds, or active tissue infections). There is evidence that colony-stimulating factors can decrease the probability of febrile neutropenia in subsequent cycles of chemotherapy after a documented occurrence in a previous cycle. These agents are effective adjuncts in progenitor-cell transplantation. The data are inadequate to support the routine use of these agents in afebrile patients or in dose-intensity programs. Colony-stimulating factors should be avoided with concomitant chemotherapy or radiotherapy. Granulocyte-macrophage colony-stimulating factor is another available growth factor, but the lack of randomized trials precludes definitive recommendations.

Neutropenia is common among blacks, and if patients are asymptomatic, this need not be evaluated further. Other causes of neutropenia include autoimmune neutropenia (which is due to an antibody), antigens, rheumatoid arthritis, and chronic active hepatitis.

Thrombocytopenia

The causes of isolated thrombocytopenia in adults are numerous and broadly include autoimmune idiopathic thrombocytopenic purpura, drug-induced thrombocytopenia, pseudothrombocytopenia, refractoriness to platelet transfusion therapy, posttransfusion purpura, and hereditary and secondary causes. Secondary causes include pregnancy, antiphospholipid antibodies syndrome, chemotherapy drugs, autoimmune systemic lupus erythematosus (in which 14%-26% of patients develop thrombocytopenia), infections (HIV, hepatitis C, rubella, and infectious mononucleosis), chronic lymphocytic leukemia, non-Hodgkin lymphoma, sarcoidosis, ovarian carcinoma, acute alcohol toxicity, and purpura of septicemia. Thrombocytopenia occurs in microangiopathic hemolytic anemias and hypersplenism.

The diagnosis of pseudothrombocytopenia should be excluded with examination of a peripheral blood smear. Causes of pseudothrombocytopenia include EDTA-induced platelet clumping, platelet satellitosis, hereditary disorders (May-Hegglin anomaly, Bernard-Soulier syndrome, and Alport syndrome), and large platelets in myeloproliferative disorders.

A spuriously low platelet count may be reported in EDTA-induced platelet agglutination. This is an antibody-mediated phenomenon caused by antibodies that bind to the patient's platelets after withdrawal of calcium in the test tube. The platelet count is spuriously low with automated techniques only; on the peripheral blood smear, the number is normal because the platelets are clumped or rarely adhere to neutrophils.

Idiopathic thrombocytopenic purpura (ITP) is an autoimmune disease characterized by thrombocytopenia with a normal WBC count and hemoglobin concentration (Table 11-16). The American Society of Hematology guidelines for this disorder were published in 1996. This group defined ITP as "isolated thrombocytopenia with no clinically apparent conditions." The diagnosis of ITP is a diagnosis of exclusion. Screen for drugs and alcohol, and patients with risk factors should be tested for HIV antibody. In adults, ITP has an insidious onset, with the diagnosis incidentally established on a routine CBC. The clinical manifestations range from asymptomatic to purpura, mucous membrane hemorrhage, and cerebromeningeal bleeding. From 7% to 28% of children and up to 40% to 60% of adults have progression to a chronic state of idiopathic thrombocytopenic purpura. In most patients, the platelet count is less than 50×10^9/L and in 30%, less than 10×10^9/L (spontaneous bleeding may occur). The mean platelet volume is increased. Only 10% of patients have splenomegaly. If it is present, one should think of other causes. A bone marrow examination is appropriate to establish the diagnosis of ITP in patients older than 60 years and in patients considered candidates for splenectomy. Bone marrow examination shows a normal to increased number of megakaryocytes. Antibodies to specific platelet-membrane glycoproteins, usually the IIb/IIIa complex, and platelet IgG (erroneously called "antiplatelet-antibody tests") are detected in most patients but are not necessary for diagnosis or treatment. Up to 10% of patients with chronic ITP may have accessory spleens. The absence of Howell-Jolly bodies on a peripheral blood smear of patients who have previously had splenectomy suggests the diagnosis, which is confirmed by radionuclide imaging or CT. Surgical removal may be beneficial. The measurement of bleeding time is not helpful because it is abnormal, with a platelet count less than 75×10^9/L.

Consider discontinuing the use of any drug that may cause the disease. The American Society of Hematology guidelines for treatment are as follows: patients with platelet counts of 50×10^9/L or higher do not routinely require treatment. Those with a platelet count less than 50×10^9/L but greater than 30×10^9/L should be treated if

Table 11-16 Idiopathic Thrombocytopenic Purpura

Characteristic	Acute	Chronic
Presentation	Abrupt onset of petechiae, purpura, mucosal bleeding	Insidious petechiae, menorrhagia
Usual age	Children (2-6 y)	Adults (20-40 y)
Female-male ratio	1:1	3:1
Antecedent infection	Common (85%) Typically an upper respiratory tract infection	Uncommon
Platelet count, $\times 10^9$/L	<20	30-80
Duration	2-6 wk	Months to years
Spontaneous remission	80% within 6 mo	Uncommon, fluctuates

From Lee GR, Bithell TC, Foerster J, Athens JW, Lukens JN. Wintrobe's clinical hematology. Vol 2. 9th ed. Philadelphia: Lea & Febiger; 1993. p. 1331. Used with permission.

there is mucous membrane bleeding or risk factors for bleeding, including hypertension, peptic ulcer disease, and vigorous lifestyle. Patients with platelet counts less than 30×10^9/L should be treated. Prednisone is the mainstay of initial treatment; initially, 70% of patients have a response, with about a 40% chance of long-term remission at the initial dosage of prednisone of 1 mg/kg daily for up to 1 month. Corticosteroids decrease antibody production in the reticuloendothelial system and decrease reticuloendothelial clearance. Patients with severe bleeding should be treated with intravenous immunoglobulin at a dosage of 1 g/kg per day for 2 days and platelets and transfusion alone or in combination with high-dose intravenous corticosteroids (methylprednisolone, 1 g daily for 2-3 consecutive days; the initial response rate is 80%).

The management of disease that does not respond completely to these measures is difficult and controversial. The American Society of Hematology had no formal recommendations. Splenectomy, the treatment of choice for steroid-refractory ITP, removes the predominant site of antibody production and platelet destruction; the likelihood of remission is 75%, with about 60% of patients remaining in long-term remission. Pneumococcal, meningococcal, and *H. influenzae* vaccines should be administered 2 weeks before splenectomy. Dexamethasone (40 mg daily for 4 sequential days every 28 days for 12 months) is an option for the treatment of resistant ITP or disease relapse. Danazol decreases the number of phagocytic cell IgG Fc receptors. A slow infusion of vincristine or vinblastine may be given to patients who do not have a response to the above measures. Other agents used in refractory cases include azathioprine (Imuran), cyclophosphamide, colchicine, cyclosporine, rituximab, and immunoadsorption apheresis on staphylococcal protein A columns.

- Spontaneous bleeding may occur with platelet counts $<10 \times 10^9$/L.
- ITP is a diagnosis of exclusion.
- The diagnosis rests on the history, screen for drugs and alcohol, physical examination, and CBC.
- Examine the peripheral blood smear (exclude microangiopathy).
- Consider discontinuing use of any drug that may cause the disease.
- A bone marrow examination is appropriate to establish the diagnosis of ITP in patients older than 60 years and in patients considered candidates for splenectomy.
- In ITP with severe bleeding, intravenous immunoglobulin is the treatment of choice, with platelet transfusions and high-dose corticosteroids.

In drug-induced thrombocytopenia, the pathophysiologic mechanism is related to haptens bound to a carrier protein. Clinically, there is acute bleeding, with a hemorrhage syndrome characterized by bleeding from mucous membranes, petechiae, and oozing after brushing the teeth. These problems subside after use of the drug is discontinued. Drug-induced thrombocytopenia subsides in 4 to 14 days except for that caused by gold, which may take much longer. In contrast, viral-induced thrombocytopenia resolves in 2 weeks to 3 months. The drugs most commonly implicated include heparin, quinidine, quinine, valproic acid, gold, trimethoprim-sulfamethoxazole, amphotericin B, carbamazepine, chlorothiazide, chlorpropamide, procainamide, rifampin, and vancomycin. Glycoprotein IIb/IIIa antagonists, drugs that inhibit the interaction with fibrinogen and platelet interaction (abciximab [ReoPro], eptifibatide [Integrilin], and tirofiban [Aggrastat]), may cause thrombocytopenia and may cause acute (within 24 hours) or delayed (up to 14 days after initiating chronic therapy) thrombocytopenia secondary to antibodies in 0.5% to 2.0% of patients.

Heparin-induced thrombocytopenia (HIT) is a clinicopathologic syndrome that has a variable incidence of 1% to 7.8% with unfractionated heparin and is patient-population dependent. Type I HIT is of no clinical relevance. It has an incidence of up to 25%, is associated with intravenous heparin, and is a common transient nonimmunologic event due to direct heparin-induced platelet aggregation occuring in the first 4 days. Type II HIT is an immunologic reaction usually occuring 4 to 14 days after heparin use and is caused by IgG antibodies to an antigen (platelet factor 4 bound to heparin)

that activates platelets through their Fc receptors. Aggregation with thrombin formation and clot follow. Clinically, the predominant feature is thrombosis, not hemorrhage. The onset is at a median of 9 days with unfractionated heparin and 14 days with LMWH. The platelet counts usually decrease 50% or more, and such a decrease should raise clinical suspicion, even if the count is greater than 150 × 10^9/L. The coagulation system may be activated, increasing the production of thrombin. HIT with thrombosis occurs in 10% of patients. Rapid-onset HIT may develop in patients who were exposed to heparin in the previous 120 days, with thrombocytopenia developing within hours after rechallenge. HIT thrombosis can occur 5 to 19 days after the cessation of heparin therapy. Venous thrombosis (deep venous thrombosis and pulmonary embolus) is more common than arterial thrombosis. Other clinical events include warfarin-induced venous limb damage, acute platelet activation syndromes (fevers, chills, or transient amnesia) 5 to 30 minutes after an intravenous bolus of heparin, and skin lesions at the site of injection of heparin (necrosis or erythematous plaques).

The diagnosis is a clinical one that may be confirmed by functional assays (serotonin release assay) or antigen assays (antibody against platelet factor 4).

The treatment of HIT is complex. All forms of heparin must be discontinued. The subsequent risk of thrombosis with discontinuing heparin or substituting warfarin is as high as 50%. Thromboembolectomy may be considered. LMWH is not used because of the high cross-reactivity of the antibody with the LMWH/platelet factor IV complex. Alternatives to heparin include the direct thrombin inhibitors (lepirudin) or argatroban. Lepirudin is the treatment of choice for isolated HIT. Both lepirudin and argatroban are monitored with the APTT. The range is 1.5 to 2.0 times normal at 4 hours after initiation of lepirudin and 1.5 to 3.0 times normal at 2 hours after initiation of argatroban. In the intensive care unit, infusion of factor VIIa at a dose of 90 mg/kg may be considered in the initial management because thrombin inhibitors do not immediately reverse anticoagulation. Argatroban is the treatment of choice for patients on dialysis because it is not excreted by the kidneys.

The risk varies with the dose of heparin, the type of heparin (unfractionated > LMWH > porcine > bovine) and clinical associations (higher risk for surgical than for medical patients). HIT is usually mild, and the patients are asymptomatic. It develops 3 to 15 days (median, 10 days) after therapy. It is not dose-related and can occur at very low doses. There are no reliable risk factors. Patients are at higher risk if there is a history of this problem. It is essential to pay attention to any substantial decrease in platelet number while patients are taking heparin.

- Drug-induced thrombocytopenia subsides in 4-14 days, except for that caused by gold.
- Viral-induced thrombocytopenia resolves in 2 weeks to 3 months.
- Heparin is the drug that most commonly causes thrombocytopenia.

The management of ITP in pregnancy is complex. The American Society of Hematology consensus panel recommended intravenous immunoglobulin for pregnant women with severe and symptomatic thrombocytopenia. The recommendations for percutaneous umbilical sampling, fetal scalp vein monitoring at the time of delivery, and the route of delivery are controversial. Neonatal hemorrhagic complications are low. After delivery, infant platelet counts should be followed for 4 days. Intravenous immunoglobulin is recommended for platelet counts less than 20 × 10^9/L, and brain imaging of the infant is recommended for platelet counts less than 50 × 10^9/L. When a platelet transfusion is indicated and subsequently initiated, a platelet count should be performed 1 hour after transfusion to assess response.

For chemotherapy-associated thrombocytopenia, the threshold for platelet transfusion is 10,000 cells/μL. Interleukin-11 is the only pharmacologic agent that is approved in the United States. It is modestly effective and associated with cytokine toxicities. When a platelet transfusion is indicated and subsequently administered, a platelet count should be performed 1 hour after transfusion to assess response.

Thrombocytopenia in Pregnancy

From 6% to 8% of pregnant women at term and 25% of women with preeclampsia have mild thrombocytopenia (with platelets >80 × 10^9/L). The most common cause of thrombocytopenia in pregnancy is incidental thrombocytopenia of pregnancy, which accounts for 75% of cases and is not associated with adverse maternal or fetal outcomes. The diagnosis is one of exclusion. No treatment is required.

Other common causes include preeclampsia, idiopathic autoimmune thrombocytopenia (or ITP), HIV infection, and thrombotic thrombocytopenic purpura. No specific therapy is required, and platelet recovery occurs 72 hours after delivery. Thrombocytopenia may occur in 3% of pregnant women with HIV infection. Intravenous immunoglobulin is effective therapy.

Other causes of thrombocytopenia in pregnancy include acute fatty liver of pregnancy, drugs (quinine/quinidine, cocaine, and heparin), folate deficiency, infections (cytomegalovirus), and antiphospholipid antibody–related thrombocytopenia. HELLP syndrome is a variant of preeclampsia. Disseminated intravascular coagulopathy develops in up to 38% of pregnant women. The primary treatment of HELLP syndrome is stabilization of the patient's condition and delivery of the fetus.

Posttransfusion Purpura

In posttransfusion purpura, thrombocytopenia occurs 5 to 8 days after blood transfusion in patients alloimmunized against the platelet antigen HPA-1a. The treatment of choice is intravenous administration of immunoglobulin and corticosteroids.

Postsplenectomy State

Postsplenectomy complications include sepsis due to pneumococcus, meningococcus, *H. influenzae*, *E. coli*, and *S. aureus*. Hematologic features include such RBC abnormalities as Howell-Jolly bodies present on the peripheral blood smear. The leukocyte count has a postsplenectomy surge and then returns to normal. Platelets also show a postsplenectomy surge; the value usually returns to normal in 1 month. If there is a history of splenectomy but no Howell-Jolly bodies on a peripheral blood smear, suspect an accessory spleen and confirm it with a liver-spleen scan.

Spontaneous Splenic Ruptures

Spontaneous splenic ruptures have been reported to occur in infectious mononucleosis, cytomegalovirus infections, acute and chronic myelogenous leukemia, acute and chronic lymphocytic leukemia, myeloproliferative diseases, and non-Hodgkin lymphoma.

Transfusion Reactions

The primary cause of transfusion-related deaths is medical error, which includes bypassed safeguards, similar patient names, and verbal or faxed communications. The major transfusion reactions include acute hemolytic transfusion reactions, transfusions associated with anti-IgA antibodies, transfusion-associated adult respiratory distress syndrome, delayed hemolytic transfusion reactions, febrile transfusion reactions, urticarial transfusion reactions, and circulatory overload (Table 11-17).

Acute Hemolytic Transfusion Reactions

Acute hemolytic transfusion reactions are the most life-threatening. These occur within minutes to hours and are caused by preexisting RBC antibodies in the recipient. The most common cause is human error, especially when blood is released on an emergency basis, and these are due to ABO mismatches. Of fatal transfusion reactions, 85% involve ABO incompatibility. Other causes include antibodies not detected before transfusion, such as Kell, Duffy (Jk^a), and Kidd (Fy^a). ABO mismatches are less frequent than with Kell, Duffy, and Kidd and have virtually disappeared from transfusion reaction complications, but clerical error may be a factor in the occurence of these reactions. Intravascular hemolysis is caused by problems related to ABO, Kell, Duffy, and Kidd. Females are at greater risk than males, because sensitization through pregnancy leads to a higher frequency of preformed antibodies. The recipient's preexisting antibodies, usually IgM, bind to the donor's RBCs and cause complement-mediated hemolysis. Obstetrical complications with massive bleeding also predispose females to acute hemolytic transfusion reactions. Age is a factor because older people receive more transfusions. Transfusion of large amounts of blood products given urgently also increases the risk. Clinically, there is pain at the intravenous site, apprehension, back pain, abdominal pain, fever, chills, chest pain, hypotension, nausea, flushing, and dyspnea. The Coombs test gives positive results in all but anti-A.

Complications include oliguria in 33.3% of patients, acute postischemic renal failure, and disseminated intravascular coagulopathy in 4%. The mortality rate is about 20%. Treatment includes immediate termination of the transfusion, intravenous access, vigorous administration of fluids, and furosemide to increase renal cortical blood flow. It is difficult to distinguish between an acute hemolytic transfusion reaction and a febrile nonhemolytic transfusion reaction at the time fever occurs. Therefore, patients with fevers occurring during transfusion should be evaluated for hemolysis.

Transfusion Reactions Associated With Anti-IgA Antibodies

Transfusion reactions associated with anti-IgA antibodies and anaphylactic reactions are due to IgA deficiency, the development of a class-specific anti-IgA antibody, normal IgA levels with anti-IgA antibodies acquired through pregnancy or previous transfusions, and ataxia-telangiectasia, in which 44% of patients have class-specific anti-IgA antibodies. The pathogenesis is due to anti-IgA antibodies of IgG type that are capable of binding complement. Clinically, patients develop apprehension, hives, hypotension, chest pain, abdominal pain, lumbar pain, flushing of the face and neck, dyspnea, and cyanosis. Wheezing, diarrhea, vomiting, unconsciousness, and chills may occur. Fevers are uncommon. Treatment includes stopping the transfusion and giving antihistamines and conventional anti-anaphylactic drugs. Transfusion protocols for patients include an IgG anti-IgA antibody assay, washed RBCs, frozen RBCs, and IgA-deficient plasma.

Transfusion-Related Acute Lung Injury

Transfusion-associated adult respiratory distress syndrome or transfusion-related acute lung injury (TRALI) is a complication of transfusion that is often undiagnosed and ranks third among causes of transfusion-related deaths. It is characterized by acute respiratory distress during transfusion or within 6 hours after completion of transfusion, hypovolemia, hypotension, bilateral pulmonary infiltrates, normal or low pulmonary capillary wedge pressure, no evidence of circulatory overload, no other temporarily related acute lung injury, and fever. Recovery is rapid, occurring in 24 to 48 hours. Most blood donors implicated in this complication have had multiple pregnancies. The pathogenesis relates to the interaction between anti-WBC antibodies in the transfused blood and the WBCs in the transfusion recipient. Possible mechanisms include leukoagglutinins

Table 11-17 Risks of Complications From Transfusions in the United States

Complication	Risk per unit
Minor allergic reaction	3/100
Circulatory overload	Unknown
Febrile, nonhemolytic	3/100
Delayed hemolytic transfusion reaction	1/4,000
Transfusion-related acute lung injury (TRALI)	1/10,000
Acute hemolytic transfusion reaction	$1/2.5 \times 10^4$-$1/1.0 \times 10^6$
HIV infection	$1/2.1 \times 10^6$
Hepatitis B virus (HBV)	$1/2.0 \times 10^5$
Hepatitis C virus (HCV)	$1/1.9 \times 10^5$
HTLV I/II infection	$1/2.0 \times 10^5$
West Nile virus	Unknown
Bacterial infections	$1/2{,}000$-$1/5.0 \times 10^5$
IgA-related anaphylaxis	$1/1.0 \times 10^5$
Graft-versus-host disease	Rare
Immunosuppression	Unknown
Posttransfusion purpura	Rare

HIV, human immunodeficiency virus; HTLV, human T-cell leukemia virus.

in plasma or HLA-specific lymphocytotoxic antibodies passively transfused from the donor to the recipient, resulting in polymorphonuclear leukocyte-complement–triggered microvascular injury that results in a leak into the pulmonary alveolar spaces and pulmonary edema and a white out on the chest radiograph. The treatment is supportive. Essentially all patients require oxygen. Many patients require a ventilator with positive end-expiratory pressure and dopamine. This disorder may be misdiagnosed as circulatory overload. From 5% to 8% of patients die of complications of the pulmonary injury.

Delayed Hemolytic Transfusion Reactions

Delayed hemolytic transfusion reactions (1 in 4,000 transfusions) occur because of the inability to detect clinically significant recipient antibodies before transfusion. This transfusion reaction, which usually occurs 5 to 10 days after transfusion, is less dramatic and less dangerous than acute hemolytic reactions and is more common in females. The recipient's plasma already contains antibody before transfusion because of previous transfusion or previous pregnancy. It usually involves the Rh or Kidd system. The antibodies become undetectable because of low antibody titers and increase quickly in titer on rapid stimulation. Results of the Coombs test are positive. There is evidence of hemolysis. One-third of patients are asymptomatic, and the others present with anemia, chills, jaundice, and fever. Management consists of monitoring hemoglobin concentration and renal output.

Urticarial Transfusion Reactions

Urticarial transfusion reactions are a complication in 3% of transfusions. Glottal edema and asthma are rarely associated with urticarial transfusion reactions. The cause is an antibody in the recipient against foreign-donor serum proteins. Treatment consists of stopping the transfusion, which is not absolutely necessary, and giving antihistamines (premedication with antihistamines if the patient had a previous reaction).

Febrile Transfusion Reactions

Febrile transfusion reactions are characterized by chills and fever an hour after the transfusion starts, with accompanying flushing, headache, tachycardia, and discomfort lasting 8 to 10 hours. This occurs in 1% of all transfusions. The causes include cytokines from WBCs and platelets against donor antigens and antiserum protein antibodies. Treatment consists of stopping the transfusion to evaluate the problem further; initially, a febrile reaction cannot be distinguished from a hemolytic transfusion reaction because both conditions may present with fever. Preventive methods include blood filters.

Circulatory Overload

Circulatory overload may cause tightness in the chest, dry cough, and acute edema in patients with an already increased intravascular volume or decreased cardiac reserve. This is a frequently overlooked diagnosis. Symptoms generally develop within several hours after transfusion. Management includes slowing the transfusion to 100 mL/h, placing the patient in the sitting position, and giving diuretics.

Posttransfusion purpura

Posttransfusion purpura is a rare syndrome characterized by the abrupt onset of severe thrombocytopenia 5 to 10 days after blood transfusion; the estimated mortality is 10% to 15%. Most cases involve patients whose platelets lack the P1A1 antigen and who have developed an antibody from a previous pregnancy or transfusion. Therapy usually is successful. Intravenous immunoglobulin at a dose of 400 to 500 mg/kg is the treatment of choice. Plasma exchange and corticosteroids are alternative treatments.

Pathogen transmission may occur with transfusions. These risks are summarized in Table 11-17.

- The most common cause of acute hemolytic transfusion reaction is clerical error.
- The risk of HIV transmission through transfusion is <1/500,000-1/1.5 million.

Thrombopoietin

Thrombopoietin and interleukin-11 have been approved for secondary prophylaxis against chemotherapy-induced thrombocytopenia. In clinical practice, even severe treatment-related thrombocytopenia only rarely leads to death or life-threatening illness because transfusion of platelet concentrates ensures that very few patients with thrombocytopenia die of hemorrhage.

Gaucher Disease

Adults have type 1 Gaucher disease, with no neurologic symptoms, splenomegaly, and no symptoms; 50% have anemia or thrombocytopenia. Bone lesions are present in 75% of patients, with the femur most commonly having an Erlenmeyer flask deformity. Avascular necrosis and pathologic fractures may occur. The pathogenesis is related to an accumulation of glucosylceramide from deficient β-glucuronidase. The Gaucher cell is large and has an eccentric nucleus and fibrillar cytoplasm that is wrinkled like tissue paper (Fig. 11-22). Treatment options include alglucerase (Ceredase) (an enzyme replacement therapy that is extraordinarily expensive), hemisplenectomy, and allogeneic bone marrow transplantation. The differential diagnosis of asymptomatic massive splenomegaly includes Gaucher disease, agnogenic myeloid metaplasia, chronic myelogenous leukemia, portal hypertension, splenic cyst, non-Hodgkin lymphoma, and hairy cell leukemia.

- The differential diagnosis of asymptomatic massive splenomegaly includes Gaucher disease, agnogenic myeloid metaplasia, chronic myelogenous leukemia, portal hypertension, splenic cyst, non-Hodgkin lymphoma, and hairy cell leukemia.

Porphyria

The porphyrias are enzyme disorders that are autosomal dominant with low disease penetrance, except for congenital erythropoietic porphyria, which is autosomal recessive, and porphyria cutanea tarda, which may be acquired. Most persons remain biochemically and clinically normal throughout life. Clinical expression is linked to environmental and acquired factors. Disease manifestations depend on the type of excess porphyrin intermediate. When

there is an excess of the earlier precursor molecules (δ-aminolevulinic acid and porphobilinogen), the clinical manifestations are neuropsychiatric. These symptoms include autonomic dysfunction (abdominal pain, vomiting, constipation, tachycardia, and hypertension), psychiatric symptoms, fever, leukocytosis, syndrome of inappropriate antidiuretic hormone, and neurologic symptoms (proximal paresis and paresthesias). If the excess is in the distal intermediates (uroporphyrins, coproporphyrins, and protoporphyrins), the manifestations are cutaneous (photosensitivity, blister formation, facial hypertrichosis, and hyperpigmentation). If the excess is early and late, there are neuropsychiatric and cutaneous manifestations. Porphobilinogen production and excretion are invariably increased during marked symptoms caused by the three neuropathic porphyrias, which include acute intermittent porphyria, hereditary coproporphyria, and porphyria variegata. In hereditary coproporphyria and porphyria variegata, there is an accumulation of coproporphyrinogen/coproporphyrin or protoporphyrinogen/protoporphyrin and a concomitant increase in δ-aminolevulinic acid and porphobilinogen. In the acute porphyrias, urinary porphobilinogen is increased during the attacks. Patients with acute intermittent porphyria lack skin lesions. It is important to check fecal porphyrins in protoporphyria, porphyria variegata, and coproporphyria. The porphyrias are compared in Table 11-18. Secondary coproporphyrinuria has many causes, including impaired hepatobiliary transport of coprophyrin (steroids) or increased liver or erythroid synthesis (alcohol, liver disease, or hemolytic anemia).

- Determine the 24-hour urinary porphobilinogen during the acute episode.

Cardiac Toxicity of Chemotherapeutic Agents

Doxorubicin has the greatest potential for cardiac toxicity. It is dose-limited at a dose of 450 to 500 mg/m^2. The course is characterized by cardiomyopathy progressing to congestive heart failure and death. The pathologic features are characterized by a diffuse patchy myocardial cell degeneration that antedates any alteration in left ventricular function. Risk factors include age older than 70 years, coronary artery disease, hypertension, combination chemotherapy and previous or concomitant mediastinal radiotherapy, and the use of other cardiotoxic agents. Weekly and prolonged continuous infusion schedules may decrease the risk of toxicity. Acutely, there may be transient and reversible nonspecific ST-segment changes, a decrease in ejection fraction, or arrhythmias. The dilated cardiomyopathy is dose-dependent: a risk of 3.5% at a total dose of 400 mg/m^2, 7% at 500 to 550 mg/m^2, and 36% at 600 mg/m^2 or greater. The clinical features of the cardiomyopathy vary widely. Follow-up examination requires evaluating left ventricular ejection fraction by radionuclide ventriculography or echocardiography. The former is more sensitive.

- Doxorubicin has the greatest potential for cardiac toxicity.
- The incidence of cardiomyopathy is dose-dependent.
- Age >70 years, coronary artery disease, and previous irradiation may potentiate toxicity.

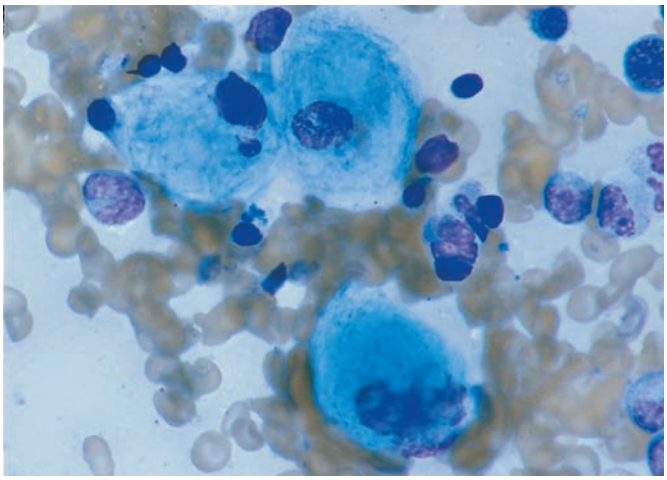

Fig. 11-22. Gaucher cells. Large cells with characteristic pale, foamy, and fibrillar cytoplasm. (Courtesy of Curtis A. Hanson, MD, Mayo Clinic.)

Superior Vena Cava Syndrome

Most cases (78%) of superior vena cava syndrome are caused by malignancy. Extrinsic compression of the thin superior vena cava, which has a low intravascular pressure, in a rigid compartment is the pathophysiologic basis of this syndrome. The causes include bronchogenic carcinoma (75% of cases, with small cell and squamous cell carcinoma most common), lymphoma (15%), testicular carcinoma (consider this if biopsy shows anaplastic or undifferentiated carcinoma; check the β-subunit of human chorionic gonadotropin and alpha fetoprotein), carcinoma, and adenocarcinoma of undetermined primary. The symptoms include suffusion of the face and conjunctiva, dyspnea, facial swelling, other swelling, cough, dysphagia, syncope, orthopnea, stridor, and lethargy. Physical examination demonstrates thoracic vein distention, neck vein distention, facial edema, cyanosis, edema of the upper extremities, paralyzed vocal cord, Horner syndrome, and heart murmurs. The diagnosis is established by the history and physical examination findings. Superior vena cava venography is not useful. A tissue diagnosis is essential to establish the diagnosis precisely. Mediastinotomy is the safest way to obtain a histologic diagnosis. If the syndrome is rapid in onset, treatment must be rapid. For patients with lymphoma, testicular carcinoma, or small cell carcinoma of the lung, treat the underlying disease initially with chemotherapy. If life-threatening problems are present, such as tracheal obstruction or increased intracranial pressure, emergency radiotherapy may be necessary for any disorder in a patient presenting with superior vena cava syndrome. Steroids may be helpful. Initial treatment with irradiation is indicated for solid tumors, with a total dose of 30 to 50 Gy or a single dose of 7 to 12 Gy. Anticoagulation is indicated only if a blood clot has been implicated in the pathophysiology. Diuretics and surgical decompression are not indicated.

- For superior vena cava syndrome, establish a tissue diagnosis.
- Features: edema of the face and neck and venous engorgement of the upper torso.

Table 11-18 Comparison of Porphyrias

Porphyria cutanea tarda	Acute intermittent porphyria	Porphyria variegata
	Features	
Most common Iron overload Skin lesions on light-exposed areas Hypertrichosis Increased uroporphyrins in urine No neuropathic features Most common of porphyrias	Increased urinary δ-aminolevulinic acid and porphobilinogen Triad: abdominal pain of 3-5 days' duration, neurologic problems of polyneuropathy & motor paresis, psychiatric problems with hallucinations, confusion, psychosis, seizures Decreased porphobilinogen deaminase Normal protoporphyrin & coproporphyrin in stool	Clinically: skin, sun-exposed, mechanical fragility; abdominal pain; neurologic problems (e.g., acute intermittent porphyria) Increased protoporphyrin & coproporphyrin in stool
	Associations	
Alcoholic liver disease Estrogens: females, males treated for prostatic carcinoma Hexachlorobenzene	Drugs: sulfonamides, barbiturates, alcohol Menstrual cycle Infection Inadequate nutrition Stress: infections, surgery	Common in South Africa, Holland
	Treatment	
Phlebotomy to remove iron Chloroquine Low-dose antimalarials	Avoid prolonged fasting & crash diets Large amounts of carbohydrate (400 g daily) Intravenous hematin Luteinizing hormone-releasing hormone agonists	Same as for acute intermittent porphyria

- It is a medical emergency in certain situations; immediate irradiation may be required.

Hypercalcemia

Virtually any malignancy may lead to hypercalcemia. Specific causes include carcinomas of the breast and lung (squamous and large cell carcinoma are common causes, and adenocarcinoma and small cell carcinoma are uncommon causes), hypernephroma, other tumors (head and neck, cervix, prostate, neuroblastoma, hepatoma, and melanoma), lymphoma, Burkitt lymphoma, multiple myeloma, Hodgkin disease, chronic myelogenous leukemia, and Waldenström macroglobulinemia. Less than 10% of cases of hypercalcemia are secondary to 1,25-dihydroxyvitamin D–secreting lymphoma or ectopic hyperparathyroidism.

The signs and symptoms include lassitude, somnolence, weakness, anorexia, nausea, vomiting, constipation, abdominal pain, peptic ulcer, pancreatitis, polyuria, polydipsia, poor intake, renal failure, hyporeflexia, Babinski sign, myopathy, stupor, coma, occasional localizing signs, visual abnormalities, psychotic behavior, bradycardia, tachycardia, shortened QT interval, digitalis sensitivity, arrhythmias, hypertension, fractures, pain, skeletal deformities, loss of height, poor skin turgor, calcinosis, and band keratopathy. It is misdiagnosed as terminal disease, brain metastases, drug toxicity, renal failure, diabetes insipidus, acute abdomen, and intractable peptic ulcer disease. The diagnosis can be confirmed by measuring serum levels of parathyroid hormone (PTH). These levels are low in malignancy and increased in primary hyperparathyroidism.

- Misdiagnoses include terminal disease, brain metastases, drug toxicity, renal failure, diabetes insipidus, acute abdomen, and intractable peptic ulcer disease.
- Less than 10% of cases of hypercalcemia are secondary to 1,25-dihydroxyvitamin D–secreting lymphoma or ectopic hyperparathyroidism.

The mechanisms of action of hypercalcemia are multiple. Osteolytic metastases may produce accelerated skeletal resorption. Osteoclast activating factors are associated with multiple myeloma, lymphoma, and Burkitt non-Hodgkin lymphoma. Most cases (80%) are secondary to humoral hypercalcemia of malignancy caused by PTH (squamous cell, renal cell, ovarian, endometrial and breast carcinomas; non-Hodgkin lymphoma; and human T-lymphotropic virus). Other factors include dehydration, mobilization, adrenal insufficiency due to tumor metastases, estrogens, androgens, progestins, and tamoxifen.

Most hypercalcemia is related to increased bone resorption. Intestinal absorption is low or low-normal in most cases. There usually is no increase in renal tubular reabsorption, but the kidney may be involved in hyperparathyroidism, breast cancer, metabolic alkalosis, and salt depletion. The course is short and rapidly progressive. There may be moderate to severe weight loss and no renal calculi; pancreatitis is rare. The serum level of calcium is greater than 14 mg/dL in 75% of patients. The serum level of alkaline phosphatase may be increased, normal, or decreased. Anemia and metabolic alkalosis may be present. The alkaline phosphatase level is increased in 50% of patients but can be increased in primary hyperparathyroidism. Hypophosphatemia can occur whether or not there is a PTH-secreting tumor. Hypoalbuminemia must be considered, when the albumin level is less than 4 g/dL, for every gram of albumin less than 4, add 1 mg/dL to the ionized calcium value. An ionized calcium level may be determined when there is doubt about the validity of the total calcium level.

Treatment is multifaceted. The use of such precipitating factors as vitamins A and D, lithium, thiazides, calcitrol, absorbable antacids, and estrogens should be discontinued. The patient should be mobilized. Also, the patient should be hydrated with a minimum of 200 to 500 mL/h of fluid in the first 24 hours. To each liter of normal saline, add 20 to 40 mEq of potassium chloride and 10 to 20 mEq of magnesium. Experimentally, if the sodium is increased from 25 mEq to 250 mEq, calcium excretion is increased threefold and is not related to the glomerulofiltration rate. Treat the underlying disease.

Glucocorticoids are efficacious in multiple myeloma and non-Hodgkin lymphomas. The typical dose is 80 mg of prednisone in divided doses daily. The mechanisms of action include antitumor effects, an antivitamin D effect, inhibition of prostaglandin synthesis or release, inhibition of osteoclast-activating factor production, anti-PTH activity, and an inhibitory effect on osteoprogenitor cells.

Furosemide should be administered after 2 L of fluid. The dosages are variable, ranging from 20 to 40 mg up to every 4 hours. Furosemide blocks the tubular reabsorption of calcium, depletes sodium, depletes potassium, and depletes magnesium.

Intravenous bisphosphonates are the safest and most effective treatment of the hypercalcemia of malignancy. Pamidronate and zoledronate have an inhibitory effect on osteoclast function and viability. The nadir concentration of serum calcium usually occurs within 4 to 7 days after initiation. Pamidronate is given by intravenous infusion at a dosage of 15 to 45 mg daily for up to 6 days.

Calcitonin is less toxic than plicamycin, but the reductions are small. Mithramycin inhibits RNA synthesis in osteoclasts. There may be subjective improvement within 12 hours and improvement in the serum levels of calcium in 36 hours. The dose is 25 µg/kg over 4 hours and may be repeated once if necessary. Side effects include thrombocytopenia, hemorrhage, renal complications, increased liver enzymes, sudden arterial occlusion, and toxic epidermal necrolysis. Contraindications include thrombocytopenia and coagulopathy. The use of phosphate should be restricted to extreme life-threatening hypercalcemia. Calcium phosphate complexes are deposited in vessels, lungs, and kidneys. Dialysis is an option for selected patients.

Hemochromatosis

Hemochromatosis is the end result of a pathologic process that evolves over years and is due to the excessive absorption of dietary iron. The causes of hemochromatosis include hereditary hemochromatosis (idiopathic), secondary anemia and ineffective erythropoiesis (thalassemia major and thalassemia minor), hereditary spherocytosis, idiopathic refractory sideroblastic anemia and myelodysplasia, oral intake of iron (medicinal), liver disease (alcoholic cirrhosis and portal caval anastomosis), drugs (isoniazid and chloramphenicol), and copper deficiency.

Patients with end-stage disease present with endocrine complications and hepatic fibrosis: 50% present with diabetes mellitus and a minority have vascular sequelae, hypogonadism (decreased libido, impotence, and amenorrhea), or hypopituitarism. Cardiac complications include congestive heart failure and arrhythmias. Skin color may be bronze or "slate gray." Patients may have arthropathy (chondrocalcinosis, bone cysts, and irregularity), hepatomegaly, abdominal pain, cirrhosis, or hepatocellular carcinoma (which develops in 30% of patients with cirrhosis).

Classic hereditary hemochromatosis is a potentially fatal autosomal recessive disorder that is among the most common deleterious genes in whites of North America and Europe and is as prevalent as the sickle cell gene in African Americans. The gene for hereditary hemochromatosis has been identified and designated the *HFE* gene. This is detectable with a polymerase chain reaction assay. Two mutations have been identified: C282Y and H63D. Patients with classic hemochromatosis do not make enough hepcidin, a plasma peptide that dampens intestinal iron absorption. Homozygotes typically develop clinical evidence of hemochromatosis. Family studies are essential because a substantial number of homozygous relatives of patients with hemochromatosis have complications of hemochromatosis yet to be detected. It is inherited as an autosomal recessive trait. Males present with the disease in the fourth to fifth decade.

About half of the persons who are homozygous for *HFE* have no signs or symptoms. Nearly every organ system can be involved. Initial symptoms include fatigue, arthritis, impotence (males), amenorrhea (females), abdominal pain, and atrial fibrillation. The transferrin saturation (serum iron/total iron-binding capacity) is greater than 45% even early in life and before tissue iron loading occurs. Screening appears to be effective and should be considered at about age 30 for men. For a young woman, it is necessary to ascertain whether she is taking oral contraceptives, which may increase the transferrin saturation. This should be repeated after iron therapy has been discontinued, when the patient is not taking oral contraceptive pills, when the patient is fasting, and it should be repeated with a ferritin assay to evaluate the total iron-binding content.

The screening test advocated most for homozygotes is transferrin saturation (results >45% on at least two occasions should raise clinical suspicion). The diagnostic test is *HFE* gene testing. The urinary iron level is increased in the range of 5 to 20 mg/24 h (reference range, <2 mg/24 h). Liver biopsy defines the degree of iron overload and is the standard for the status of the liver (fibrosis, cirrhosis, and hepatitis) but is not required in many cases. Considerations for liver biopsy include patients with abnormal aminotransferase levels, serum

ferritin levels greater than 1,000 µg/L, and platelet count less than 200 × 10^9/L. The reference standard for diagnosis is liver biopsy, and hepatic iron by dry weight is markedly increased at 200 to 1,800 µg/100 ng dry weight (reference range, 30-140 µg/100 ng). Supporting evidence is also provided by the amount of iron removed by phlebotomy therapy (>5 g) and pedigree studies. Family members, including all first-degree relatives (parents, siblings, and children), should have screening tests.

About 82% of patients with clinically severe hereditary hemochromatosis of European descent are homozygous for the hemochromatosis *HFE* mutation. The molecular genetics of non–HLA-linked African hemochromatosis has not been elucidated.

The goal of treatment is to improve prognosis and the clinical course in patients with established liver damage. The mainstay of treatment is phlebotomy. Chelation until the ferritin level is less than 20 µg/L is the treatment goal; 200 to 250 mg of iron are removed per phlebotomy unit. Patients initially have phlebotomy once or twice weekly until the ferritin concentration is less than 50 µg/L. Maintenance phlebotomies are required, typically every 3 months. Iron chelation therapy (deferoxamine, 10 mg daily by continuous infusion) is not the treatment of choice because of cost and inconvenience.

Timely diagnosis and therapy can prevent irreversible organ failure. Features not altered by chelation include arthropathy, hormonal inefficiencies, liver cirrhosis, development of hepatocellular carcinoma, and diabetes mellitus. Adverse prognostic factors include cirrhosis and diabetes mellitus. Liver transplantation has a role in the management of these patients. Patients who begin treatment before end-organ damage have a normal life span. The risk to siblings is 25%; thus, all of them should have screening tests for iron or genetic testing.

- Endocrine dysfunction: 50% have diabetes mellitus at presentation and a minority have vascular sequelae; hypogonadism (decreased libido, impotence, and amenorrhea); hypopituitarism.
- Cardiac: congestive heart failure and arrhythmias.
- Skin: bronze, "slate gray."
- Arthropathy: chondrocalcinosis, bone cysts, and irregularity.
- Hepatomegaly, abdominal pain, cirrhosis, and hepatocellular carcinoma; 30% of patients with cirrhosis develop hepatocellular carcinoma.
- Transferrin saturation >45% on at least two occasions should raise clinical suspicion.
- After an index case is identified, first-degree relatives must have screening tests.
- The gene for hereditary hemochromatosis (*HFE*) and two mutations (C282Y and H63D) have been defined.
- About 82% of patients with clinically severe hereditary hemochromatosis of European descent are homozygous for the hemochromatosis *HFE* mutation.
- The molecular genetics of non–HLA-linked African hemochromatosis has not been elucidated.
- Treatment: phlebotomy.
- Typical clinical scenario: The patient is asymptomatic but has fatigue, impotence, amenorrhea, abdominal pain, and atrial fibrillation. The ferritin level and iron-binding capacity are increased.

Hematology of Acquired Immunodeficiency

Lymphocytopenias are the hallmark of AIDS. There is an absolute decrease of T4 lymphocytes, with a relative reduction of the T4:T8 ratio. Also, T4 lymphocytes are functionally impaired. Whereas T8 lymphocytes may increase in number early in the disease during infection, they decrease late in the disease. Neutropenia occurs in 50% of the patients. Natural killer cells are normal in number but altered in function. Neutropenia may be due to autoimmune destruction with antigranulocyte antibodies in two-thirds of patients, decreased production, zidovudine (AZT), ganciclovir, trimethoprim-sulfamethoxazole, pentamidine, coexisting infections, non-Hodgkin lymphoma, or antineoplastic chemotherapy. Neutrophil dysfunction is also manifested by decreased chemotaxis, granulation, and phagocytosis.

Anemia occurs in 70% of HIV-infected patients. Most commonly, the anemia is normochromic normocytic. The degree of anemia is a prognostic factor. Anemia occurs in 10% of asymptomatic HIV-positive patients, in 50% of patients with AIDS-related complex, and in more than 75% of patients with overt AIDS. HIV-associated RBC problems include decreased RBC production; 70% of AIDS patients have decreased erythropoietin levels. Approximately 25% of patients have positive results on the Coombs test, but marked hemolysis is not common. Of patients treated with zidovudine, 30% develop pronounced anemia, which is characteristically macrocytic. Decreased RBC production is a principal cause. Erythropoietin has been given successfully to those with an erythropoietin level less than 500 IU/mL. Clinical studies have demonstrated that transfusions may decrease survival and increase the risk of cytomegalovirus infection. Anemia is also associated with infections from *Mycobacterium avium* complex, parvovirus B19, *Mycobacterium tuberculosis*, and *Histoplasma* species. Anemia may be malignancy-related. Decreased vitamin B_{12} levels are detected in 20% of HIV-infected patients and are due to altered serum transport of vitamin B_{12} and not to a deficiency in body stores unless there has been prolonged malabsorption. Microangiopathic hemolytic anemia is milder than with other causes of this disorder. Plasmapheresis with plasma exchange is the treatment of choice. Vincristine may be efficacious in refractory cases.

Thrombocytopenia occurs in 40% of HIV-infected patients and is often detected early in the disease. Platelet survival is decreased in HIV-infected patients. The serum and cell-bound antibodies are frequently positive. Circulating complexes are either the cause of immune cytopenias or are associated with them. ITP is usually accompanied by platelet-associated antibodies and responds to zidovudine (80% of patients), prednisone (90%), danazol, dapsone (60%), immunoglobulin given intravenously, and splenectomy (80%). Other HIV associations include thrombotic thrombocytopenic purpura, decreased platelet production, and peripheral platelet sequestration. Other associations, including non-HIV associations, are therapy, infection, and malignancy. Coagulation disorders may complicate HIV disorders. The lupus-like anticoagulant is present in 20% of

HIV patients, usually in association with opportunistic infections, and is rarely associated with thrombosis or bleeding. Vitamin K deficiencies due to nutritional abnormalities, drugs, or liver dysfunction may occur. Other problems include increased level of vWF:Ag (with a poor prognosis if >200%), increased level of t-PA (with a poor prognosis if >20 ng/mL), and increased level of fibrinogen.

Non-Hodgkin lymphoma is the second most common HIV-associated malignancy, occurring in 2.9% of patients. Diffuse large B-cell lymphoma and Burkitt lymphoma are the most characteristic histologic findings. Extranodal disease occurs in 66% of patients. Up to one-third of patients with lymphoma may have bone involvement. There is also an increased risk of Hodgkin disease among HIV patients, but this is not one of the diagnostic criteria for AIDS.

Parvovirus Infection

Parvovirus infection (B19), or fifth disease, is a highly contagious disease in children. Adults with this infection may develop a polyarthralgia syndrome or cytopenia. Abnormalities in the erythroid line include severe anemia, reticulocytopenia, and RBC hypoplasia in the bone marrow. Pancytopenia may occur. Immunoglobulin therapy administered intravenously is the treatment of choice.

Hematology Pharmacy Review

Robert C. Wolf, PharmD, Darryl C. Grendahl, RPh, Thomas M. Habermann, MD

Drug	Toxic/adverse effects	Comments
	Alkylating agents	
Carmustine	Delayed marrow suppression, nausea, vomiting, pulmonary, hepatotoxicity, secondary leukemia	Cumulative marrow suppression, crosses blood-brain barrier
Busulfan	Pulmonary fibrosis, hepatic veno-occlusive disease, skin hyperpigmentation	Liver metabolism, renal excretion
Carboplatin	Marrow suppression, nausea & vomiting, less nephrotoxicity & neurotoxicity than cisplatin	Renal excretion
Chlorambucil	Pulmonary, secondary leukemia, myelosuppression	Hepatic metabolism
Cisplatin	Nephrotoxicity, peripheral neuropathy, ototoxicity, magnesium depletion	Renal excretion, Raynaud phenomenon
Cyclophosphamide	Acute nonlymphocytic leukemia & dysmyelopoietic syndromes (monosomy 5 and 7), bladder cancer, leukopenia, hemorrhagic cystitis, pulmonary fibrosis, SIADH, alopecia, nausea, vomiting	Liver metabolism to active compound, renal excretion, lower dose with renal failure, late transitional cell carcinoma of bladder
Dacarbazine	Marrow suppression, flulike syndrome, severe nausea & vomiting, fever	
Melphalan	Marrow suppression, secondary leukemia, stomatitis (high dose)	Absence of renal clearance allows use of high-dose melphalan in patients with renal failure, erratic oral absorption
Nitrogen mustard	Marrow suppression, nausea & vomiting, sterility, secondary leukemia	
Streptozocin	Diabetes, marrow suppression, severe nausea & vomiting, renal	Leads to pancreatic & endocrine insufficiency
Procarbazine	Secondary leukemia, sterility	
Ifosfamide	Myelosuppression, CNS toxicity (lethargy, confusion), cystitis	Liver metabolism, renal elimination
	Antibiotics	
Bleomycin	Pulmonary fibrosis (threshold 400 μg/lifetime but may recur at lower doses), fever & chills, myalgias, skin pigmentation, alopecia, adult respiratory distress syndrome with oxygen	Lower dose with renal insufficiency
Dactinomycin	Marrow suppression, radiation recall, nausea & vomiting, mucositis, alopecia	
Daunorubicin	Marrow suppression, radiation recall, cardiomyopathy, mucositis, nausea & vomiting, alopecia, acute nonlymphocytic leukemia	Decrease dose by 50% if bilirubin >1.5 mg/dL or by 75% if bilirubin >3.0 mg/dL
Doxorubicin	Dose-related cardiomyopathy, marrow suppression, alopecia, nausea & vomiting, stomatitis, radiation recall, acute nonlymphocytic leukemia	Liver metabolism, biliary excretion, decrease dose by 50% if bilirubin >1.5 mg/dL or by 75% if bilirubin >3.0 mg/dL
Idarubicin	Myelosuppression, alopecia	
Mitomycin C	Delayed marrow suppression, nausea & vomiting, alopecia, hepatotoxicity, microangiopathic hemolytic anemia	Vesicant, alkylator, forms free radicals

Hematology Pharmacy Review (continued)

Drug	Toxic/adverse effects	Comments
	Antibiotics (continued)	
Mitoxantrone	Marrow suppression, cardiac toxicity, nausea & vomiting, mucositis, alopecia, blue sclera & urine	
	Hormones	
Corticosteroids	Diabetes, hepatotoxicity, aseptic necrosis, adrenal insufficiency, myopathy, infection, osteoporosis, peptic ulcer disease, hypokalemia, psychosis, cataract	
	Plant Derivatives	
Etoposide (VP-16)	Acute nonlymphocytic leukemia, t(11q23), myelosuppression, hypotension, mucositis	
Vincristine	Neurotoxicity (peripheral, autonomic, cranial)	
Vinblastine	SIADH, myelosuppression	
	Antimetabolites	
2'-Deoxycoformycin Fludarabine 2-Chlorodeoxyadenosine	Myelosuppression & immunosuppression Opportunistic infections	
Methotrexate	Myelosuppression, mucositis, hepatotoxicity	Drug interactions: NSAIDs, probenecid
Cytarabine	Myelosuppression, neurotoxicity (high dose), conjunctivitis (high dose)	
	Other agents	
Alemtuzumab	Fever, chills/rigors, opportunistic infections	Monoclonal antibody to CD52
Bortezomib	Sensory peripheral neuropathy, orthostatic hypertension, fever, thrombocytopenia, neutropenia	Proteasome inhibitor
Asparaginase PEG-asparaginase	Hypersensitivity, hemorrhage/thrombosis, hyperglycemia, pancreatitis, increased LFTs, somnolence/confusion	
Hydroxyurea	Myelosuppression (rapid), anorexia, hyperpigmentation	
Tretinoin	Retinoic acid syndrome; xerostomia, cheilitis, skin desquamation; dry, irritated eyes; myalgias; hyperleukocytosis; teratogenic; hypertriglyceridemia	Pulmonary infiltrates, fluid retention, hypotension (responsive/preventable with dexamethasone)
Thalidomide	Sedation, peripheral neuropathy, constipation, rash, teratogenic	
Arsenic trioxide	Acute promyelocytic leukemia differentiation syndrome, QT-interval prolongation, myelosuppression, targeted therapy	Fever, dyspnea, weight gain, pleural or pericardial effusion ± leukocytosis

Hematology Pharmacy Review (continued)

Drug	Toxic/adverse effects	Comments
	Targeted therapy	
Rituximab	Fever, chills/rigors, headache, hypotension, anaphylactoid symptoms	Monoclonal antibody to CD20
Imatinib (STI571)	Myelosuppression, fluid retention, nausea, muscle cramps, diarrhea, headache, myalgia, arthralgia	Tyrosine kinase inhibitor Multiple potential drug interactions via cytochrome P-450-3A4 pathway
	Immunotherapy	
Interferon alfa	Fatigue, flu-like symptoms, myelosuppression, increased LFTs	Cytochrome P-450 inhibitor (multiple potential drug interactions)
Filgrastim (G-CSF)	Bone pain, fever	
Sargramostim (GM-CSF)	Bone pain, fever	
Oprelvekin (interleukin 11)	Fluid retention, tachycardia, fatigue	
Gemtuzumab ozogamicin	Myelosuppression, fever, chills/rigors, hypotension, increased LFTs	Monoclonal antibody to CD33 conjugated to calicheamicin (antitumor antibiotic)

CNS, central nervous system; G-CSF, granulocyte colony-stimulating factor; GM-CSF, granulocyte-macrophage colony-stimulating factor; LFT, liver function test; NSAID, nonsteroidal anti-inflammatory drug; SIADH, syndrome of inappropriate antidiuretic hormone.

Hematology Pharmacy Review (continued)

Hematologically Active Agents Used in Cardiology

Drug	Toxic/adverse effects	Hypersensitivity	Pregnancy category
Argatroban	Hemorrhage, hypotension	Coughing, dyspnea, rash	B
Bivalirudin	Hemorrhage, GI symptoms	None	B
Lepirudin	Hemorrhage, heart failure	Anaphylactoid, angioedema (rare), cough, bronchial spasm, stridor, rash	B
Cilostazol	Headache, diarrhea, flushing, hypotension, tachycardia	Rash	C
Ximelagatran	Hemorrhage, elevated LFTs	Unknown	Unknown

GI, gastrointestinal; LFT, liver function test.

HIV Infection

Zelalem Temesgen, MD

Human immunodeficiency virus (HIV) belongs to the family Retroviridae, subfamily Lentiviridae. Retroviridae organisms share a distinct biologic characteristic: an initial stage of primary infection followed by a relatively asymptomatic period of months to years and a final stage of overt disease.

There are two types of HIV: HIV-1 and HIV-2. Most reported cases of HIV disease around the world are caused by HIV-1. HIV-1 is further classified into subtypes M, N, and O, referred to as clades. Subtype M (main) is the collective name for a group of clades designated "A" to "K." For example, clade "B" is responsible for most HIV infections reported in the United States. HIV-2 is found predominantly in western Africa. Although HIV-1 and HIV-2 are clinically indistinguishable and have identical modes of transmission, HIV-2 appears to be less easily transmitted than HIV-1 and slower to progress to acquired immunodeficiency syndrome (AIDS).

- There are two types of HIV: HIV-1 and HIV-2.
- Most reported cases of HIV disease are caused by HIV-1.

Epidemiology

The AIDS epidemic is currently in its third decade and continues to affect a significant number of people throughout the world. According to "The AIDS Epidemic Update: December 2004" released by the joint United Nations Program on HIV/AIDS (UNAIDS), an estimated 39.4 million (35.9-44.3 million) people are living with HIV infection. 4.9 million (4.3-6.4 million) people acquired HIV in 2004, and 3.1 million (2.8-3.5 million) people died as a result of it during the same period. The number of people living with HIV has been increasing in every region. However, Sub-Saharan Africa continues to be the world's most affected region: approximately 64 % of all cases of AIDS occur there and 76% of all women living with HIV reported worldwide live there. In the United States, 850,000-950,000 persons are living with HIV, including 180,000-280,000 who do not know they are infected. Of all HIV and AIDS cases diagnosed in 2003, 50% were in blacks. The cumulative estimated number of diagnoses of AIDS in the United States from the beginning of the epidemic through 2003 is 929,985. Men who have sex with men (45%) and persons exposed through heterosexual contact (34%) accounted for 79% of all HIV and AIDS cases diagnosed in 2003.

Transmission

HIV is transmitted sexually, perinatally, by parenteral inoculation (intravenous drug injection, occupational exposure), through blood products, and, less commonly, through donated organs or semen. Sexual transmission is the most common means of infection. Some of the conditions that may increase the risk of sexually acquiring HIV infection are traumatic intercourse (such as receptive anal); ulcerative genital infections such as syphilis, herpes simplex, and chancroid; and lack of circumcision. The use of latex condoms, especially if used properly, reduces the risk of HIV transmission.

- HIV is transmitted sexually, perinatally, by parenteral inoculation, through blood products, and through donated organs or semen.

In the United States, all blood donations have been routinely tested for HIV-1 antibody since early 1985. Since June 1, 1992, all U.S. blood centers test for antibodies to both HIV-1 and HIV-2.

- In the United States, all blood donations have been routinely tested for HIV-1 antibody since early 1985.

Laboratory Diagnosis

The enzyme-linked immunosorbent assays and enzyme immunoassays are the most common assays used as a screening test for HIV-1 infection. They detect specific HIV antibodies. They have high (>99%) sensitivity and specificity but low positive predictive values in low-prevalence populations. For this reason, positive results require verification with an additional test. False-positive results can occur for several reasons. These include the presence of cross-reacting antibodies in certain patients (such as multiparous women, patients with multiple transfusions) and participation in HIV vaccine studies.

Causes of false-negative results include testing during the pre-seroconversion (window) period, use of replacement transfusions, bone marrow transplantation, agammaglobulinemia, seroreversion in late-stage disease, unusual HIV subtypes (HIV-2, clade O and N), and atypical immune response. Technical or laboratory error can be a cause of both false-positive and false-negative results. Rapid tests for HIV have been approved by the U.S. Food and Drug Administration; they use whole-blood samples obtained from fingerstick, plasma, serum, or oral fluid specimens. Positive results of these tests are termed "preliminary positive" and also require confirmatory testing.

Individuals with positive or indeterminate results of enzyme-linked immunosorbent assay or enzyme immunoassay should have the test repeated. If results are repeatedly positive, the patient should undergo additional confirmatory testing, usually Western blot testing. The Western blot test detects specific viral proteins, such as Gag (p18, p24, p55), Pol (p31, p51, p66), and Env (gp41, gp120/gp160) gene products. The guidelines of the Centers for Disease Control and Prevention for interpretation of the Western blot are as follows. The presence of antibody against any two of the three major viral gene products (p24, gp41, or gp120/gp160) is classified as positive. A Western blot result is classified as negative if no bands are present. Results that cannot be classified as positive or negative on the basis of these criteria are categorized as indeterminate. If results are indeterminate, the clinician should assess the risk of HIV infection in the patient and retest in 3 to 6 months (Fig. 12-1). HIV RNA assays may be of additional help in these cases. The risk of HIV infection is extremely low in patients with repeatedly indeterminate results of Western blot testing.

- Enzyme-linked immunosorbent assay or enzyme immunoassay should be repeated in persons with positive or indeterminate results.
- Western blot testing is used to confirm the results of enzyme-linked immunosorbent assay or enzyme immunoassay.

Pathogenesis

Contrary to previously held beliefs, HIV is not dormant during the so-called clinical latency period. There is active virus replication at all stages of disease. As many as 10 billion viral particles are produced and cleared daily in an HIV-infected person throughout all stages of disease. Concurrent with this rapid turnover of the HIV virus, more than 2 billion CD4 lymphocytes are produced every day.

- HIV is not dormant during the so-called clinical latency period.

Synonyms for primary HIV infection syndrome are acute HIV infection and acute retroviral syndrome. Within days to weeks after exposure to HIV, upwards of 40% of infected individuals present with a brief illness that may last for a few days to a few weeks. This period of illness is associated with a huge amount of circulating virus, a rapid decline in the CD4 cell count, and a vigorous immune response.

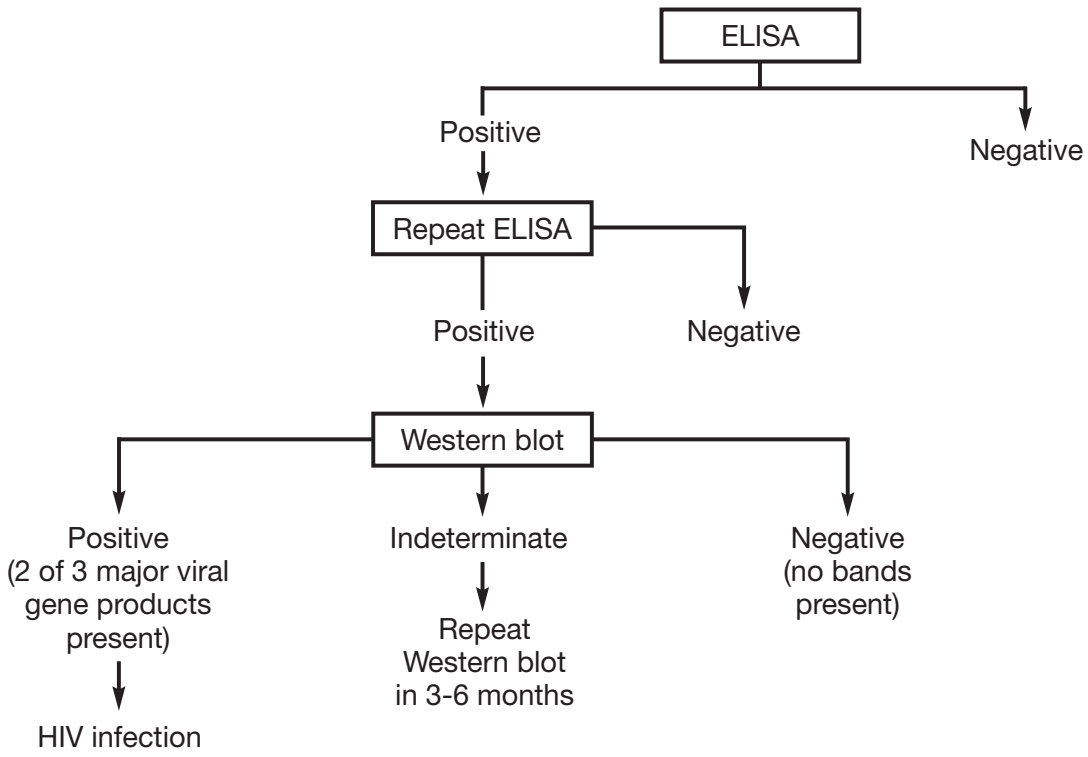

Fig. 12-1. Testing for human immunodeficiency virus (HIV). ELISA, enzyme-linked immunosorbent assay.

Patients usually present with a mononucleosis-like illness, but the clinical manifestations may be protean (Table 12-1). An atypical lymphocytosis is present in approximately 50% of patients. Results of enzyme-linked immunosorbent assay may be negative (window period), whereas p24 antigen, HIV culture, or polymerase chain reaction results may provide the diagnosis. The differential diagnosis includes infection due to Ebstein-Barr virus, cytomegalovirus, primary herpes simplex virus, toxoplasmosis, rubella, viral hepatitis, secondary syphilis, and drug reactions. Currently, treatment with the most potent antiretroviral combination regimen available is recommended with the hope of intervening before the HIV infection is fully established, when the viral population is relatively homogeneous and the host immune system is relatively intact.

- Acute HIV infection occurs within days to weeks after exposure to HIV.
- Patients usually present with a mononucleosis-type illness.
- Results of ELISA may be negative for HIV.
- HIV p24 antigen, HIV culture, and HIV polymerase chain reaction results may provide the diagnosis.
- Treatment is with the most potent antiretroviral combination regimen.

Selected Infections and Conditions Associated With HIV Infection

Pneumocystis carinii Pneumonia

Pneumocystis carinii pneumonia (PCP) is one of the most common opportunistic infections in patients with AIDS. It typically occurs in patients with CD4 counts less than 200 cells/μL. Other factors associated with a higher risk of PCP include CD4 percentage less than 15%, oral thrush, recurrent bacterial pneumonia, high HIV-1 RNA level, unintentional weight loss, and previous episodes of PCP. The onset of illness is insidious, with several days to weeks of fever, exertional dyspnea, chest discomfort, weight loss, malaise, and night sweats. Chest radiography typically shows bilateral interstitial pulmonary infiltrates, but a lobar distribution and spontaneous pneumothoraces may occur. Patients with early disease might have a normal chest radiograph. Pleural effusion is uncommon. Thin-section computed tomography usually shows patchy ground-glass infiltrates. Arterial blood gas analysis usually indicates hypoxemia and respiratory alkalosis. A wide A-a gradient (>35 mm Hg) and low P_{O_2} (<70 mm Hg) are associated with increased mortality. Increased lactate dehydrogenase level is common but is nonspecific. Several methods are used for the diagnosis of PCP. Staining for PCP in hypertonic saline-induced expectorated sputum is 30% to 85% sensitive. The sensitivity improves with liquefaction and the use of monoclonal antibody staining, and it may decrease with the use of PCP prophylaxis. Bronchoalveolar lavage is 85% to 90% sensitive. In rare circumstances, transbronchial lung biopsy may be needed to make the diagnosis. Open lung biopsy is even less commonly required. Extrapulmonary disease is uncommon but can be present in any organ.

- PCP is one of the most common opportunistic infections in AIDS.
- Bronchoalveolar lavage is 85%-90% sensitive for the diagnosis of PCP.

The treatment of choice for PCP is trimethoprim-sulfamethoxazole. The usual recommended dosage is 15 mg/kg per day (trimethoprim component) in 3 or 4 equally divided doses for 21 days. If there is no improvement 4 to 8 days after treatment is begun, switching to or adding another drug should be considered. Alternative treatment options are listed in Table 12-2. Controlled studies have shown that adjunctive corticosteroid therapy increases survival in patients with moderate-to-severe disease, defined as room air P_{O_2} less than 70 mm Hg or an alveolar-arterial P_{O_2} difference (A-a gradient) more than 35 mm Hg. When indicated, adjunctive corticosteroid therapy should be started immediately; a delay may compromise its effectiveness.

- The treatment of choice for PCP is trimethoprim-sulfamethoxazole.
- Adjunctive corticosteroid therapy increases survival in patients with moderate-to-severe disease.

Prophylaxis against PCP is indicated in all HIV-infected patients with the previously detailed factors that are associated with a higher risk of PCP. Drugs used for prophylaxis of PCP are listed in Table 12-3. The agent of choice is trimethoprim-sulfamethoxazole, which

Table 12-1 Clinical Manifestations of Primary Human Immunodeficiency Virus Infection

General	Neuropathic	Dermatologic	Gastrointestinal
Fever	Headache, retro-orbital pain	Maculopapular rash	Oral candidiasis
Pharyngitis	Meningoencephalitis	Roseola-like rash	Nausea, vomiting
Lymphadenopathy	Peripheral neuropathy	Diffuse urticaria	Diarrhea
Myalgia	Radiculopathy	Desquamation	
Lethargy	Guillain-Barré syndrome	Alopecia	
Anorexia, weight loss	Cognitive impairment	Mucocutaneous ulceration	

From Tindall B, Imrie A, Donovan B, Penny R, Cooper DA. Primary HIV infection. In: Sande MA, Volberding PA, editors. The medical management of AIDS. 3rd ed. Philadelphia: WB Saunders Company; 1992. p. 67-86. Used with permission.

Table 12-2 Drugs for the Treatment of *Pneumocystis carinii* Pneumonia

Drug
Trimethoprim-sulfamethoxazole 15 mg/kg per day
Trimethoprim PO 15 mg/kg per day + dapsone PO 100 mg/day
Clindamycin IV 600 every 8 h (or PO 300-450 mg every 6 h) + primaquine PO 30 mg base/day
Pentamidine IV 4 mg/kg per day
Atovaquone suspension 750 mg twice daily
Trimetrexate IV 45 mg/m^2 per day + leucovorin (folinic acid) IV 20 mg/m^2 every 6 h
Prednisone* 40 mg PO twice daily for 5 days, followed by 40 mg PO daily for 5 days, then 20 mg PO daily until completion of therapy.

IV, intravenously; PO, orally.
*PaO_2 is less than 70 mm Hg or A-a gradient is more than 35 mm Hg.

Table 12-3 Drugs Used for Prophylaxis Against *Pneumocystis carinii* Pneumonia

Drug
Trimethoprim-sulfamethoxazole
1 double-strength tablet each day
1 double-strength tablet 3 times per week
1 single-strength tablet daily
Dapsone 100 mg PO daily
Aerosolized pentamidine 300 mg inhaled monthly via nebulizer
Dapsone 50 mg PO daily + pyrimethamine* 50 mg PO three times a week
Dapsone 200 mg PO weekly + pyrimethamine* 75 mg PO weekly
Atovaquone 1,500 mg PO daily

PO, orally.
*Plus leucovorin (folinic acid) 25 mg PO weekly.

has the additional benefit of potential protection against other infectious agents (*Nocardia*, *Toxoplasma gondii*, *Staphylococcus aureus*, *Streptococcus pneumoniae*, *Haemophilus influenzae*, *Listeria monocytogenes*, *Isospora belli*) and prevention of extrapulmonary pneumocystosis. Secondary prophylaxis should be discontinued if patients have sustained a CD4 count of more than 200 cells/μL for at least 3 months as a result of antiretroviral therapy. Prophylaxis should be reintroduced if the CD4 count declines to less than 200 cells/μL or if PCP recurs at a CD4 count of more than 200 cells/μL.

- Typical clinical scenario: A 50-year-old patient with known HIV presents with shortness of breath and a 2-week history of fever and night sweats. Chest radiography shows bilateral pulmonary infiltrates. Arterial blood gas study reveals a room air P_{O_2} of 60 mm Hg. The A-a gradient is increased.
- PCP prophylaxis is indicated with a CD4 count <200 cells/ μL, CD4 percentage less than 15%, oral thrush, recurrent bacterial pneumonia, high HIV-1 RNA level, unintentional weight loss, and previous episodes of PCP.

Tuberculosis

The resurgence of tuberculosis in the United States is not entirely explained by the HIV epidemic. Factors such as socioeconomic conditions, immigration, breakdown of the public health infrastructure, and lack of interest of the medical and scientific community in tuberculosis all play a role. In addition to the impact of HIV on the incidence of tuberculosis, there are other important interactions between HIV infection and *Mycobacterium tuberculosis*: tuberculosis may accelerate the course of HIV infection; unlike many of the opportunistic infections in patients with HIV infection, tuberculosis can be cured if diagnosed promptly and treated appropriately; and tuberculosis can be prevented. Tuberculosis occurs among HIV-infected persons at all CD4 counts. However, its clinical manifestation may differ depending on the degree of immunosuppression. When tuberculosis occurs later in the course of HIV infection, it tends to have atypical features, such as extrapulmonary disease, disseminated disease, and unusual chest radiographic appearance (lower lung zone lesions, intrathoracic adenopathy, diffuse infiltrations, and lower frequency of cavitation). When tuberculosis occurs early in the course of HIV infection (CD4 count >350 cells/μL), it tends to manifest with the classic presentation of upper lobe fibronodular infiltrates with cavitation. Outbreaks of multiple drug-resistant tuberculosis have been reported. Patients may have a fulminant course with high mortality (>70%) and a rapid course to death in 2 to 3 months.

- Tuberculosis can occur at all CD4 counts in HIV infection.
- Tuberculosis that occurs late in HIV infection tends to have atypical features.

The diagnosis of tuberculosis requires evaluation with a chest radiograph, sputum samples for acid-fast bacillus smear and culture, and aspiration or tissue biopsy if extrapulmonary disease is suspected. Mycobacterial blood cultures are useful in cases of disseminated disease. In patients with relatively intact immune function, the yield of sputum smear and culture is similar to that in HIV-negative patients.

The management of HIV-infected patients taking antiretroviral agents and undergoing treatment for active tuberculosis is complex. Treatment of tuberculosis in the setting of HIV should follow the general principles that apply to the treatment of non–HIV-infected patients; however, several issues require additional consideration. Protease inhibitors and nonnucleoside analogue reverse transcriptase inhibitors (NNRTIs) have substantive interactions with the rifamycins (rifampin, rifabutin, and rifapentine) used to treat mycobacterial infections. Protease inhibitors and NNRTIs not only are substrates for but also may inhibit or induce the cytochrome P-450 system. Rifamycins, however, induce cytochrome P-450 and may substantially decrease blood levels of the antiretroviral drugs. Compared with rifampin, rifabutin has substantially less activity as an inducer of cytochrome P-450, and when used in appropriately modified doses it might not be associated with a clinically significant

reduction of protease inhibitors or NNRTIs. Thus, the substitution of rifabutin for rifampin in treatment regimens for tuberculosis has been proposed as a practical choice for patients who are also undergoing therapy with protease inhibitors or with NNRTIs. A 6-month course may still be used for the treatment of tuberculosis that is susceptible to all first-line antituberculosis drugs. However, there is an increased risk for acquired rifamycin resistance that has led to specific recommendations about dosing schedules. Clinicians should also consider the factors that increase a person's risk for a poor clinical outcome (e.g., lack of adherence to tuberculosis therapy, delayed conversion of *M. tuberculosis* sputum cultures from positive to negative, and delayed clinical response) when deciding the total duration of tuberculosis therapy. Directly observed therapy should be strongly considered in all cases. Patients who have successfully completed a regimen of treatment for tuberculosis do not require secondary prophylaxis or chronic maintenance therapy. Patients with multiple drug-resistant tuberculosis are at high risk for relapse and treatment failure. Optimal regimens for these patients are unknown.

- Antituberculosis drugs interact with anti-HIV drugs.
- A 6-month course of treatment may be used for tuberculosis that is susceptible to all first-line antituberculosis drugs.
- Optimal regimens for multiple drug-resistant tuberculosis are unknown.

Recently, paradoxical reactions have been reported with the concurrent administration of antiretroviral and antituberculosis therapy. These reactions are attributed to recovery of the patient's delayed hypersensitivity response and include hectic fevers, lymphadenopathy, worsening of chest radiographic manifestations of tuberculosis (e.g., miliary infiltrates, pleural effusions), and worsening of original tuberculous lesions (expanding central nervous system lesions). Changes in antituberculosis or antiretroviral therapy are rarely needed. If the symptoms are severe, a short course of steroids to suppress the enhanced immune response can be attempted while continuing with antituberculous and antiretroviral therapy.

HIV-positive patients who have skin reactions of more than 5 mm after administration of 5 tuberculin units of purified protein derivative and who do not have active tuberculosis are considered to have latent tuberculosis infection. Drug regimens recommended for treatment of latent tuberculosis infection are listed in Table 12-4. The use of pyrazinamide and rifampin together in a daily or twice-weekly regimen for the treatment of latent tuberculosis infection is no longer recommended because of high rates of hospitalization and death from liver injury associated with their use.

- Treatment of latent tuberculosis infection is recommended for all patients who are HIV-positive and have skin reactions of more than 5 mm to 5 tuberculin units of purified protein derivative and who do not have active tuberculosis.

Mycobacterium avium Complex Infection

Organisms of the *Mycobacterium avium* complex are ubiquitous in the environment and include *M. avium* and *M. intracellulare*. They cause disseminated infection in HIV-infected persons, especially when immunosuppression is severe (CD4 count <50 cells/μL). Disseminated *M. avium* complex infection is the most common systemic bacterial infection in patients with HIV infection. Common presentations include low-grade fever, night sweats, weight loss, fatigue, abdominal pain, and diarrhea. Hepatomegaly, splenomegaly, and lymphadenopathy may be present. Common laboratory abnormalities include anemia and increased alkaline phosphatase levels. Blood cultures are usually positive; however, organisms can also be isolated from stool, respiratory tract secretions, bone marrow, liver, and other biopsy specimens.

- *Mycobacterium avium* complex causes infection when immunosuppression is severe (CD4 count <50 cells/μL).
- *M. avium* complex is the most common systemic bacterial infection in HIV-infected patients.

The organisms of *M. avium* complex are resistant to conventional antimycobacterial agents. The current recommended treatment regimen includes one of the newer macrolides (clarithromycin, azithromycin), ethambutol, and one or two additional drugs with activity against *M. avium* complex. These include rifabutin, ciprofloxacin, amikacin, rifampin, and clofazimine. Rifabutin is thought to be the best option for a third agent and in randomized clinical trials has been shown to improve survival and to reduce the emergence of drug resistance. Similar to the paradoxical reactions with tuberculosis, an immune reconstitution and inflammatory syndrome of focal lymphadenitis and fever but without bacteremia has been noted. Treatment for *M. avium* complex can be discontinued in patients who have completed more than 12 months of treatment, are asymptomatic, and have a sustained increase in their CD4 counts more than 100 cells/μL for at least 6 months after antiretroviral therapy. However, therapy will need to be resumed if CD4 counts decrease to less than 100 cells/μL.

- *Mycobacterium avium* complex is resistant to conventional antimycobacterial drugs.

For patients with AIDS whose CD4 count is less than 50 cells/μL, prophylaxis with clarithromycin 500 mg twice daily or azithromycin 1,200 mg weekly is recommended. Rifabutin 300 mg daily is an alternative if these are not tolerated. The detection of *M. avium* complex organisms in the respiratory or gastrointestinal tract when a blood culture is negative is not, in itself, an indication for prophylaxis. Primary prophylaxis may be discontinued in patients with CD4

Table 12-4 Preferred Regimens for the Treatment of Latent Tuberculosis Infection

Isoniazid 300 mg PO daily + pyridoxine 50 mg PO daily for 9 mo
Isoniazid 900 mg twice weekly + pyridoxine 50 mg PO twice weekly for 9 mo
Rifampin 600 mg PO daily for 4 mo

PO, orally.

counts of more than 100 cells/μL and a sustained suppression of HIV plasma RNA for more than 3 to 6 months.

- Prophylaxis for *Mycobacterium avium* complex is indicated for patients with AIDS whose CD4 count is less than 50 cells/μL.

Cryptococcus neoformans Disease

Cryptococcus neoformans is a round or oval yeast that is acquired from the environment. It is inhaled into the lungs, where it usually causes asymptomatic infection, but it has a strong propensity for dissemination to the central nervous system. Other potential sites for dissemination include skin, bone, and the genitourinary tract. The most common manifestation of *C. neoformans* disease is cryptococcal meningitis, which usually occurs when the CD4 count is less than 50 cells/μL. The onset is insidious, symptoms are nonspecific (fever, headache, malaise), and symptoms may have a waxing and waning course. Classic meningeal symptoms (e.g., neck stiffness or photophobia) are present in only one-fourth to one-third of patients. Brain imaging findings are also nonspecific; cerebral atrophy and ventricular enlargement are the most common findings. Cerebrospinal fluid findings may be minimal or include an increased opening pressure, mild mononuclear pleocytosis, and increased protein value. Glucose levels may be normal or slightly low. The India ink preparation is positive in more than 70% of cases. The serum and cerebrospinal fluid cryptococcal antigen test has a sensitivity of 93% to 99%. Cultures of cerebrospinal fluid are usually positive. In up to 75% of patients, results of blood cultures are positive for *C. neoformans*. Adverse prognostic factors include altered mental status on presentation and high fungal burden (positive result of India ink test, high antigen titers, and extraneural disease).

- *Cryptococcus neoformans* has a strong propensity for dissemination to the central nervous system.
- The most common manifestation of *C. neoformans* disease is cryptococcal meningitis.
- The India ink preparation is positive in more than 70% of cases.

Initial therapy should include amphotericin B with flucytosine for 2 weeks, followed by fluconazole 400 mg daily for a total of 10 weeks. This initial therapy is followed by fluconazole (200 mg daily) for chronic suppression or maintenance therapy. Chronic suppression or maintenance therapy can be discontinued if patients remain asymptomatic and have a sustained increase in their CD4 counts more than 100 to 200 cells/μL for at least 6 months after antiretroviral therapy. However, chronic suppression or maintenance therapy needs to be reinitiated if the CD4 counts decrease to less than 100 to 200 cells/μL. Although fluconazole and itraconazole can reduce the frequency of cryptococcal disease, routine primary prophylaxis is not recommended for several reasons. These include cost, the relative infrequency of cryptococcosis, the possibility of drug interactions, and the potential for development of drug resistance.

- Typical clinical scenario: A patient with known HIV and a CD4 count of 20 cells/μL presents with fever and headache. Computed tomography of the head shows mild cerebral atrophy but no specific lesions. Cerebrospinal fluid examination shows increased cerebrospinal fluid pressure, mild lymphocytosis, and increased protein concentration.
- Initial therapy for *Cryptococcus neoformans* infection in HIV includes amphotericin B with flucytosine followed by fluconazole.
- Routine primary prophylaxis for *C. neoformans* disease is not recommended.

Cytomegalovirus

Cytomegalovirus disease usually affects persons with advanced HIV disease (CD4 count <50 cells/μL). Other risk factors include previous opportunistic infections and high plasma HIV-1 RNA level (>100,000 copies/mL). Chorioretinitis is the most common clinical manifestation of cytomegalovirus disease. The usual symptoms are floaters, visual field deficits, and painless loss of vision. Funduscopic examination reveals yellowish white retinal infiltrates with or without intraretinal hemorrhage. Cytomegalovirus gastrointestinal disease most commonly involves the esophagus and colon and manifests with dysphagia, abdominal pain, and bloody diarrhea. Cytomegalovirus also can cause hepatitis, pneumonitis, sclerosing cholangitis, encephalitis, adrenalitis, polyradiculopathy, and myelopathy. Agents used for the treatment of cytomegalovirus disease and their general characteristics are listed in Table 12-5. After an induction course of therapy for 2 to 3 weeks or until clinical stability, maintenance therapy is continued with a reduced dose to prevent relapse. For gastrointestinal disease, maintenance therapy can be deferred until relapse is actually demonstrated. Relapses are generally treated with reinduction courses using the initial agent. If this fails or if the progression is rapid, treatment with an alternative agent or combination regimens (e.g., ganciclovir plus foscarnet) should be considered.

Immune recovery uveitis, characterized by inflammation in the anterior chamber or vitreous, occurs in patients who experience a substantial increase in the CD4 count in the 4 to 12 weeks after antiretroviral therapy. Prophylaxis could be considered for cytomegalovirus-seropositive HIV-infected patients with a CD4 count of less than 50 cells/μL. However, treatment-induced toxicities such as neutropenia, anemia, conflicting reports of efficacy, lack of proven survival benefit, and cost have precluded its routine use. Chronic maintenance therapy can be discontinued if patients remain asymptomatic and have a sustained increase in their CD4 counts to more than 100 to 150 cells/μL for at least 6 months after antiretroviral therapy. All patients whose maintenance therapy is discontinued should undergo regular ophthalmologic monitoring for detection of relapse and immune recovery uveitis. Chronic maintenance therapy will need to be reinitiated if there is ophthalmologic evidence of relapse or the CD4 counts decrease to less than 50 to 100 cells/μL.

- Typical clinical scenario: A patient with known advanced HIV disease presents with painless loss of vision in both eyes. Fundal examination reveals yellowish white granules, exudates, and hemorrhages. Therapy with ganciclovir or other effective cytomegalovirus agents should be initiated promptly.
- Cytomegalovirus disease usually affects persons with advanced HIV disease.

Table 12-5 Induction Treatment of Cytomegalovirus Retinitis

Drug	Dosage	Major adverse effect
Ganciclovir intraocular-release device (Vitrasert)*	Every 6 mo	Retinal detachment
Ganciclovir IV	5 mg/kg twice daily	Bone marrow suppression
Valganciclovir	900 mg PO twice daily	Bone marrow suppression
Foscarnet IV	60 mg/kg three times daily or 90 mg/kg twice daily	Renal toxicity
Cidofovir IV†	5 mg/kg weekly for 2 weeks, followed by 5 mg/kg every 2 weeks	Renal toxicity
Ganciclovir intravitreal injection*	2,000 μg in 0.05-0.1 mL	Bone marrow suppression
Foscarnet intravitreal injection*	1.2-2.4 mg in 0.1 mL	Renal toxicity

IV, intravenously; PO, orally.
*Local anti-cytomegalovirus therapy should be accompanied by systemic therapy, such as oral ganciclovir, to avoid the risk of development of extraocular diseases.
†Vigorous hydration and coadministration of probenecid are required to limit renal toxicity.

- In HIV, cytomegalovirus can cause chorioretinitis, gastrointestinal disease, hepatitis, and other organ involvement.
- Maintenance therapy is indicated after treatment of initial cytomegalovirus infection.

Syphilis

Sexually transmitted diseases, including syphilis, that cause genital ulceration may be cofactors for acquiring HIV infection. In general, the clinical manifestations of syphilis are similar to those among non–HIV-infected persons. However, atypical presentations may occur. For example, in primary syphilis, multiple or atypical chancres can occur and primary lesions might be absent or missed. The manifestations of secondary syphilis are protean and might persist from a few days to several weeks before resolving or evolving to latent or later stages. The most common manifestations are macular, maculopapular, or pustular skin lesions characteristically involving the palms and soles and accompanied by generalized lymphadenopathy and constitutional symptoms of fever, malaise, anorexia, arthralgias, and headache. Manifestations of tertiary or late syphilis include neurosyphilis, cardiovascular syphilis, and gummatous syphilis. Neurosyphilis has been reported to occur earlier and more frequently and to progress more rapidly in patients with AIDS than in HIV-negative patients. Concomitant uveitis and meningitis also may be more common among HIV-1–infected patients with syphilis. There are reports of false-negative and false-positive serologic tests for syphilis in patients with HIV. However, serologic response to infection in general seems to be the same in HIV-positive and HIV-negative persons and there are no specific clinical manifestations of syphilis that are unique to HIV. Management of HIV-1–infected patients with syphilis is similar to the management of non–HIV-infected persons. However, HIV-infected patients require the following additional attention:

Closer follow-up to detect potential treatment failures or disease progression

Evaluation for clinical evidence of central nervous system or ocular involvement

Penicillin-based regimens, whenever possible, for all stages of syphilis in HIV-infected persons

- In general, syphilis presents similarly in patients with AIDS and in HIV-negative patients.
- Syphilis can facilitate transmission of HIV.

Toxoplasmosis

Toxoplasma gondii, a protozoan, is the most common cause of focal central nervous system lesions in patients with AIDS. The most common symptoms of *Toxoplasma* encephalitis include headache and confusion; fever may be absent. Focal neurologic deficits occur in 69% of cases. The median CD4 count at diagnosis is 50 cells/μL. Multiple ring-enhancing lesions with associated edema are usually noted on brain imaging studies. Magnetic resonance imaging is more sensitive than computed tomography for identifying lesions. The differential diagnosis of central nervous system mass lesions in patients with AIDS includes toxoplasmosis, lymphoma, and bacterial brain abscesses and infections caused by *C. neoformans*, *Coccidioides immitis*, *M. tuberculosis*, and *Nocardia asteroides*, among others.

- *Toxoplasma gondii* is the most common cause of focal central nervous system lesions in patients with AIDS.
- Multiple ring-enhancing lesions usually are noted on brain imaging studies.

Empiric antitoxoplasmosis therapy is indicated in patients with AIDS and positive *Toxoplasma* serologic testing who present with multiple intracranial lesions. The absence of antitoxoplasma IgG antibody makes a diagnosis of toxoplasmosis unlikely. The presence of only a single lesion on magnetic resonance imaging requires a more definitive diagnosis of toxoplasma encephalitis. Effective treatment should result not only in amelioration of symptoms but also in a reduction of the number, size, and contrast enhancement of the brain lesions. If the patient is seronegative for *Toxoplasma*, has a single mass lesion on both computed tomography and magnetic resonance

imaging, or did not achieve the desired response after an empiric course of antitoxoplasmosis therapy for 10 to 14 days, the presumptive diagnosis of *Toxoplasma* encephalitis becomes doubtful and a diagnostic brain biopsy is indicated.

Drugs used for the treatment of HIV-associated toxoplasmosis are listed in Table 12-6. The initial regimen of choice is the combination of pyrimethamine plus sulfadiazine plus leucovorin. The preferred alternative regimen for patients unable to tolerate or who fail to respond to first-line therapy is pyrimethamine plus clindamycin plus leucovorin. Acute therapy should be continued for at least 6 weeks if there is clinical and radiologic improvement. Lifelong suppressive therapy (secondary prophylaxis), with the same agents used for acute therapy but at a reduced dose, is necessary to prevent relapse. Secondary prophylaxis can be discontinued in patients who successfully complete initial therapy, remain asymptomatic with respect to signs and symptoms of toxoplasmosis, and have a sustained (i.e., >6 months) increase in their CD4 counts to more than 200 cells/μL with antiretroviral therapy. Secondary prophylaxis should be started again if the CD4 count decreases to less than 200 cells/μL. All HIV-infected persons with a CD4 count of less than 100 cells/μL who are seropositive for *Toxoplasma* should receive primary prophylaxis against *Toxoplasma* encephalitis. The agent of choice for this is trimethoprim-sulfamethoxazole (1 double-strength tablet daily); dapsone plus pyrimethamine is an alternative regimen. Atovaquone with or without pyrimethamine also may be considered.

- Lifelong suppressive therapy is needed to prevent relapse of HIV-associated toxoplasmosis.
- The agent of choice for primary prophylaxis against *Toxoplasma* encephalitis is trimethoprim-sulfamethoxazole.

HIV-infected patients should be tested for IgG antibody to *Toxoplasma* as part of their initial work-up; if the result is negative, they should be counseled about the various potential sources of *Toxoplasma* infection, such as raw or undercooked meat and handling of cat litter.

- Typical clinical scenario: A patient with known HIV disease presents with headache and confusion. There is evidence of upper and lower extremity weakness. Computed tomography shows multiple ring-enhancing lesions on brain imaging studies.

Table 12-6 Drugs Used for the Treatment of HIV-Associated Toxoplasmosis

Drug
Preferred regimens
Pyrimethamine* 200 mg PO loading dose followed by 50-75 mg PO daily + sulfadiazine 1,000-1,500 mg PO every 6 h
Pyrimethamine* 200 mg PO loading dose followed by 50-75 mg PO daily + clindamycin 600 mg IV or PO every 6 h
Alternative regimens
Trimethoprim-sulfamethoxazole IV or PO 5 mg/kg trimethoprim + 25 mg/kg sulfamethoxazole every 12 h
Pyrimethamine* 200 mg PO loading dose followed by 50-75 mg PO daily + clarithromycin 500 mg PO every 12 h
Pyrimethamine* 200 mg PO loading dose followed by 50-75 mg PO daily + azithromycin 900-1,200 mg PO daily
Atovaquone 1,500 mg PO twice daily + sulfadiazine 1,000-1,500 mg PO every 6 h
Pyrimethamine* 200 mg PO loading dose followed by 75 mg PO daily + atovaquone 1,500 mg PO twice daily

IV, intravenously; PO, oral, orally.
*With folinic acid 10 to 20 mg daily.

Progressive Multifocal Leukoencephalopathy

This is a demyelinating disease caused by the JC virus, a polyoma virus. Symptoms and signs are variable and consist of focal neurologic deficits without altered sensorium or a systemic toxic state. These symptoms include cognitive dysfunction, dementia, seizures, ataxia, aphasia, cranial nerve deficits, and hemiparesis or quadriparesis. Fever is usually absent. Symptoms evolve rapidly over weeks to months. Diagnosis is based on clinical findings and magnetic resonance imaging, which shows characteristic white matter changes (bright areas on T2-weighted images) without contrast enhancement or mass effect. Routine cerebrospinal fluid studies are generally nondiagnostic, but identification of JC virus DNA in the cerebrospinal fluid by polymerase chain reaction may confirm the diagnosis. Prognosis is poor, and there is no proven effective treatment. Neurologic improvement has been reported in some patients after the initiation of antiretroviral therapy.

- Progressive multifocal leukoencephalopathy is caused by the JC virus.
- The diagnosis is based on clinical findings and on white matter changes on magnetic resonance imaging.
- There is no proven effective therapy.

Mucocutaneous Candidiasis

Mucocutaneous disease, such as oral thrush, recurrent vaginitis, and candidal esophagitis, is common. The majority of infection is caused by *Candida albicans*. Candidal esophagitis is an AIDS-defining condition. Systemic candidal infection, including candidemia, is rare unless additional risk factors for disseminated fungal infection such as severe neutropenia and indwelling catheters are involved. Oropharyngeal candidiasis commonly presents with painless, creamy-white, plaquelike lesions of the buccal or oropharyngeal mucosa or tongue surface which can easily be scraped off with a tongue depressor. Less commonly, erythematous patches without white plaques or angular cheilosis can be noted. Esophageal candidiasis presents with retrosternal burning pain or discomfort and odynophagia. Endoscopic examination shows whitish plaques. Vulvovaginitis is characterized by a creamy to yellow-white adherent vaginal discharge associated with mucosal burning and itching.

For mucocutaneous disease, initial treatment with clotrimazole troches or nystatin may be adequate. Fluconazole or itraconazole is used for the treatment of candidal esophagitis and topical treatment failures. Amphotericin B can be used for azole failures.

Diagnosis of oropharyngeal candidiasis is usually clinical and is based on the appearance of lesions. Visualization of the organisms by microscopic examination of scrapings provides supportive diagnostic information.

The diagnosis of esophageal candidiasis is usually made presumptively on clinical grounds, but confirmation requires endoscopic visualization of lesions with histopathologic demonstration of the yeast forms in tissue. The diagnosis of vulvovaginal candidiasis is also based on the clinical presentation. Demonstration of the yeast forms in vaginal secretions microscopically supports the diagnosis.

Initial episodes of oropharyngeal candidiasis can be adequately treated topically, including clotrimazole troches or nystatin suspension or pastilles. However, oral fluconazole is as effective, more convenient, and generally better tolerated. Systemic therapy with a 14- to 21-day course of either fluconazole or itraconazole solution is required for effective treatment of esophageal candidiasis. Uncomplicated vulvovaginal candidiasis is effectively treated with short courses and responds readily to topical (clotrimazole, butaconazole, miconazole, ticonazole, terconazole, nystatin) or systemic (itraconazole oral solution, fluconazole) antifungals. Patients who have a history of one or more episodes of documented esophageal candidiasis should be considered candidates for secondary prophylaxis with fluconazole 100 to 200 mg daily.

Enteric Disease

Initial evaluation of patients with AIDS who have abdominal pain, diarrhea, and weight loss should include stool cultures for bacteria, three separate stool specimens for ova and parasites, and specific examination for cryptosporidiosis, isosporiasis, microsporidiosis, and *Cyclospora*, as indicated. *Cytomegalovirus* or *M. avium-intracellulare* should be considered in the differential diagnosis, particularly in patients with advanced HIV infection. If no diagnosis is made, upper and lower gastrointestinal endoscopy and biopsy may yield pathogens that are treatable. The most common causes of bacterial diarrhea among patients with HIV-1 infection in the United States are *Salmonella*, *Campylobacter*, and *Shigella* species.

Salmonella *Infection*

In contrast to immunocompetent persons, HIV-infected persons are more likely to have *Salmonella* infection that is severe, invasive, and widespread. Bacteremia is common and constitutes an AIDS-defining diagnosis. The incidence of salmonellosis is 20- to 100-fold higher in HIV-infected persons than that in the general population. The source for *Salmonella* infection is ingestion of contaminated food, particularly undercooked poultry. Salmonellosis can present in three ways in HIV infection: a self-limited gastroenteritis; a more severe and prolonged diarrheal disease associated with fever, bloody diarrhea, and weight loss; and septicemia, with or without gastrointestinal symptoms. In the United States, the majority of cases of *Salmonella* septicemia are caused by nontyphoidal strains, in particular *S. enteritidis* and *S. typhimurium*. Bacteremia can occur with each of these syndromes and has a propensity for relapse.

Ciprofloxacin is the preferred agent for treatment. The treatment duration for mild gastroenteritis without bacteremia is 10 to 14 days. However, for patients with advanced HIV-1 disease (CD4 count <200 cells/μL) or for those who have *Salmonella* bacteremia treatment for at least 4 to 6 weeks is recommended. Alternatives to the fluoroquinolone antibiotics include trimethoprim-sulfamethoxazole or third-generation cephalosporins (e.g., ceftriaxone or cefotaxime).

- HIV-infected persons are more likely to have *Salmonella* infection that is severe, invasive, and widespread.
- Ciprofloxacin is the preferred antibiotic for the treatment of salmonella infection.

Campylobacter *Infection*

The prevalence of *Campylobacter* infection seems to be higher in HIV-infected individuals. The incidence of *Campylobacter jejuni* is reported to be up to 39 times higher among HIV-1–infected persons, particularly men who have sex with men, than in the general population. Clinically, *Campylobacter* infection presents with a more prolonged diarrhea, invasive disease, bacteremia, and extraintestinal involvement (cellulitis, osteomyelitis, vasculitis, rheumatologic symptoms). In addition to stool and blood cultures, lower endoscopy for biopsy and histopathologic examination occasionally are required. For mild-to-moderate disease, a fluoroquinolone (ciprofloxacin) or a macrolide (azithromycin) for 7 days may be adequate, but patients with bacteremia should be treated for at least 2 weeks. A second active agent (e.g., an aminoglycoside) might be required.

Shigellosis

Similar to *Campylobacter* and *Salmonella* infection, the risk for development of shigellosis is increased in persons with HIV-1 infection. In this setting, shigellosis presents as an acute, febrile, diarrheal illness with prominent upper and lower gastrointestinal symptoms. Bloody diarrhea and bacteremia also may be present. Relapses in gastroenteritis and bacteremia after appropriate treatment also have been reported. The recommended treatment is with a fluoroquinolone for 3 to 7 days. Alternatives to fluoroquinolones include trimethoprim-sulfamethoxazole or azithromycin. Treatment of bacteremia may require extension of treatment to 14 days or more.

Cryptosporidiosis

Cryptosporidium parvum is a protozoal organism that causes massive, watery diarrhea, crampy abdominal pain, anorexia, flatulence, and malaise. Fever and bloody diarrhea are uncommon, but malabsorption and dehydration are common. Cryptosporidiosis is diagnosed by identification of *C. parvum* oocysts in fecal samples or biopsy specimens. The specimens are stained with either a modified acid-fast procedure or a fluorescent assay (immunofluorescent assay or enzyme immunoassay) that uses monoclonal antibodies to *Cryptosporidium* antigens. Biliary tract involvement may occur with cryptosporidiosis. If the CD4 count is more than 180 cells/μL, cryptosporidium infection is usually self-limited (<4 weeks); if it is less than 140 cells/μL, persistent disease develops in 80% to 90%. In adults, there are no proven regimens for the treatment of cryptosporidiosis, but paromomycin, a nonabsorbable aminoglycoside used for the treatment of *Entamoeba histolytica*, has been effective in some patients.

Recently, a new drug, nitazoxanide, was approved by the U.S. Food and Drug Administration for the treatment of diarrhea caused by *C. parvum* and *Giardia lamblia* in pediatric patients 1 to 11 years of age.

- *Cryptosporidium parvum* causes massive, watery diarrhea, crampy abdominal pain, anorexia, flatulence, and malaise.
- Cryptosporidiosis is diagnosed by identification of *C. parvum* oocysts in fecal samples or biopsy specimens.
- Paromomycin has been effective in some patients.

Isosporiasis

Isospora belli causes illness similar to that caused by *C. parvum*: profuse diarrhea without blood but accompanied by abdominal pain and malabsorption. Systemic symptoms, including fever, headache, and weight loss, also may be present. Isosporiasis is endemic in developing countries. The organism is identified with a modified acid-fast stain on fecal or biopsy specimens. Trimethoprim-sulfamethoxazole DS (160 mg of trimethoprim and 800 mg of sulfamethoxazole) four times daily for 10 days is effective for the treatment of *I. belli* infections, but lifelong suppressive therapy may be required. Antiretroviral therapy has been associated with more rapid resolution of symptoms and fewer relapses.

- Isosporiasis: profuse diarrhea without blood but accompanied by abdominal pain and malabsorption.
- Trimethoprim-sulfamethoxazole DS is effective treatment for isosporiasis.

Microsporidiosis

Two species of *Microsporidia*, *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis*, cause enteric and biliary disease in patients with AIDS. Infection with these organisms resembles infection with *C. parvum*, with perhaps less voluminous diarrhea. Extraintestinal manifestations include keratoconjunctivitis, disseminated disease, hepatitis, myositis, sinusitis, kidney and urogenital infection, ascites, and cholangitis. Gastrointestinal microsporidiosis is diagnosed by examination of stool specimens with light microscopy using selective stains that help differentiate the spores of the *Microsporidia* and the cells and debris in clinical samples. Ultrastructural examination with electron microscopy may be required for definitive diagnosis. The antiprotozoal agent albendazole has shown promise in the treatment of disease caused by *E. intestinalis*. Another drug, fumagillin, has been reported to be effective for the treatment of intestinal microsporidiosis due to *E. bieneusi* in patients with HIV infection.

- *Microsporidia* species cause enteric and biliary disease in patients with AIDS.
- Electron microscopy of biopsy specimens and special stains are required for diagnosis.

Cyclospora *Infection*

Cyclospora cayetanensis organisms are protozoal and cause gastrointestinal disease similar to cryptosporidiosis. Symptoms include watery diarrhea, fatigue, anorexia, myalgia, abdominal cramps, flatus, and nausea. Dehydration and weight loss are common. Biliary tract involvement is possible. In patients with AIDS, illness tends to be more severe and prolonged. Standard ova and parasite testing cannot detect the organisms; special staining techniques or electron microscopy may be required for diagnosis. Trimethoprim-sulfamethoxazole is effective for the treatment of *Cyclospora*. For patients with HIV infection, because relapse is common, the recommendation is four times daily dosing for 10 days followed by chronic suppression three times per week. Ciprofloxacin is an acceptable alternative for patients with sulfonamide allergy or intolerance.

- Symptoms of *Cyclospora* infection: watery diarrhea, fatigue, anorexia, myalgia, abdominal cramps, flatus, nausea, dehydration, and weight loss.
- Special staining or electron microscopy may be required for diagnosis.
- Trimethoprim-sulfamethoxazole is effective treatment.

Bacillary Angiomatosis

Bacillary angiomatosis was first described in 1983, and the causative organisms, *Bartonella quintana* and *Bartonella henselae*, were isolated for the first time in 1992. Bacillary angiomatosis is characterized by vascular proliferative lesions that can involve any organ in the body. The most commonly involved site is the skin, where it may present as nodules or plaques that are sometimes difficult to differentiate from those of Kaposi sarcoma. Other sites include bone, lymph nodes, brain, respiratory tract, and gastrointestinal tract. Characteristic fluid-filled spaces occasionally are noted in the liver and spleen and are called peliosis hepatis or peliosis splenis. Diagnosis is established by biopsy, demonstration of the organism on Warthin-Starry stain, and cultivation of the causative organisms. Results of blood culture (lysis centrifugation technique) also may be positive if incubation is prolonged. Treatment is with erythromycin or doxycycline. Clarithromycin or azithromycin are considered second-line alternatives. The duration of treatment is at least 3 months.

- Bacillary angiomatosis is characterized by vascular proliferative lesions in skin and other organs.
- The differential diagnosis includes Kaposi sarcoma.
- The diagnosis is based on positive results of Warthin-Starry stain and cultivation of the causative organism.
- Treatment is with erythromycin or doxycycline.

AIDS-Associated Malignancies

Kaposi Sarcoma

Kaposi sarcoma is a tumor of uncertain origin; vascular proliferation is its most prominent feature. It is the most common neoplasm affecting HIV-infected persons. It is most common in the homosexual and bisexual population with AIDS. Herpes-like DNA sequences have been identified in AIDS-associated Kaposi sarcoma. These are thought to represent a new human herpesvirus, now designated human herpesvirus 8 (HHV-8). Seroepidemiologic studies have made a strong association between HHV-8 and Kaposi sarcoma. In addition, HHV-8 was found to be associated with all forms of Kaposi sarcoma, and its seroconversion precedes the appearance

of Kaposi sarcoma in HIV-infected persons. However, routine screening for HHV-8 with polymerase chain reaction or serologic testing is not indicated for HIV-1–infected persons. Clinical manifestations include nodules, plaques, lymph node enlargement, and signs and symptoms of visceral involvement. Skin, lung, and the gastrointestinal tract are the commonly affected organs. Lung involvement may mimic infection. Treatment options include local therapy (radiotherapy, intralesional chemotherapy, cryotherapy) and systemic therapy (chemotherapy, interferon-alfa). Liposome-encapsulated anthracycline chemotherapeutic agents recently have become available, potentially enabling delivery of higher doses of effective drug with fewer toxic side effects. Antiretroviral therapy also has resulted in a reduction in the frequency of occurrence of Kaposi sarcoma and a reduction in tumor burden and disease progression. Antiviral agents with in vitro activity against HHN-8, ganciclovir, foscarnet, and cidofovir, have been reported to reduce disease progression or lesion regression in limited studies. However, this effect remains to be confirmed in larger studies.

- Kaposi sarcoma is the most common neoplasm in HIV-infected persons.
- It is most common in the homosexual and bisexual population with AIDS.
- Kaposi sarcoma is possibly related to HHV-8 infection.
- Clinical manifestations include nodules, plaques, lymph node enlargement, and signs and symptoms of visceral involvement.

Non-Hodgkin Lymphoma

Non-Hodgkin lymphoma is much more common (as high as 200-fold increased risk) among HIV-infected patients than in the general population. It is a heterogeneous group of malignancies with varying biologic behavior and occurs in individuals with widely ranging levels of immune function. The vast majority of non-Hodgkin lymphomas in patients with HIV are of B-cell origin. Intermediate- or high-grade B-cell non-Hodgkin lymphoma is a Centers for Disease Control and Prevention-defined AIDS diagnosis. As patients with AIDS live longer, this complication will become more frequent. It commonly presents with constitutional symptoms (fever, night sweats, weight loss), lymphadenopathy, and involvement of extranodal sites such as the central nervous system, bone marrow, gastrointestinal tract, and liver. Involvement of the brain can be as an isolated disease (primary central nervous system lymphoma) or as leptomeningeal involvement in the context of spread of lymphoma elsewhere. The optimal treatment of HIV-associated non-Hodgkin lymphoma has not been well defined. Current recommendations suggest that most patients should receive standard-dose chemotherapy with PCP prophylaxis (regardless of CD4 count) and growth factor support. Additionally, highly active antiretroviral therapy should be a component of the strategy.

- The vast majority of non-Hodgkin lymphomas in patients with HIV are of B-cell origin.
- Non-Hodgkin lymphoma in HIV commonly presents with constitutional symptoms (fever, night sweats, weight loss), lymphadenopathy, and involvement of extranodal sites.
- Intermediate- or high-grade B-cell non-Hodgkin lymphoma is an AIDS-defining diagnosis.

Primary Central Nervous System Lymphoma

The incidence of primary central nervous system lymphoma in HIV-infected individuals is 1,000-fold higher than that in the general population. It occurs most often in the advanced stages of AIDS at a median CD4 count of less than 50 cells/μL and is associated with Epstein-Barr virus in almost 100% of cases. The clinical presentation includes headache, confusion, lethargy, personality changes, memory loss, focal neurologic deficits, and seizure. Brain imaging studies show single or multiple contrast-enhancing lesions, often difficult to distinguish from those of toxoplasmosis. Biopsy is required for diagnosis. Whole-brain radiation has been the primary treatment of primary central nervous system lymphoma. Despite good initial radiographic response rates, the survival rate has remained dismal, with median survival times of 2 to 5 months. As has been the case with non-Hodgkin lymphoma, the advent of highly active antiretroviral therapy has rekindled interest in an aggressive approach to patients with primary central nervous system lymphoma. Whether the combination of radiotherapy or chemotherapy with highly active antiretroviral therapy will result in improved treatment outcome remains to be determined. Since the advent of highly active antiretroviral therapy, the incidence of primary central nervous system lymphoma has declined.

- Typical clinical scenario: A patient with known HIV disease and a CD4 count of 30 cells/μL presents with headache and weakness of the right upper and lower extremities. Imaging shows two contrast-enhancing lesions in the left frontoparietal lobe.
- Primary central nervous system lymphoma is associated with Epstein-Barr virus.
- Clinical presentation includes headache, confusion, lethargy, personality changes, memory loss, focal neurologic deficits, and seizure.
- Biopsy is required for diagnosis.

Antiretroviral Agents

The Replication Cycle of HIV

A working knowledge of the HIV replication cycle is essential for understanding the mechanism of action of antiretroviral agents (Fig. 12-2). The human immunodeficiency virus is an enveloped virus that contains two copies of viral genomic RNA and associated transfer RNA molecules in its core. In addition to the copies of RNA, the viral core also contains various Gag and Pol protein products. The first step in the HIV replication cycle is the interaction between the envelope proteins of the virus and specific surface receptors (e.g., CD4 receptor) of the host cell, leading to the binding of the viral envelope and the host cytoplasmic membrane. Recently, additional cell surface proteins, so called co-receptors, that are required for the virus entry into the host cell have been identified. After entry into the cell, the viral reverse transcriptase enzyme catalyzes the conversion of viral RNA into DNA. This viral DNA enters the nucleus and becomes inserted into the

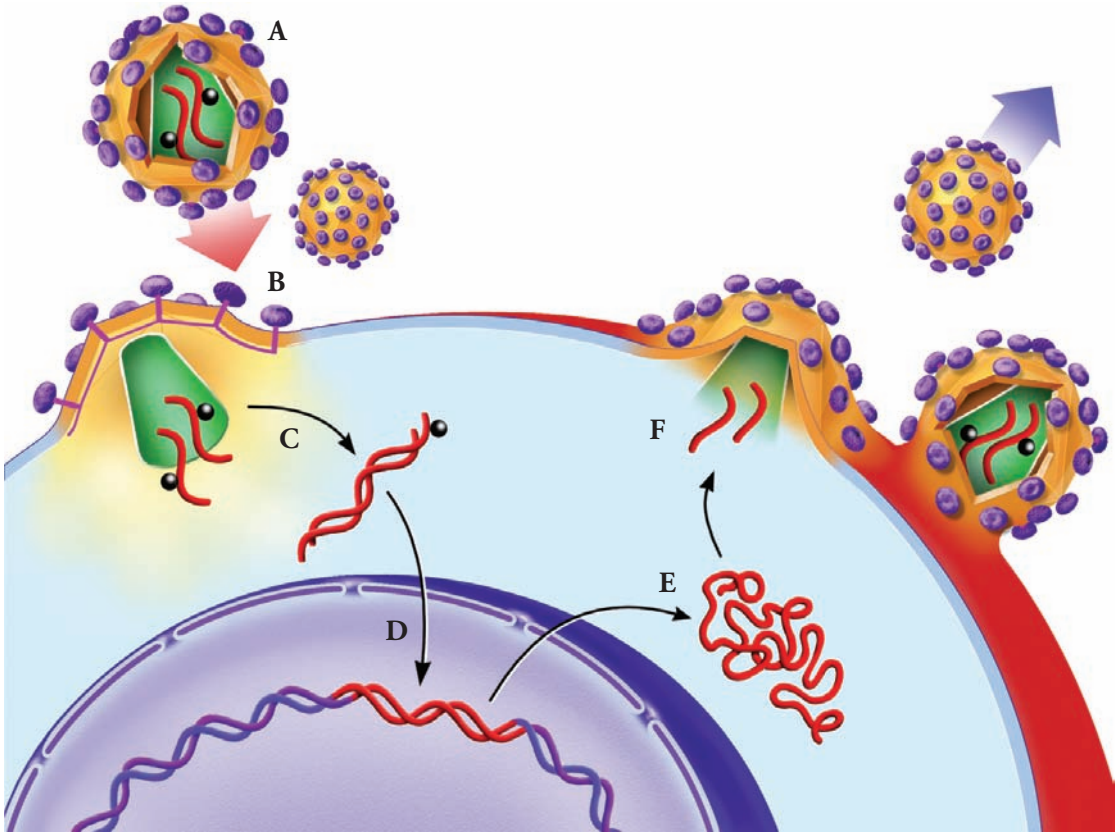

Fig. 12-2. Life cycle of human immunodeficiency virus. *A*, The virus is an enveloped virus that contains viral genomic RNA and various *gag* and *pol* protein products. *B*, The interaction between the envelope proteins of the virus and CD4 receptor and other receptors of the host cell leads to the binding of the viral envelope and the host cytoplasmic membrane. *C*, The viral reverse transcriptase enzyme catalyzes the conversion of viral RNA into DNA. *D*, The viral DNA enters the nucleus and becomes inserted into the chromosomal DNA of the host cell. *E*, Expression of the viral genes leads to production of viral RNA and proteins. *F*, These viral proteins, as well as viral RNA, are assembled at the cell surface into new viral particles and leave the host cell by a process called budding. During the process of budding, they acquire the outer layer and envelope. At this stage, the protease enzyme cleaves the precursor *gag* and *gag-pol* proteins into their mature products.

chromosomal DNA of the host cell (integration). This integrated DNA may remain in an unexpressed form (e.g., in resting lymphocytes) and persist in a latent state for a long period. In acutely infected cells, however, expression of the viral genes leads to production of viral proteins. The precursor Gag and Gag-Pol proteins, as well as viral RNA, are assembled at the cell surface into new viral particles and leave the host cell by a process called budding. During the process of budding, they acquire the outer layer and envelope. At this stage, the protease enzyme cleaves the precursor Gag and Gag-Pol proteins into their mature products. If this final phase of the replication cycle does not take place, the released viral particles are noninfectious and not competent to initiate the replication cycle in other susceptible cells.

The various steps in the HIV replication cycle (e.g., viral entry, integration) are being investigated as potential sites of action for antiretroviral therapy.

Currently, 20 individual antiretroviral drugs and 4 co-formulated products categorized in four classes have been approved by the U.S. Food and Drug Administration for the treatment of HIV. The four classes of antiretroviral drugs are nucleoside/nucleotide analogue reverse transcriptase inhibitors, nonnucleoside analogue reverse transcriptase inhibitors, protease inhibitors, and fusion inhibitors.

Nucleoside/Nucleotide Analogue Reverse Transcriptase Inhibitors

Nucleoside/nucleotide analogue reverse transcriptase inhibitors (NRTIs) were the first agents to be developed as antiretrovirals. These agents are structurally similar to the building blocks of nucleic acids (RNA, DNA) but differ from their natural analogues by the replacement of the hydroxy (–OH) group in the 3′ position by another group that is unable to form the 5′ to 3′ phosphodiester linkage essential for DNA elongation. NRTIs block reverse transcriptase activity by competing with the natural substrates and incorporating into viral DNA to act as chain terminators in the synthesis of proviral DNA. To exert their antiviral activity, NRTIs must first be intracellularly phosphorylated to their active 5′-triphosphate forms by cellular kinases.

- NRTIs are structurally similar to the building blocks of nucleic acids.
- NRTIs block reverse transcriptase activity.

Resistance to NRTIs is associated with mutations in the *pol* gene that codes for the enzyme reverse transcriptase. Specific mutations that confer resistance to individual agents have been identified. High-level zidovudine resistance has been associated with broad cross-resistance to other nucleoside analogues. Other mutations that confer cross-resistance to several agents also have been observed. The M184V mutation, associated with resistance to lamivudine, has a complex effect on other nucleoside analogues. This mutation may confer limited cross-resistance to didanosine and zalcitabine. It also may delay the development of zidovudine resistance and restore zidovudine activity once resistance emerges. This "ZDV resensitization" effect also has been noted with the L74V mutation, selected for by didanosine.

- Resistance to NRTIs is associated with mutations in the *pol* gene that codes for the enzyme reverse transcriptase.

There have been reports of a rare and potentially fatal syndrome consisting of severe hepatomegaly with steatosis and lactic acidosis in the absence of hypoxemia. This syndrome can occur with any of the NRTIs. When recognized, treatment with nucleoside analogues should be suspended.

- A rare and potentially fatal syndrome of severe hepatomegaly with steatosis and lactic acidosis in the absence of hypoxemia has been reported in association with NRTIs.

Hypersensitivity reactions have been reported in approximately 5% of patients receiving abacavir. Symptoms consist of rash accompanied by systemic signs and symptoms such as fever, fatigue, nausea, vomiting, diarrhea, or abdominal pain. These symptoms usually appear within the first 6 weeks of treatment. The rash is usually maculopapular but can be variable in appearance. Hypersensitivity reactions also may occur without a rash. Symptoms usually resolve rapidly when use of the drug is discontinued. Once use of abacavir has been discontinued, it should not be reintroduced. More severe symptoms, including death, have been reported when use of abacavir is reinstituted.

General characteristics of currently available NRTIs are shown in Table 12-7.

Nonnucleoside Analogue Reverse Transcriptase Inhibitors

Nonnucleoside analogue reverse transcriptase inhibitors (NNRTIs) bind directly and noncompetitively to the enzyme reverse transcriptase. Although the drugs differ chemically from each other, they all bind to the same site, a site distinct from the substrate (dNTP) binding site. They block DNA polymerase activity by causing conformational change and disrupting the catalytic site of the enzyme. Unlike nucleoside analogues, NNRTIs do not require phosphorylation to become active and are not incorporated into viral DNA. They also have no activity against HIV-2.

- NNRTIs bind directly and noncompetitively to the enzyme reverse transcriptase.
- NNRTIs block DNA polymerase activity.
- NNRTIs do not require phosphorylation.
- NNRTIs are not active against HIV-2.

When NNRTIs are administered as a single agent or as a part of an inadequately suppressive treatment regimen, resistance emerges rapidly. Mutations conferring resistance to one drug in this class

Table 12-7 General Characteristics of Currently Available Nucleoside Analogue Reverse Transcriptase Inhibitors

	Drug				
Characteristic	Zidovudine	Didanosine	Zalcitabine	Stavudine	Lamivudine
Dose	300 mg twice daily or 200 mg three times daily	200 mg twice daily or 400 mg once daily	0.75 mg three times daily	40 mg twice daily	150 mg twice daily
Bioavailability, %	65	30-40	80	>80	>80
Protein binding, %	24-28	<5	<4	Negligible	<36
CSF penetration, %*	53	20	9-37	40	5.6-30.9
Major adverse effects	Bone marrow suppression	Pancreatitis, peripheral neuropathy	Peripheral neuropathy, oral ulcers	Peripheral neuropathy	Minimal
Food effects	No significant effect†	Take on empty stomach	No significant effect†	No significant effect†	No significant effect†

CSF, cerebrospinal fluid.
*As percentage of concurrent serum levels.
†No significant effect means drug can be taken without regard to food.

generally confer cross-resistance to most other NNRTIs. Cross-resistance to nucleoside analogues or protease inhibitors has not been observed. However, the Y181C mutation, selected for by nevirapine, reverses zidovudine resistance when introduced into isolates that carry the major zidovudine resistance mutations. Nevirapine and efavirenz are inducers of the hepatic cytochrome P-450 system. Delavirdine, however, inhibits P-450. Through this interaction with the P-450 enzyme system, NNRTIs may change the metabolism of and thus lower (nevirapine, efavirenz) or increase (delavirdine) the plasma levels of coadministered drugs that are metabolized by the cytochrome P-450 system. Similarly, drugs that induce or inhibit cytochrome P-450 activity may have an effect on the plasma concentrations of NNRTIs. Malformations of the fetus have been noted in primates and humans exposed to efavirenz. Therefore, efavirenz is contraindicated in pregnant women.

- Mutations conferring resistance to one drug in NNRTIs generally confer cross-resistance to most other NNRTIs.

The general characteristics of the three NNRTIs currently approved for clinical use are listed in Table 12-8.

Protease Inhibitors

Protease inhibitors exert their antiviral effect by inhibiting HIV-1 protease. HIV-1 protease is a complex enzyme composed of two identical halves (i.e., a symmetrical dimer) with an active site located at the base of the cleft. It is responsible for the cleavage of the large viral *gag* and *gag-pol* polypeptide chains into smaller, functional proteins, thus allowing maturation of the HIV virion. This process takes place in the final stages of the HIV life cycle. Inhibition of the protease enzyme results in the release of structurally disorganized and noninfectious viral particles. Protease inhibitors have antiviral activity in both acutely and chronically infected cells. Protease inhibitors are metabolized by the cytochrome P-450 system and are themselves, to varying degrees, inhibitors of this system. This leads to a significant number of interactions with drugs that are inducers, inhibitors, or substrates of this system. General characteristics of currently available protease inhibitors are listed in Table 12-9.

- Protease inhibitors exert their antiviral effect by inhibiting HIV-1 protease.
- Protease inhibitors have antiviral activity in both acutely and chronically infected cells.
- Protease inhibitors have significant interactions with drugs that are metabolized through the P-450 system.

Protease inhibitors have shown potent antiretroviral, immunologic, and clinical benefits in HIV-infected persons, but their long-term efficacy and safety have not been completely elucidated. In fact, new side effects have become manifest with the continued widespread use of these drugs. Metabolic complications of these drugs have included hyperglycemia, frank diabetes mellitus, and abnormalities of lipid metabolism and lipid deposition. These complications have been noted even in patients who have responded well virologically to treatment and are otherwise in improved health. The biochemical and physiologic basis of protease inhibitor-related metabolic complications has, as of yet, not been adequately investigated and remains obscure. Of note, similar metabolic abnormalities have been reported in patients taking antiretroviral regimens that do not contain protease inhibitors.

- The long-term efficacy and safety of protease inhibitors have not been completely elucidated.

Table 12-8 General Characteristics of Currently Available Nonnucleoside Analogue Reverse Transcriptase Inhibitors

Characteristic	Drug		
	Nevirapine	Delavirdine	Efavirenz
Dose	200 mg twice daily	400 mg three times daily	600 mg once daily
Bioavailability, %	90	85	42
Protein binding, %	60	98	99.5-99.75
CSF penetration, %*	45	<1	0.26-1.19
Major adverse effects	Rash, hepatitis	Rash	Rash, central nervous system symptoms, fetal malformations
Food effects	No significant effect†	No significant effect†	Avoid high-fat meals
Effect on cytochrome P-450	Induction	Inhibition	Induction and inhibition

CSF, cerebrospinal fluid.

*As percentage of concurrent serum levels.

†No significant effect means drug can be taken without regard to food.

Table 12-9 General Characteristics of Currently Available Protease Inhibitors

Characteristic	Drug				
	Saquinavir	Ritonavir	Indinavir	Nelfinavir	Amprenavir
Dose	1,200 mg three times daily	600 mg twice daily	800 mg every 8 h	750 mg three times daily	1,200 mg twice daily
Bioavailability, %	12	75	60	20-80	60-80
Protein binding, %	98	98-99	?	>98	90
Adverse effects	Gastrointestinal	Gastrointestinal, paresthesia, taste, perversion (liquid)	Gastrointestinal, nephrolithiasis, hyperbilirubinemia	Diarrhea	Gastrointestinal, rash, paresthesias
Food effects	With fatty snacks or full meal	With meals	On empty stomach or with light snack	With meals	With or without, but avoid high-fat meals
P-450 inhibition	++	++++	++	++	++

++, moderate; ++++, severe.

- Metabolic complications of protease inhibitors have included hyperglycemia, frank diabetes mellitus, and abnormalities of lipid metabolism and lipid deposition.

Spontaneous bleeding has been reported in patients with hemophilia A and B treated with protease inhibitors, but a causal relationship between these incidents and protease inhibitor therapy has not been established.

The issue of resistance among protease inhibitors is complex and incompletely understood. Mutations that confer drug resistance have been identified in protease genes. Several of these mutations have been found to be key for individual protease inhibitors. Nevertheless, accumulation of several mutations is usually necessary for high-level resistance to occur, and cross-resistance is common among the various protease inhibitors that are currently in use. There is no cross-resistance between protease inhibitors and reverse transcriptase inhibitors.

The inhibitory effect of protease inhibitors on each other's metabolism has led to the evaluation of specific combinations (*dual protease-inhibitor regimens*) that may delay or prevent the onset of resistance and allow for dose reductions, more convenient dosing regimens, and less toxicity. Currently, the ritonavir-saquinavir combination is the combination for which the most data are available and is the only one recommended by the Department of Health and Human Services guidelines. Other combinations, including ritonavir-indinavir, indinavir-nelfinavir, ritonavir-nelfinavir, nelfinavir-saquinavir, and amprenavir-based regimens, are currently being evaluated. The long-term safety and efficacy of these combinations are unknown. Recently, this pharmacokinetic property of protease inhibitors has been exploited to produce a combination drug of two protease inhibitors, lopinavir and ritonavir (Kaletra). Ritonavir is present at a low dose, sufficient to inhibit the cytochrome P-450 system. This results in a significant increase in lopinavir concentrations that exceed the in vitro inhibitory concentrations (IC_{50} or IC_{95}) for wild-type or even some drug-resistant strains of HIV.

Fusion Inhibitors

Enfuvirtide (T-20) is the only fusion inhibitor that is currently approved by the U.S. Food and Drug Administration. It binds a region of the HIV envelope glycoprotein gp41 and prevents viral fusion with the target cell membrane. Enfuvirtide is administered by subcutaneous injection. The standard dose is 90 mg twice daily. Enfuvirtide is packaged in powder form in single-dose vials and must be reconstituted with sterile water. The current indication for enfuvirtide is for treatment in patients who have experienced multiple regimen failures. Three significant and noteworthy toxicities have been reported in clinical trials of enfuvirtide. Almost everyone experiences injection-site reactions that are typically erythematous nodules, mild-to-moderate in severity, and rarely cause discontinuation of use of the drug. Much less frequent are hypersensitivity reactions. Bacterial pneumonia was noted at a higher frequency in enfuvirtide-treated patients than patients in the comparator arms. The explanation for this difference and its clinical significance is unknown. HIV can become resistant to enfuvirtide, but there is no cross-resistance to the other currently approved antiretroviral drugs.

Guidelines for Use of Antiretroviral Therapy for HIV Infection

Advances in the management of HIV infection have made earlier state-of-the-art treatment guidelines and recommendations obsolete. In recent months, guidelines addressing the issue of antiretroviral therapy in different populations and situations have become available.

Guidelines for Use of Antiretroviral Agents in HIV-Infected Adults

A panel of leading AIDS specialists, convened by the Department of Health and Human Services in collaboration with the Henry J. Kaiser Family Foundation, has developed recommendations for use of antiretroviral agents in HIV-infected adults and adolescents. There is general consensus for treating patients with the acute HIV

syndrome, those within 6 months of seroconversion, and those with symptoms ascribed to HIV infection. However, the HIV-1 RNA or the CD4 level that should trigger initiation of treatment in an asymptomatic HIV-infected person with a high CD4 count continues to be debated. In general, the decision to treat asymptomatic patients should be based on the willingness and readiness of the individual to begin therapy; the degree of existing immunodeficiency as determined by the CD4 count; the risk of disease progression as determined by the CD4 count and level of plasma HIV-1 RNA; the potential benefits and risks of initiating therapy in asymptomatic individuals; and the likelihood, after counseling and education, of adherence to the prescribed treatment regimen. The Department of Health and Human Services panel recommends initiating therapy before the CD4 count decreases to less than 200 cells/μL. The data for treating before the count decreases to less than 350 cells/μL are inconsistent, but some clinicians opt to consider treatment in patients with a CD4 count more than 350 cells/μL and HIV-1 RNA level more than 100,000 copies/mL. In all cases, patients must actively participate in all therapeutic decisions, understand the benefits and risks of treatment, and make an informed commitment to a complex long-term treatment. Treatment should be offered to all patients with symptoms ascribed to HIV infection.

- Recommendation for use of antiretroviral agents: treat patients with acute HIV syndrome, those within 6 months of seroconversion, and those with symptoms ascribed to HIV infection.

The goal of treatment is maximal viral suppression for as long as possible. Response to treatment is evaluated with plasma HIV RNA (viral load) levels. HIV-1 RNA testing should be performed at baseline and repeated every 3 to 4 months during therapy, or at more frequent intervals if the situation warrants. A minimal change in plasma viremia is considered a threefold or 0.5-$\log_{10}$ increase or decrease. A substantial decrease in CD4 count is a decrease of more than 30% from baseline for absolute cell numbers and a decrease of more than 3% from baseline in percentages of cells. In cases of therapy failures, a new regimen consisting of at least two new agents, without cross-resistance to the drugs in the failed regimen, should be substituted. Resistance testing (genotyping or phenotyping) has been found useful for making the appropriate drug selection for incorporation into a salvage treatment regimen.

Recommendations for Use of Antiretroviral Drugs in Pregnant Women

In the past few years, perinatal transmission of HIV has dramatically decreased in the United States. This decrease is a result of recommendations from the U.S. Public Health Service for universal prenatal HIV counseling and testing with consent for all pregnant women and the use of zidovudine for reduction of perinatal HIV transmission. These recommendations were based on the results of Pediatric AIDS Clinical Trial Group Protocol 076. This trial demonstrated that zidovudine, when administered to the mother during the antepartum and intrapartum periods and to the newborn for the first 6 weeks of life, reduces the perinatal transmission of HIV by two-thirds. The advances in understanding the pathogenesis of HIV and the changes in antiretroviral therapy and monitoring of disease have made the establishment of new guidelines necessary. Consequently, the U.S. Public Health Service has updated its recommendations for the use of antiretroviral drugs in pregnant women.

Health care providers of pregnant HIV-infected women must address two separate but related issues: treatment of the mother's HIV infection and reduction of the risk for HIV transmission to the fetus. The benefits of therapy must therefore be weighed against the potential risk for adverse events to the fetus or newborn. Decisions regarding initiation or alterations in therapy should involve the same factors as those used for women who are not pregnant, with the additional consideration of the potential impact of such therapy on the fetus and infant. HIV-infected pregnant women should be provided with the most complete and current information regarding the use of antiretroviral therapy, mode of delivery, and other issues and should be allowed to make their own decisions. The woman's autonomy in decision making should be respected. Antiretroviral therapy should be offered to all HIV-1–infected women during pregnancy, whether primarily for HIV-1 infection or for reduction of perinatal transmission or for both purposes. Additionally, to prevent perinatal transmission, zidovudine chemoprophylaxis should be incorporated into the antiretroviral regimen.

- Zidovudine administered to the mother during the antepartum and intrapartum periods and to the newborn for the first 6 weeks of life reduces perinatal transmission of HIV by two-thirds.

Recommendations for Postexposure Prophylaxis

Numerous studies have estimated that the average risk for HIV transmission is approximately 0.3% after percutaneous exposure to HIV-infected blood and 0.09% after mucous membrane exposure. A retrospective case-control study of health care workers documented that the use of zidovudine was associated with a 79% decrease in the risk for HIV transmission. Results of that study, as well as results from studies in animals and data from the Pediatric AIDS Clinical Trial Group on the efficacy of zidovudine for preventing perinatal transmission of HIV, prompted the U.S. Public Health Service to issue recommendations for prophylaxis in health care workers after occupational exposure to HIV. With the availability of new drugs and the accumulation of more knowledge, these 1996 guidelines have recently been updated.

- In health care workers, the use of zidovudine is associated with a 79% decrease in the risk for HIV transmission.

The risk of infection is a function of the type of exposure and the infectivity of the exposure source. The guidelines provide an algorithm to guide clinicians in assessing risk and deciding when to offer postexposure prophylaxis. Systems, including written protocols, should be in place to prompt reporting and facilitate management of exposed health care workers. For most HIV exposures, a 4-week regimen of two antiretroviral drugs (zidovudine and lamivudine) is recommended. The addition of a protease inhibitor (indinavir or nelfinavir) is recommended for exposures with an increased risk of transmission or when resistance to one of the recommended drugs

is known or suspected. Individual clinicians may, of course, prefer other antiretroviral drugs or combinations because of local knowledge and experience. These recommendations are based on information available at the time they were developed. A mechanism has been put in place, through the HIV/AIDS Treatment Information Service Web site, to regularly refine and update the recommendations in tandem with the evolution of knowledge about HIV infection.

- The risk of infection is a function of the type of exposure and the infectivity of the exposing source.
- For most HIV exposures, a 4-week regimen of two antiretroviral drugs (zidovudine and lamivudine) is recommended.
- A protease inhibitor is added to the regimen for exposures with an increased risk of transmission or when resistance to a recommended drug is known or suspected.

HIV Infection Pharmacy Review

Lynn L. Estes, PharmD

Drug (trade name)	Normal adult dosage*	Dosing instructions	Toxic/adverse effects	Drug interactions†
			Nucleoside/nucleotide analogue reverse transcriptase inhibitors (NRTIs)	
Abacavir (Ziagen) Also contained in: Abacavir with zidovudine and lamivudine (Trizivir) Abacavir with lamivudine (Epzicom)	300 mg twice daily Abacavir 300 mg/ zidovudine 300 mg/lamivudine 150 mg twice daily Abacavir 300 mg/ lamivudine 300 mg once daily	Take without regard to food	Hypersensitivity reaction usually occurs within days to 6 wk of initiation: fever, malaise, abdominal cramping, nausea, diarrhea, with or without rash, may be associated with increased values on LFTs and of creatine kinase. Hypersensitivity reactions also may present with respiratory symptoms such as cough, dyspnea, or pharyngitis. Rechallenge after a hypersensitivity reaction is *contraindicated* and can have severe or fatal consequences. Severe or fatal reactions also have been noted in patients who had a therapy interruption for reasons unrelated to hypersensitivity, followed by reinitiation of abacavir Other side effects include N/V/D, fever, malaise, headache, rare bone marrow suppression, increased values on LFTs NRTI class: fat redistribution, lactic acidosis, and hepatomegaly with steatosis have been reported with NRTIs	Can inhibit or be affected by other drugs that inhibit alcohol dehydrogenase or UDP-glucuronyl transferase Alcohol increases abacavir levels
Didanosine (ddI, Videx)	≥60 kg Tablets/EC capsules: 200 mg twice daily or 400 mg EC daily Powder: 250 mg twice daily <60 kg Tablets/EC capsules: 125 mg twice daily or 250 mg EC daily Powder: 167 mg twice daily	Take all formulations on empty stomach Buffered tablets and oral powder: Thoroughly chew, crush, or disperse in water or apple juice Do not mix with acidic juices Pediatric formulation: Must mix with an antacid—see package insert	Major: 1) peripheral neuropathy; 2) pancreatitis—increased risk with history of pancreatitis, advanced HIV, alcoholism, concurrent medications that cause pancreatitis (e.g., pentamidine, stavudine); 3) GI intolerance (nausea, diarrhea) Minor or infrequent: hyperuricemia, hepatitis, rash Fatal lactic acidosis has been reported in pregnant patients receiving a combination of stavudine and didanosine—avoid combination in pregnancy NRTI class: fat redistribution, lactic acidosis, and hepatomegaly with steatosis have been reported with NRTIs	Space buffered tablets and powder apart from drugs that are affected by increased gastric pH (e.g., itraconazole capsules) and drugs that may be chelated (e.g., quinolones, tetracyclines) Tenofovir can substantially increase didanosine concentrations—didanosine dose reduction recommended Ribavirin can increase didanosine exposure and risk of toxicity. Use combination with caution Methadone can decrease didanosine levels—consider dose increase Hydroxyurea can increase potential for toxicity

HIV Infection Pharmacy Review (continued)

Drug (trade name)	Normal adult dosage*	Dosing instructions	Toxic/adverse effects	Drug interactions†
Nucleoside/nucleotide analogue reverse transcriptase inhibitors (NRTIs) (continued)				
Emtricitabine (Emtriva) Also contained in: Emtricitabine with tenofovir (Truvada)	200 mg daily Emtricitabine 200 mg/tenofovir 300 mg once daily	Take without regard to food	Generally well tolerated Most common: headache, diarrhea, nausea, and mild-to-moderate rash. Can cause skin discoloration (hyperpigmentation on palms or soles)—generally mild. Has activity against hepatitis B, and flares of hepatitis B may occur on discontinuation NRTI class: fat redistribution; lactic acidosis and hepatomegaly with steatosis have been reported with NRTIs	
Lamivudine (3TC, Epivir) Also contained in: Lamivudine with zidovudine (Combivir) Lamivudine with abacavir (Epzicom) Lamivudine with zidovudine and abacavir (Trizivir)	150 mg twice daily or 300 mg daily (<50 kg: 2 mg/kg twice daily) Lamivudine 150 mg/zidovudine 300 mg twice daily Lamivudine 300 mg/abacavir 600 mg once daily Lamivudine 150 mg/zidovudine 300 mg/abacavir 300 mg twice daily	Take without regard to food	Generally well tolerated Minor or infrequent: headache, nausea, diarrhea, abdominal pain, insomnia, pancreatitis in pediatric patients (rare in adults). Has activity against hepatitis B and flares of hepatitis B may occur on discontinuation NRTI class: fat redistribution; lactic acidosis and hepatomegaly with steatosis have been reported with NRTIs	
Stavudine (d4t, Zerit)	≥60 kg: 40 mg twice daily <60 kg: 30 mg twice daily	Take without regard to food	Major: peripheral neuropathy Other: N/V/D, decreased appetite, headache, insomnia, hyperlipidemia Rare: pancreatitis, anemia, hepatotoxicity, ascending neuromuscular weakness Fatal lactic acidosis has been reported in pregnant patients receiving a combination of stavudine and didanosine—avoid combination in pregnancy NRTI class: fat redistribution (may be more common with stavudine); lactic acidosis and hepatomegaly with steatosis have been reported with NRTIs	Possible increased pancreatitis, neuropathy, hepatotoxicity, lactic acidosis risk with didanosine or hydroxyurea

HIV Infection Pharmacy Review (continued)

Drug (trade name)	Normal adult dosage*	Dosing instructions	Toxic/adverse effects	Drug interactions†
Nucleoside/nucleotide analogue reverse transcriptase inhibitors (NRTIs) (continued)				
Tenofovir (Viread) Also contained in: Emtricitabine with tenofovir (Truvada)	300 mg daily Emtricitabine 200 mg/tenofovir 300 mg once daily	Take without regard to food	Mild GI complaints, asthenia, headache, anecdotal reports of renal dysfunction (may be best to avoid in patients with renal dysfunction), osteomalacia Has activity against hepatitis B and flares of hepatitis B may occur on discontinuation NRTI class: fat redistribution; lactic acidosis and hepatomegaly with steatosis have been reported with NRTIs	Can substantially increase didanosine levels—didanosine dose reduction recommended Can decrease atazanavir levels—use of atazanavir plus ritonavir suggested
Zalcitabine (Hivid, ddC)	0.75 mg three times daily	Do not take with antacids	Major: peripheral neuropathy (15%-30%) Minor or infrequent: pancreatitis (about 1%), hepatotoxicity, arthralgia, oral & esophageal ulcers, myalgia, leukopenia, abdominal pain, N/V/D, headache, hypersensitivity NRTI class: fat redistribution; lactic acidosis and hepatomegaly with steatosis have been reported with NRTIs	
Zidovdine (AZT, ZDV, Retrovir) Also contained in: Lamivudine with zidovudine (Combivir) Abacavir with zidovudine and lamivudine (Trizivir)	200 mg three times daily or 300 mg twice daily Lamivudine 150 mg/ zidovudine 300 mg twice daily Abacavir 300 mg/ zidovudine 300 mg/ lamivudine 150 mg twice daily	Take without regard to food	Major: 1) bone marrow suppression with anemia or neutropenia—frequency and severity related to dose, duration, and disease state; 2) malaise, GI intolerance, insomnia, headache, or asthenia—dose-related and may resolve with continued therapy Minor or infrequent: myopathy with increased CPK, hepatitis with increased transaminases (AST, ALT), fingernail discoloration NRTI class: fat redistribution; lactic acidosis and hepatomegaly with streatosis have been reported with NRTIs	Ribavirin can inhibit phosphorylation and activation of zidovudine—avoid if possible
Nonnucleoside analogue reverse transcriptase inhibitors (NNRTIs)				
Delavirdine (Rescriptor)	400 mg three times daily	Take without regard to food	Rash is most common (can usually treat through this, but can be serious in some cases). Mild headache, fatigue, GI complaints, increased values on LFTs also may occur	Substrate for CYP 3A4‡,§ and 2d6 Can inhibit CYP 3A4,// 2D6, 2C9, and 2C19 Avoid histamine$_2$ blockers or proton pump inhibitors
Efavirenz (Sustiva)	600 mg daily (preferably at bedtime to start)	Take with or without food, except that a high-fat meal can increase bioavailability up to 50% and should be avoided	Major: rash (can usually treat through this) and central nervous system symptoms, e.g., dizziness, light-headedness, nightmares, feeling of disengagement, impaired concentration—especially during first couple of weeks. Central nervous system symptoms can be minimized by taking at bedtime, and they often subside after 2-4 wk	Substrate for CYP 3A4‡,§ Can induce or inhibit CYP 3A4// (induction most common) In vitro also inhibits 2C9, 2C19 Can decrease methadone levels or effect—titrate dose

HIV Infection Pharmacy Review (continued)

Drug (trade name)	Normal adult dosage*	Dosing instructions	Toxic/adverse effects	Drug interactions†
Nonnucleoside analogue reverse transcriptase inhibitors (continued)				
			Can cause increased values on LFTs, especially in patients with hepatitis C. Teratogenic—avoid in pregnancy. Case reports of psychosis, delusional thoughts, suicidal ideation, and depression—more frequent in patients with history of mental illness. Modest increases of triglycerides and cholesterol possible. Can cause false-positive urine test for marijuana. Can increase cholesterol and triglyceride values by 10%-20% in some patients	
Nevirapine (Viramune)	200 mg daily ×14 d, then 200 mg twice daily	Start with 2-week lead-in of reduced dose to reduce incidence of rash Autoinduction occurs and stabilizes at 2-4 wk	Major: rash (29%), which often can be treated through if mild. Also, more rarely causes serious cutaneous reactions (Stevens-Johnson also reported). Rash occurs usually in first 28 days; decreased incidence with 14-day lower dose lead-in. Severe and fatal cases of hepatotoxicity have been reported, particularly in first 12 weeks. Increased values on LFTs or history of hepatitis B or C, pregnancy, a CD4 >250 in women may increase risk of hepatotoxicity. If hepatitis occurs, nevirapine should be permanently discontinued Other: nausea, headache, abdominal pain, diarrhea, mouth sores, somnolence During first 8 wk: patients should be intensively monitored for serious cutaneous reactions and signs of hepatotoxicity. Liver function should be monitored	Substrate for CYP 3A4‡,§ Induces CYP 3A4// Decreases methadone levels Decreases oral contraceptive levels—use alternative birth control
Protease inhibitors (PIs)				
Amprenavir (Agenerase)	>50 kg: 1,200 mg twice daily; often combined with boosting doses of ritonavir and lower daily doses of amprenavir	Take with or without food but avoid a high-fat meal (can decrease absorption) Pediatric solution contains 46 IU/mL of vitamin E	Amprenavir is a sulfonamide and could have cross-allergenicity with other sulfonamides. Other adverse effects may include nausea, vomiting, headache, rash; question about long-term effects of large amounts of vitamin E (avoid extra vitamin E supplementation) Oral solution is contraindicated in infants and children <4 y, pregnant women, patients with liver or renal failure, and patients on disulfiram or metronidazole due to the high content of propylene glycol and potential accumulation	Substrate for CYP 3A4‡,§ Can inhibit or induce CYP 3A4// (potency similar to indinavir and nelfinavir) Decreases oral contraceptive levels—use alternative birth control Space from didanosine buffered tablets (not needed with EC formulation) Space apart from antacids

HIV Infection Pharmacy Review (continued)

Drug (trade name)	Normal adult dosage*	Dosing instructions	Toxic/adverse effects	Drug interactions†
			Protease inhibitors (PIs) (continued)	
			PI class: diabetes or hyperglycemia, hemolytic anemia, and in hemophiliacs, spontaneous bleeding or hematomas. Also can cause increased lipid values and lipodystrophy (possibly somewhat less with amprenavir)	
Atazanavir (Reyatez)	400 mg daily (can be combined with boosting doses of ritonavir in a dose of 300 mg atazanavir/100 mg ritonavir daily)	Take with food	Increased indirect bilirubin value, jaundice, GI effects, rash, prolonged PR interval or heart block in some patients (rare) PI class: diabetes or hyperglycemia (less likely with atazanavir), hemolytic anemia, and, in hemophiliacs, spontaneous bleeding or hematomas. Also can cause lipodystrophy. Atazanavir does not appear to increase lipid values, in contrast to other PIs	Substrate for CYP 3A4‡,§ Can inhibibit CYP 3A4// 1A2, 2C9 Tenofovir and efavirenz can decrease atazanavir levels—use of atazanavir plus ritonavir suggested Space from didanosine buffered tablets (not needed with EC formulation) Space apart from antacids, avoid use with histamine 2 and proton pump inhibitors
Fosamprenavir (Lexiva)	Antiretroviral naive: fosamprenavir 1,400 mg or fosamprenavir 1,400 mg with ritonavir 200 mg once daily or fosamprenavir 700 mg with ritonavir 100 mg twice daily Antiretroviral experienced: fosamprenavir 700 mg with ritonavir 100 mg twice daily	Take without regard to food	Rash, GI adverse effects, headache, increased transaminases PI class: diabetes or hyperglycemia, hemolytic anemia, and, in hemophiliacs, spontaneous bleeding or hematomas. Also can cause increased lipid values and lipodystrophy	With efavirenz, use fosamprenavir plus ritonavir Substrate for CYP 3A4‡,§ Can inhibit or induce CYP 3A4//
Indinavir (Crixivan)	800 mg every 8 h (often used in lower-dose twice-daily regimens in combination with ritonavir 100 or 200 mg)	Empty stomach preferred Alternatively, can take with liquids or a light meal Drink ≥48 oz water/d to decrease nephrolithiasis If given with ritonavir, can give without regard to food	Major: nephrolithiasis up to 4% (can decrease risk by drinking >48 ounces of liquids per day) ± hematuria. Asymptomatic increase in bilirubin without LFT elevations Infrequent: increased hepatic transaminase values, headache, N/V/D, metallic taste, fatigue, dry skin or lips, ingrown toenails PI class: diabetes or hyperglycemia, hemolytic anemia, and, in hemophiliacs, spontaneous bleeding or hematomas. Also can cause lipodystrophy and increased lipid values	Substrate for CYP 3A4‡,§ Inhibits CYP 3A4// Space apart from didanosine buffered tablets Grapefruit juice substantially decreases indinavir levels, so should be avoided

HIV Infection Pharmacy Review (continued)

Drug (trade name)	Normal adult dosage*	Dosing instructions	Toxic/adverse effects	Drug interactions†
			Protease inhibitors (PIs) (continued)	
Lopinivir and ritonavir (Kaletra)	>40 kg: 400/100 mg (3 capsules) twice daily; 4 capsules twice daily in combination with nevirapine and efavirenz	Take with food	Frequent: abnormal bowel movements, diarrhea, weakness or fatigue, headache, nausea, rash in children, higher incidence of increased triglyceride and cholesterol values than with other PIs Infrequent: worsening liver disease in patients with hepatitis B or C Oral solution contains alcohol—avoid with metronidazole or disulfiram PI class: diabetes or hyperglycemia, hemolytic anemia, and, in hemophiliacs, spontaneous bleeding or hematomas. Also can cause lipodystrophy and increased lipid values	Substrate for CYP 3A4‡,§ Both are very potent inhibitors of CYP 3A4// Ritonavir also inhibits CYP 2D6, inhibits or competes for CYP 2C9, 2C19, and induces CYP 1A2 (decreases theophylline levels) Decreases methadone levels Decreases oral contraceptive levels—use alternative birth control Space apart from didanosine
Nelfinavir (Viracept)	1,250 mg twice daily or 750 mg three times daily; can also be used with boosted regimens with low-dose ritonavir	Take with food	Frequent: mild diarrhea or soft stool Minor or infrequent: nausea, abdominal pain, flatulence, asthenia, rash Avoid powder formulation in patients with phenylketonuria PI class: diabetes or hyperglycemia, hemolytic anemia, and, in hemophiliacs, spontaneous bleeding or hematomas. Also can cause lipodystrophy and increased lipid values	Substrate for CYP 3A4‡,§ Inhibits CYP 3A4// (induces CYP 3A4 occasionally) Decreases oral contraceptive levels—use alternative birth control
Ritonavir (Norvir)	600 mg twice daily (taper up to this over 5-10 days); often used in combination with other PIs as a "boosting" agent at doses of 100-400 mg once or twice daily	Take with food May mix solution with chocolate milk or liquid nutritional supplement	Frequent: GI intolerance (dose-related, may resolve with continued therapy)—less common when used in low-dose boosting regimens Other: taste changes; dizziness, headache, somnolence, paresthesiaas (circumoral and extremities), hyperlipidemia, hypertriglyceridemia (increase >200%), increased CPK and uric acid, hepatotoxicity PI class: diabetes or hyperglycemia, hemolytic anemia, and, in hemophiliacs, spontaneous bleeding or hematomas. Also can cause lipodystrophy and increased lipid values; these may be more severe with full-dose ritonavir than with other PIs	Substrate for CYP 3A4‡,§ Very potent inhibitor of CYP 3A4// Inhibits or competes for CYP 2C9, 2C19, 2D6 and induces CYP 1A2 (decreases theophylline levels) Can increase meperidine toxicity Decreases methadone levels Decreases oral contraceptive levels—use alternative birth control Space apart from didanosine

HIV Infection Pharmacy Review (continued)

Drug (trade name)	Normal adult dosage*	Dosing instructions	Toxic/adverse effects	Drug interactions†
			Protease inhibitors (PIs) (continued)	
Saquinavir (Invirase)	Recommended in combination with ritonavir: saquinavir 1,000 mg with ritonovir 100 mg twice daily	Take with a full meal (or within 2 h afterward)	Frequent: dose-related GI intolerance (may subside with continued therapy), nausea, abdominal pain, diarrhea, headache, asthenia, mouth ulcers, paresthesias, rash, increased values on LFTs, increased lipid values PI class: diabetes or hyperglycemia, hemolytic anemia, and, in hemophiliacs, spontaneous bleeding or hematomas. Also can cause lipodystrophy and increased lipid values	Substrate for CYP 3A4‡,§ Inhibits CYP 3A4// Dexamethasone decreases saquinavir levels Grapefruit juice increases saquinavir levels
			Fusion inhibitors	
Enfuvirtide (Fuzeon)	90 mg subcutaneously twice daily	Each 108-mg vial should be reconstituted 1:1 with sterile water for injection Reconstituted injection should be refrigerated and used within 24 h	Major: local injection site reactions Other: possible increased rate of bacterial pneumonia, hypersensitivity reaction	

ALT, alanine aminotransferase; AST, aspartate aminotransferase; CPK, creatine phosphokinase; CYP, cytochrome P-450; GI, gastrointestinal; HIV, human immunodeficiency virus; LFTs, liver function tests; N/V/D, nausea, vomiting, diarrhea.

*Without substantial hepatic or renal dysfunction.

†Not all-inclusive and does not include drugs with overlapping toxic effects. See package insert and other resources for specific drug interactions.

‡Abbreviated list of CYP 3A4 inducers—can decrease levels or effect of substrates for CYP 3A4 (PIs, NNRTIs): rifampin (avoid with PIs except ritonavir), rifabutin, rifapentine, carbamazepine, phenobarbital, phenytoin, nevirapine, efavirenz, St. John's wort (avoid with PIs).

§Abbreviated list of CYP 3A4 inhibitors—can potentially increase levels or effect of substrates for CYP 3A4 (PIs, NNRTIs): PIs, erythromycin, azole antifungals, amiodarone, cimetidine.

//Abbreviated list of CYP 3A4 substrates—levels or effect can be increased by CYP 3A4 inhibitors such as PIs; levels potentially can be decreased by CYP 3A4 inducers such as nevirapine or efavirenz: benzodiazepines (avoid midazolam, triazolam; can use lorazepam with PIs), statins (avoid use of lovastatin, simvastatin with PIs; pravastatin does not interact and atorvastatin can be used with caution/monitoring), dihydropyridine calcium channel blockers, ergot alkaloids (avoid with PIs), sildenafil (dose reduction needed with PIs), some antidysrhythmics, warfarin may be inconsistently affected, cisapride (avoid with PIs), pimozide (avoid with PIs), rifabutin (may need dose alterations of one or both drugs), some antidepressants, anticonvulsants (carbamazepine, phenytoin, phenobarbital)—monitor levels, immunosuppressants (cyclosporine, tacrolimus, sirolimus), azole antifungals.

Hypertension

Gary L. Schwartz, MD

Hypertension

Definition

Because blood pressure is a continuously distributed trait in the population and the risk of cardiovascular disease associated with the level of blood pressure increases progressively as it exceeds 115 mm Hg systolic or 75 mm Hg diastolic, the definition of hypertension is somewhat arbitrary. Currently for adults, *hypertension* is defined as systolic blood pressure 140 mm Hg or higher or diastolic blood pressure 90 mm Hg or higher. Hypertension is further stratified into two stages on the basis of the highest level of either systolic or diastolic blood pressure (Table 13-1). Systolic blood pressure between 120 and 139 mm Hg or diastolic blood pressure between 80 and 89 mm Hg is considered *prehypertension*. Persons with prehypertension are at increased risk of cardiovascular disease and progression to hypertension over time compared with persons with normal blood pressure.

Table 13-1 Classification of Blood Pressure for Adults 18 Years or Older*

Category	Blood pressure level, mm Hg		
	Systolic		Diastolic
Normal	<120	and	<80
Prehypertension	120-139	or	80-89
Hypertension			
Stage 1	140-159	or	90-99
Stage 2	≥160	or	≥100

*Not taking antihypertensive drugs and not acutely ill. When systolic and diastolic blood pressures fall into different categories, the higher category should be selected to classify the person's blood pressure status.

Modified from Chobian AV, Bakris GL, Black HR, Cushman WC, Green LA, Izzo JL Jr, et al. Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. Hypertension. 2003;42:1206-52.

- Hypertension is defined as systolic blood pressure ≥140 mm Hg or diastolic blood pressure ≥90 mm Hg.
- Prehypertension is defined as systolic blood pressure 120-139 mm Hg or diastolic blood pressure 80-89 mm Hg.
- Prehypertension is associated with increased risk of cardiovascular disease and hypertension.

Isolated Systolic Hypertension

Isolated systolic hypertension, mainly a problem of people older than 55 years, is defined as systolic blood pressure 140 mm Hg or higher and diastolic blood pressure less than 90 mm Hg. Secondary causes include disorders associated with either increased cardiac output (anemia, thyrotoxicosis, arteriovenous fistula, Paget disease of bone, and beriberi) or increased cardiac stroke volume (aortic insufficiency and complete heart block).

- Isolated systolic hypertension is defined as systolic blood pressure ≥140 mm Hg with diastolic pressure <90 mm Hg.
- Isolated systolic hypertension mainly affects people older than 55 years.
- Secondary causes include increased cardiac output (anemia, thyrotoxicosis, arteriovenous fistula, Paget disease of bone, and beriberi) and increased cardiac stroke volume (aortic insufficiency and complete heart block).

Epidemiology

Blood pressure increases with age. Systolic blood pressure increases throughout life, but diastolic blood pressure plateaus in the fifth decade. Thus, both the incidence and prevalence of hypertension increase with age, and isolated systolic hypertension becomes the most common subtype in older persons. For a middle-aged person with normal blood pressure who lives to age 85 years, the residual lifetime risk of developing hypertension is 90%.

In addition to age, other nonreversible factors associated with increased risk of hypertension include being African American or having a family history of hypertension. Reversible factors include having a blood pressure level in the prehypertensive range, being overweight, having a sedentary lifestyle, ingesting a high-sodium–low-potassium

diet, having excessive intake of alcohol, or having metabolic syndrome. Metabolic syndrome is defined by the presence of three or more of the following conditions: abdominal obesity (waist circumference >40 inches in men or >35 inches in women), impaired fasting blood glucose (fasting glucose ≥110 mg/dL), blood pressure 130/85 mm Hg or higher, increased plasma level of triglycerides (≥150 mg/dL), or low high-density lipoprotein (HDL) cholesterol (<40 mg/dL in men or <50 mg/dL in women). It is hypothesized that insulin resistance may be an underlying pathophysiologic factor for metabolic syndrome. Correcting reversible factors can lower blood pressure and prevent the development of hypertension.

In young adulthood and early middle age, hypertension is more common in men than in women. In people older than 60 years, the reverse is true. Hypertension is more common in African Americans than in whites at all ages, and in both races it is more common in the economically disadvantaged.

Hypertension is a major risk factor for cardiovascular disease morbidity and mortality (myocardial infarction, congestive heart failure, stroke, progressive atherosclerosis), chronic kidney disease, and dementia. Although risk is continuous and proportionate over both systolic and diastolic blood pressure levels, diastolic blood pressure is the better predictor of risk in young people and systolic blood pressure is the dominant predictor of risk in people older than 60 years.

For any given level of blood pressure, the risk is greater in men than in women, in African Americans than in whites or other racial-ethnic groups, in older people than in younger people, and in those with longer duration of hypertension, additional risk factors for cardiovascular disease, or target organ injury. It is estimated that 65 million Americans have hypertension or are taking medication to decrease blood pressure. In addition to definite hypertension, an additional 45 million Americans have prehypertension.

- Nonreversible risk factors for hypertension: older age, being African American, and having a family history of hypertension.
- Reversible risk factors for hypertension: prehypertension, overweight, sedentary lifestyle, high-sodium–low-potassium diet, excessive alcohol intake, and metabolic syndrome.
- Metabolic syndrome is defined by the presence of at least three of the following: abdominal obesity (waist circumference >40 inches in men or >35 inches in women), impaired fasting blood glucose (fasting glucose ≥110 mg/dL), blood pressure ≥130/85 mm Hg, plasma triglycerides ≥150 mg/dL, or HDL cholesterol <40 mg/dL in men or <50 mg/dL in women.
- Treatment of reversible risk factors can prevent or delay the development of hypertension and lower the risk of cardiovascular disease.
- Treatment of metabolic syndrome can prevent cardiovascular disease and the development of hypertension.
- Hypertension is a major risk factor for cardiovascular disease, renal disease, and dementia.
- Diastolic blood pressure is the best predictor of cardiovascular disease in young people.
- Systolic blood pressure is the dominant predictor of risk of cardiovascular disease in older people.
- Individual risk from hypertension is related to its level, duration, and the presence of other risk factors for cardiovascular disease or target organ injury.
- At any given level of blood pressure, African Americans and men are at the greatest risk.

For persons with hypertension, death is most often due to complications of coronary artery disease. Factors that add to this risk are tobacco use, hyperlipidemia, diabetes mellitus, obesity, sedentary lifestyle, metabolic syndrome, gender (men and postmenopausal women), age older than 60 years, and a family history of premature cardiovascular disease (women <65 years, men <55 years). The presence of target organ damage (stroke, left ventricular hypertrophy, ischemic heart disease, congestive heart failure, renal disease, retinopathy, peripheral vascular disease, and dementia) increases the risk of cardiovascular disease events even if blood pressure is subsequently controlled. This fact argues for early identification and prompt treatment of hypertension to avoid the development of target organ injury.

- The most common cause of death among persons with hypertension is coronary artery disease.
- Other risk factors for coronary artery disease include tobacco use, hyperlipidemia, diabetes mellitus, obesity, sedentary lifestyle, metabolic syndrome, male gender, postmenopausal state, older age, and family history of premature cardiovascular disease.
- Target organ damage increases the risk of cardiovascular disease events even if blood pressure is subsequently controlled.

Left ventricular hypertrophy is a strong predictor of sudden death and myocardial infarction in persons with hypertension. Other factors associated with increased left ventricular muscle mass include older age, obesity, and regular vigorous physical activity. Unlike increases in left ventricular mass associated with hypertension, obesity, and age, an increase due to vigorous physical activity is not associated with a higher risk of cardiovascular disease (athletic heart). Echocardiography is more sensitive than electrocardiography in detecting left ventricular hypertrophy.

- Left ventricular hypertrophy is a strong predictor of sudden death and myocardial infarction in persons with hypertension.
- Echocardiography is more sensitive than electrocardiography in detecting left ventricular hypertrophy.

Microalbuminuria is defined as a persistent urinary albumin excretion rate of 30 to 300 mg/24 h. In hypertensive persons, it is associated with an increased risk of cardiovascular disease and is a marker of vascular endothelial dysfunction. It is an early manifestation of nephropathy in type 1 diabetes mellitus but is often present at the time of diagnosis in type 2 diabetes mellitus and may simply reflect generalized vascular injury. In persons without diabetes, it is unclear whether microalbuminuria represents early kidney disease. Transient microalbuminuria can be due to fever, vigorous exercise, heart failure, or, in diabetic patients, poor glycemic control. Measurement of the albumin-creatinine ratio in an untimed urine specimen is a

sensitive screening test. A value of more than 30 mg/g indicates an increased probability of microalbuminuria. A 24-hour urine collection is the diagnostic standard. Testing for microalbuminuria is recommended in persons with diabetes and is elective to further define cardiovasular risk in persons without diabetes who have hypertension. In hypertensive persons it is unclear whether specific treatment (angiotensin-converting enzyme inhibitors [ACEIs] or angiotensin II receptor blockers [ARBs]) designed to reduce microalbuminuria is beneficial beyond effects on blood pressure control.

- Microalbuminuria is a persistent urinary albumin excretion rate of 30-300 mg/24 h.
- Transient microalbuminuria can be due to fever, vigorous exercise, heart failure, or, in diabetic patients, poor glycemic control.
- In hypertension, microalbuminuria is a marker of increased cardiovascular risk.
- In type 1 diabetes mellitus, microalbuminuria is an early manifestation of nephropathy.
- Measurement of the albumin-creatinine ratio in an untimed urine specimen is a sensitive screening method for microalbuminuria.
- The diagnostic standard for microalbuminuria is a 24-hour urine collection.

Table 13-2 **Follow-up Recommendations Based on Screening Blood Pressure Level in Adults**

Screening blood pressure	Follow-up*
Normal	Recheck in 2 y
Prehypertension	Recheck in 1 y
Hypertension	
Stage 1	Confirm within 2 mo
Stage 2	Confirm within 1 mo; if blood pressure >180/110 mm Hg, confirm within 1 wk or treat immediately, depending on clinical situation

*Modify the follow-up schedule on the basis of knowledge of previous blood pressure measurement, other cardiovascular risk factors, or target organ disease.

Modified from Chobian AV, Bakris GL, Black HR, Cushman WC, Green LA, Izzo JL Jr, et al. Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. Hypertension. 2003;42:1206-52.

Diagnosis

The diagnosis of hypertension relies on several measures of blood pressure performed in a rigorous manner with a validated and well-maintained mercury or aneroid sphygmomanometer and with an appropriate-sized cuff (the bladder should encircle at least 80% of the arm). The person should be at rest in the seated position (back and feet supported) for at least 5 minutes before the measurement. Recent physical activity, use of tobacco or caffeine (within 30 minutes of the measurement), or a full urinary bladder can transiently increase blood pressure and should be avoided. The arm should be bare (no tight clothing constricting the upper arm) and positioned so the cuff is at the level of the heart. The cuff should be inflated to 20 to 30 mm Hg above the level that obliterates the palpable radial pulse. The cuff deflation rate should be 2 mm Hg per second. The systolic blood pressure is the point at which the first of two or more Korotkoff sounds is heard, and the diastolic blood pressure is the point at which the Korotkoff sounds are no longer heard. The diagnosis of hypertension in a person with an elevated blood pressure at screening is confirmed at one or more subsequent office visits. At least two standardized measures of blood pressure should be made at each visit and the results averaged. Appropriate timing of follow-up based on the screening blood pressure level is shown in Table 13-2. For most persons, confirmation can occur over 1 to 2 months. If initial blood pressure is severely elevated or if the patient has additional risk factors for cardiovascular disease or has clinical cardiovascular disease, confirmation should be made in a shorter time.

Some persons have elevated blood pressure when it is measured in the clinic environment but have normal blood pressure at all other times. This is called *office hypertension* or *white coat hypertension*. Whether adverse consequences of sustained hypertension develop in these persons is uncertain; therefore, they usually require no treatment initially but need to be followed and periodically assessed for the development of hypertensive damage to target organs. Self-measurement of blood pressure outside the office setting can identify white coat hypertension. However, the diagnosis is best confirmed with noninvasive ambulatory blood pressure monitoring. On average, self-recorded blood pressure or average awake blood pressure by ambulatory monitoring is 5 mm Hg lower than office blood pressure and, therefore, values greater than 135 mm Hg systolic or greater than 85 mm Hg diastolic are considered elevated (i.e., hypertension is blood pressure ≥135/85 mm Hg by home or average awake ambulatory blood pressure). Blood pressure devices for home use need to be validated at regular intervals (twice yearly) by the health care provider.

Older persons may have *pseudohypertension*, a falsely increased systolic and diastolic blood pressure when measured by the cuff method; it is the result of a stiff vascular tree caused by atherosclerosis. Similar to persons with white coat hypertension, persons with pseudohypertension may have marked elevations of blood pressure but lack expected target organ injury. They may also complain of symptoms that suggest low blood pressure with treatment. Pseudohypertension may exist if the radial artery remains palpable after the brachial artery is occluded by cuff inflation (Osler maneuver). However, the Osler maneuver is not a very sensitive screening method for pseudohypertension. Confirmation requires intra-arterial blood pressure measurement.

- The diagnosis of hypertension requires several blood pressure measurements made in a standardized fashion on different occasions.
- Recent physical exercise, use of tobacco or caffeine, or a full urinary bladder can transiently elevate blood pressure.

- Hypertension by self-measurement or average awake ambulatory level is blood pressure ≥135/85 mm Hg.
- Office (white coat) hypertension: elevated blood pressure only when measured in the clinic environment.
- Pseudohypertension: inaccurately high cuff blood pressure as a result of a stiff vascular tree in older persons.

Evaluation

After the diagnosis of hypertension has been established, 1) identify lifestyle factors that contribute to higher blood pressure, 2) identify other risk factors for cardiovascular disease, 3) assess for target organ damage (Table 13-3), and 4) consider the possibility of secondary hypertension. Secondary hypertension accounts for approximately 5% to 10% of all cases of high blood pressure.

- Secondary hypertension accounts for 5%-10% of all cases of high blood pressure.

Clues to secondary hypertension are features that are inconsistent with essential hypertension. Classic features of essential hypertension are onset in the fourth or fifth decade of life, a positive family history for hypertension, initial blood pressure level categorized as stage 1 hypertension and easily controlled with one or two medications, no target organ damage, normal results of routine laboratory studies, and blood pressure that does not increase over a short period. Factors inconsistent with essential hypertension are listed in Table 13-4.

- Consider secondary hypertension if the presenting features are inconsistent with those of essential hypertension.

Table 13-3 **Hypertensive Target Organ Injury**

Target organ	Injury	Clinical marker/diagnosis
Heart	Left ventricular hypertrophy	S_4 gallop Forceful and prolonged apical thrust Displacement of point of maximal intensity Chest x-ray film, electrocardiography, echocardiography
	Angina Prior myocardial infarction Prior revascularization	History, electrocardiography
	Heart failure (systolic or diastolic)	History Lung rales S_3 gallop Edema Chest x-ray film, echocardiography
Brain	Stroke	History
	Leukoaraiosis	Computed tomography or magnetic resonance imaging
	Transient ischemic attack	History
	Dementia	History Cognitive testing
Kidney	Chronic kidney disease	Creatinine, blood urea nitrogen, urinalysis
Arteries	Peripheral artery disease	History of claudication Bruits Diminished pulses
Eye	Retinopathy	Funduscopic examination: Generalized and focal arteriolar narrowing* "Copper-wiring" of arterioles Arteriovenous nicking Cotton-wool spots† Microaneurysms and macroaneurysms† Flame and blot-shaped retinal hemorrhages† Retinal vein occlusion Optic disk swelling

*Feature predicts increased risk of coronary artery disease.
†Feature predicts increased risk of stroke.

Table 13-4 Factors Inconsistent With Essential Hypertension

General
Age at onset <30 y or >50 y
Blood pressure >180/110 mm Hg at diagnosis
Significant target organ damage at diagnosis
Hemorrhages and exudates on retinal examination
Renal insufficiency
Cardiomegaly
Left ventricular hypertrophy
Poor response to an appropriate 3-drug program
Features suggesting specific secondary causes of hypertension
Primary aldosteronism
Unprovoked hypokalemia, Chvostek sign, Trousseau sign
Pheochromocytoma
Labile blood pressure with diaphoresis, tachycardia, headache, pallor, neurofibromas, orofacial neuromas (MEN 2)
Renovascular disease
Abdominal bruit
Cushing disease
Truncal obesity, pigmented striae, impaired fasting glucose, hypokalemia
Coarctation of the aorta
Delayed or absent femoral pulses
"3" Sign and rib notching on chest x-ray film*
Polycystic kidney disease
Abdominal or flank mass, family history of renal disease

MEN 2, multiple endocrine neoplasia type 2.
*See "Coarctation of the Aorta" subsection in the "Secondary Hypertension" section.

Drugs

Certain drugs can cause or aggravate hypertension or interfere with the action of antihypertensive medications. These drugs and their mechanisms of action are listed in Table 13-5.

- Oral contraceptives increase blood pressure by inducing sodium retention, increasing renin substrate, and facilitating the action of catecholamines.
- Nonsteroidal anti-inflammatory drugs increase blood pressure by inducing sodium retention by blocking the formation of renal vasodilating, natriuretic prostaglandins and also interfere with the effectiveness of diuretics, β-blockers, and ACEIs.
- Tricyclic antidepressants inhibit the action of centrally acting agents (methyldopa and clonidine).

Laboratory Studies

Routine laboratory tests should include a complete blood count; measurements of sodium, potassium, glucose, creatinine (for estimation of glomerular filtration rate [GFR]), uric acid, calcium, cholesterol (total and HDL), and triglycerides; urinalysis; chest radiography; and electrocardiography. Urine albumin excretion or the albumin-creatinine ratio should be measured in patients who have diabetes mellitus or chronic kidney disease. Additional studies should not be performed unless abnormalities are identified on initial screening tests or the history or examination suggests a secondary form of hypertension.

Treatment

The goal of therapy is to eliminate the morbidity and mortality of cardiovascular disease attributable to hypertension by decreasing blood pressure to less than 140/90 mm Hg. A lower goal of less than 130/80 mm Hg is appropriate for persons with diabetes mellitus or chronic kidney disease.

Lifestyle Modifications

Lifestyle modifications lower blood pressure and should be encouraged for all persons with prehypertension (Table 13-6). The modifications may be sufficient as initial therapy for some persons with stage 1 hypertension. They are adjunctive therapy for those with more severe hypertension.

The Dietary Approaches to Stop Hypertension (DASH) eating plan is effective in lowering blood pressure in patients with prehypertension or stage 1 hypertension. The DASH eating plan includes consuming a diet rich in fruits, vegetables (high potassium), and low-fat dairy products (high calcium) with a reduced content of total and saturated fat.

The prevalence of hypertension is greater among persons who are obese. An increase in blood pressure often parallels weight gain, and numerous clinical trials have documented the effectiveness of weight loss to decrease blood pressure. Weight reduction to within the normal range (body mass index 18.5-24.9) is the goal, although losses as small as 10 lb may decrease blood pressure.

Restriction of daily sodium intake to 100 mEq (2.4 g sodium or 6 g salt) decreases blood pressure in some but not all hypertensive persons. Although salt sensitivity is more common among persons who are African American, obese, or elderly or who have low-renin hypertension, higher blood pressure levels, or chronic kidney disease, the antihypertensive effect of many medications is enhanced by sodium restriction. Also, sodium restriction minimizes diuretic-induced potassium losses.

Regular aerobic exercise may decrease blood pressure directly and indirectly by facilitating weight loss. At least 30 minutes of daily aerobic activity, such as walking, should be encouraged.

Restriction of daily alcohol intake to less than 1 oz (30 mL) of ethanol (<0.5 oz for women or lighter-weight men) is often associated with a decrease in blood pressure. Alcohol is a source of calories, and its use is often associated with poor compliance with antihypertensive therapy. Excessive alcohol intake may cause labile hypertension that is difficult to control in association with other symptoms (flushing and tachycardia) that suggest pheochromocytoma.

Because complications of coronary artery disease are the most common causes of death in hypertensive persons, all risks for cardiovascular disease must be addressed. The benefits of blood pressure reduction are diminished in smokers. Components of metabolic syndrome coexist more often in hypertensive persons than in normotensive persons. Treatment of metabolic syndrome decreases the

Table 13-5 Drugs That Can Increase Blood Pressure or Interfere With Antihypertensive Therapy

Drug	Mechanism
Oral contraceptives (with high estrogenic activity)	Induce sodium retention Increase renin substrate Facilitate action of catecholamines
Alcohol (>1 oz daily)	Activates sympathetic nervous system Increases cortisol secretion Increases intracellular calcium levels
Sympathomimetics and amphetamine-like substances (cold formulas, allergy medications, diet pills)	Increase peripheral vascular resistance Interfere with action of guanethidine and guanadrel
Nonsteroidal anti-inflammatory drugs	Induce sodium retention by blocking formation of renal vasodilating, natriuretic prostaglandins, thus interfering with action of diuretics, β-blockers, and angiotensin-converting enzyme inhibitors
Corticosteroids, corticotropin	Iatrogenic Cushing disease
Tricyclic antidepressants	Block uptake of guanethidine Inhibit action of centrally acting drugs such as methyldopa and clonidine
Monoamine oxidase inhibitors (in combination with tyramine—found in aged cheeses and some red wines)	Prevent degradation and metabolism of norepinephrine released by tyramine-containing foods Increase blood pressure when combined with reserpine/guanethidine
Cocaine	Vasoconstriction Interferes with action of adrenergic inhibitors
Marijuana	Increases systolic blood pressure
Cyclosporine, tacrolimus	Renal and systemic vasoconstriction
Erythropoietin	Systemic vasoconstriction
Serotonin	Systemic vasoconstriction
Glycyrrhizinic acid (chewing tobacco, imported licorice, health food products)	Inhibits renal cortisol catabolism

risk of cardiovascular disease and hypertension developing. It includes instruction in eating a low-fat, weight-loss diet; encouragement to exercise regularly; and use of medications to improve serum levels of lipids, blood pressure, and insulin sensitivity when appropriate.

- Follow the DASH eating plan.
- Reduce weight to within the normal range.
- Restrict daily sodium intake to 100 mEq.
- Exercise for at least 30 minutes daily.
- Restrict alcohol intake to <1 oz daily.
- Address all risk factors for cardiovascular disease.

A diet deficient in potassium may increase blood pressure; therefore, an adequate intake of potassium should be encouraged. The DASH eating plan is high in potassium. Studies do not support the use of biofeedback or relaxation therapies for blood pressure control.

Encouragement of lifestyle modifications is appropriate treatment for prehypertension. A trial of lifestyle modifications alone for up to 12 months is appropriate for patients with stage 1 hypertension who do not have diabetes or other risk factors for cardiovascular disease, target organ involvement, or clinical cardiovascular disease. If lifestyle modifications fail to decrease blood pressure to less than 140/90 mm Hg, drug treatment should be initiated. For patients at increased

Table 13-6 Effect of Lifestyle Modifications on Systolic Blood Pressure

Modification	Recommendation	Expected decrease in systolic blood pressure, mm Hg*
Adopt DASH eating plan	Consume a diet rich in fruits, vegetables, and low-fat dairy products with a reduced content of saturated and total fat	8-14
Reduce weight	Normal body weight (BMI, 18.5-24.9)	5-20 (per 10 kg)
Restrict dietary sodium	Restrict daily sodium intake to ≤2.4 g (6 g sodium chloride)	2-8
Increase physical activity	Regular aerobic exercise (e.g., brisk walking for 30 min) most days of the week	4-9
Limit alcohol intake	For most men: ≤2 drinks daily (1 oz alcohol) For women: ≤1 drink daily	2-4

BMI, body mass index; DASH, Dietary Approaches to Stop Hypertension.

*Effects on blood pressure may be greater in some individuals.

Modified from Chobian AV, Bakris GL, Black HR, Cushman WC, Green LA, Izzo JL Jr, et al. Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure. Hypertension. 2003;42:1206-52.

risk because of additional risk factors for cardiovascular disease, drug treatment should be started if lifestyle modifications are ineffective after 3 to 6 months. Drug treatment should be considered initially in addition to lifestyle modifications for patients with stage 2 hypertension or for those with stage 1 hypertension who also have diabetes, target organ involvement, or clinical cardiovascular disease. Successful changes in lifestyle (weight loss, reductions in salt and alcohol intake, and increased exercise) may allow tapering of an established drug program.

- Lifestyle modifications are the treatment for prehypertension.
- A trial of lifestyle modifications alone for up to 12 months is appropriate initial therapy for stage 1 hypertension in the absence of diabetes, other risk factors, target organ involvement, or clinical cardiovascular disease.
- Stage 2 hypertension or stage 1 hypertension with concurrent diabetes, other risk factors, target organ damage, or clinical cardiovascular disease should be treated initially with both lifestyle modifications and drug therapy.

Pharmacologic Therapy

In more than 50% of persons with stage 1 hypertension, blood pressure can be controlled with single-drug therapy. Important factors to consider when selecting a drug for initial therapy are its efficacy as monotherapy, route of elimination, drug interactions, side effects, and cost. Proper drug selection is important for maintaining long-term compliance.

Patients with stage 2 hypertension, those with initial blood pressure more than 20/10 mm Hg above the goal, and those targeted to lower blood pressure goals (chronic kidney disease or diabetes) will often require two or more drugs for blood pressure control. Consideration of initial therapy with a combination of two drugs (one of which is a diuretic appropriate for the level of renal function) should be considered.

Drugs appropriate for monotherapy are thiazide-type diuretics, β-blockers, calcium channel blockers (CCBs), ACEIs, and ARBs. Low-dose combinations may also be used for initial therapy, as noted above. Thiazide diuretics should be considered as the initial therapy of choice for most patients with uncomplicated hypertension who lack clear indications for other choices. Other classes of drugs should be considered if diuretics are ineffective or contraindicated or in settings in which the efficacy of an alternative drug has been established (e.g., ACEIs in a hypertensive person with congestive heart failure [see indications for specific drugs below]). Centrally acting α-agonists (clonidine, methyldopa, guanabenz, and guanfacine) and traditional vasodilators (hydralazine and minoxidil) may be associated with pseudotolerance. Pseudotolerance is reflex stimulation of the renin-angiotensin-aldosterone system or the sympathetic nervous system (or both systems) that results in fluid retention, an increase in vascular resistance, or an increase in cardiac output with subsequent loss of efficacy with prolonged use. Therefore, these drugs are not ordinarily used as monotherapy. A centrally acting α-agonist is appropriate when given in combination with a diuretic, whereas traditional vasodilators are best as a third drug in combination with a diuretic and an adrenergic inhibitor. Additional important factors influencing drug selection include the recognition that certain drugs work better according to a person's age and race (diuretics and CCBs are more effective in African Americans and the elderly; β-blockers, ACEIs, and ARBs are more effective in whites and younger patients). With combination therapy, make certain that the chosen drugs work in combination and that two drugs of the same class are not given simultaneously. Usually, one of the drugs in the combination should be a diuretic. Fatigue and impotence are potential side effects of all antihypertensive drugs.

- Drugs for monotherapy: diuretics, β-blockers, CCBs, ACEIs, and ARBs.
- Thiazide-type diuretics: the drugs of choice for most patients with uncomplicated hypertension.
- Combination therapy with two drugs should be considered for stage 2 hypertension or if initial blood pressure is >20/10 mm Hg above the goal.
- Centrally acting α-agonists are not ordinarily used as monotherapy but are appropriate in combination with a diuretic.

- Traditional vasodilators are best as a third drug in combination with a diuretic and an adrenergic inhibitor.

Thiazide Diuretics

Thiazide diuretics inhibit sodium reabsorption in the initial portion of the distal convoluted tubule of the nephron, where 5% to 8% of filtered sodium is reabsorbed. Acute effects to lower blood pressure are due to volume contraction and decreased cardiac output, but chronically they cause a reduction in peripheral vascular resistance through unknown mechanisms. The antihypertensive effect is limited by stimulation of the renin-angiotensin-aldosterone axis. In large group studies, diuretics are most effective in older persons and African Americans. They are also effective in the presence of obesity and diabetes. They are recommended for the initial treatment of uncomplicated hypertension and isolated systolic hypertension in the elderly. Concomitant diseases for which these drugs should be considered are edema states and heart failure associated with congestion. Thiazides have been shown to prevent first strokes and heart failure and to reduce cardiovascular mortality. They decrease the risk of osteoporotic fractures in postmenopausal women, lessen the risk of recurrent calcium nephrolithiasis, and are effective in lessening the risk of cardiovascular disease events in persons with diabetes or in those at high risk of coronary heart disease. They also are effective in the secondary prevention of stroke. In addition to their role as initial therapy, thiazide diuretics potentiate the effect of most other antihypertensive drugs. Metabolic disturbances associated with their use include hypokalemia, hyperuricemia, hypercalcemia (thiazides decrease urinary calcium excretion), hypomagnesemia, hyponatremia (more common in the elderly), fasting hyperglycemia (insulin resistance), hypochloremic metabolic alkalosis, and increased levels of low-density lipoprotein (LDL) cholesterol and triglycerides. Long-term therapy increases the risk of diabetes. Because of these potential adverse effects, relative contraindications to the use of thiazide diuretics include diet-controlled type 2 diabetes, gout, hyponatremia, hyperlipidemia, cardiac arrhythmias, and ischemic heart disease. The adverse metabolic effects of thiazide diuretics are dose-dependent and often of little consequence when currently recommended low doses are used (e.g., 12.5-25 mg hydrochlorothiazide).

Drug interactions include potentiation of lithium toxicity (thiazides decrease the renal clearance of lithium), lessening of the anticoagulant effect of warfarin, and enhancement of digitalis toxicity and the effects of skeletal muscle relaxants. Nonsteroidal anti-inflammatory drugs and high dietary sodium decrease the antihypertensive effect of thiazide diuretics. They are usually ineffective when the serum creatinine level is greater than 1.5 to 2.0 mg/dL (estimated GFR <30 mL/min). Under these circumstances, a more potent loop diuretic or metolazone is more effective. Volume expansion is often etiologically important in hypertension accompanying chronic kidney disease with reduced GFR. Thiazide diuretics have been associated with volume depletion, pancreatitis, vasculitis, mesenteric infarction, hepatitis, intrahepatic cholestasis, interstitial nephritis, and photosensitivity. Rarely, they cause blood dyscrasias.
