- Important indications for thiazide diuretics: uncomplicated hypertension, heart failure with congestion, edema states, isolated systolic hypertension in the elderly, high risk of coronary artery disease, or history of stroke.
- Thiazides increase the risk of diabetes developing but decrease the risk of cardiovascular events in persons with preexisting diabetes.
- Thiazides decrease the risk of osteoporosis-related fracture and recurrent calcium nephrolithiasis.
- Thiazides (except metolazone) are ineffective when estimated GFR is <30 mL/min.
- Metabolic disturbances: hypokalemia, hyperuricemia, hypercalcemia, hypomagnesemia, hyponatremia, fasting hyperglycemia, hypochloremic metabolic alkalosis, and increased levels of LDL cholesterol and triglycerides.
- Adverse effects: pancreatitis, vasculitis, mesenteric infarction, hepatitis, and photosensitivity.
- Drug interactions: potentiates lithium toxicity (increases lithium levels by enhancing proximal tubular reabsorption of the drug) and enhances digitalis toxicity and the effects of skeletal muscle relaxants while lessening the anticoagulant effect of warfarin.

Loop Diuretics

Loop diuretics inhibit sodium reabsorption from the thick ascending portion of the loop of Henle in the nephron, where 35% to 45% of filtered sodium is reabsorbed.

Furosemide

The major indication for furosemide is hypertension associated with chronic kidney disease and an estimated GFR of less than 30 mL/min. Because of its short duration of action, furosemide must be given twice daily to maintain a reduced body fluid volume essential for an antihypertensive effect. Similar to thiazide diuretics, furosemide can cause volume depletion, hypokalemia, hyperuricemia, fasting hyperglycemia, and hypochloremic alkalosis. Unlike thiazide diuretics, furosemide increases urinary calcium excretion (which can cause hypocalcemia). Potential adverse effects include reversible deafness, postural hypotension (especially in older persons), photosensitivity, pancreatitis, blood dyscrasias, nephrocalcinosis, and interstitial nephritis. Furosemide enhances salicylate clearance and the effects of skeletal muscle relaxants but is not associated with an increase in lithium level. It is synergistic when used with metolazone, and the combination is effective in states of resistant edema. Avoid administration with aminoglycosides or other ototoxic drugs. Nonsteroidal anti-inflammatory drugs and high dietary sodium reduce the antihypertensive effect of all diuretics.

- Important indication for furosemide: hypertension associated with chronic kidney disease and estimated GFR <30 mL/min.
- Metabolic effects: hypokalemia, hyperuricemia, fasting hyperglycemia, hypochloremic alkalosis, and increased urinary calcium excretion (hypocalcemia).
- Adverse effects: reversible deafness and postural hypotension.

Bumetanide

The actions of bumetanide, including adverse effects, electrolyte alterations, and drug interactions, are identical to those of furosemide;

however, bumetanide is a more potent diuretic on a milligram-per-milligram basis (1 mg is equivalent to 40 mg furosemide) and has twice the bioavailability of furosemide.

Ethacrynic Acid
The actions of ethacrynic acid are similar to those of furosemide. Although permanent hearing loss is a risk, ethacrynic acid is an alternative diuretic for patients with sulfa sensitivity because it is not a sulfonamide derivative.

Torsemide
Torsemide is different from the other loop diuretics in that it is eliminated mainly by liver metabolism, which prolongs its duration of action as long as 12 hours. Otherwise, its actions are similar to those of other loop agents.

Potassium-Sparing Diuretics

Spironolactone
Spironolactone is a mineralocorticoid receptor antagonist given specifically to persons who have primary aldosteronism or severe secondary aldosteronism. Use of this drug in severe heart failure has been shown to decrease the risk of morbidity and death. Its diuretic effect is antagonized by the concomitant use of salicylates. Adverse effects include hyponatremia, hyperkalemia, hyperchloremic acidosis, gynecomastia (but not breast cancer), mastodynia, menorrhagia, and skin rash. Spironolactone is often given in combination with thiazides to limit hypokalemia.

- Important indications for spironolactone: primary aldosteronism and states of secondary aldosteronism, especially severe heart failure.
- The diuretic effect is antagonized by the concomitant use of salicylates.
- Adverse effects: hyperkalemia, gynecomastia, mastodynia, menorrhagia, and skin rash.

Eplerenone
Eplerenone is a mineralocorticoid receptor antagonist similar to spironolactone, and its indications for use are generally the same as for spironolactone. This drug may lessen mortality in persons with heart failure following myocardial infarction. Eplerenone differs from spironolactone by having less affinity for progesterone and androgen receptors. Gynecomastia occurs less often; however, impotence and menstrual irregularities can occur. Hyperkalemia is the most common adverse effect. Inhibitors of the cytochrome P-450 enzyme CYP3A4 may increase serum levels of eplerenone.

- Eplerenone may be better tolerated than spironolactone, primarily because of less risk of gynecomastia in men.

Triamterene
Triamterene inhibits renal potassium wasting by blocking the epithelial sodium channel in the distal tubule of the nephron. It is used most often in combination with thiazide diuretics to limit renal potassium wasting. Side effects include hyperkalemia and skin rash. Acute renal failure can occur if triamterene is used in combination with indomethacin. Triamterene may be excreted into the urine as crystals that can form stones, often containing calcium. The drug should not be used during pregnancy because it is a folic acid antagonist.

- Triamterene inhibits renal potassium wasting by blocking the epithelial sodium channel in the distal tubule of the nephron.
- Do not use in combination with indomethacin or during pregnancy.

Amiloride
Amiloride limits renal potassium wasting by the same mechanism as triamterene and is used most often in combination with thiazide diuretics. Its side effects are hyperkalemia, gastrointestinal distress, and skin rash.

Of the potassium-sparing diuretics, only spironolactone and eplerenone can cause gynecomastia. Except under special circumstances, potassium-sparing drugs should be avoided in cases of renal failure and when ACEIs or ARBs are used.

- In general, avoid potassium-sparing diuretics in renal failure and when ACEIs or ARBs are used.

Adrenergic Inhibitors
If a diuretic fails to control blood pressure, an adrenergic inhibitor can be added. Adrenergic inhibitors are divided into centrally acting and peripherally acting drugs.

Peripherally Acting Inhibitors
1. Reserpine. Reserpine blocks the transport of norepinephrine into storage granules in postganglionic sympathetic neurons, decreasing sympathetic nervous system tone. Side effects include depression, nasal congestion, and stimulation of gastric acid secretion; thus, contraindications for reserpine are a history of depression or peptic ulcer disease. Its use is also contraindicated in advanced renal insufficiency (GFR <10 mL/min). Reserpine is not commonly used in current practice; however, small doses (≤0.1 mg/d) in combination with a diuretic provide an inexpensive, well-tolerated, and effective combination for blood pressure control.

- Major side effects of reserpine: depression, nasal congestion, and stimulation of gastric acid secretion.
- Small dosages in combination with a diuretic provide an inexpensive, well-tolerated, and effective combination for blood pressure control.

2. Guanethidine. Guanethidine, which is used only as part of a combination drug program to treat resistant hypertension, is used uncommonly in current practice. It decreases blood pressure by causing degranulation of catecholamine storage granules in postganglionic sympathetic neurons. It does not enter the central nervous system. It has a long half-life. The maximal hypotensive effect of a given dose may not be manifested for 2 or 3 weeks. It should be given only once

daily, and titration requires several weeks. Its major side effects are postural hypotension, fluid retention, diarrhea, and retrograde ejaculation. Tricyclic antidepressants, antihistamines, and ephedrine interfere with its action. Guanadrel sulfate, a short-acting form of guanethidine, is easier to titrate to an effective dose because it has a shorter half-life.

- An important indication for guanethidine is resistant hypertension.
- Major side effects: postural hypotension, fluid retention, diarrhea, and retrograde ejaculation.
- Tricyclic antidepressants, antihistamines, and ephedrine interfere with its action.

3. α_1-Receptor blockers. These drugs block α_1-adrenergic receptors on vascular smooth muscle cells, impairing catecholamine-induced vasoconstriction. They do not interfere with norepinephrine reuptake by peripheral sympathetic neurons; thus, there is no increase in levels of circulating catecholamines or heart rate. Because the initial dose can precipitate hypotension and syncope, it should be taken at bedtime. Longer acting peripheral α_1-receptor blockers (doxazosin and terazosin) allow single daily dosing. Prazosin, an older drug, must be taken at least twice daily. These drugs may lessen voiding symptoms associated with benign prostatic hypertrophy. In elderly patients, the use of α_1-receptor blockers is frequently associated with orthostatic hypotension, but they do not have adverse metabolic side effects. Other side effects include gastrointestinal distress and, rarely, sedation, edema, and dry mouth. Because this class of drugs is less effective than diuretics in reducing the risk of congestive heart failure, it is no longer considered an option for the initial management of hypertension.

- α_1-Receptor blockers are no longer considered appropriate initial therapy for hypertension.
- Because the first dose can cause hypotension and syncope, it should be taken at bedtime.
- In elderly patients, these drugs are often associated with orthostatic hypotension, but they have no adverse metabolic side effects and may lessen symptoms of prostatism.

4. β-Blockers. Many β-blockers are available. They differ in cardioselectivity (affinity for cardiac β_1 receptors is greater than for noncardiac [vascular and bronchiolar] β_2 receptors), lipid solubility, and whether they have partial intrinsic (agonist) sympathomimetic activity (ISA). Non-ISA β-blockers lower blood pressure by reducing cardiac output and inhibiting both renin release and central sympathetic outflow. β-Blockers with ISA activity do not reduce cardiac output but cause mild peripheral vasodilatation. As lipid solubility increases (lipophilic), the liver metabolizes more of the drug, more of it enters the brain, and its duration of action is shorter. As lipid solubility decreases (hydrophilic), the drug is eliminated mainly by renal excretion, less of it enters the brain, and its duration of action is longer. The most lipid-soluble drugs are propranolol, penbutolol, and carvedilol. Intermediate lipid-soluble drugs are metoprolol, pindolol, and timolol. The least lipid-soluble drugs are atenolol, betaxolol, carteolol, celiprolol, esmolol, sotalol, and nadolol.

- β-Blockers differ by cardioselectivity, lipid solubility, and the presence or absence of ISA.
- As lipid solubility increases, the liver metabolizes more of the drug, more of the drug enters the brain, and its duration of action is shorter.
- As lipid solubility decreases, the drug is eliminated mainly by renal excretion, less of the drug enters the brain, and its duration of action is longer.
- The most lipid-soluble drugs (lipophilic): propranolol, penbutolol, and carvedilol (preferred in the presence of renal disease).
- The least lipid-soluble drugs (hydrophilic): atenolol, betaxolol, carteolol, celiprolol, esmolol, sotalol, and nadolol (preferred in the presence of liver disease).

β_1-Cardioselective β-blockers are acebutolol, atenolol, betaxolol, bisoprolol, celiprolol, esmolol, metoprolol, and nebivolol. Cardioselectivity is relative; at high doses, all β-blockers are nonselective (i.e., they block both cardiac β_1 and noncardiac β_2 receptors). β-Blockers with ISA activity are pindolol, acebutolol, carteolol, celiprolol, and penbutolol. Cardioselectivity is not associated with a difference in blood pressure–lowering effect. However, it may be associated with less adverse effects on lipids (β-blockers can increase triglycerides and lower HDL cholesterol) and may allow quicker recovery from hypoglycemia in diabetic patients. Paradoxical increases in blood pressure under stress are also less likely with cardioselective drugs.

β-Blockers are appropriate initial therapy for hypertension. In large group studies, they are most effective in younger persons and whites. Certain comorbid conditions suggest the use of these drugs. Three β-blockers—propranolol, timolol, and metoprolol tartrate—prevent sudden death and recurrent myocardial infarction after an initial event. Most persons with congestive heart failure should be receiving a β-blocker (metoprolol succinate, bisoprolol, or carvedilol). Also, these drugs should be considered for patients with hypertension who have concomitant angina or hypertrophic cardiomyopathy. Other concomitant conditions that may benefit from the use of these drugs are supraventricular arrhythmias, glaucoma, migraine headache, and essential tremor. Noncardioselective drugs may be effective in preventing migraines and inhibiting essential tremor. Given preoperatively, β-blockers (atenolol or bisoprolol) decrease the risk of postoperative myocardial infarction in persons at increased risk of coronary artery disease. Although severe or poorly controlled asthma is a contraindication for β-blockers, many persons with well-controlled or mild asthma or mild chronic obstructive pulmonary disease can tolerate low doses of cardioselective agents. Contraindications to β-blocker therapy are conduction system disease of the heart, angina due to coronary vasospasm, Raynaud phenomenon, severe (but not mild) occlusive peripheral vascular disease, pheochromocytoma (in the absence of α-blockade), and depression. Because β-blockers may mask the symptoms of hypoglycemia and delay recovery from it, caution is required when these agents are given to patients with diabetes who are taking hypoglycemic drugs or insulin. Complete heart block can occur if a β-blocker is given in combination with verapamil. Side effects include cold extremities (non-ISA β-blockers), decreased exercise capacity, bronchospasm, dyslipidemia (elevated

triglyceride level, lower HDL cholesterol [worse with lipid-soluble, non-ISA, noncardioselective drugs]), worsening of psoriasis, fatigue, insomnia, nasal congestion, and, possibly, depression.

- Cardioselectivity is relative; all β-blockers are nonselective at high doses.
- Propranolol, timolol, and metoprolol tartrate prevent sudden death and recurrent myocardial infarction after an initial event.
- Most patients with congestive heart failure should be receiving a β-blocker.
- Contraindications: severe reactive airway disease, conduction system disease of the heart, angina due to coronary vasospasm, Raynaud phenomenon, severe occlusive peripheral vascular disease, pheochromocytoma (before α-blockade), and depression.
- β-Blockers (especially noncardioselective) may mask hypoglycemia and delay recovery from it, so they should be prescribed carefully for diabetics who take insulin or oral hypoglycemic drugs.
- Side effects: cold extremities, fatigue, impaired exercise tolerance, bronchospasm, dyslipidemia, insomnia, nasal congestion, and, possibly, depression.

5. Labetalol. Labetalol is the combination of a nonselective β-blocker and a postsynaptic α_1-receptor blocker. The ratio of α- to β-blocking action is 1:4. The drug lowers blood pressure primarily by decreasing peripheral vascular resistance. Labetalol can be given intravenously to treat hypertensive crisis. All the precautions applying to β-blockers apply to this drug. Labetalol can cause liver dysfunction and an increase in antinuclear antibody and antimitochondrial antibody titers. Common side effects are orthostatic hypotension and scalp itching. Labetalol may interfere with metanephrine and catecholamine assays, resulting in a false-positive test for pheochromocytoma.

- Labetalol can be given intravenously for hypertensive crisis.
- All precautions applying to β-blockers apply to labetalol.
- Labetalol can cause an increase in liver enzymes and in antinuclear and antimitochondrial antibody titers.
- Common side effects: orthostatic hypotension and scalp itching.
- Labetalol may result in a false-positive test for pheochromocytoma.

6. Carvedilol. Carvedilol is a weak β_1-selective blocker with α_1-blocking activity. This drug reduces the risk of death and hospitalization in persons with heart failure.

- Carvedilol is beneficial in heart failure.

Centrally Acting α_{2a} Agonists

These drugs stimulate central α receptors that exert an inhibitory effect on sympathetic outflow. Blood pressure is reduced because of a decrease in cardiac output and peripheral vascular resistance. Norepinephrine and renin levels decrease. Fluid retention occurs; thus, these agents should be used in combination with diuretics. Side effects common to all these agents are orthostatic hypotension, sedation, bradycardia, and dry mouth. Sudden discontinuation of any of these agents can cause a sudden rebound rise in blood pressure. This effect is augmented in the presence of concomitant β-blocker therapy.

- Common side effects of all centrally acting α_{2a} agonists are sedation, dry mouth, bradycardia, and withdrawal hypertension.

1. Methyldopa. Daily doses should not exceed 3 g. Side effects include hepatitis, fever, positive Coombs test, hemolytic anemia, leukopenia, thrombocytopenia, and increased antinuclear antibody titers. Hemoglobin and liver enzymes should be checked periodically. Methyldopa potentiates lithium and haloperidol toxicity, increases prolactin levels with consequent breast stimulation, and interferes with metanephrine assays. Because newer centrally acting agents are safer, this drug should not be used often. Currently, a major use for this drug is in the treatment of hypertension in pregnancy, for which its safety has been established.

- An important indication for methyldopa is hypertension in pregnancy.
- Methyldopa side effects: hepatitis, fever, positive Coombs test, hemolytic anemia, leukopenia, thrombocytopenia, and antinuclear antibody positivity.
- It potentiates lithium and haloperidol toxicity and increases prolactin levels.

2. Clonidine. In contrast to methyldopa, clonidine is not associated with liver toxicity or hematologic abnormalities. Because of the possibility of rebound hypertension with sudden discontinuation, as with all central agents, clonidine should be tapered and discontinued preoperatively if oral medications will not be allowed for several days postoperatively. Alternatively, with clonidine, conversion preoperatively to the transdermal form of the drug can be considered. The transdermal formulation takes 48 hours for therapeutic efficacy. Comorbid conditions that may benefit from clonidine include restless legs, menopausal hot flashes, and diabetic diarrhea.

- Clonidine is not associated with liver toxicity or hematologic abnormalities.
- An alternative to tapering the drug preoperatively is to switch to the transdermal form.
- Clonidine may help restless legs, menopausal hot flashes, and diabetic diarrhea.

3. Guanabenz. Guanabenz is similar in action to clonidine and methyldopa. It may also have weak peripheral neuronal blocking properties. Similar to clonidine and unlike methyldopa, it is not associated with liver toxicity or hematologic abnormalities. Also, unlike other central agents, guanabenz does not cause fluid retention.

- Guanabenz is not associated with liver toxicity or hematologic abnormalities.
- It is the only central α-agonist that does not cause fluid retention.

4. Guanfacine. Guanfacine, a newer clonidine-like drug, can be given once daily and may have fewer central nervous system side effects. Similar to guanabenz and clonidine, it is not associated with liver toxicity or a positive Coombs test.

- Guanfacine is not associated with liver toxicity or hematologic abnormalities.

Traditional Vasodilators

The traditional vasodilators are usually given as a third agent in combination with a diuretic and an adrenergic inhibitor to persons with severe or resistant hypertension. They are used most properly only in combination with a diuretic and an adrenergic inhibitor because they cause stimulation of the sympathetic nervous system (increase in heart rate and cardiac output) and renin release (fluid retention).

Hydralazine

Hydralazine decreases blood pressure by directly dilating arterioles. The daily dose should not exceed 200 mg. Its plasma half-life is prolonged in renal insufficiency. It can be used safely in pregnancy and is efficacious when used in combination with nitrates for congestive heart failure. Side effects include headache, palpitations, tachycardia, fluid retention, and a lupus-like syndrome (arthralgias, splenomegaly, and pleural or pericardial effusions). In addition, the drug can cause peripheral cytopenias (anemia, leukopenia, and thrombocytopenia), and peripheral neuropathy from pyridoxine deficiency. The liver enzyme *N*-acetyltransferase inactivates the drug. The level of this enzyme is genetically determined and persons are characterized as being "rapid acetylators" (high levels of the enzyme) or "slow acetylators" (low levels of the enzyme). Rapid acetylators require larger doses of the drug for an effect. Lupus-like syndrome is more common in slow acetylators. Hydralazine should not be used in the setting of recent cerebral hemorrhage, acute myocardial infarction, or a dissecting aortic aneurysm because of its tendency to increase cardiac output and cerebral blood flow.

- Hydralazine causes direct dilatation of arterioles.
- The daily dose should not exceed 200 mg.
- Side effects: headache, palpitations, tachycardia, fluid retention, lupus-like syndrome, cytopenias, and peripheral neuropathy.
- It can be used safely in pregnancy and in combination with nitrates for congestive heart failure.
- Do not use in the setting of recent cerebral hemorrhage, acute myocardial infarction, or dissecting aortic aneurysm.

Minoxidil

Minoxidil is a potent, direct vasodilator used to treat severe hypertension with or without renal insufficiency. Its side effects include substantial volume expansion with edema, hirsutism, and pericardial effusion. Often, high doses of both a loop diuretic and an adrenergic inhibitor are required to control reactive sympathetic stimulation and fluid retention.

- Minoxidil is a more potent vasodilator than hydralazine.
- Side effects: volume expansion with edema, hirsutism, and pericardial effusion.

Angiotensin-Converting Enzyme Inhibitors

ACEIs (benazepril, captopril, enalapril, fosinopril, lisinopril, moexipril, perindopril, quinapril, ramipril, and trandolapril) decrease blood pressure by inhibiting the enzyme that converts angiotensin I to angiotensin II (angiotensin-converting enzyme [ACE]) and that causes the breakdown of bradykinin (kininase II). Pressor effects of angiotensin II that are reduced include direct vasoconstriction, stimulation of the sympathetic nervous system, thirst, renal sodium reabsorption, and antidiuretic hormone and aldosterone secretion. ACEIs also enhance the activity of bradykinin, a vasodilator. The effects of angiotensin II to promote cardiac and vascular smooth muscle hypertrophy are also reduced. Although they are vasodilators, ACEIs do not induce reactive fluid retention or sympathetic stimulation.

ACEIs are appropriate initial therapy for hypertension, and they work well in combination with other antihypertensive agents, particularly diuretics. In large group studies, ACEIs have been most effective in younger persons and whites. ACEIs retard progression of nephropathy in type 1 diabetes mellitus (captopril) and prevent the development of congestive heart failure and recurrent myocardial infarction in persons who have had an initial myocardial infarction complicated by reduced left ventricular function (captopril, lisinopril, ramipril, and trandolapril). ACEIs are an important treatment for established congestive heart failure (captopril, enalapril, fosinopril, lisinopril, quinapril, ramipril, and trandolapril) and may induce regression of left ventricular hypertrophy more effectively than other antihypertensive agents. ACEIs are antiproteinuric and slow the progression of nondiabetic, proteinuric renal disease in both whites and African Americans. They may decrease the risk of nephropathy in patients who have type 2 diabetes mellitus with microalbuminuria. Also, they decrease the risk of death, myocardial infarction, and stroke in high-risk persons (i.e., persons with known coronary artery disease, previous stroke, peripheral vascular disease, or diabetes with at least one additional risk factor) (ramipril). The combination of an ACEI and a diuretic (indapemide with perindopril) may prevent recurrent stroke. ACEIs are useful in the treatment of hypertensive crisis associated with scleroderma.

ACEIs increase insulin sensitivity and may lessen the risk of diabetes developing. Their use can be associated with hypoglycemia in diabetic patients. Captopril is the only sulfhydryl-containing ACEI. Unique side effects presumed to be due to the sulfhydryl group in captopril are skin rash, loss of taste, proteinuria with membranous glomerulonephropathy, and leukopenia. Leukopenia is more likely to occur in the presence of collagen vascular disease and renal insufficiency. Nonsulfhydryl-containing ACEIs are benazepril, enalapril, fosinopril, lisinopril, moexipril, perindopril, quinapril, ramipril, and trandolapril.

The side effects shared by all ACEIs are orthostatic hypotension (most common with diuretic therapy), hyperkalemia (most common with renal insufficiency or diabetes or with concomitant use of potassium-sparing diuretics, nonsteroidal anti-inflammatory drugs, or potassium supplements), cough (more common in women), bronchospasm, angioedema (more common in African Americans), and

loss of renal function. Minor increases in creatinine are common after initiation of ACEI therapy. In persons with bilateral renal artery stenosis, ACEIs can cause acute renal failure because of disruption of autoregulation of glomerular filtration in the presence of severe renal ischemia. If serum creatinine increases by 20% or more from baseline with ACEI therapy, evaluation for bilateral renal artery stenosis should be considered. If creatinine increases by 30% or more, the drug should be stopped. Anaphylactic reactions can occur in patients during dialysis or apheresis.

All ACEIs except captopril and lisinopril are prodrugs and require conversion in the liver to the active form. This is only of concern in advanced liver disease. The kidneys eliminate all ACEIs except fosinopril and trandolapril, which have a balanced renal and hepatic elimination, with increased hepatic elimination in the setting of renal dysfunction. ACEIs differ in their ability to inhibit noncirculating ACE present in tissues (tissue ACE) and in lipophilicity, but these differences are of uncertain clinical significance. Drugs that inhibit tissue ACE include quinapril, benazapril, ramipril, perindopril, and trandolapril. The most lipophilic ACEIs are captopril, ramipril, fosinopril, trandolapril, and quinapril. ACEIs are contraindicated in pregnancy because they can cause fetal toxicity.

- ACEIs inhibit the enzyme that converts angiotensin I to angiotensin II and is responsible for the metabolism of bradykinin.
- ACEIs are appropriate initial therapy for hypertension.
- ACEIs retard progression of nephropathy in patients with type 1 diabetes.
- ACEIs are antiproteinuric and slow the progression of nondiabetic proteinuric renal disease.
- ACEIs are important in the treatment of congestive heart failure.
- ACEIs prevent recurrent myocardial infarction and the development of congestive heart failure in persons who have had a myocardial infarction complicated by reduced left ventricular function.
- ACEIs may lessen the risk of death, myocardial infarction, and stroke in persons with known atherosclerotic vascular disease or diabetes and at least one additional risk factor.
- The combination of an ACEI and a diuretic may prevent recurrent stroke.
- Side effects of captopril: skin rash, loss of taste, proteinuria with membranous glomerulonephropathy, and leukopenia.
- Side effects of all ACEIs: orthostatic hypotension, hyperkalemia, cough, angioedema, and loss of renal function.
- ACEIs are contraindicated in pregnancy.

Angiotensin II Receptor Blockers

ARBs (candesartan, eprosartan, irbesartan, losartan, olmesartan, telmisartan, and valsartan) lower blood pressure by blocking the cell surface receptors (AT_1) that angiotensin II interacts with to produce all its known pressor effects. Similar to ACEIs, ARBs increase plasma renin activity (PRA), but unlike ACEIs, ARBs also increase (not decrease) angiotensin II levels and ARBs do not increase bradykinin levels. Candesartan and olmesartan are prodrugs. Insurmountable antagonists of the AT_1 receptor are candesartan, irbesartan, olmesartan, telmisartan, and valsartan. The clinical importance of insurmountable antagonism of the receptor is uncertain.

ARBs are appropriate initial therapy for hypertension, and in large group studies, they have been most effective in younger persons and whites. ARBs are generally effective in the same clinical settings as ACEIs; thus, they are primarily alternatives to ACEIs when these agents are indicated but not tolerated. ARBs are antiproteinuric and have been shown to lessen the progression of nephropathy associated with type 2 diabetes mellitus (losartan and irbesartan). The combination of ACEI and ARB therapy may have an additive antiproteinuric effect, but the role of combination therapy in retarding progression of renal disease is uncertain. Unlike with ACEIs, special benefits with ARBs after myocardial infarction or in congestive heart failure have not been established, with two exceptions: valsartan, which is indicated as an alternative drug for congestive heart failure in the presence of ACEI intolerance, and candesartan, which reduces heart failure mortality. ARBs (losartan) decrease the risk of stroke in hypertensive persons with left ventricular hypertrophy.

The most common side effect of ARBs is dizziness. Diuretics or salt and volume depletion can potentiate their hypotensive effect. Similar to ACEIs, ARBs can cause fetal toxicity and should be avoided in pregnancy. They also can precipitate acute renal failure in persons with bilateral renal artery stenosis and can cause angioedema. In general, persons who experience angioedema with an ACEI should not be given an ARB. Unlike ACEIs, ARBs do not cause cough (cough may be due to high levels of bradykinin), and the risk of hyperkalemia may be less than with ACEIs. Losartan is the only ARB that is uricosuric. These drugs have no adverse effect on plasma lipids or glucose.

- ARBs inhibit the actions of angiotensin II by blocking its cell surface receptors.
- The major role for ARBs: a substitute for an ACEI when an ACEI is indicated but not tolerated.
- Side effects of ARBs: dizziness, hyperkalemia, acute renal failure, angioedema.
- ARBs do not cause cough but can cause angioedema.
- Avoid ARBs in pregnancy because of fetal toxicity.

Calcium Channel Blockers

CCBs block the influx of calcium into vascular smooth muscle cells, causing vasodilation. They are divided into dihydropyridines (amlodipine, felodipine, isradipine, nicardipine, nifedipine, nisoldipine, and nitrendipine), benzothiazepines (diltiazem), and phenylalkylamines (verapamil). Only long-acting forms are approved for use in hypertension. The short-acting forms should not be used. Verapamil (and, to a lesser extent, diltiazem) slows the heart rate, depresses cardiac contractility, and inhibits cardiac atrioventricular nodal conduction. The dihydropyridines have less effect on cardiac conduction and heart contractility. CCBs are appropriate for initial therapy of hypertension.

Earlier studies suggested an increase in coronary heart disease events with the use of dihydropyridine CCBs, but more recent studies do not support this concern. In large group studies, CCBs have been most effective in older persons (especially with isolated systolic hypertension) and African Americans. They should be considered for persons with concomitant ischemic heart disease and chronic, stable

angina (amlodipine, nicardipine, nifedipine, diltiazem, and verapamil); variant angina due to coronary vasospasm (amlodipine, nifedipine, and diltiazem); supraventricular arrhythmias (verapamil and diltiazem); Raynaud phenomenon (nifedipine); migraine headaches (verapamil); and esophageal spasm. Verapamil decreases the risk of a subsequent myocardial infarction if the first one was not associated with pulmonary congestion. Diltiazem decreases the risk of a subsequent myocardial infarction after a non–Q-wave infarction. The long-term use of nifedipine delays the need for valve replacement in chronic aortic insufficiency and may lower pressure in primary pulmonary hypertension. Dihydropyridine CCBs (nitrendipine) lessen the risk of stroke in older persons with isolated systolic hypertension. Nondihydropyridines reduce proteinuria and have additive effects when used with ACEIs or ARBs. CCBs are helpful in cyclosporine-induced hypertension.

Use of all CCBs should be avoided in the setting of acute myocardial infarction. Verapamil and diltiazem should be avoided in the presence of cardiac conduction system disease (sick sinus syndrome and second-degree or greater heart block) or when the left ventricular ejection fraction is less than 40%. All CCBs should be avoided in symptomatic heart failure, although dihydropyridine CCBs can be used safely in asymptomatic persons who require additional treatment to control blood pressure or angina. Verapamil in combination with β-blockers can lead to complete heart block and profound cardiodepression. Because it decreases the renal and nonrenal elimination of digoxin, verapamil increases the risk of digoxin toxicity. Quinidine and verapamil in combination can cause serious hypotension in persons with idiopathic hypertrophic subaortic stenosis.

- CCBs are direct vasodilators.
- Verapamil and diltiazem should not be used in sick sinus syndrome or heart block of second degree or greater.
- Avoid using verapamil in combination with β-blockers.
- Avoid verapamil and diltiazem if the left ventricular ejection fraction is <40%.
- Verapamil increases the risk of digoxin toxicity.
- All CCBs should be avoided in persons with symptomatic heart failure.

All CCBs can increase liver enzymes and cause hepatic necrosis. The most common side effect of verapamil is constipation, and the most serious side effect is heart block. Most of the side effects associated with dihydropyridine CCBs are related to peripheral vasodilation. These include headache, tachycardia, flushing, and dependent edema. The dependent edema associated with CCBs is not improved with diuretics but may be lessened by ACEIs. Gingival hyperplasia most commonly occurs with dihydropyridines but can occur with all CCBs. All CCBs can worsen esophageal reflux. Rarely, serious cutaneous eruptions can occur with CCBs. Cimetidine and other drugs that decrease blood flow to the liver may increase the biologic effects of CCBs. CCBs increase cyclosporine blood levels. Unlike other antihypertensive agents, nonsteroidal anti-inflammatory drugs do not interfere with the blood pressure–lowering effect of CCBs and a high-sodium diet may increase the blood pressure–lowering effect. The liver metabolizes all CCBs, and dose adjustments may be necessary if liver disease is present. CCBs can be used safely in renal insufficiency.

- The most common side effect of verapamil: constipation.
- The most serious side effect of verapamil: heart block.
- Common side effects: headache, tachycardia, flushing, and edema.
- CCBs can cause gingival hyperplasia.
- CCBs increase cyclosporine blood levels.
- CCBs can increase liver enzymes and cause hepatic necrosis.
- Nonsteroidal anti-inflammatory drugs and a high-salt diet do not lessen the blood pressure–lowering effect of CCBs.
- All CCBs are metabolized in the liver, so dose adjustments are necessary if liver disease is present.

Follow-up

After initiation of drug therapy, follow-up visits should be scheduled at monthly intervals until treatment goals are attained. For high-risk persons with stage 2 hypertension, follow-up intervals should be 1 to 2 weeks. If the first chosen drug fails to control blood pressure, but a response is observed and the drug is well tolerated, the dose can be increased or a second drug added. If no response is observed or severe side effects occur, the drug should be replaced with one from a different class. Serum creatinine and potassium levels should be checked within 1 to 2 weeks after initiation of ACEI or ARB therapy. Adverse metabolic effects of diuretics (i.e., adverse effects on sodium, potassium, uric acid, glucose, cholesterol, and triglyceride levels) should be assessed after 1 month of therapy. When the blood pressure goal is achieved, follow-up visits should be considered at intervals of 3 to 6 months. Other comorbidities (diabetes, coronary artery disease, heart failure, and renal disease) may influence the frequency of follow-up visits and laboratory tests. In addition to blood pressure control, other cardiovascular risk factors should be monitored and treatment initiated to achieve the appropriate goals. After blood pressure is controlled, the addition of low-dose aspirin (81 mg daily) should be considered because its use has been shown to lessen cardiovascular disease events in persons with controlled hypertension. In persons with inadequately controlled hypertension, aspirin use is associated with increased risk of hemorrhagic stroke.

Secondary Hypertension

Known secondary forms of hypertension account for approximately 10% of all cases of hypertension. Secondary forms are often considered in patients who have clinical features that are inconsistent with essential hypertension, as discussed earlier. Common general clinical clues are an unusual age at onset (younger or older than for essential hypertension), a sudden, unexplained increase in blood pressure from a previous state of control, or primary or acquired resistance to treatment. Common secondary causes include drugs (Table 13-5), increasing obesity, and obstructive sleep apnea. The traditional secondary causes are reviewed here. The clinical clues suggestive of secondary hypertension should be recognized, and when secondary hypertension is suspected, consultation with a subspecialist should be considered.

Renovascular Hypertension

Renovascular hypertension is the most common form of potentially curable secondary hypertension. It occurs in 1% to 3% of the general hypertensive population, in 10% of persons with resistant hypertension, and in up to 30% of those with hypertensive crisis. It is less common in African Americans than in Caucasians. *Critical stenosis* of a renal artery (i.e., ≥70% luminal narrowing) increases renin production from the ischemic kidney. Renin acts on circulating renin substrate to produce angiotensin I, which is converted to angiotensin II (a potent vasoconstrictor) by ACE in the lung and other tissues. In addition to vasoconstriction, angiotensin II directly increases renal sodium reabsorption and also stimulates aldosterone production, resulting in extracellular volume expansion. Angiotensin II also stimulates the sympathetic nervous system, contributing further to increased vascular resistance, and stimulates thirst and the release of vasopressin, contributing further to increased extracellular volume.

In unilateral disease, the nonischemic kidney is subjected to increased perfusion, resulting in higher sodium excretion and suppression of renin release. These effects lessen the degree of hypertension but perpetuate underperfusion of the ischemic kidney, which, in turn, perpetuates excess renin production. In bilateral disease, initial increases in renin cause extracellular volume expansion and volume-dependent hypertension, which persists because there is no contralateral normal kidney to excrete more sodium. In persons with bilateral disease, the hypertension is volume dependent but becomes renin dependent with extracellular volume depletion.

- Renovascular disease is the most common form of potentially curable secondary hypertension.
- Renal artery stenosis activates the renin-angiotensin system.
- Angiotensin II is a potent vasoconstrictor; it increases renal sodium reabsorption directly and through stimulation of aldosterone production, and also increases sympathetic nervous system activity, thirst, and vasopressin release.
- Renovascular hypertension is due to extracellular volume expansion and increased peripheral vascular resistance.
- Unilateral disease is associated with renin-dependent hypertension, whereas bilateral disease is associated with volume-dependent hypertension.

Correcting renal ischemia eliminates the stimulus for excess renin release and can cure or lessen hypertension. In unilateral renal artery stenosis, prolonged hypertension eventually causes nephrosclerosis in the nonischemic kidney (in combination with other cardiovascular risk factors) or ischemic injury to the involved kidney. If either occurs, relieving renal arterial stenosis may not cure hypertension. The longer the duration of hypertension before diagnosis, the greater the likelihood of these untoward renal outcomes and the less the likelihood of cure of hypertension with intervention.

- Correcting renal ischemia eliminates excess renin release.
- The longer the duration of hypertension before diagnosis, the less likely that correction of renal ischemia will be beneficial.

Fibromuscular disease is the most common cause of renovascular hypertension in younger persons, especially women between 15 and 50 years old. It accounts for 15% of renovascular hypertension in the population. Lesions usually affect the middle and distal portions of the main renal vessels, often extending into branches. The disease more commonly affects the right renal artery and is often bilateral. Three subtypes have been defined on the basis of the portion of the arterial wall involved: 1) intimal fibroplasia (1%-2% of cases), 2) medial fibromuscular dysplasia (95% of cases), and 3) periadventitial fibrosis (1%-2% of cases). Medial fibromuscular dysplasia, the most common subtype in adults, has a classic string-of-beads appearance (representing aneurysmal dilatations associated with intravascular webs) on angiography (Fig. 13-1) and progresses in 30% of cases. Medial fibromuscular dysplasia may also occur in other vessels branching off the aorta (e.g., the carotid and celiac arteries). The rare subtypes of intimal fibroplasia and periadventitial fibrosis can progress rapidly to severe stenoses. Dissection and thrombosis can occur and are seen more commonly with the rare subtypes. Occlusion of the renal artery is rare.

- Fibromuscular disease is the most common cause of renovascular hypertension in younger persons, especially women of childbearing age.
- Medial fibromuscular dysplasia is the most common subtype and has a string-of-beads appearance on angiography.
- Dissection and thrombosis of a renal artery are complications most commonly seen with rare subtypes.
- Renal artery occlusion is rare.

Atheromatous disease is the most common cause of renovascular hypertension in middle-aged or older persons. It accounts for 85% of renovascular hypertension in the population and is more common in men than in women. The lesions usually are in the proximal third of the renal artery, often near or at the orifice (Fig. 13-2). In many instances, renal artery obstruction is due to extension of aortic atheromatous disease across the orifice of the artery. Although atheromatous renal artery disease is common in older persons with hypertension (especially in diabetics or persons with evidence of atherosclerosis in other vascular beds), it causes or aggravates hypertension less often. The disease is bilateral in 30% of cases, and in 35% of cases it progresses even if blood pressure is controlled. Atherosclerosis of the renal artery can progress to occlusion of the vessel. Progressive disease can cause end-stage renal disease.

- Atheromatous disease is the most common cause of renovascular hypertension in middle-aged or older persons.
- The disease is bilateral in 30% of cases and progressive in 35%.
- It can cause renal artery occlusion.

Clues suggesting renovascular hypertension include lack of a family history of hypertension, onset of hypertension before age 30 (consider fibromuscular dysplasia, especially in a woman), onset of hypertension after age 50 (consider atherosclerotic renovascular disease, especially in a smoker or a person with coronary or peripheral arterial disease), presentation with accelerated or malignant hypertension,

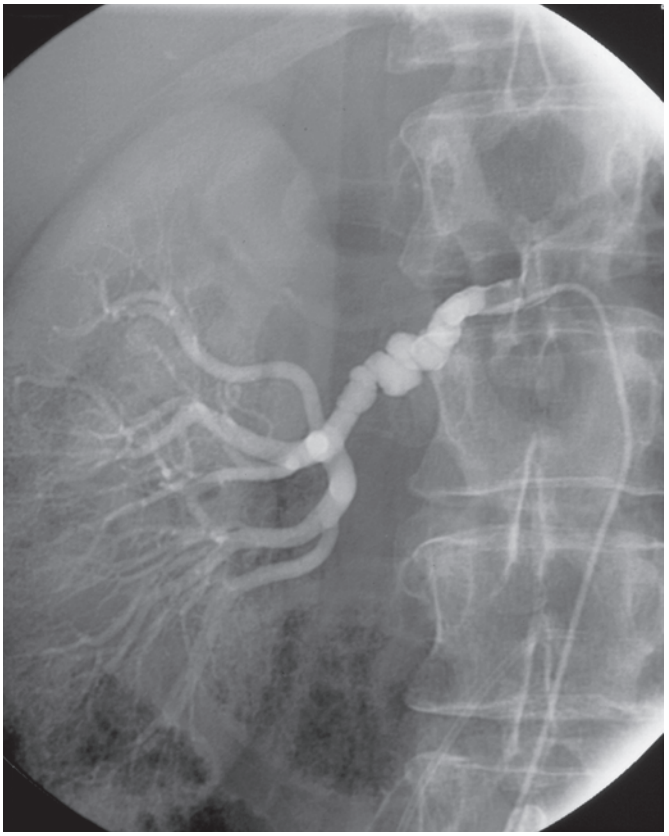

Fig. 13-1. Fibromuscular renal vascular disease (medial fibromuscular dysplasia).

or sudden worsening of preexisting hypertension in a middle-aged or older person (renovascular hypertension superimposed on essential hypertension). Persons with cardiovascular risk factors (tobacco use, hyperlipidemia, or diabetes) are at increased risk of atherosclerotic renal artery stenosis. The most important physical finding is an abdominal bruit, especially a high-pitched systolic-diastolic bruit in the upper abdomen or flank. However, 50% of persons with renovascular hypertension do not have this finding. Other physical clues are severe retinopathy of accelerated or malignant hypertension (hemorrhages, exudates, and papilledema) or evidence of atherosclerotic occlusive disease in other vascular beds (atherosclerotic renal artery stenosis of >50% is observed in up to 20% of persons with coronary artery disease and in up to 50% of persons with peripheral arterial disease). Laboratory abnormalities are hypokalemia (due to secondary aldosteronism), an increased serum level of creatinine, proteinuria (rarely in the nephrotic range), and a small kidney seen on an imaging study.

- For hypertension before age 30, especially in a woman, consider fibromuscular dysplasia.
- For hypertension after age 50, especially in a smoker or a person with coronary or peripheral arterial disease, consider atherosclerotic renovascular disease.
- The most important physical finding is an abdominal bruit; however, it is present in only 50% of cases.
- Laboratory abnormalities: hypokalemia, increased serum level of creatinine, proteinuria, and a small kidney seen on an imaging study.

Underlying bilateral renal artery stenosis may be indicated by an acute decline in renal function (≥20% increase in serum creatinine) either after the initiation of therapy with an ACEI or an ARB or after a drug-induced, sudden decrease in blood pressure. Other signs in patients presenting with bilateral renal artery stenosis (i.e., ischemic nephropathy) include the sudden development of pulmonary edema accompanied by severe hypertension (flash pulmonary edema), frequent episodes of symptomatic congestive heart failure accompanied by increases in blood pressure, or a subacute decline in renal function with or without worsening hypertension.

Patients with atheroembolic renal disease may also present with a sudden onset or worsening of hypertension and a subacute decline in renal function. Historical clues (e.g., occurrence after angiography or vascular surgery), physical findings (distal livedo reticularis and peripheral emboli), and laboratory abnormalities (increased erythrocyte sedimentation rate, anemia, hematuria, eosinophilia, and eosinophiluria) help identify this disorder.

- A sudden decline in renal function with the use of an ACEI or an ARB or an episode of unexplained pulmonary edema may indicate bilateral renal artery disease.
- The sudden onset or worsening of hypertension accompanied by a subacute decline in renal function may also be due to atheroembolic renal disease (especially if onset is after an angiogram or vascular surgery).

Fig. 13-2. Atherosclerotic renovascular disease.

In young persons who have hypertension (even if not severe) of short duration and suggestive clinical features, evaluation for renovascular disease is indicated. Renal artery stenosis in these persons can be identified and corrected with a low risk of morbidity and mortality and a high probability of cure. Older persons should be evaluated for renovascular hypertension on a selective basis. In general, selection should be restricted to persons who have suggestive clinical features and blood pressure that cannot be controlled medically or who have an unexplained, observed decline in renal function or a cardiorenal syndrome (recurrent flash pulmonary edema or resistant heart failure) and who are considered reasonable risks for (and are willing to undergo) interventional therapy.

- In young persons with hypertension of short duration, evaluate for renovascular disease.
- Older persons should be evaluated for renovascular hypertension on a selective basis.

Screening Tests

Although several tests are available to screen for renal artery stenosis, duplex renal ultrasonography, magnetic resonance angiography, and spiral computed tomographic (CT) angiography are considered the initial screening tests of choice. The major concern with all available screening tests is inadequate sensitivity leading to a missed opportunity to identify a correctable cause of hypertension.

Duplex Ultrasonography

Duplex ultrasonography is noninvasive and does not use contrast media. Its usefulness extends to persons who have renal insufficiency or a history of contrast allergy. Performance of the test does not require discontinuation of any antihypertensive drug. It identifies increases in blood flow velocity that occur with luminal narrowing of a renal artery. Criteria for a positive test are 1) a ratio of peak flow velocity in the involved renal artery to peak flow velocity in the aorta of more than 3.5 and 2) renal artery peak systolic flow of 180 cm/s or more. The resistive index in segmental vessels is a measure of small-vessel disease in the kidney and is calculated as

$$1 - (\text{end-diastolic velocity}/\text{peak systolic velocity}) \times 100$$

The resistive index is used to identify persons more (low resistive index) or less (high resistive index [>80]) likely to benefit from interventional therapy, and it provides information on kidney size, screens for obstructive uropathy and aortic aneurysm, and identifies bilateral renal artery stenosis. Overlying bowel gas or other technical problems limit the complete study of both renal arteries in up to 50% of cases. Often, accessory or branch vessel disease is not identified. The sensitivity and specificity are 75% to 80%.

- Consider duplex ultrasonography in persons with renal insufficiency or a history of contrast allergy.
- Sensitivity and specificity are 75% to 80%.
- The resistive index can be used to determine the likelihood of benefit from intervention.
- The resistive index measures renal size and screens for obstructive uropathy and aortic aneurysm.
- In up to 50% of persons, one or both renal arteries cannot be studied adequately.
- Accessory or branch vessel disease may not be identified.

Magnetic Resonance Angiography

Magnetic resonance angiography (MRA) visualizes the main renal arteries without use of a radiocontrast agent or exposure to radiation. Its usefulness extends to persons with renal insufficiency or those with a history of radiocontrast allergy. Also, it is a reasonable choice for persons with a high likelihood of the disorder who have concomitant severe, diffuse atherosclerosis and, thus, are at high risk of atheroembolization with angiography. Field limitations may decrease the ability to see lesions in the distal main renal arteries or lesions in branch vessels (common sites of fibromuscular disease). Accessory renal arteries may not be identified, the degree of arterial stenosis may be overestimated, and persons prone to claustrophobia may not tolerate being placed in the magnetic resonance equipment. Renal stents cause imaging artifacts, and persons with cardiac pacemakers, metallic artificial cardiac valves, or cerebral artery aneurysm clips cannot be imaged. Sensitivity is 80% to 90% (less for fibromuscular dysplasia), and specificity is 90%. This is an expensive screening test.

- MRA visualizes the renal arteries without a radiocontrast agent or radiation exposure.
- It is a good choice for persons with renal insufficiency or radiocontrast allergy.
- It is not a good test if fibromuscular disease is the concern.
- Renal stents cause imaging artifacts.
- Patients may feel claustrophobic.
- MRA cannot be used in persons with cardiac pacemakers or other metallic implants.
- It is expensive.

Spiral Computed Tomographic Angiography

Spiral CT angiography offers excellent three-dimensional images but requires a considerable amount of radiocontrast agent and patient cooperation. This is an option for persons with normal renal function who do not have a contrast allergy and in whom MRA is contraindicated. Renal stents do not cause imaging artifacts. Sensitivity and specificity are similar to those for MRA. This is also an expensive test.

- Spiral CT angiography requires a considerable amount of radiocontrast agent.
- Consider spiral CT angiography for persons with normal renal function in whom MRA is contraindicated.

Other noninvasive tests are available to screen for renal artery stenosis; however, they are used less often because the test characteristics are inferior compared with those of duplex ultrasonography, MRA, and spiral CT angiography.

Historically, the intravenous pyelogram (IVP) was the mainstay screening test for renovascular hypertension. For screening,

radiographs that are taken at 1-minute intervals for the first 5 minutes after injection of contrast medium are used to identify a delay in the appearance of contrast medium in the renal collecting system on the side of a renal artery stenosis. This is referred to as the hypertensive IVP. Characteristic findings on a hypertensive IVP suggesting renal artery stenosis are 1) unilateral reduction in renal size (≥1.5-cm decrease in pole-to-pole diameter of the smaller kidney); 2) delayed appearance of contrast medium in the collecting system of the ischemic kidney; 3) hyperconcentration of contrast medium in the ischemic kidney; 4) ureteral scalloping by collateral vessels; and 5) cortical thinning or irregularity. Sensitivity is 70% to 75%, and specificity is 85%.

Captopril Radionuclide Renal Scan

Some still consider the captopril radionuclide renal scan to be a useful screening test. However, recent reviews suggest a lower test sensitivity than was reported earlier. Currently, sensitivity is estimated at 75% and specificity at 85%. Pretest treatment of patients with captopril (25-50 mg given 1 hour before isotope injection) increases the sensitivity of the scan compared with that of standard renography. The rationale is that glomerular filtration in an ischemic kidney depends on the vasoconstricting effect of angiotensin II on the efferent arteriole of the nephron to maintain effective transglomerular filtration pressure. Treatment with an ACEI causes efferent arteriolar dilatation, with loss of filtration pressure in the nephron. This causes a decline of glomerular filtration in the ischemic kidney, with less of an effect on renal blood flow. These changes are identified with the scanning technique. The radionuclides used most commonly are iodine 131 orthoiodohippuric acid (OIH) and Tc-99m mercaptoacetyltriglycine (MAG3), which are markers for renal blood flow (they are excreted primarily by renal tubular secretion), and Tc-99m diethylenetriamine pentaacetic acid (DPTA), which is a marker for glomerular filtration rate (it is excreted primarily by glomerular filtration). Criteria for a positive test with DPTA are time to peak activity in the kidney of 11 minutes or more and a ratio of the glomerular filtration rate between the kidneys of 1.5 or more. The criterion for a positive test with OIH or MAG3 is residual cortical activity at 20 minutes of 30% or more of peak activity. The renal scan is safe for persons with a history of contrast allergy. The interpretive value is reduced by renal insufficiency (creatinine >2.0 mg/dL) or by bilateral or branch renal artery disease. Urinary outflow obstruction may mimic renal artery stenosis.

- Some consider the captopril radionuclide renal scan a useful screening test.
- Sensitivity is 75%, and specificity is 85%.
- It is safe for persons with a history of contrast allergy.
- It is ineffective in renal insufficiency.
- Findings with unilateral urinary outflow obstruction are similar to those with renal artery stenosis.

Captopril Test

Acute blockade of angiotensin II formation by ACEIs induces a reactive increase in PRA. The magnitude of this increase is usually greater in renovascular hypertension than in essential hypertension and is the basis for the captopril test. The use of antihypertensive drugs that influence the renin-angiotensin-aldosterone axis must be discontinued for several days before the test. PRA is measured at baseline and at 60 minutes after administering captopril orally. Criteria for a positive test are 1) PRA of more than 12 ng/mL per hour after administration of captopril, 2) absolute increase in PRA over baseline of at least 10 ng/mL per hour, and 3) increase in PRA of 150% or more if the baseline PRA is more than 3 ng/mL per hour or 400% or more if the baseline PRA is less than 3 ng/mL per hour. The results are compromised if the person has renal insufficiency. Sensitivity is 39% to 100%, and specificity is 72% to 100%. Because the results can be influenced by many factors that are difficult to identify and control, predictive accuracy is low.

- Captopril test: difficult to control all factors that influence test results.
- Sensitivity is 39%-100%, and specificity is 72%-100%.
- The test is unreliable in persons with renal insufficiency.

Renal Vein Renins

Lateralization of renal vein renins is a good predictor of a favorable outcome after intervention for unilateral renal artery stenosis; however, because many factors that influence renin secretion are difficult to identify and control (as noted for the captopril test), the predictive value of the test is low. It is invasive and expensive. Lateralization is present if the ratio of renin activity on the affected side compared with that on the normal side is 1.5:1.0 or more. Sensitivity is 63% to 77%, and specificity is 60% to 95%.

- Measurement of renal vein renin activity is an expensive and invasive test.
- Sensitivity is 63%-77%, and specificity is 60%-95%.
- Lateralization of renal vein renins is a good predictor of a favorable outcome after intervention for unilateral renal artery stenosis.

Digital Venous Subtraction Angiography

Digital venous subtraction angiography uses contrast media, but access to the circulation is through a peripheral vein. With the advent of newer screening tests, it is used less often. This technique provides adequate visualization of the proximal portion of the main renal arteries (usual location of atherosclerotic disease) in 90% of persons but less effective visualization of the distal portions of the main renal arteries or branches (the usual location of fibromuscular dysplasia). This technique is expensive, and in 20% to 30% of persons, neither renal artery is identified because of superimposition of abdominal vessels or patient motion. Both the sensitivity and the specificity are 85% to 90%.

- In current practice, digital venous subtraction angiography is used less often.
- Both sensitivity and specificity are 85%-90%.
- The proximal portions of the main renal arteries are visualized in 90% of persons.
- It is less effective for assessing distal portions of the main renal arteries or branches.

- It is expensive.
- At least one renal artery is not identified in 20%-30% of cases.

Renal Arteriography

Conventional renal arteriography is the diagnostic standard test to identify renal artery stenosis. In clinical situations in which the pretest likelihood is high (≥50%), a negative result from a screening test still leaves a significant posttest probability of disease (≥20%). Thus, in these settings, consideration should be given to performing renal angiography without first performing screening tests. Exceptions may be when patients have diabetes or severe generalized atherosclerosis with concomitant renal insufficiency and use of a noninvasive test initially, such as MRA or duplex ultrasonography, may be reasonable. This is because in these settings, the risk of contrast-induced acute renal failure or atheroembolism is significant. Contrast toxicity from angiography can be reduced with the use of gadolinium or carbon dioxide as the contrast agent. However, these techniques do not reduce the risk of atheroembolism.

- Renal arteriography: the diagnostic standard test for identifying renal artery stenosis.
- If pretest likelihood is high and the person is at low risk of contrast toxicity or atheroembolism, consider renal angiography as the initial test.

Therapy for Renovascular Hypertension

Options for the management of renovascular hypertension include medical and interventional therapies. Percutaneous balloon angioplasty, stent placement, and surgical procedures to relieve renal ischemia are the interventional treatments. Goals of interventional therapy are to cure or improve hypertension or to preserve renal function. Medical therapy is reserved for persons who are not considered candidates for interventional therapy (because of the extent or location of the vascular lesions, high surgical risk, or uncertainty about the causative significance of the lesion) or who are unwilling to undergo interventional therapy. As noted earlier, selection of persons for screening excludes older persons with controlled hypertension and no evidence of progressive renal dysfunction even if renovascular disease is suspected.

Percutaneous transluminal angioplasty is the treatment of choice for amenable lesions caused by fibromuscular dysplasia and is an option with or without stent placement in some cases of atherosclerotic renovascular disease. Hypertension is cured in 50% and improved in 35% of persons with fibromuscular dysplasia. The failure rate is 15%. In contrast, hypertension is cured in 20% and improved in 50%, with a failure rate of 30%, in persons with atherosclerotic renovascular disease. Complications of angioplasty include groin hematoma, dye-induced azotemia, dissection of the renal artery, renal infarction, and, rarely, rupture of the renal artery, with the potential for loss of the kidney and the need for immediate surgery. Atheroembolization is a risk in older persons with diffuse atherosclerosis.

- Angioplasty is the treatment of choice for amenable lesions caused by fibromuscular dysplasia and is an option for some lesions caused by atherosclerosis.
- Complications of angioplasty: groin hematoma, dye-induced azotemia, dissection of the renal artery, renal infarction, and, rarely, rupture of the renal artery.

Stent-supported angioplasty is an appropriate option for some persons with atherosclerotic renal artery stenosis, especially for orificial disease. In the presence of aneurysmal or severe atherosclerotic disease of the aorta requiring concomitant aortic reconstruction, or in persons in whom percutaneous intervention has failed, surgical intervention is the treatment of choice. Kidneys with a pole-to-pole length of 8 cm or less should be removed—not revascularized—if intervention is indicated and removal will not jeopardize overall renal function.

The role of interventional therapy for preservation of renal function in ischemic nephropathy is uncertain. In most cases, the underlying disease is atherosclerosis. Improvement in renal function, defined as a decrease in serum creatinine, occurs in 30% of cases. In approximately 50% of cases, the creatinine level does not decrease; however, benefit may be defined as stabilization of renal function. Of concern is that in 20% of cases, renal function deteriorates rapidly after the intervention, most likely from a combination of several factors, including contrast toxicity, acute renal artery thrombosis, or atheroembolization.

- Stent-supported angioplasty is an option for some patients with atherosclerotic renal artery stenosis.
- Surgical treatment is best for cases of atheromatous renal artery disease associated with aneurysmal or severe atherosclerotic disease of the aorta requiring concomitant aortic reconstruction and for percutaneous intervention failures.
- Intervention to preserve renal function in ischemic nephropathy is uncertain.

The medical treatment of renovascular hypertension is not different from that of essential hypertension. Both volume retention (due to aldosterone) and vasoconstriction (due to activation of the sympathetic nervous system and angiotensin II) contribute to the elevation of blood pressure. ACEIs and ARBs can precipitate acute renal failure in the presence of bilateral renal artery stenosis. Medical treatment does not correct the underlying ischemia of the affected kidney, and decreases in systemic blood pressure may further aggravate loss of renal function. Progression of atherosclerotic renal artery disease can be slowed by control of all modifiable risk factors, including the use of statin drugs for aggressive lowering of cholesterol. In medically managed persons, renal function should be followed carefully because deterioration may be a sign of progressive disease.

- The medical treatment of renovascular hypertension is similar to that of essential hypertension.
- If there is bilateral renal artery stenosis, ACEIs and ARBs can precipitate acute renal failure.
- Medical treatment does not correct the underlying ischemia of the affected kidney.
- Management of all modifiable cardiovascular risk factors can lessen the risk of progression of atherosclerotic renovascular disease.

- Typical clinical scenario for renovascular hypertension due to fibromuscular dysplasia: A 30-year-old woman complains of new-onset headaches for the past 2 months. She has no past history of hypertension. On examination, blood pressure is 180/110 mm Hg. Retinal examination shows hemorrhages. On auscultation of the abdomen, a systolic-diastolic bruit is heard in the left upper quadrant.
- Typical clinical scenario for renovascular hypertension due to atherosclerosis: A 54-year-old man has a several-year history of mild hypertension that has been well controlled. He has a 30 pack-year history of cigarette smoking and hypercholesterolemia that is diet-controlled. He has a past history of coronary artery bypass graft surgery. Blood pressure suddenly worsens and is now 170/115 mm Hg. On auscultation of the abdomen, a systolic bruit is detected in the right upper quadrant. Bilateral femoral bruits are also noted.

Renal Parenchymal Disease

Renal parenchymal disease is the most common secondary cause of hypertension and is present in 2% to 5% of persons with elevated blood pressure. Also, hypertension is a common cause of chronic kidney disease and is the second most common cause of end-stage renal failure in the population. Persons with chronic kidney disease and hypertension are at high risk of cardiovascular disease. Contributing to this increased risk is a loss of the normal nocturnal decline in blood pressure ("non-dipper") in persons with renal disease.

Regardless of the cause of chronic kidney disease, hypertension is associated with a more rapid loss of renal function. This may be due to transmission of higher pressures into the glomerulus as afferent renal artery resistance fails to limit transmission of higher systemic pressures into the nephron. Higher glomerular transcapillary pressures and flows injure glomerular cells by several mechanisms, ultimately leading to glomerulosclerosis. In addition, the degree of proteinuria is an independent predictor of progressive loss of renal function.

At least three major mechanisms are involved in the hypertension of renal disease: volume expansion from impaired renal elimination of salt and water, oversecretion of renin, and decreased production of renal vasodilators (i.e., prostaglandins, kallikrein, or kinin). In addition, accumulation of mediators of oxidative stress, reducing the availability of the vasodilator nitric oxide, and increased levels of the vasoconstrictor endothelin may also contribute.

The blood pressure goal in chronic kidney disease is less than 130/80 mm Hg. Achieving this goal lessens the risk of progressive loss of renal function and often requires the use of three or more antihypertensive drugs. Treatment should begin with dietary sodium restriction. In addition, diuretic therapy is often essential for blood pressure control. If serum creatinine is more than 2.0 mg/dL (GFR <30 mL/min), the more potent loop agents or metolazone is necessary. In diuretic-resistant persons, the combination of a loop agent with a thiazide may be required. Oversecretion of renin occurs in only a small proportion of persons with chronic kidney disease; however, ACEIs reduce proteinuria and high glomerular transcapillary pressures by decreasing resistance in the efferent arteriole of the nephron. These actions retard further loss of renal function in persons with diabetic or nondiabetic renal disease. ACEIs can cause hyperkalemia and an acute decline in renal function. Unless severe, modest acute declines in renal function (<30%) should be tolerated because the acute decline is often followed by stabilization and preservation of renal function chronically. An increase in serum levels of potassium of up to 5.5 mEq/L is usually well tolerated. An acute, severe decline in renal function with ACEI therapy (>30%) raises the possibility of bilateral renal artery stenosis. ARBs can be used if ACEIs are not tolerated and may be used instead of ACEIs in persons with type 2 diabetes and nephropathy. CCBs are effective blood pressure–lowering drugs in persons with chronic kidney disease. Nondihydropyridine CCBs reduce proteinuria, but dihydropyridine CCBs do not. In proteinuric renal disease not controlled with adequate doses of a diuretic and an ACEI, a nondihydropyridine CCB could be added as a third agent. β-Blockers should be considered if the person has angina or previously had a myocardial infarction. In advanced renal insufficiency, avoid the use of lipid-insoluble β-blockers, which rely on the kidney for excretion. Hydralazine or minoxidil should be considered for resistant hypertension (requires concomitant use of an adrenergic inhibitor and diuretic).

- Renal parenchymal disease: the most common secondary cause of hypertension.
- Hypertension: the second most common cause of end-stage renal disease.
- Treatment of hypertension in renal disease should include sodium restriction, diuretics appropriate to level of renal function, and ACEIs.
- ACEIs slow the progression of proteinuric renal disease.
- In chronic kidney disease, ACEI therapy can cause hyperkalemia and acute declines in renal function.
- ARBs are alternatives in ACEI-intolerant persons.
- Hydralazine or minoxidil should be considered for resistant hypertension.

Primary Aldosteronism

Hypertension, hypokalemia (with renal wasting of potassium and alkalosis), suppressed plasma renin activity, and increased aldosterone levels characterize the syndrome of primary aldosteronism. Prevalence estimates range from 2% to 15% of the hypertensive population. Its main subtypes are unilateral aldosterone-producing adenoma (30%-40% of cases) and bilateral idiopathic zona granulosa adrenal hyperplasia (60%-70% of cases). Rarer subtypes are unilateral hyperplasia, glucocorticoid suppressible hyperplasia, and aldosterone-producing cortical carcinoma. Primary aldosteronism should be suspected in any hypertensive person who presents with spontaneous hypokalemia or marked hypokalemia precipitated by usual doses of diuretics (potassium <3.0 mEq/L). Other causes of hypokalemic hypertensive syndromes should be considered: diuretics, renovascular hypertension, exogenous steroids, Cushing disease, excess deoxycorticosterone, Liddle syndrome, 11β-hydroxylase deficiency, and ingestion of licorice containing glycyrrhizinic acid (renal cortisol catabolism inhibitor). Primary aldosteronism may be the cause of resistant hypertension even in the absence of hypokalemia because

approximately 30% of cases are not associated with spontaneous hypokalemia. It also should be considered in persons who have hypertension and a known adrenal mass (in addition to Cushing disease and pheochromocytoma) or in persons who have hypokalemia despite taking ACEIs or ARBs for treatment of hypertension (in the presence or absence of concomitant diuretic use).

- Primary aldosteronism: hypertension, hypokalemia (with renal wasting of potassium and alkalosis), suppressed plasma renin activity, and increased aldosterone.
- Main subtypes: unilateral aldosterone-producing adenoma and bilateral adrenal hyperplasia.
- Suspect primary aldosteronism in persons with spontaneous hypokalemia, marked hypokalemia precipitated by usual doses of diuretics, resistant hypertension, hypertension and an adrenal mass, or hypokalemia despite use of ACEIs or ARBs.

Clinical Features

Clinical symptoms are uncommon. Most persons with primary aldosteronism cannot be distinguished from those with essential hypertension. Rarely, severe hypokalemia may cause muscle weakness, cramps, headache, palpitations, polydipsia, polyuria, or nocturia. Hypertension is usually moderate, but it may be severe and resistant to control. Retinal vascular changes of severe hypertension may be present. Left ventricular hypertrophy and heart failure may be more common than with essential hypertension, in part because of the profibrotic effects of aldosterone on the heart. Rarely, the sign of Trousseau or Chvostek may be present if marked alkalosis is associated with the hypokalemia. Peripheral edema is rare.

- Clinical symptoms are uncommon.
- Severe hypokalemia may cause muscle weakness, cramps, headache, palpitations, polydipsia, polyuria, or nocturia.
- Peripheral edema is rare.

Laboratory Features

Characteristic laboratory abnormalities include hypokalemia, mild metabolic alkalosis (serum bicarbonate >31 mEq/L), and relative hypernatremia (serum sodium concentration >142 mEq/L). Relative hypernatremia is related to suppression of vasopressin from volume expansion, resetting of the central osmostat for vasopressin release, altered thirst, and hypokalemia-induced suppression of vasopressin release or action. A mild increase in the fasting blood glucose level is detected in 25% of persons (hypokalemia suppresses insulin release). The electrocardiogram may show changes of hypokalemia (prolongation of the ST segment, U waves, and T-wave inversions) as well as left ventricular hypertrophy.

- Laboratory abnormalities in primary aldosteronism: hypokalemia, mild metabolic alkalosis, relative hypernatremia, and increased fasting glucose level.
- Electrocardiogram may show changes of hypokalemia (prolongation of the ST segment, U waves, and T-wave inversions) or left ventricular hypertrophy.

Diagnosis

The investigation for primary aldosteronism is divided into three phases: 1) screening, 2) confirmation of the diagnosis, and 3) determination of the subtype.

Screening studies should include measurement of serum sodium, potassium, PRA, and bicarbonate. If the person is hypokalemic, a 24-hour urine collection for potassium should be performed initially to determine whether the hypokalemia is from renal potassium wasting (>30 mEq of potassium in a 24-hour collection in the presence of hypokalemia defines renal potassium wasting). A plasma aldosterone concentration (PAC) may be determined because some advocate calculating the ratio of PAC to PRA. A ratio greater than 15 suggests the diagnosis of primary aldosteronism. Ideally, PRA and PAC should be measured in the morning after discontinuing the use of drugs that could influence the measurements (diuretics, β-blockers, ACEIs, ARBs, and spironolactone). Because PRA and PAC can vary significantly in persons with the disorder, a single normal value for the ratio does not exclude the diagnosis. Sensitivity of the ratio is 75% when measured with persons receiving antihypertensive medications and 85% when measured with persons not receiving antihypertensive drug therapy. Specificity is relatively low (75%) under either condition of measurement.

In persons with positive screening test results, 24-hour urinary aldosterone excretion should be measured during the fourth day of a high-salt diet. The diagnosis of primary aldosteronism rests on demonstrating renin suppression and inappropriately high aldosterone excretion in a sodium-replete state (24-hour sodium excretion >200-250 mEq) in hypertensive persons. Before a diagnostic evaluation is initiated, the use of potentially interfering drugs must be discontinued and plasma volume status assessed. Spironolactone influences the renin-angiotensin-aldosterone axis and must be discontinued for at least 6 weeks before investigation. Diuretics, ACEIs, and ARBs may increase and β-blockers may decrease PRA levels in persons with primary aldosteronism. If hypertension must be treated in the interim, guanadrel, α-blockers, or CCBs may be used. After a high-salt diet for 3 days (and with concomitant vigorous potassium supplementation), a 24-hour urine specimen should be collected for measurement of sodium, potassium, creatinine, and aldosterone. PRA should also be measured. Creatinine can be used as an approximation of the adequacy of the collection. A 24-hour urine aldosterone greater than 12 to 14 μg (when urine sodium is >200-250 mEq) with a concomitant PRA less than 1.0 ng/mL per hour confirms the diagnosis of primary aldosteronism.

- In a hypokalemic, hypertensive person, a PAC:PRA ratio >15 suggests primary aldosteronism.
- Before diagnostic evaluation, discontinue the use of drugs that could influence PRA or PAC levels and assess plasma volume status.
- During the fourth day of a high-salt diet, measure PRA and collect a 24-hour urine specimen for measurement of sodium, potassium, creatinine, and aldosterone.
- A 24-hour urine aldosterone >12 to 14 μg (with concomitant urine sodium >200-250 mEq) along with a PRA <1.0 ng/mL per hour confirms the diagnosis of primary aldosteronism.

The major subtypes to distinguish are unilateral aldosterone-producing adenoma and bilateral adrenal hyperplasia. Removing an aldosterone-producing adenoma normalizes blood pressure in approximately 30% of cases and relieves hypokalemia in 100%. Unilateral or bilateral adrenalectomy seldom corrects hypertension when bilateral adrenal hyperplasia is present. CT or magnetic resonance imaging (MRI) of the adrenal glands is the initial study for distinguishing between subtypes. CT is effective in localizing adenomas larger than 1 cm in diameter when the adrenal glands are imaged at 0.3-cm intervals. Generally, if a single adenoma larger than 1 cm in diameter is clearly identified, surgical treatment is the choice. If no mass is identified, assume the diagnosis is bilateral hyperplasia and prescribe spironolactone, eplerenome, or other potassium-retaining diuretics. Often, additional medications are needed for blood pressure control.

- Removing an aldosterone-producing adenoma normalizes blood pressure in 30% of cases and hypokalemia in 100%.
- Unilateral or bilateral adrenalectomy seldom corrects hypertension in persons with bilateral adrenal hyperplasia.
- CT or MRI of the adrenal glands is the initial study for distinguishing between subtypes.
- If a single adenoma is >1 cm in diameter, the treatment is surgical.
- If no mass is detected, prescribe spironolactone, eplerenone, or other potassium-retaining diuretics and other medications as needed to control blood pressure.

If the results are equivocal or the gland opposite that containing the presumed adenoma is abnormal or if CT findings are normal in a person with severe hypertension, hypokalemia, and markedly elevated aldosterone (findings suggestive of an adenoma), sampling blood from the adrenal veins for aldosterone may identify the adrenal gland containing the functioning adenoma not clearly detected on imaging. In these situations, subspecialty consultation should be sought.

- If the results are equivocal, sampling blood from the adrenal veins for aldosterone may identify the adrenal gland containing the functioning adenoma.
- Typical clinical scenario for primary aldosteronism: A 42-year-old man is evaluated for resistant hypertension. The physical examination findings are normal except for an elevated blood pressure of 150/105 mm Hg despite treatment with an ACEI, a β-blocker, and a CCB. Initial laboratory values are sodium 144 mEq/L, potassium 2.9 mEq/L, glucose 110 mg/dL, and creatinine 1.0 mg/dL.

Pheochromocytoma

Pheochromocytomas are tumors of chromaffin cell origin (derived from the embryonic neural crest) that cause paroxysmal or sustained hypertension due to excess production of catecholamines. Tumors are present in the adrenal medulla (pheochromocytomas) or sympathetic ganglia (extra-adrenal pheochomocytomas or paragangliomas). Nonchromaffin paragangliomas (chemodectomas) arise from parasympathetic ganglia in the head and neck (carotid body and glomus jugulare [cranial nerves IX and X]). Patients with paragangliomas below the neck usually present with catecholamine excess, whereas patients with paragangliomas in the head or neck often present with clinical features associated with a mass effect (cranial nerve palsies or tinnitus).

The incidence in the general population is 2 to 8 cases per million persons per year. The prevalence is 0.5% among persons with hypertension and suggestive symptoms and 4% among hypertensive persons with an adrenal tumor. A "rule of 10" is often quoted for pheochromocytoma: 10% are extra-adrenal (90% are located in one or both adrenal glands); 10% of extra-adrenal gland tumors are extra-abdominal (90% are located in the abdomen or pelvis); 10% occur in children (90% occur in adults between the third and fifth decades of life; equal occurrence in men and women); 10% are multiple or bilateral; 10% recur after the initial resection; 10% are malignant; 10% are found in persons without hypertension; and 10% are familial. Recent studies suggest that up to 11% of patients with presumed sporadic pheochromocytomas (solitary adrenal tumor, negative family history, and no associated disease) may still have an inherited form of the disease. Thus, more than 10% of pheochromocytomas may actually be familial in origin.

Extra-adrenal pheochromocytomas may occur anywhere along the sympathetic chain (paragangliomas) and occasionally in aberrant sites (superior para-aortic region [46%], glomus jugulare, inferior para-aortic region [29%], bladder [10%], or thorax [10%]). Chromaffin cells synthesize catecholamines from tyrosine. Norepinephrine is the end product in all sites except the adrenal medulla, where 75% of norepinephrine is metabolized to epinephrine. Extra-adrenal tumors produce only norepinephrine, whereas adrenal tumors may produce an excess of one or both catecholamines. A person with a tumor that secretes predominantly epinephrine has mainly systolic hypertension, tachycardia, sweating, flushing, and tremulousness and may present with hypotension. A person with a tumor that secretes mainly norepinephrine has both systolic and diastolic hypertension, less tachycardia, and fewer paroxysms of anxiety and palpitations.

- Pheochromocytoma: remember the "rule of 10."
- Ninety percent are in one or both adrenal glands.
- Tumors may occur anywhere along the sympathetic chain (paragangliomas).
- It is malignant in up to 10% of cases.
- An extra-adrenal tumor produces only norepinephrine.
- An adrenal tumor can produce an excess of epinephrine or norepinephrine (or both).

Pheochromocytomas associated with familial syndromes are more likely to be bilateral or extra-adrenal and occur at a young age. Familial syndromes have an inheritance pattern that is autosomal dominant with variable penetrance and include the following:

1. Multiple endocrine neoplasia type 2A (medullary carcinoma of the thyroid [increased plasma level of calcitonin], pheochromocytoma, and hyperparathyroidism due to primary hyperplasia) and type 2B (medullary carcinoma of the thyroid, pheochromocytoma, mucosal neuromas, thickened corneal nerves, intestinal ganglioneuromatosis, and marfanoid body

habitus [Fig. 13-3 and 13-4]). These are associated with activating mutations of the *RET* proto-oncogene. The risk of pheochromocytoma is 50%.
2. Neurofibromatosis (café au lait spots). The risk of pheochromocytoma, due to mutations in the *NF-I* gene, is 0.1% to 5.7%.
3. von Hippel-Lindau disease (pheochromocytoma, retinal hemangiomatosis, cerebellar hemangioblastomas, epididymal cystadenoma, renal and pancreatic cysts, and renal cell carcinoma). It is associated with loss-of-function mutations in the *VHL* tumor suppressor gene. The risk of pheochromocytoma is 10% to 20%.
4. Familial paraganglioma syndrome (tumors of the head or neck [glomus tumors]) or carotid body. They are associated with mutations in the *SDHD* and *SDHB* genes. The risk of pheochromocytoma is 20%.
5. A simple form without other glandular abnormalities.

Persons with a suspected familial pheochromocytoma should undergo genetic testing. This includes persons with a family history of pheochromocytoma and persons with an apparent sporadic tumor but with a presentation consistent with a familial tumor, such as young age (<21 years) and bilateral or extraadrenal tumors. If a tumor is found, screening should be considered for first-degree relatives because of the autosomal dominant pattern of inheritance.

- Familial pheochromocytomas tend to be bilateral or extra-adrenal and occur at a young age.
- Pheochromocytoma is associated with neurofibromatosis, von Hippel-Lindau disease, multiple endocrine neoplasia types 2A and 2B, and familial paraganglioma syndrome.
- Screening should be considered for first-degree relatives of persons with familial pheochromocytomas.

Signs and Symptoms

Symptomatic paroxysms of hypertension occur in less than 50% of persons; most have sustained hypertension. Paroxysms are characterized by the classic triad of headache, diaphoresis, and palpitations. A paroxysm is usually rapid in onset, rapid in offset, and may be triggered by exercise, bending, urination, defecation, induction of anesthesia, smoking, or infusion of intravenous contrast media. Some persons have unintended weight loss, hyperglycemia, and other signs and symptoms of hypermetabolism. Others have both hypertension and orthostatic hypotension. Rarely, persons may present with catecholamine-induced cardiomyopathy, secondary erythrocytosis, fever, or peripheral vasospasm. The hypertension can be severe, resistant to control, and associated with retinopathy of accelerated-malignant hypertension.

- Classic triad of symptoms associated with pheochromocytoma: paroxysms of headache, diaphoresis, and palpitations.
- Paroxysms can be induced by exercise, bending, urination, defecation, induction of anesthesia, smoking, or infusion of contrast media.
- Some persons have unintended weight loss, hyperglycemia, or peripheral vasospasm; others have both hypertension and orthostatic hypotension.

Fig. 13-3. Marfanoid appearance of a patient with multiple endocrine neoplasia type 2B.

Fig. 13-4. Oral neuromas associated with multiple endocrine neoplasia type 2B.

Screening

Screening for pheochromocytoma should be selective. Candidates for screening are persons with paroxysmal hypertension with or without suggestive symptoms, an adrenal mass, refractory hypertension, concomitant diabetes mellitus, unintended weight loss and other features of hypermetabolism, marked hypertension in response to anesthesia induction, neurocutaneous lesions, retinal angiomas, orthostatic hypotension, or a family history of pheochromocytoma, medullary carcinoma of the thyroid, or hyperparathyroidism. States of sympathetic overactivity other than pheochromocytoma should be considered before screening. These include disorders associated with dysautonomia, significant physical or emotional stress, use of sympathomimetic drugs, coadministration of monoamine oxidase inhibitors and tyramine-containing foods ("cheese reaction"), acute withdrawal from alcohol, centrally acting antihypertensive drugs, or benzodiazepines.

Screening involves measurement of the *O*-methylated metabolites of catecholamines (metanephrine is the *O*-methylated metabolite of epinephrine, and normetanephrine is the *O*-methylated metabolite of norepinephrine). Plasma or urine measures of catecholamines alone lack diagnostic accuracy. Measurement of plasma free metanephrines (metanephrine and normetanephrine) is considered the screening test of choice because of its high sensitivity. The largest source of free metanephrines is adrenal chromaffin cells. In persons with pheochromocytoma, free metanephrines are produced within the tumor cells from catecholamines that leak from storage vesicles. This process occurs continuously and is independent of catecholamine secretion by the tumor. Measurement of the 24-hour urinary excretion of total and fractionated metanephrines (metanephrine and normetanephrine) is an alternative if the plasma test is unavailable. The urine test is less sensitive but more specific for pheochromocytoma (fewer false-positive results). Measurement of plasma free metanephrines should be strongly considered if a familial syndrome is suspected, if the person has a previous history of pheochromocytoma, or if clinical suspicion is high (hypertension with a known vascular adrenal mass). A negative result for either plasma or urinary metanephrines excludes the diagnosis in most cases.

Because of the low prevalence of pheochromocytoma, false-positive results outnumber true-positive results among persons screened for this disorder. Dietary factors, drugs, and physiologic stresses can interfere with screening test results. Ideally, screening should be performed after discontinuing the use of drugs that are known to increase catecholamine levels or interfere with the analyses. Some of these are listed in Table 13-7. Phenoxybenzamine and tricyclic antidepressants can increase plasma and urinary normetanephrine. Buspirone can increase urinary metanephrine (but not plasma values). β-Blockers (including labetalol) can increase plasma metanephrine and urinary metanephrine and normetanephrine. Diuretics, CCBs, ACEIs, ARBs, and selective α_1-adrenoceptor blockers do not interfere with plasma or urinary screening. Sympathomimetics can cause false-positive results for both plasma and urine tests. In those with marginally positive results, the factors noted in Table 13-7, if present, should be eliminated and the screening test repeated.

In persons with negative results from screening tests but who present with paroxysmal hypertension, other diagnoses should be considered. Many persons who have screening tests for pheochromocytoma have panic disorder or other undiagnosed disorders associated with emotional distress (pseudopheochromocytoma).

- Screening for pheochromocytoma: history of paroxysmal hypertension with or without suggestive symptoms, hypertension and an adrenal mass, refractory hypertension, hypertension with diabetes mellitus, hypermetabolism and unintended weight loss, or marked hypertension in response to anesthesia induction.
- The most sensitive screening test is plasma free metanephrines.
- Dietary factors, drugs, and physiologic stresses can interfere with screening test results.

Diagnosis and Treatment

CT or MRI of the abdomen is the initial test used to locate a tumor (90% of all tumors are in one or both adrenal glands and 99% of all tumors are in the abdomen) and should be performed only after biochemical testing has confirmed the presence of the disorder. The sensitivity for identifying a tumor that has a diameter of 1 cm or larger is 85% to 94% with CT and 90% with MRI. Total body MRI can be considered if a lesion is not found with abdominal imaging. Specialized studies are occasionally necessary to identify extra-adrenal tumors or small tumors not identified with CT or MRI (i.e., ^{123}I-metaiodobenzylguanidine [MIBG] scintigraphy or positron emission tomography using [^{18}F]fluorodeoxyglucose, [^{11}C]hydroxyephedrine, or 6-[^{18}F]fluorodopamine). If a large adrenal tumor or an extra-adrenal tumor is found on CT or MRI imaging, a subsequent MIBG scan should be considered. Large tumors are at increased risk of being malignant (with metastases), and extra-adrenal tumors may be multiple.

After the tumor has been identified, treatment is surgical. Preoperatively, administer α-blockers (phenoxybenzamine), followed by β-blockers if needed to control blood pressure and cardiac rhythm. Persons with hypertensive crisis can be given α-blockers or sodium nitroprusside intravenously. β-Blockers can be given if tachycardia is excessive. Because pheochromocytomas can recur in 10% of cases, long-term biochemical follow-up is required.

Table 13-7 Causes of False-Positive Results From Plasma or Urine Screening Tests for Fractionated Metanephrines

Phenoxybenzamine
Tricyclic antidepressants
β-Blockers (including labetalol)
Buspirone
Drugs containing catecholamines (e.g., decongestants)
Discontinuation of use of clonidine or related drugs
Discontinuation of use of benzodiazepine
Discontinuation of use of ethanol
Untreated obstructive sleep apnea

- Use CT or MRI of the abdomen to locate the tumor.
- The treatment is surgical.
- Preoperatively, administer α-blockers, followed by β-blockers.
- Typical clinical scenario for pheochromocytoma: A 25-year-old college student is evaluated for spells. These are sudden in onset and offset and last 25 to 35 minutes. Symptoms include frontal headache, diaphoresis, pounding pulse, and nausea. According to persons witnessing a spell, the patient is pale. Since the onset of these spells, he has lost 20 lb. During a recent spell, his blood pressure was noted to be 220/160 mm Hg. He has no past history of hypertension. The examination findings are essentially normal except for evidence of weight loss, a resting pulse of 105 beats/min, and blood pressure of 160/110 mm Hg.

Coarctation of the Aorta

Coarctation of the aorta is a constriction of the vessel, commonly just beyond the takeoff of the left subclavian artery (see Chapter 3, "Cardiology"). It usually is detected in childhood, but occasionally the diagnosis is not made until adulthood. The classic feature is increased blood pressure in the upper extremities, with low or unobtainable blood pressure in the lower extremities. The mechanism of hypertension involves both volume expansion and inappropriate renin secretion. Symptoms of coarctation include headache, cold feet, and exercise-induced leg pain (claudication). Clinical signs include elevated blood pressure in the arms, murmurs in the front or back of the chest, visible pulsations in the neck or chest wall, and weak femoral pulses or delay when the radial and femoral pulses are palpated simultaneously. Chest radiography can be diagnostic. A characteristic "3 sign" is due to dilatation above and below the constriction plus notching of the ribs (Fig. 13-5) by enlarged collateral vessels. The diagnosis is made with transesophageal echocardiography or MRI of the aorta.

Traditionally, treatment has been surgical repair of the aorta. Balloon angioplasty with or without stenting is becoming the treatment of choice. After repair, hypertension is usually transient and may be associated with mesenteric vasculitis and bowel infarction. Plasma renin activity levels are usually high. The recommended treatment for hypertension after repair is β-blockers or ACEIs.

- Coarctation of the aorta is usually just beyond the takeoff of the left subclavian artery.
- It usually is detected in childhood but may not be identified until adulthood.
- Classic feature: increased blood pressure in the upper extremities and low or unobtainable blood pressure in the lower extremities.
- Mechanism of hypertension: volume expansion and inappropriate renin secretion.
- Symptoms: headache, cold feet, and exercise-induced leg pain.
- Signs: murmurs in the front or back of the chest, visible pulsations in the neck or chest wall, and weak femoral pulses.
- Transesophageal echocardiography or MRI is used to make the diagnosis.
- Treatment is with balloon angioplasty or surgery.

Other Causes of Hypertension

Cushing syndrome (see Chapter 6, "Endocrinology") is often associated with hypertension and always should be considered in the hypertensive person who has impaired fasting glucose and unexplained hypokalemia. Hypothyroidism is associated with diastolic hypertension. It is a state of decreased cardiac output and contractility. Tissue perfusion is maintained by an increase in peripheral vascular resistance mediated by increased activity of the sympathetic nervous system. In contrast, hyperthyroidism is associated with systolic hypertension and a wide pulse pressure due to increased cardiac output and decreased peripheral vascular resistance.

Hyperparathyroidism may be associated with hypertension. Hypercalcemia may increase blood pressure directly by increasing peripheral vascular resistance and indirectly by increasing vascular sensitivity to catecholamines.

Approximately 35% of persons with acromegaly have hypertension, which is largely due to the sodium-retaining effects of growth hormone.

Obstructive sleep apnea is associated with hypertension that may be severe and resistant to control. Upper body obesity is a risk factor for obstructive sleep apnea and is common in hypertensive persons. Consider the diagnosis of obstructive sleep apnea in persons who are overweight, snore loudly, and complain of morning headaches and daytime sleepiness. Bed partners may observe breath-holding episodes at night. The mechanism of hypertension involves increased sympathetic nervous system activity. This condition can be associated with increased metanephrines.

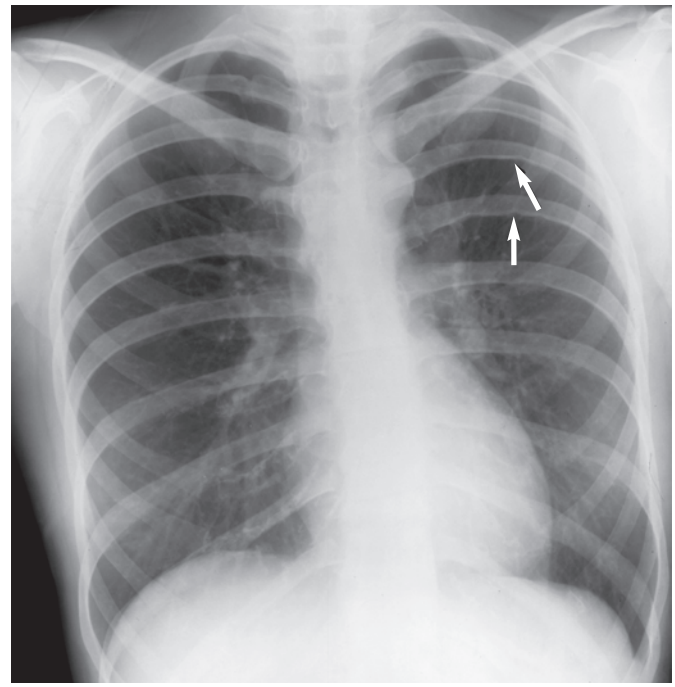

Fig. 13-5. Chest radiograph of a patient with coarctation of the aorta showing notching (*arrows*) of ribs from collateral vessels.

Intracranial tumors, especially those occurring in the posterior fossa, may cause hypertension. Occasionally, hypertension is labile, with features suggesting pheochromocytoma.

Panic syndrome also may be associated with a labile increase in blood pressure and symptoms that suggest pheochromocytoma. Acute stress from various causes (emotional or physical) can increase blood pressure through intense stimulation of the sympathetic nervous system and the renin-angiotensin system (especially if volume contraction is present).

- Hypothyroidism can cause diastolic hypertension.
- Hyperthyroidism can cause systolic hypertension.
- Hyperparathyroidism and acromegaly may be associated with hypertension.
- Obstructive sleep apnea can cause hypertension and may increase metanephrines.
- Brain tumors in the posterior fossa and panic syndrome can cause labile hypertension, suggesting pheochromocytoma.
- Acute stress can increase blood pressure.

Hypertension in Pregnancy

Normally, blood pressure decreases early in pregnancy (first 16-18 weeks) and then gradually increases to the levels before pregnancy (and plateaus at 36 weeks). Blood pressure decreases in normal pregnancy because of reduced peripheral vascular resistance. Systolic blood pressure is affected less than diastolic blood pressure because of increased cardiac output in response to vasodilatation. The usual nocturnal decrease in blood pressure is preserved during normal pregnancy.

During pregnancy, plasma angiotensinogen, renin activity, and aldosterone increase. Other substances that increase during normal pregnancy are estrogen, deoxycorticosterone, and vasodilating prostaglandins produced by the uteroplacental unit. Vessels are hyporesponsive to pressor agents, including norepinephrine and angiotensin II, in part because of the effect of prostaglandins and nitric oxide produced by the uteroplacental unit. Although aldosterone levels increase, renal sodium retention is not marked, probably because progesterone and prostaglandins are natriuretic. Progesterone is also a vasodilator. Plasma volume and cardiac output increase 50% to 60% from baseline during normal pregnancy, and renal blood flow and glomerular filtration rate increase by 35%.

- Blood pressure decreases early in pregnancy and gradually increases to the levels before pregnancy.
- Angiotensinogen, renin activity, and aldosterone increase.
- During pregnancy, vessels are hyporesponsive to norepinephrine and angiotensin II.
- Renal sodium retention is not marked, probably because progesterone and prostaglandins are natriuretic.
- In normal pregnancy, blood pressure decreases because of reduced peripheral vascular resistance.

Definition

Hypertension during pregnancy is defined as systolic blood pressure 140 mm Hg or greater or diastolic blood pressure 90 mm Hg or greater. The diagnosis is confirmed by documentation of elevated blood pressure on two determinations made 6 hours apart. Hypertensive disorders of pregnancy are associated with increased neonatal morbidity and mortality and account for 18% of maternal deaths.

Four major hypertensive syndromes in pregnancy are 1) chronic hypertension—hypertension known to be present before pregnancy or diagnosed before the 20th week of gestation (complicates 3% of pregnancies), 2) preeclampsia-eclampsia (described below; complicates 5%-8% of pregnancies), 3) chronic hypertension with superimposed preeclampsia (complicates 25% of pregnancies in hypertensive women), and 4) gestational hypertension—hypertension that develops for the first time after the 20th week of gestation without other findings of preeclampsia (complicates 6% of pregnancies), but it can evolve into preeclampsia. If gestational hypertension does not evolve into preeclampsia by delivery, and if blood pressure normalizes within 12 weeks post partum, the hypertension is called *transient hypertension of pregnancy*. This is a predictor for the future development of essential hypertension. If blood pressure remains elevated, it is recognized retrospectively as *chronic hypertension* that was previously undiagnosed and masked by the decrease in blood pressure that occurs during early pregnancy.

Women with hypertension developing before the 20th week of gestation or with early gestational hypertension are among a group more likely to have a secondary form (caused by renovascular disease, primary aldosteronism, Cushing syndrome, or pheochromocytoma). Further evaluation with noninvasive testing should be considered, especially if suggestive clinical clues are present.

- Hypertension during pregnancy: Blood pressure ≥140 mm Hg systolic or ≥90 mm Hg diastolic.
- Transient hypertension is a predictor of the future development of essential hypertension.
- Consider secondary causes of hypertension in this age group.

The pregnancy-specific syndrome of preeclampsia is characterized by hypertension (blood pressure ≥140/90 mm Hg) and proteinuria (24-hour urine protein excretion ≥0.3 g) that develops after the 20th week of gestation. Eclampsia is defined by seizures that occur in the presence of preeclampsia which cannot be attributed to other causes. Findings that increase the certainty of the diagnosis of preeclampsia (and increase the risk of eclampsia) and the need for close monitoring and consideration for delivery include headache, blurring of vision and other cerebral symptoms, epigastric pain, nephrotic range proteinuria (≥3.5 g/24 h), oliguria, systolic blood pressure 160 mm Hg or higher or diastolic blood pressure 110 mm Hg or higher, creatinine level greater than 1.2 mg/dL, platelet count less than 100×10^9/L, evidence of microangiopathic hemolytic anemia (abnormal blood smear or increased lactate dehydrogenase), elevated liver enzymes (aspartate aminotransferase [AST] and alanine aminotransferase [ALT]), or pulmonary edema.

Preeclampsia occurs more commonly in African American women and in women who are relatively young or old to be pregnant (<18 years or >35 years), who are having their first pregnancy or a twin pregnancy, who are obese, who have diabetes mellitus or

insulin resistance, who have a family history of preeclampsia in their mother, who have had preeclampsia with a previous pregnancy, or who have renal disease, chronic hypertension, a collagen vascular disease, or a congenital thrombophilia disorder. Preeclampsia that develops before the 20th week of gestation suggests molar pregnancy, fetal hydrops, α-thalassemia, or renal disease.

- Preeclampsia: hypertension and proteinuria after the 20th week of gestation.
- Eclampsia: preeclampsia with seizures.
- Risk factors for preeclampsia: African American race, relatively young or old for pregnancy, first or twin pregnancy, obesity, diabetes mellitus or insulin resistance, family history of preeclampsia in the mother, preeclampsia with a previous pregnancy, renal disease, chronic hypertension, collagen vascular disease, or congenital thrombophilia disorder.

In preeclampsia, the endovascular trophoblastic cells of the placenta do not adequately invade the uterine spiral arteries (abnormal placentation). Consequently, the normally thick-walled muscular spiral arteries are not transformed into saclike flaccid vessels capable of accommodating the tenfold increase in uterine blood flow associated with normal pregnancy. This leads to underperfusion of the placenta (placental insufficiency). There is maternal intolerance to the fetal response to placental insufficiency, but this does not occur in all cases. Unknown maternal factors (genetic and environmental) are probably required. When present, circulating mediators produced by the hypoperfused placenta act on the common target organ in preeclampsia, the vascular endothelium. The altered vascular endothelial cells produce several factors (procoagulants, vasoconstrictors, and mitogens) that constrict and obstruct vascular beds, producing the characteristic pathologic changes (hemorrhage and necrosis) that may be seen in the brain, heart, and liver of women with preeclampsia. Oxidative stress and inflammation are also important. Preeclampsia is a disorder of endothelial dysfunction and systemic vasoconstriction.

Unlike women with normal pregnancy, those with preeclampsia are sensitive to the pressor effects of norepinephrine and angiotensin II. Peripheral resistance markedly increases. Renal blood flow and glomerular filtration rate decrease (but may remain above the levels before pregnancy). Vascular volume decreases and is often associated with hemoconcentration. This hemoconcentration may result from extravasation of albumin into the interstitial space. Central venous pressure and pulmonary capillary wedge pressure are often low. Placental prostaglandin levels decrease. Renal fractional urate clearance decreases, and uric acid is most often increased. Hyperuricemia often distinguishes patients with preeclampsia from those with chronic hypertension in pregnancy. An increase in uric acid concentration and a decrease in the platelet count are the earliest laboratory findings associated with preeclampsia. The HELLP syndrome (**H**emolysis [elevated lactate dehydrogenase or bilirubin], **E**levated **L**iver enzymes, and **L**ow **P**latelet count) occurs when intravascular coagulation and liver ischemia develop in preeclampsia. The HELLP syndrome can rapidly develop into a life-threatening disorder of liver failure and worsening thrombocytopenia in the presence of only mild or moderate hypertension. The most serious complication of the HELLP syndrome is liver rupture (right upper quadrant abdominal pain), which is associated with high maternal and fetal mortality.

Studies indicate that women who have had preeclampsia are more likely to have insulin resistance, altered endothelial function, and dyslipidemia than women who have had normal pregnancies.

- Women with preeclampsia are sensitive to the pressor effects of norepinephrine and angiotensin II.
- With preeclampsia, peripheral vascular resistance markedly increases.
- Uric acid is most often increased; this distinguishes women with preeclampsia from those with chronic hypertension in pregnancy.
- An increase in uric acid and a decrease in the platelet count are the earliest laboratory abnormalities in preeclampsia.
- Laboratory evaluation for hypertension developing after the 20th week of gestation: hemoglobin/hematocrit, platelet count, 24-hour urine protein, creatinine, uric acid level, AST/ALT, albumin, lactate dehydrogenase, blood smear, coagulation profile.

Treatment of Chronic Hypertension in Pregnancy

Most women with stage 1 hypertension and normal renal function have good outcomes even without treatment. As blood pressure decreases in early pregnancy, previous drug therapy can often be reduced or discontinued. Lifestyle modifications (mild weight loss, low impact exercise, dietary salt restriction, and cessation of alcohol and tobacco use) should be recommended. For stage 1 hypertension, there is no evidence that drug therapy improves neonatal outcomes. Drug therapy should be considered if diastolic blood pressure is 100 mm Hg or higher, if systolic blood pressure is 150 mm Hg or higher in the second trimester or 160 mm Hg or higher in the third trimester, or if target organ injury occurs (left ventricular hypertrophy or increased creatinine level). Methyldopa (which has been studied most completely) is recommended as initial therapy. This is the only drug that has been shown to decrease perinatal mortality and for which long-term studies on the offspring are available.

If methyldopa is ineffective or not tolerated, other drugs can be considered. Except for ACEIs and ARBs, none of the currently available drugs are known to increase perinatal morbidity or mortality. ACEIs or ARBs are contraindicated because exposure to these agents in the second or third trimester of pregnancy can cause serious fetal abnormalities (limb defects, lung hypoplasia, craniofacial deformities, and renal dysplasia). However, use of these agents in the first trimester is not associated with a high teratogenic risk and, thus, is not an indication for elective termination of pregnancy.

The use of β-blockers (atenolol) in the second trimester has been associated with intrauterine fetal growth retardation and low placental weight. Their use should be restricted to the third trimester. However, use in the third trimester can be associated with fetal bradycardia, impaired fetal compensatory response to hypoxia, and neonatal hypoglycemia. There is evidence that labetalol and pindolol are safe and effective for treating chronic hypertension in pregnancy.

Only limited data are available for CCBs, but they seem to be safe (nifedipine). They are potent tocolytics and can affect progression

of labor. Their use can be associated with profound hypotension and circulatory collapse if magnesium sulfate is given concurrently for seizure prophylaxis in preeclampsia.

Because of theoretical concerns about diuretics decreasing vascular volume and placental blood flow, CCBs are not considered first-line agents. However, if indicated (in salt-sensitive hypertension or in the presence of renal or cardiac disease), they are considered safe, and they can potentiate the effects of other agents to lower blood pressure. They are contraindicated in preeclampsia and intrauterine growth retardation.

- Lifestyle modifications can be used initially to treat mild hypertension.
- Use drug therapy if diastolic blood pressure is ≥100 mm Hg or systolic blood pressure is ≥150 mm Hg in the second trimester or ≥160 mm Hg in the third trimester.
- Recommended initial drug therapy: methyldopa.
- ACEIs and ARBs are contraindicated during pregnancy; however, use in the first trimester is not an indication for elective termination of pregnancy.

Treatment of Preeclampsia-Eclampsia

Prevention strategies for preeclampsia have limited value. In recent studies calcium supplements have not been shown to lessen the risk. The use of low-dose aspirin early in pregnancy may reduce the risk, but this is controversial. It is important to identify the high-risk woman and to monitor her closely to identify preeclampsia early. Recent studies suggest that before the clinical onset of preeclampsia, increased levels of an antiangiogenic protein, soluble fms-like tyrosine kinase 1(sFlt1), bind to the proangiogenic protein, placental growth factor (PIGF), causing its level to be reduced. Thus, increased sFlt1 levels and decreased PIGF levels may be markers for increased risk of preeclampsia. The diagnostic accuracy of these tests has not been determined prospectively, and they are not currently available for clinical use. At present, early recognition of preeclampsia is based primarily on diagnostic blood pressure increases in the late second or early third trimester. Proteinuria is an important sign of progression and usually warrants hospitalization. The woman should be kept at rest in bed. Monitor blood pressure, urine output, and fluid retention (weigh the patient) daily. Periodically determine the platelet count, creatinine level, uric acid level, albumin level, and urine protein excretion. Evidence of central nervous system involvement (headache, disorientation, or visual symptoms) or liver distention (abdominal pain or liver tenderness) are important findings that suggest progression of preeclampsia. Hepatic rupture is associated with 65% mortality and can be prevented only by delivery of the fetus. Evidence of progressive preeclampsia after the 34th week of gestation is an indication for delivery. When gestational age is critical (<34 weeks), worsening maternal symptoms, laboratory evidence of end-organ dysfunction, or deterioration of the fetal condition indicates delivery. If a fetus is immature and preeclampsia is nonprogressive, a period of observation is warranted. Hypertension should be treated with drugs if diastolic blood pressure is 100 mm Hg or greater. The oral agent of choice is methyldopa. Reasonable alternatives are α-β-blockers, CCBs, or hydralazine. Severe hypertension (i.e., >160/110 mm Hg) is associated with increased risk of intracerebral hemorrhage and death and requires treatment. Persons with hypertensive encephalopathy or eclampsia require parenteral therapy to decrease blood pressure to less than 160/100 mm Hg (see below).

- Proteinuria is an important sign of progression and usually warrants hospitalization.
- Keep the woman at rest in bed.
- Central nervous system involvement or liver distention suggests progression of preeclampsia.
- Progressive preeclampsia after the 34th week of gestation is an indication for delivery.
- Before the 34th week of gestation, worsening maternal symptoms, laboratory evidence of end-organ dysfunction, or deterioration of the fetal condition indicates delivery.
- If diastolic blood pressure is ≥100 mm Hg, treat with drugs.
- Oral agent of choice: methyldopa.

Magnesium sulfate is the treatment of choice for impending eclampsia or for preventing recurrent seizures. It should be given as a continuous intravenous infusion during labor and delivery and for at least 24 hours post partum. Monitor the patient's patellar reflex, urine output, and respirations while giving magnesium. The usual loading dose can be given in the setting of marked renal dysfunction, but subsequent dosing must be guided by frequent monitoring of blood levels. Calcium gluconate is the treatment of choice for magnesium toxicity and should be kept at the bedside.

- Magnesium sulfate: treatment of choice for impending eclampsia or for preventing recurrent seizures.
- Calcium gluconate: treatment of choice for magnesium toxicity.

Treatment of Hypertensive Crisis

The drugs of choice for treatment of hypertensive crisis during pregnancy are intravenous labetalol or oral nifedipine. Treatment with labetalol can be initiated with a 20-mg intravenous bolus. If the response is inadequate, 40 mg can be given 10 minutes later and, if necessary, 80 mg can be given at 10-minute intervals for two additional doses (maximal dose, 220 mg). If blood pressure is not controlled, an alternative drug should be considered. Nifedipine tablets (10-20 mg every 30 minutes to a maximum of 50 mg) can be used, but remember the precautions with nifedipine (tocolytic; interaction with magnesium sulfate causes profound hypotension). It is important to note that the U.S. Food and Drug Administration has not approved rapidly acting nifedipine for the treatment of hypertension. Hydralazine can be used but is associated with more maternal and perinatal adverse effects than the other agents. Treatment can be initiated with a 5- to 10-mg bolus, followed by 5 to 10 mg every 20 to 30 minutes until control is achieved and then repeated as needed (usually every 3 hours). Side effects include tachycardia and headache. Avoid giving hydralazine to women with congestive heart failure or asthma. Generally, sodium nitroprusside should be avoided (cyanide poisoning in the fetus); rarely, however, it may be needed for hypertension that does not respond to the drugs mentioned

above. An infusion can be started at a rate of 0.25 µg/kg per minute and increased as needed to a maximal rate of 5 µg/kg per minute. Risk of fetal toxicity increases with infusions that last longer than 4 hours.

- The drug of choice for treating hypertensive crisis: labetalol administered intravenously.
- For hypertension refractory to labetalol, consider oral nifedipine or hydralazine intravenously.
- Administer sodium nitroprusside only if blood pressure does not respond to other drugs.

Pregnancy, Hypertension, and Renal Disease

Renal disease is a risk factor for preeclampsia. The combination of mild renal disease (serum creatinine <1.4 mg/dL) and preexisting hypertension or hypertension occurring early in pregnancy is associated with increased maternal and fetal complications with a tenfold increase in relative risk of fetal loss. The renal disease usually does not progress. Moderate or severe renal insufficiency often worsens during pregnancy and is associated with a risk of hypertension developing, if not present before conception, that is more than 50%. Risk of fetal loss is high. Hypertension in this setting often has a volume component requiring the use of loop diuretics. Magnesium sulfate is potentially hazardous with severe renal insufficiency, and maintenance doses must be reduced. For women on long-term dialysis, conception is generally discouraged because of significant maternal morbidity and lower fetal survival. All pregnancies in renal transplant recipients are considered high risk. Pregnancy should not be considered until at least 1.5 to 2 years after transplantation, and creatinine should be stable and no more than 2.0 mg/dL.

- Renal disease is a risk factor for hypertension and for preeclampsia.
- Renal disease increases the risk of maternal morbidity and fetal loss.
- Moderate or severe renal insufficiency may progress during pregnancy.
- Conception is discouraged for women on long-term hemodialysis.
- Conception can be considered in renal transplant recipients after 2 years if renal function is stable and creatinine ≤2.0 mg/dL.

Hypertension and Breast-feeding

Elevated blood pressure may persist for 6 to 12 weeks after delivery in preeclampsia or gestational hypertension. Most antihypertensive drugs are compatible with breast-feeding, and all studied drugs are excreted into breast milk. Methyldopa and hydralazine have been shown to be safe. Propranolol and labetalol are the preferred β-blockers. ACEIs and ARBs should be avoided because their use may be associated with adverse neonatal renal effects, and diuretics may suppress milk volume. Regardless of the drug chosen, the infant should be carefully monitored for adverse effects.

- Most antihypertensive drugs are compatible with breast-feeding.
- Avoid ACEIs or ARBs.
- Diuretics may suppress milk production.

Hypertensive Emergencies and Urgencies

Acute or severe increases in blood pressure are serious medical concerns; prompt therapy may be lifesaving. Clinically, these situations can be classified either as hypertensive urgencies or as hypertensive emergencies (crisis).

Definitions

Hypertensive Emergency

The term *hypertensive emergency* is defined as severe hypertension or a sudden increase in blood pressure with evidence of acute injury to target organs (brain, heart, kidney, vasculature, and retina). It implies the need for hospitalization to immediately lower blood pressure with parenteral therapy. Examples include malignant hypertension, hypertensive encephalopathy, aortic dissection, unstable angina, acute myocardial infarction, eclampsia, pulmonary edema, and acute renal failure. Malignant hypertension is a clinical syndrome associated with severe elevation of blood pressure that is frequently fatal if not treated promptly. It is characterized by a marked increase in peripheral vascular resistance due to systemic (angiotensin II) or locally generated (endothelin) vasoconstrictor substances. Any form of hypertension can progress to the malignant phase. Clinical features include severe hypertension (diastolic blood pressure >130 mm Hg), retinal hemorrhages and exudates, papilledema, oliguria, azotemia, nausea and vomiting, findings of heart failure, and encephalopathy. Encephalopathy is the result of cerebral edema due to breakthrough hyperperfusion of the brain caused by severely increased blood pressure. Manifestations include papilledema, headache, confusion, somnolence, stupor, gastrointestinal distress, visual loss, focal neurologic deficits, coma, and seizures.

Fibrinoid necrosis of arterioles is the characteristic vascular lesion of malignant hypertension. Arteriolar injury worsens ischemia and promotes further release of vasoactive substances, setting up a vicious cycle. Microangiopathic hemolysis with fragmentation of erythrocytes and intravascular coagulation may occur with fibrinoid necrosis.

- Hypertensive emergency: severely elevated or suddenly increased blood pressure associated with acute injury to target organs.
- Hospitalization and parenteral therapy to decrease blood pressure immediately are required.
- Hypertensive encephalopathy: papilledema, headache, somnolence, confusion, stupor, gastrointestinal distress, visual loss, focal neurologic deficits, coma, and seizures.
- Malignant hypertension: a rapidly progressive vasospastic disorder.
- Angiotensin II levels are increased.
- If not reversed, blood vessel walls undergo necrosis.

Hypertensive Urgency

The term *hypertensive urgency* is defined as severe hypertension without evidence of acute target organ injury but occurring in a setting in which it is important to decrease blood pressure to safer levels over a 24- to 48-hour period. Oral therapy in the outpatient setting is often adequate. Examples include severe hypertension in a person with known coronary artery disease, an aneurysm of the aorta (or other site), or a history of congestive heart failure or severe

hypertension immediately following major surgery. *Accelerated hypertension* is a subacute, progressive increase in blood pressure associated with hemorrhages and exudates (but not papilledema) on retinal examination. If left untreated, it may progress to malignant hypertension.

- Hypertensive urgency: severe hypertension without acute target organ injury.
- Treatment is administered orally and hospitalization usually is not required.
- Accelerated hypertension may progress to malignant hypertension if not treated.

Causes

The causes of hypertensive urgencies and emergencies include the development of accelerated-malignant hypertension on the background of neglected essential hypertension (approximately 7% of cases of untreated hypertension progress to the malignant phase), sudden discontinuation of antihypertensive therapy (especially multidrug programs or programs containing clonidine and β-blockers), renovascular disease, collagen vascular diseases (especially scleroderma), eclampsia, acute glomerulonephritis, pheochromocytoma, monoamine oxidase inhibitors and tyramine-containing foods, intracerebral or subarachnoid hemorrhage, acute aortic dissection, acute head injury, and acute stroke. Approximately 50% of hypertensive crises occur in persons with preexisting hypertension.

- Common causes of hypertensive urgencies and emergencies: neglected essential hypertension, discontinuation of antihypertensive therapy, renovascular disease, scleroderma, pheochromocytoma, and stroke.

Evaluation and Management

Persons with hypertensive emergencies should be hospitalized in an intensive care unit. An arterial catheter should be inserted to monitor blood pressure continuously. In addition to a focused history (compliance with previously prescribed medications, use of blood pressure–raising drugs) and examination (retinal examination is mandatory), initial laboratory studies should include chest radiography, electrocardiography, creatinine or blood urea nitrogen, urinalysis, glucose, sodium, potassium, hemoglobin, and blood smear (fragmented erythrocytes). Studies to determine the underlying cause should be deferred. The challenge of treating hypertensive emergencies is to lower blood pressure promptly without compromising the function of vital organs. Blood pressure should be lowered quickly to a diastolic level of approximately 110 mm Hg (reduce mean blood pressure by 20%), followed by careful monitoring for evidence of worsening cerebral, renal, or cardiac function. Blood pressure is then gradually decreased to a diastolic level of 90 to 100 mm Hg. Ischemic pancreatitis and intestinal infarction are potential serious complications.

Generally, sodium nitroprusside is the drug of choice, but caution should be observed in states of increased intracranial pressure. It must be given in an intensive care setting, with an arterial catheter in place. This balanced arterial and venous dilator decreases both preload and afterload. The dose is 0.25 to 10.0 μg/kg per minute by intravenous infusion. Adjustments in dose can be made at 5-minute intervals until the blood pressure goal is achieved. The infusion must be protected from light. Toxicity is related to the metabolism of nitroprusside to cyanide in erythrocytes (metabolic acidosis). Thus, thiocyanate levels should be monitored every 48 hours and therapy discontinued if the blood level is greater than 12 mg/dL. The risk is greater in the presence of renal disease. Sodium nitrite or hydroxocobalamin (25 mg/h) can be infused in case of toxicity. Side effects of sodium nitroprusside include nausea, vomiting, agitation, disorientation, psychosis, muscular twitching, coarse tremor, and flushing. Frequently, patients with malignant hypertension are volume depleted because of pressure natriuresis. However, as blood pressure decreases, fluid retention occurs and the addition of a loop diuretic is often required.

- Sodium nitroprusside: the drug of choice for a hypertensive emergency.
- Toxicity is related to the metabolism of nitroprusside to cyanide in erythrocytes.
- Monitor thiocyanate levels every 48 hours.
- In case of toxicity, infuse sodium nitrite or hydroxocobalamin.
- Sodium nitroprusside side effects: nausea, vomiting, agitation, muscular twitching, coarse tremor, and flushing.

Several alternative parenteral agents are available for the management of hypertensive emergencies and urgencies.

Labetalol is a combination α-blocker and nonselective β-blocker with an onset of action of 5 to 10 minutes. It can be given in repetitive intravenous miniboluses of 20 to 80 mg or as a constant infusion at a dose of 0.5 to 2 mg/min. Its duration of action is 3 to 6 hours. It can be used in most situations except acute heart failure. It is especially useful for postoperative hypertension, acute aortic dissection, and hypertensive crisis of pregnancy. The same cautions and contraindications apply to this drug as to other β-blockers (asthma and heart block). Adverse effects include scalp tingling, vomiting, heart block, and orthostatic hypotension.

Glyceryl trinitrate (nitroglycerin) is a direct arteriolar and venous vasodilator with an onset of action of 2 to 5 minutes and with a duration of action of 3 to 5 minutes. It is given as a constant infusion of 5 to 100 μg/min. This drug decreases myocardial oxygen demand by decreasing preload and afterload. It dilates epicardial coronary arteries and collaterals. Tolerance can develop with prolonged infusion. It is especially useful if acute coronary ischemia or acute congestive heart failure is present. Adverse effects include headache, flushing, nausea, and methemoglobinemia.

Hydralazine is a direct arteriolar vasodilator with an onset of action of 10 to 20 minutes if given intravenously and 20 to 30 minutes if given intramuscularly. The usual dose is 10 to 20 mg intravenously or 10 to 50 mg intramuscularly. Its duration of action is 3 to 8 hours. Hydralazine is used primarily to treat hypertensive crisis of pregnancy. Adverse effects include headache, flushing, nausea, vomiting, and myocardial ischemia (due to reflex increases in heart rate and stroke volume). Use of the drug should be avoided in acute

aortic dissection and states of myocardial ischemia. Hydrozones form when hydralazine is mixed with dextrose.

Esmolol is a cardioselective β-blocker with an onset of action of 1 to 2 minutes and a duration of action of 10 to 20 minutes. It is given as a constant intravenous infusion in a dose of 50 to 300 μg/kg per minute. Esmolol is useful in postoperative hypertension, aortic dissection, and ischemic heart disease. It is often used in combination with vasodilators for effective control of blood pressure. The cautions and contraindications that apply to β-blockers also apply to this drug. Adverse effects include nausea and bradycardia.

Enalaprilat is an ACEI with an onset of action of 15 minutes and a duration of action of 6 hours. It is given intravenously in doses of 1.25 to 5 mg every 6 hours, with a maximal dose of 20 mg in 24 hours or a smaller dose if renal disease is present. It is useful in postoperative hypertension and in settings of acute heart failure. Adverse effects include ACEI side effects, a precipitous decrease in blood pressure in high renin states (volume depletion), and an acute decline in renal function if renal artery disease is present. Its use should be avoided in pregnancy.

Nicardipine is a dihydropyridine CCB with an onset of action of 5 to 10 minutes and a duration of action of 1 to 4 hours. It is given as a constant intravenous infusion of 5 to 15 mg per hour. It is useful for postoperative hypertension. Nicardipine should not be given in the setting of acute heart failure. Adverse effects include headache, nausea, flushing, and phlebitis.

Phentolamine is an α-blocker that is administered intravenously in doses of 5 to 15 mg. The duration of action of a single bolus is approximately 15 minutes. It is most effective for states of catecholamine excess (discontinuation of use of clonidine, interaction between monoamine oxidase inhibitor and tyramine-containing food) and is the drug of choice if pheochromocytoma is suspected. Adverse effects include tachycardia and flushing.

Fenoldopam is a selective dopamine receptor (D_1) agonist that is given by constant intravenous infusion of 0.1 to 1.6 mg/kg per minute. It causes arteriolar vasodilatation. The onset of action is within 5 minutes and offset is over 30 to 60 minutes. This drug is useful with impaired renal function because it increases renal blood flow and sodium excretion. Side effects are nausea, vomiting, headache, and flushing.

Diazoxide is considered obsolete with the availability of newer and safer drugs.

- Glyceryl trinitrate (nitroglycerin) is useful in acute congestive heart failure or coronary ischemia.
- Tolerance can develop to glyceryl trinitrate.
- Labetalol and hydralazine are used for hypertensive crisis of pregnancy.
- Avoid use of hydralazine in acute myocardial infarction or angina and in dissecting aortic aneurysm.
- Esmolol, enalaprilat, and nicardipine are useful for postoperative hypertension.
- Phentolamine is the drug of choice if pheochromocytoma is suspected.
- Fenoldopam increases renal blood flow and sodium excretion.

As soon as possible, initiate regular oral treatment and taper intravenous treatment. After blood pressure has been controlled, search for the cause of the hypertensive crisis and consider secondary causes, especially renovascular disease, pheochromocytoma, and primary aldosteronism.

- Typical clinical scenario: A 54-year-old man has a 12-year history of hypertension. It was controlled with a combination of hydrochlorothiazide, clonidine, and amlodipine. Because of cost and side effects, the patient stopped all therapy abruptly 3 weeks ago. Over the past 2 days, a headache of increasing severity has developed. His wife has noted that he is confused and his speech is slurred; this prompted his visit to the office. On examination, the patient is stuporous and confused. His speech is slurred. Blood pressure is 230/140 mm Hg and the pulse is 115 beats/min. Retinal hemorrhages and papilledema are noted. Rales are present in both lung bases. An S_3 gallop is noted on heart examination. A chest radiograph shows findings of pulmonary edema. The creatinine level is 2.4 mg/dL. Erythrocytes are noted on urinalysis.

Hypertension Pharmacy Review

John G. O'Meara, PharmD, Jamie M. Gardner, PharmD, Todd M. Johnson, PharmD

Drug (trade name)	Dose, mg	Frequency	Toxic/adverse effects	Drug interactions	Comments
Diuretics					
Thiazide-type (selected)			Glucose intolerance & insulin resistance, hyperlipidemia, hyperuricemia, hypokalemia, hyponatremia, hypomagnesemia)	Lithium (increased lithium levels), NSAIDs (decreased diuretic effectiveness), bile acid sequestrants (decreased thiazide absorption)	Preferred in JNC 7 as the initial drug choice for most, either alone or in combination Metolazone & indapamide may be effective in renally impaired patients Lower doses avoid adverse metabolic effects May be favorable for patients with concurrent osteoporosis (decreased renal calcium elimination) Effective for isolated hypertension in the elderly
Hydrochlorothiazide (HydroDIURIL, Esidrix)	12.5-50	1/d			
Chlorthalidone (Hygroton)	12.5-25	1/d			
Indapamide (Lozol)	1.25-2.5	1/d			
Metolazone (Zaroxolyn, Diulo)	2.5-5	1/d			
Metolazone (Mykrox)	0.5-1	1/d			
Loop			Similar to thiazide-type agents except may cause hypocalcemia; monitor for dehydration, circulatory collapse, metabolic alkalosis Ototoxicity (usually associated with rapid IV injection, severe renal impairment, high doses, or concurrent use of other ototoxic drugs)	Similar to thiazides	Reserved for hypertensive patients with renal insufficiency
Bumetanide (Bumex)	0.5-2	2/d			
Ethacrynic acid (Edecrin)	25-100	2/d			
Furosemide (Lasix)	20-80	2/d			
Torsemide (Demadex)	2.5-10	1/d			
Potassium-sparing			Hyperkalemia	Potassium supplements, ACEIs, angiotensin II blockers (all increase risk of hyperkalemia); dofetilide (decreased renal elimination of dofetilide, with potential cardiac toxicity)	Weak diuretics alone, used in combination with other diuretics to avoid hypokalemia
Amiloride (Midamor)	5-10	1 or 2/d			
Triamterene (Dyrenium)	50-100	1 or 2/d			
Adrenergic inhibitors					
α_1-Blockers			Postural hypotension, tachycardia, dizziness, headache	Midodrine (decreased midodrine effectiveness)	Avoid "first-dose syncope" by starting with a low dose given at bedtime Not considered first-line agents because of negative ALLHAT trial outcomes with doxazosin
Doxazosin (Cardura)	1-16	1/d			
Prazosin (Minipress)	2-20	2 or 3/d			
Terazosin (Hytrin)	1-20	1 or 2/d			

Hypertension Pharmacy Review (continued)

Drug (trade name)	Dose, mg	Frequency	Toxic/adverse effects	Drug interactions	Comments
Adrenergic inhibitors (continued)					
β-Blockers (cardioselective)			Bronchospasm, bradycardia, decreased exercise tolerance, may mask symptoms of insulin-induced hypoglycemia, impaired peripheral circulation, insomnia, fatigue, decreased exercise tolerance, increased triglycerides (except agents with ISA), decreased HDL cholesterol	Non-DHP CCBs (heart block), sympathomimetics (unopposed α-adrenergic stimulation)	Acebutolol, carteolol, penbutolol, pindolol possess ISA Contraindications: sinus bradycardia, ≥2nd-degree heart block, cardiogenic shock, & asthma/severe COPD
Acebutolol (Sectral)	200-800	2/d			
Atenolol (Tenormin)	25-100	1/d			
Betaxolol (Kerlone)	5-20	1/d			
Bisoprolol (Zebeta)	2.5-10	1/d			
Metoprolol (Lopressor, Toprol XL)	50-100	1 or 2/d			
β-Blockers (noncardioselective)					
Carteolol (Cartrol)	2.5-10	1/d			
Nadolol (Corgard)	40-120	1/d			
Penbutolol (Levatol)	10-40	1/d			
Pindolol (Visken)	10-40	2/d			
Propranolol (Inderal)	40-480	2/d			
Timolol (Blocadren)	20-60	2/d			
α-β-Blockers			Postural hypotension, bronchospasm, hepatotoxicity (labetolol)	Rifampin (decreased carvedilol plasma concentration)	
Carvedilol (Coreg)	12.5-50	2/d			
Labetolol (Trandate, Normodyne)	200-800	2/d			
Central α-agonists			Sedation, dry mouth, withdrawal hypertension, depression Hepatic & autoimmune disorders (methyldopa)	β-Blockers, tricyclic antidepressants (decreased antihypertensive effectiveness)	Avoid abrupt withdrawal of clonidine (rebound hypertension) Methyldopa is the preferred antihypertensive in pregnancy
Clonidine (Catapres)	0.2-0.8	2 or 3/d			
Clonidine (Catapres-TTS)	0.1-0.3	Weekly (patch)			
Guanabenz (Wytensin)	8-32	2/d			
Guanfacine (Tenex)	0.5-2	1/d			
Methyldopa (Aldomet)	250-1,000	2/d			
Peripheral agents			Postural hypotension, diarrhea, depression, sedation, peptic ulcer	Tricyclic antidepressants (decreased antihypertensive effectiveness)	Reserpine contraindicated in depression, active peptic ulcer, ulcerative colitis
Guanadrel (Hylorel)	10-75	2/d			
Guanethidine (Ismelin)	10-150	1/d			
Reserpine (Serpasil)	0.05-0.25	1/d			
Calcium channel antagonists					
DHPs			Edema, headache, flushing, postural dizziness, tachycardia, gingival hyperplasia	CYP3A4 inhibitors (may increase CCB plasma concentrations) CYP3A4 inducers (e.g., rifampin, carbamazepine, barbiturates) may decrease plasma CCB concentrations	Immediate-release nifedipine not recommended for severe hypertension Long-acting DHPs effective for isolated systolic hypertension in the elderly
Nisoldipine (Sular)	10-40	1/d			
Nifedipine (Procardia XL, Adalat CC)	30-120	1/d			
Nicardipine (Cardene)	60-120	2/d			
Isradipine (DynaCirc)	2.5-10	2/d			
Felodipine (Plendil)	2.5-20	1/d			
Amlodipine (Norvasc)	2.5-10	1/d			

Hypertension Pharmacy Review (continued)

Drug (trade name)	Dose, mg	Frequency	Toxic/adverse effects	Drug interactions	Comments
Calcium channel antagonists (continued)					
Non-DHPs			AV nodal block, bradycardia, worsening systolic function; constipation (verapamil), rash (diltiazem)	Diltiazem & verapamil (CYP3A4 inhibitors) increase plasma levels of benzodiazepine, carbamazepine, tacrolimus, cyclosporine, lovastatin, simvastatin, pimozide, protease inhibitors, rifabutin, & ergot alkaloid	Non-DHPs contraindicated in ≥2nd degree AV block
Diltiazem (Cardizem, Tiamate, Tiazac, Dilacor, Diltia)	120-540	1 or 2/d			
Verapamil (Calan, Isoptin, Verelan, Covera HS)	120-480	1 or 2/d			
Direct vasodilators					
Hydralazine (Apresoline)	25-100	2/d	Headache, palpitations, tachycardia, angina, sodium & water retention, SLE (hydralazine), hypertrichosis (minoxidil)	Diuretics, hypotensive agents, MAO inhibitors	Use both agents with a β-blocker & diuretic to minimize reflex tachycardia & fluid retention
Minoxidil (Loniten)	2.5-80	1 or 2/d			
ACEIs					
Benazepril (Lotensin)	10-40	1 or 2/d	Cough (~15%), dizziness, rash, hyperkalemia, angioedema (rare)	Potassium-sparing diuretics, potassium salts (increased risk of hyperkalemia), lithium (increased lithium levels), NSAIDs (decreased ACEI effectiveness)	Contraindicated in pregnancy, renal artery stenosis (bilateral or solitary kidney) First-line agents for hypertensives with left ventricular dysfunction or heart failure Preferred in hypertensive diabetics with nephropathy
Captopril (Capoten)	12.5-100	2 or 3/d			
Enalapril (Vasotec)	2.5-40	1 or 2/d			
Fosinopril (Monopril)	10-40	1/d			
Lisinopril (Zestril, Prinivil)	10-40	1/d			
Moexipril (Univasc)	7.5-30	1/d			
Perindopril (Aceon)	4-8	1 or 2/d			
Quinapril (Accupril)	10-40	1/d			
Ramipril (Altace)	2.5-20	1/d			
Trandolapril (Mavik)	1-4	1/d			
Angiotensin II antagonists					
Losartan (Cozaar)	25-100	1 or 2/d	Similar to ACEIs but lower incidence of cough		Contraindicated in pregnancy, renal artery stenosis (bilateral or solitary kidney); alternative for patients with ACEI-induced cough
Valsartan (Diovan)	80-320	1/d			
Irbesartan (Avapro)	150-300	1/d			
Candesartan (Atacand)	8-32	1/d			
Telmisartan (Micardis)	20-80	1/d			
Eprosartan (Teveten)	400-800	1 or 2/d			
Olmesartan (Benicar)	20-40	1/d			
Aldosterone receptor antagonists					
Eplerenone (Inspra)	50-100	1 or 2/d	Hyperkalemia, hypertriglyceridemia	ACEIs, angiotensin II blockers, potassium supplements, & potassium-sparing diuretics (all increase risk of hyperkalemia), CYP3A4 inhibitors (increased levels of eplerenone)	Contraindications: serum potassium >5.5 mEq/L; type 2 diabetes with microalbuminuria; serum creatinine >2.0 mg/dL in males or >1.8 mg/dL in females; creatinine clearance <50 mL/min; concomitant use with potassium supplements or potassium-sparing diuretics, strong CYP3A4 inhibitors

Hypertension Pharmacy Review (continued)

Drug (trade name)	Dose, mg	Frequency	Toxic/adverse effects	Drug interactions	Comments
Aldosterone receptor antagonists (continued)					
Spironolactone (Aldactone)	25-50	1 or 2/d	Hyperkalemia, gynecomastia	Potassium supplements, ACEIs, angiotensin II blockers (all increase risk of hyperkalemia)	Avoid in renal impairment (serum creatinine >2.5)

ACEI, angiotensin-converting enzyme inhibitor; ALLHAT, Antihypertensive and Lipid-Lowering Treatment to Prevent Heart Attack Trial; AV, atrioventricular; CCB, calcium channel blocker; COPD, chronic obstructive pulmonary disease; DHP, dihydropyridine; HDL, high-density lipoprotein; ISA, intrinsic sympathomimetic activity; IV, intravenous; JNC 7, The Seventh Report of the Joint National Committee on Prevention, Detection, Evaluation, and Treatment of High Blood Pressure: the JNC 7 report (JAMA 2003;289:2560-72); MAO, monoamine oxidase; NSAID, nonsteroidal anti-inflammatory drug; SLE, systemic lupus erythematosus.

Part I

William F. Marshall, MD
Abinash Virk, MD

This chapter approaches the field of infectious diseases from three perspectives. The first section reviews the characteristics of specific pathogenic organisms, the second covers clinical syndromes associated with various infections, and the third section reviews the antimicrobial drugs.

Specific Microorganisms

Gram-Positive Cocci

Group A β-Hemolytic Streptococci: *Streptococcus pyogenes*

Infections

Group A streptococci are reemerging as an important cause of human disease. They are responsible for several different clinical syndromes. *S. pyogenes* is the most common cause of bacterial pharyngitis. Although the pharyngitis is usually self-limited, antibiotic therapy (penicillin) should be given to prevent acute rheumatic fever. Penicillin also will shorten the duration of symptoms if it is given within the first 24 hours of infection. Rapid diagnostic tests for streptococcal pharyngitis are easily administered and are specific but not as sensitive (50%-70%) as a throat culture for detecting *S. pyogenes*. Common complications of streptococcal pharyngitis include paratonsillar abscesses, otitis media, and sinusitis.

- Common complications of streptococcal pharyngitis include paratonsillar abscesses, otitis media, and sinusitis.

S. pyogenes is a virulent organism that is responsible for many skin and soft tissue infections. Several terms are used to differentiate these by the depth of infection and resulting clinical appearance.

Impetigo describes a superficial skin infection (Fig. 14-1). Historically, *S. pyogenes* was the most common cause of impetigo. Since the 1980s, however, most cases of impetigo have been caused by *Staphylococcus aureus* or mixed infections with both *S. aureus* and β-hemolytic streptococci.

Erysipelas is an infection of the skin with involvement of cutaneous lymphatic vessels. It often occurs on the face and produces a

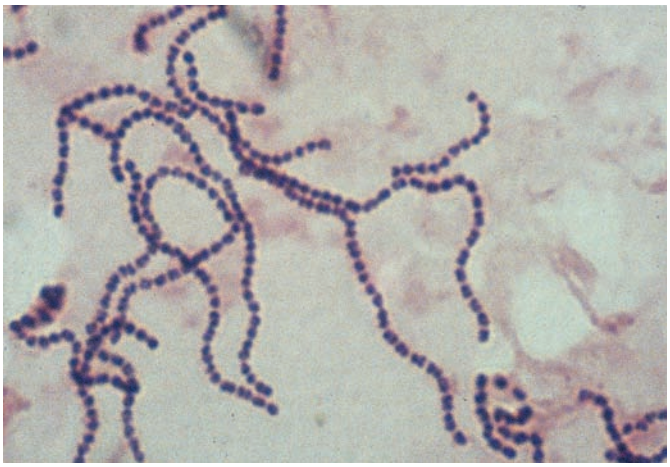

Fig. 14-1. Chaining of β-hemolytic *Streptococcus* in a blood culture. (Gram stain.)

raised, violaceous rash with a well-demarcated border. This infection is painful and most often occurs in the elderly. Recent reports have associated erysipelas with "toxic strep" syndrome.

In *cellulitis*, the infection involves the skin and subcutaneous tissue. Cellulitis is most common in tissue damaged by trauma and in extremities with impaired venous or lymphatic drainage (e.g., the arm after mastectomy or the leg after saphenous vein harvest for coronary artery bypass grafting). Minor inflammation or skin tears from tinea pedis may serve as a portal of entry for β-hemolytic streptococci.

Invasive Group A Streptococcal Infection

Since the mid 1980s, there have been increasing reports of severe group A streptococcal infection, including necrotizing fasciitis, myonecrosis, and a toxic shock–like syndrome. Suggested causes for the increase include the spread of virulent strains (especially M1 and M3), specific virulence factors (streptococcal pyogenic exotoxin and proteases), and a lack of immunity to these strains in the affected patients. In an outbreak of streptococcal necrotizing fasciitis in Minnesota, schoolchildren served as a reservoir for the responsible organism. Victims were mostly older and in poor health.

The overall mortality rate of streptococcal necrotizing fasciitis is 30%, even in previously healthy patients and with appropriate treatment. Many victims require amputation or extensive debridement of affected tissues. Effective treatment requires early recognition of the illness with prompt initiation of antibiotics, along with early and aggressive surgical debridement of devitalized tissue when indicated.

Unlike many other pathogens, group A streptococci remain exquisitely susceptible to the penicillins. The cephalosporins (first-generation) and vancomycin are effective alternative drugs. Erythromycin-resistant strains are reported but are so far uncommon in the United States. There is mounting evidence that clindamycin is the most effective antibiotic for treating streptococcal necrotizing fasciitis.

- Clindamycin is the most effective antibiotic for treating streptococcal necrotizing fasciitis.

Toxins

Group A streptococci produce many disease-causing exotoxins. Scarlet fever may develop in persons with no previous immunity to erythrogenic toxin. Production of hyaluronidase causes the rapidly advancing margins characteristic of cellulitis due to β-hemolytic streptococci. Streptococcal exotoxin A is similar to the toxin produced by *S. aureus* which causes toxic shock syndrome.

Nonsuppurative Complications

The nonsuppurative complications of group A streptococcal infection are *acute rheumatic fever* and *acute glomerulonephritis*. In the United States, there was a resurgence of acute rheumatic fever among children and military recruits during the 1980s. Rheumatic fever occurs only after streptococcal pharyngitis, never after skin infections. The diagnostic criteria for rheumatic fever are described in Table 14-1. Decreasing inflammation with aspirin (or corticosteroids) is the main therapy for acute rheumatic fever, although it will not prevent the development of chronic rheumatic heart disease.

- There was a resurgence of acute rheumatic fever among children and military recruits in the 1980s.

The risk for recurrent episodes of acute rheumatic fever with subsequent streptococcal infection is extremely high. Continuous antibiotic prophylaxis is effective for preventing these recurrences. Monthly injections of benzathine penicillin G and orally administered penicillin, sulfonamides, and erythromycin are effective for preventing recurrences of rheumatic fever. If there was no carditis with the acute rheumatic fever episode and no attack within the previous 5 years, prophylaxis may be discontinued after the age of 25 years. For patients who had significant carditis with residual valvular disease, lifelong prophylaxis may be necessary. Endocarditis prophylaxis is a separate issue. Endocarditis prophylaxis is recommended for people with significant rheumatic valvular disease who undergo dental or medically invasive procedures.

Acute glomerulonephritis may occur after infection with nephritogenic strains of *S. pyogenes*. Both cutaneous infections and pharyngitis can result in acute glomerulonephritis.

Table 14-1 Jones Criteria for Diagnosis of Initial Attack of Rheumatic Fever* (1992 Update)

Major manifestations
Carditis
Polyarthritis
Chorea
Erythema marginatum
Subcutaneous nodules
Minor manifestations
Clinical findings
Arthralgia
Fever
Laboratory findings
Elevated acute-phase reactants (erythrocyte sedimentation rate, C-reactive protein)
Prolonged PR interval
Supporting evidence of antecedent group A streptococcal infection
Positive throat culture or rapid diagnostic test
Elevated or rising streptococcal antibody titer

*If supported by evidence of recent *Streptococcus pyogenes* infection, then the presence of two major, or one major and two minor, criteria is enough for diagnosis. Exceptions in which the Jones criteria do not need to be fulfilled: 1) recurrent rheumatic fever (a single major or several minor criteria are sufficient if there is supporting evidence of a recent *S. pyogenes* infection), 2) isolated chorea, and 3) indolent carditis.

From Special Writing Group of the Committee on Rheumatic Fever, Endocarditis, and Kawasaki Disease of the Council on Cardiovascular Disease in the Young of the American Heart Association. Guidelines for the diagnosis of rheumatic fever: Jones Criteria, 1992 update. JAMA. 1992;268:2069-73. Used with permission.

- Continuous prophylactic antibiotics are used to prevent recurrent acute rheumatic fever.
- Acute glomerulonephritis may occur after either streptococcal skin infections or pharyngitis.
- Patients with significant rheumatic valvular disease require endocarditis prophylaxis for dental or medically invasive procedures.

Group B: *Streptococcus agalactiae*

This organism, part of the normal flora of the genital and gastrointestinal tracts, is an important cause of postpartum maternal and neonatal infections. The penicillins are the treatment of choice for infections caused by *S. agalactiae*. Meningitis, which most commonly occurs in neonates, is best treated with penicillin or ampicillin plus gentamicin. Prepartum vaginal culture for group B streptococcus may identify persons at highest risk for infection and allow eradication of the organism before delivery.

Group D Streptococci

Streptococcus bovis is the most clinically important of the group D streptococci. There is an association between *S. bovis* bacteremia and carcinoma of the colon or other colonic disease. *S. bovis* is clinically similar to the viridans group of streptococci and is generally susceptible to penicillin and the cephalosporins.

- Typical clinical scenario: A 59-year-old man with bacteremia and *S. bovis* endocarditis. Colonoscopy shows carcinoma of the colon. Penicillin (alone or with an aminoglycoside) is the treatment of choice for endocarditis caused by *S. bovis*.

Enterococci

The enterococci are an important cause of nosocomial infections. All enterococci are intrinsically resistant to many antimicrobial agents, including all of the cephalosporins. This resistance allows the organisms to proliferate and cause infections in the hospital setting. In fact, the enterococci are only inhibited, not killed, by the penicillins or vancomycin alone. Strains that are resistant to both the penicillins and vancomycin (vancomycin-resistant enterococci) are spreading worldwide. Linezolid and quinupristin/dalfopristin are two newer antibiotics that inhibit the growth of vancomycin-resistant enterococci. Neither agent is bactericidal against the enterococci. Quinupristin/dalfopristin is active against only *Enterococcus faecium*.

To achieve the bactericidal activity necessary to cure endocarditis due to enterococci, a combination of penicillin (or ampicillin) plus gentamicin or streptomycin is required. The choice of aminoglycoside depends on the results of susceptibility testing. The duration of therapy depends on how long the patient has been ill with endocarditis. Four weeks of therapy is adequate if the illness has been present for less than 3 months. When a patient is symptomatic for longer than 3 months, there is an unacceptable failure rate with the 4-week regimen. Therefore, 6 weeks of therapy is recommended. Vancomycin can be used in place of penicillin in the allergic patient, but it is considerably less effective. Optimal regimens for isolates resistant to both gentamicin and streptomycin are unknown. A valve replacement procedure may increase the chance for successfully treating subacute bacterial endocarditis due to drug-resistant enterococci.

- Enterococcal endocarditis is best treated with a combination of penicillin (or ampicillin) plus streptomycin or gentamicin.

Enterococcal urinary tract infections or simple bacteremia usually responds to treatment with either a penicillin or vancomycin alone, as long as the strains are susceptible in vitro. Alternatives for treatment of uncomplicated urinary tract infections in penicillin-allergic patients include the fluoroquinolones, nitrofurantoin, or vancomycin.

Streptococcus pneumoniae

S. pneumoniae (pneumococcus) is a leading cause of community-acquired infections such as pneumonia, meningitis, otitis media, and sinusitis. Like many organisms, it is becoming increasingly resistant to traditional antibiotics. Potential complications of pneumococcal pneumonia include empyema and pericarditis from direct extension of infection. Empyema should be suspected when fever persists despite appropriate antibiotic therapy of pneumococcal pneumonia.

S. pneumoniae is the most common cause of bacterial meningitis in adults (Fig. 14-2), including those with recurrent meningitis due to cerebrospinal fluid leaks. Meningitis due to susceptible *S. pneumoniae* can still be treated successfully with high-dose penicillin G. However, given the spread of penicillin-resistant strains, meningitis should be treated with high-dose cefotaxime or ceftriaxone, possibly in combination with vancomycin while the results of susceptibility testing are awaited. Adjunctive treatment of meningitis with dexamethasone has been shown to be beneficial if started at the same time as the first dose of antibiotic.

- *S. pneumoniae* is the most common cause of bacterial meningitis in adults.
- Consider the possibility of a cerebrospinal fluid leak in patients with recurrent *S. pneumoniae* meningitis.

Asplenia predisposes individuals to severe infections with *S. pneumoniae* (and other encapsulated organisms). After splenectomy, fulminant, often fatal, pneumococcal bacteremia with disseminated

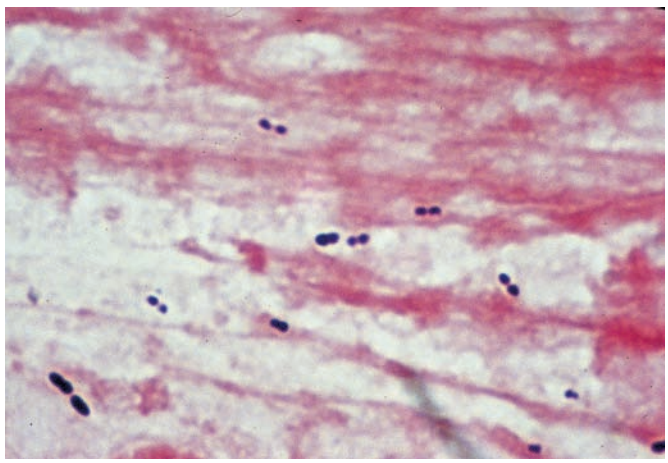

Fig. 14-2. *Streptococcus pneumoniae* in sputum. (Gram stain.)

intravascular coagulation is more common. Similarly, *S. pneumoniae* infections are more frequent and unusually severe in patients with sickle cell disease, multiple myeloma, alcoholism, or hypogammaglobulinemia.

S. pneumoniae is the leading cause of invasive bacterial respiratory disease in patients with human immunodeficiency virus (HIV) infection. Prophylaxis for *Pneumocystis carinii* pneumonia with trimethoprim-sulfamethoxazole may provide effective primary or secondary prophylaxis, but breakthrough infections with resistant organisms are not uncommon.

- Splenectomy predisposes to fulminant, often fatal, pneumococcal bacteremia with disseminated intravascular coagulation.
- *S. pneumoniae* infections are more frequent and unusually severe in patients with sickle cell disease, multiple myeloma, alcoholism, and hypogammaglobulinemia.
- *S. pneumoniae* is the leading cause of invasive bacterial respiratory disease in patients with HIV infection.

Infections due to *S. pneumoniae* have traditionally been treated with penicillin. However, the rate of penicillin resistance (minimal inhibitory concentration, >2 μg/mL) is increasing dramatically. As of 2002, 12% of pneumococcal isolates in Minnesota had high-level resistance to penicillin. Penicillin-resistant strains are often resistant to the effects of other antibiotics such as the cephalosporins. Penicillin resistance is conferred by an alteration of the penicillin-binding proteins which results in a decreased affinity of these cell wall components for the penicillins. Risk factors for development of infection due to penicillin-resistant pneumococci include previous use of β-lactam antibiotics, nosocomial acquisition, and multiple previous hospitalizations.

Penicillin-resistant strains of *S. pneumoniae* remain susceptible to vancomycin. High doses of cefotaxime, ceftriaxone, and imipenem also may be effective. Ciprofloxacin is usually not effective; however, the newer fluoroquinolones (levofloxacin, gatifloxacin, and moxifloxacin) are active against pneumococci. However, strains resistant to the quinolones already have been detected in Canada.

The pneumococcal vaccine is polyvalent, containing capsular polysaccharide from the 23 serotypes that most commonly cause pneumococcal infection. It is recommended for adults 65 years or older, those with chronic lung, kidney, or heart disease, and immunosuppressed and splenectomized persons. The vaccine can be given simultaneously with influenza virus vaccine. Pneumococcal vaccine booster is recommended 5 years after the initial dose in high-risk patients.

- Typical clinical scenario: Pneumococcal infection in a splenectomized patient presents with fulminant bacteremia with disseminated intravascular coagulation. The diagnosis is *S. pneumoniae* sepsis.

Viridans Streptococci

Several species of non-Lancefield typable streptococci are referred to as the "viridans group of streptococci." They are normal oral and enteric flora. This group of organisms is a common cause of subacute bacterial endocarditis, which should be suspected when viridans streptococci are found in blood cultures. Like the pneumococci, these organisms are increasingly likely to display resistance to penicillin. Viridans streptococcal bacteremia may be associated with shock and respiratory distress in neutropenic recipients of a bone marrow transplant.

One species of viridans streptococci, *Streptococcus milleri*, is more frequently associated with pyogenic abscesses. This is often a monomicrobial abscess and not necessarily associated with endocarditis.

- Typical clinical scenario: A 40-year-old man, 14 days after bone marrow transplantation, is neutropenic and has bacteremia with viridans streptococci, shock, and respiratory distress.

Staphylococci

Staphylococcus aureus (Coagulase-Positive *Staphylococcus*)

Toxins

Preformed enterotoxins produced by *S. aureus* are a common cause of food poisoning in the United States. The toxin is heat stable and, therefore, is not destroyed by cooking contaminated foods. Exfoliatins are exotoxins produced by *S. aureus* belonging to phage group II which cause scalded skin syndrome, an erythematous rash that progresses to bullous lesions, most commonly in children. It can be differentiated from toxic epidermal necrolysis by skin biopsy. Toxic shock syndrome is due to an exotoxin (TSST-1) produced by *S. aureus* that may be causing an otherwise subclinical infection.

- Preformed enterotoxins produced by *S. aureus* are not destroyed by cooking food.
- Toxic shock syndrome is due to an exotoxin (TSST-1) produced by *S. aureus* that may be causing an otherwise subclinical infection.

Clinical Syndromes

S. aureus is the causative agent of several superficial infections, including folliculitis (infection of hair follicles without involvement of skin or subcutaneous tissues), furunculosis (a more extensive follicular infection often involving subcutaneous tissues), carbuncles (infection in thick inelastic tissues of the scalp or upper back), and impetigo (although this is most commonly caused by group A β-hemolytic streptococci). Surgical drainage of infected lesions occasionally is required.

S. aureus is the most common cause of osteomyelitis in adults. It is the second most common cause of prosthetic joint infection, the coagulase-negative staphylococci being the most common.

- *S. aureus* is a common cause of chronic osteomyelitis in adults.
- *S. aureus* is the second most common cause of prosthetic joint infection.

Most cases of community-acquired *S. aureus* bacteremia should be treated for 4 to 6 weeks with parenteral antibiotics because of the potential for metastatic abscesses and infective endocarditis. If

nosocomial *S. aureus* bacteremia is caused by a removable focus of infection (such as an intravenous catheter), 10 to 14 days of therapy is usually sufficient. Some experts recommend using transesophageal echocardiography to screen for endocarditis in all patients with *S. aureus* bacteremia. *S. aureus* infrequently causes community-acquired pneumonia, but it may develop as a complication of influenza. *S. aureus* is a common cause of nosocomial infection, including postoperative wound infections, line-associated bacteremias, and ventilator-associated pneumonia. Detection of *S. aureus* in the urine should raise concern for an underlying bacteremia with secondary seeding of the urinary tract.

- Cases of community-acquired *S. aureus* bacteremia should be treated for 4 to 6 weeks with parenteral antibiotics.
- *S. aureus* infrequently causes community-acquired pneumonia, but it may develop as a complication of influenza.

Mechanisms of Resistance

Most *S. aureus* strains produce β-lactamase and thus are resistant to penicillin G. The semisynthetic penicillins (nafcillin, oxacillin) and first-generation cephalosporins remain active against such strains. Since first encountered in the 1970s, strains of *S. aureus* with intrinsic resistance to the β-lactam antibiotics have spread worldwide. This resistance is caused by an alteration of the penicillin-binding proteins in the cell wall. These strains, referred to as MRSA ("methicillin-resistant *S. aureus*," or "multiple drug-resistant *S. aureus*"), are resistant to all β-lactam drugs and often to other classes of antibiotics.

Community-Acquired MRSA

MRSA is a well-known nosocomial pathogen. However, new MRSA strains are now causing community-acquired infections. Genetic analyses show that these community-acquired MRSA strains are not merely known nosocomial strains that have "escaped" from the hospital. Rather, they are unique new strains that are causing both sporadic infections and localized outbreaks. Community-acquired MRSA may be more virulent than typical *S. aureus* strains.

Community-acquired MRSA is by definition resistant to the effects of all β-lactam antibiotics. Unlike nosocomial strains, community-acquired MRSA often remains susceptible to many other antibiotics, such as clindamycin and cotrimoxazole. Clinically, community-acquired MRSA infections may manifest as recurrent skin and soft tissue infections, necrotizing fasciitis, and hemorrhagic pneumonia. Outbreaks of skin infections among family members and within professional sports teams have been described.

Treatment

If *S. aureus* is penicillin-susceptible (approximately 5% of clinical isolates), penicillin G is the most active agent. For penicillin-allergic patients, effective alternatives include cefazolin and vancomycin. If the isolate is methicillin-susceptible, then nafcillin, oxacillin, cephalosporins (first-generation), vancomycin, and imipenem are active. Vancomycin is the most reliably active drug for treating serious infections caused by MRSA. Community-acquired MRSA is often susceptible to clindamycin and cotrimoxazole. Linezolid and quinupristin/dalfopristin are newer drugs that are also active against MRSA. Occasional strains of MRSA may still be susceptible to trimethoprim-sulfamethoxazole, minocycline, or the macrolides. However, these antibiotics are mostly used for treatment of non–life-threatening infections.

S. aureus organisms commonly colonize the nares, which may predispose to invasive infections. Subclinical nasal colonization can result in nosocomial transmission of MRSA. Topical mupirocin ointment or other therapies (such as cotrimoxazole with or without rifampin) may temporarily eradicate the nasal colonization, but relapse is common.

- Vancomycin is the most reliably active drug for treating serious infections caused by MRSA.
- Community-acquired MRSA is often susceptible to clindamycin and cotrimoxazole.

Coagulase-Negative Staphylococci

Staphylococcus epidermidis is the most common of the coagulase-negative staphylococci, although many other staphylococcal species are included in this group. For clinical purposes, they are interchangeable. Coagulase-negative staphylococci are normal skin flora. They are opportunistic pathogens that commonly cause infections associated with medical devices. They rarely cause disease in otherwise healthy persons.

Clinical Syndromes

Coagulase-negative staphylococci are most commonly associated with intravascular device-related bacteremia, prosthetic valve endocarditis, osteomyelitis (usually after joint arthroplasty or other prosthetic implantations), and meningitis after neurosurgical procedures. Treatment usually requires removal of the foreign body and administration of appropriate antibiotics. Coagulase-negative staphylococci can cause peritonitis in patients undergoing chronic ambulatory peritoneal dialysis.

Staphylococcus saprophyticus is a unique species of coagulase-negative staphylococcus that is a common cause of urinary tract infections in young women.

Treatment

Coagulase-negative staphylococci are usually resistant to the β-lactam antibiotics. Unless in vitro susceptibility testing shows other active agents, infections due to coagulase-negative staphylococci should be treated with vancomycin. The fluoroquinolones may be active against some strains, but resistance may emerge rapidly. *S. saprophyticus* is an exception because it is usually susceptible to the penicillins and many other antibiotics.

Determining the significance of blood cultures growing coagulase-negative staphylococci can be difficult. True infections generally result in multiple positive blood cultures, whereas one positive culture usually is considered to be contaminated.

A regimen of vancomycin plus rifampin for 6 weeks, with gentamicin added for the first 2 weeks, is recommended for the treatment of prosthetic valve endocarditis caused by coagulase-negative staphylococci. Valve replacement may be necessary in recalcitrant cases.

- Unless in vitro susceptibility testing shows other active agents, infections due to coagulase-negative staphylococci should be treated with vancomycin.
- Typical clinical scenario: A 29-year-old woman with an indwelling intravascular catheter has fever of 102°F. The diagnosis was infection with coagulase-negative *Staphylococcus*.

Gram-Negative Bacilli

Escherichia coli

E. coli organisms cause invasive disease as a result of ascending infection (such as in the urinary tract) or a break in a mucosal barrier (such as intra-abdominal infection). *E. coli* bacteremia is often related to focal infections such as intra-abdominal abscesses or pyelonephritis. *E. coli* is the most common cause of urinary tract infections and spontaneous bacterial peritonitis. Like most gram-negative bacilli, *E. coli* is variably susceptible to ampicillin, the cephalosporins (including first-generation agents), trimethoprim-sulfamethoxazole, aminoglycosides, and the fluoroquinolones.

E. coli O157:H7 produces a cytotoxic exotoxin that causes hemorrhagic colitis and may be complicated by hemolytic-uremic syndrome in approximately 10% of cases. This strain of *E. coli* is a normal part of bovine fecal flora that can contaminate undercooked hamburger, unpasteurized apple cider, and other food products. Treatment of *E. coli*-associated hemorrhagic colitis is supportive only. Antibiotics are actually contraindicated because their use will increase the risk for development of hemolytic-uremic syndrome.

- Antibiotics are contraindicated in the treatment of *E. coli* O157:H7-associated hemorrhagic colitis.

Klebsiella, *Enterobacter*, and *Serratia*

Klebsiella pneumoniae is an important cause of both community-acquired and nosocomial pneumonia and often is associated with alcoholism, diabetes mellitus, and chronic obstructive pulmonary disease. Red currant jelly-colored sputum is characteristic. Lung abscess and empyema are more frequent with *K. pneumoniae* than with other pneumonia-causing organisms. Cephalosporins are the drugs of choice for treating most types of *Klebsiella*. Strains of *Klebsiella* resistant to ceftazidime have emerged. This resistance is caused by a broad-spectrum β-lactamase. Susceptibility testing results for such strains may erroneously report that they are susceptible to cefotaxime. If resistant to ceftazidime, consider them resistant to all cephalosporins.

- Lung abscess and empyema are more frequent with *K. pneumoniae* than with other pneumonia-causing organisms.

Enterobacter and *Serratia* primarily are associated with nosocomial infections. *Enterobacter* species often are resistant to third-generation cephalosporins such as cefotaxime. Despite in vitro data suggesting susceptibility, β-lactamase production is induced when grown in the presence of cephalosporins. Carbapenems such as imipenem or meropenem, fluoroquinolones, cefepime, and trimethoprim-sulfamethoxazole are usually active against these strains.

- *Enterobacter* species often are resistant to third-generation cephalosporins such as cefotaxime, despite in vitro data suggesting susceptibility.

Pseudomonas aeruginosa

This organism predominantly causes nosocomial infection and is resistant to many common antibiotics. *P. aeruginosa*, together with *Staphylococcus aureus*, is the most frequent cause of infections complicating severe burn injuries. Other infections caused by *P. aeruginosa* include folliculitis associated with hot tubs, osteomyelitis (particularly in injection drug users), malignant otitis externa in patients with diabetes mellitus, complicated urinary tract infections, ventilator-associated pneumonia, and pulmonary infections in patients with cystic fibrosis. Patients with neutropenia are also at particularly high risk for *Pseudomonas* infection, especially bacteremia. Hence, the febrile neutropenic patient should be treated empirically with antipseudomonal antibiotics while culture results are awaited. Ecthyma gangrenosum is a necrotizing skin lesion that may develop in neutropenic patients with bacteremia due to *P. aeruginosa*.

- *P. aeruginosa*, together with *S. aureus*, is the most frequent cause of infections complicating massive burns.
- Typical clinical scenarios: *P. aeruginosa* causes malignant otitis externa in patients with diabetes mellitus. Ecthyma gangrenosum is a necrotizing skin lesion that develops in neutropenic patients with bacteremia due to *P. aeruginosa*.

Agents active against most *P. aeruginosa* organisms include the extended-spectrum penicillins (piperacillin, ticarcillin), aminoglycosides, ceftazidime and cefepime (the only cephalosporins reliably active against this organism), aztreonam, imipenem, and ciprofloxacin. Administering two active drugs, usually a β-lactam and an aminoglycoside, is recommended when treating serious infections caused by *P. aeruginosa*. Antibiotic resistance frequently emerges during and after treatment.

Stenotrophomonas (Xanthomonas) maltophilia

This organism most commonly causes nosocomial infections. Its most notable trait is intrinsic resistance to imipenem and meropenem (as well as the aminoglycosides, quinolones, and most β-lactam drugs). *S. maltophilia* usually is susceptible to trimethoprim-sulfamethoxazole and ticarcillin-clavulanate.

- *S. maltophilia* is intrinsically resistant to imipenem and meropenem.

Salmonella

Salmonella infections are increasing in the United States. Well-identified outbreaks have been associated with food contamination. Undercooked chicken or eggs are often sources of infection. Gastroenteritis is the most common manifestation. However, more serious illnesses, including infections of atherosclerotic aortic aneurysms, may occur.

Salmonella typhi is rare in the United States. Patients with typhoid fever have relative bradycardia and rose spots (50%). The leukocyte count may be decreased. Blood cultures usually are positive within

approximately 10 days of symptom onset, whereas stool cultures become positive later.

Salmonella choleraesuis causes chronic bacteremia and mycotic aneurysms. *Salmonella typhimurium* and *Salmonella enteritidis* produce gastroenteritis and occasionally bacteremia. Urinary tract infections caused by *Salmonella* occur in patients from the Middle East who are infected with *Schistosoma haematobium*.

- *Salmonella* causes infections of atherosclerotic aortic aneurysms.

As with many organisms, antimicrobial resistance is increasingly common with *Salmonella*. Most cases of *Salmonella* gastroenteritis resolve without therapy. In fact, treatment with antibiotics may actually prolong the duration of intestinal carriage and fecal shedding. Serious or invasive infections should be treated with a third-generation cephalosporin or fluoroquinolone while results of susceptibility testing are awaited.

- Most cases of *Salmonella* gastroenteritis should not be treated with antibiotics because treatment prolongs the carrier state.

Haemophilus influenzae

Widespread use of the vaccine against *H. influenzae* B has dramatically reduced the incidence of invasive disease in children. Nontypable strains of *H. influenzae* more commonly cause disease in adults (primarily respiratory infection). Infections caused by *H. influenzae* include pneumonia, meningitis, epiglottitis, and primary bacteremia. Chronic lung disease, pregnancy, HIV infection, splenectomy, and malignancy are risk factors for invasive disease.

- Chronic lung disease, pregnancy, HIV infection, splenectomy, and malignancy are risk factors for invasive disease due to *H. influenzae*.

Up to 40% of *H. influenzae* organisms recovered from adults with invasive disease are resistant to ampicillin by virtue of β-lactamase production. They can be treated with cotrimoxazole, third-generation cephalosporins, fluoroquinolones, or a β-lactam–β-lactamase inhibitor combination such as ampicillin-sulbactam.

- Approximately 40% of *H. influenzae* clinical isolates are resistant to ampicillin.

H. influenzae is an uncommon cause of meningitis in adults, although it can occur with hypogammaglobulinemia, asplenia, or cerebrospinal fluid leak. Third-generation cephalosporins (cefotaxime or ceftriaxone) are the drugs of choice for *H. influenzae* meningitis.

Other *Haemophilus* Species

Haemophilus parainfluenzae, *Haemophilus aphrophilus*, and *Haemophilus paraphrophilus* are normal oral flora. When these or other members of the HACEK (***H****aemophilus aphrophilus*, *paraphrophilus*, and *parainfluenzae*; ***A****ctinobacillus actinomycetemcomitans*; ***C****ardiobacterium hominis*; ***E****ikenella corrodens*; ***K****ingella* species) group of organisms are grown from blood cultures, their presence should always raise the suspicion for endocarditis. Large valvular vegetations with systemic emboli are common with HACEK endocarditis. Usual treatment is with ampicillin (if the organism is susceptible) or a third-generation cephalosporin for 3 weeks.

Bordetella pertussis

The incidence of whooping cough is increasing as the protection afforded by immunization declines with age. Twelve percent of cases now occur in persons older than 15 years. *B. pertussis* infection often results in persistent coughing in older children and adults. As many as 50 million adults are now susceptible to infection as a result of waning immunity. Whooping cough may cause severe lymphocytosis (>100 lymphocytes × 10^9/L). Diagnosis of *B. pertussis* infection may be difficult. Culture or molecular testing of a nasopharyngeal aspirate is most sensitive. Early treatment of pertussis with a macrolide antibiotic is most effective. Aerosolized bronchodilators or corticosteroids may alleviate the persistent coughing.

- *B. pertussis* may cause severe lymphocytosis (>100 lymphocytes × 10^9/L).
- *B. pertussis* can cause persistent coughing in older children and adults.

Brucella

Although rare in the United States, brucellosis may occur in meat handlers, persons exposed to livestock, or persons who drink unpasteurized milk. Most cases occur in four states (Texas, California, Virginia, and Florida). Brucellosis may cause a chronic granulomatous disease with caseating granulomas. Brucellosis (along with tuberculosis) is a cause of "sterile" pyuria. Chronic brucellosis is one of the infectious causes of fever of undetermined origin. Calcifications in the spleen may be an indication of the presence of infection (although histoplasmosis also causes splenic calcifications). Serologic testing, special blood cultures, and bone marrow cultures are helpful for making the diagnosis. Treatment is with doxycycline along with streptomycin or rifampin. Cotrimoxazole may be effective.

- Brucellosis may cause fever of unknown origin and is associated with animal exposures.

Legionella

Legionellae are fastidious gram-negative bacilli. *Legionella pneumophila* causes both community-acquired and nosocomial pneumonia, typically occurring in the summer months. Nosocomial legionellosis may be due to contaminated water supplies. Immunocompromised patients, especially those receiving chronic corticosteroid therapy, are especially susceptible to *Legionella* infections. Typical clinical features of legionellosis include weakness, malaise, fever, dry cough, diarrhea, pleuritic chest pain, relative bradycardia, diffuse rales bilaterally, and patchy bilateral pulmonary infiltrates.

Characteristic laboratory features of *Legionella* pneumonia include decreased sodium and phosphorus values, increased leukocyte level, and increased liver enzyme values. Legionellae organisms will not grow on standard media. Diagnosis depends on results of

special culture, finding organisms by direct fluorescent antibody staining, or detecting an increase in anti-*Legionella* antibody titers. Urine antigen detection is a more sensitive (>80%) and simple diagnostic test for *L. pneumophila* infections.

Legionellae are intracellular parasites. As such, they are resistant to all β-lactam drugs and aminoglycosides in vivo. Effective agents for treating *Legionella* include macrolides, fluoroquinolones, and, to a lesser extent, doxycycline. Some authorities recommend adding rifampin for severe infection.

- Immunocompromised patients, especially those receiving chronic corticosteroid therapy, are especially susceptible to *Legionella* infections.
- Laboratory features of legionellosis include decreased serum sodium and phosphorus values, increased leukocyte level, and increased liver enzyme values.
- Typical clinical scenario: A 63-year-old man who is receiving chronic corticosteroid therapy presents with fever, dry cough, diarrhea, and patchy bilateral infiltrates on chest radiography. Laboratory tests show hyponatremia and increased liver function values. Diagnosis is *Legionella* infection and can be established by special *Legionella* culture, serologic tests, and urinary antigen detection. Therapy is with macrolides or fluoroquinolones.

Francisella tularensis

F. tularensis is spread by the bite of a tick or deer fly, by aerosol droplets, or by direct contact with tissues of infected animals (rabbits, muskrats, squirrels, beavers). Typically, infection causes an eschar at the site of inoculation, regional lymphadenopathy, and high fevers. Pneumonia also can occur. Streptomycin and gentamicin are the most effective therapies. Tetracycline is also active, but its use is associated with a 10% relapse rate. Tularemia has been identified as a potential bioterrorism agent.

- *F. tularensis* is spread by arthropod bite, aerosol droplets, or direct contact with tissues of infected animals.

Yersinia pestis

From 1950 to 1991, there were 336 cases of plague in the United States, and more than 50% of these occurred after 1980. Plague is enzootic in the southwestern United States. New Mexico had 56% of cases, and 29% of cases are among American Indians. Rats and fleas are the vectors. Clinical presentations include 1) lymphadenopathy with septicemia—the most common form—and 2) the pneumonic form (high case-fatality rate). Treatment is with streptomycin or tetracycline. As with tularemia, there is concern that plague could be used for bioterrorism.

Pasteurella multocida

P. multocida is a common cause of cutaneous infection after a cat or dog bite. Onset of illness is typically within 24 hours of the bite. It causes local inflammation, a rapidly progressing cellulitis, and bacteremia. *P. multocida* is susceptible to penicillin, amoxicillin, amoxicillin-clavulanate, tetracyclines, and fluoroquinolones. First-generation cephalosporins (cephalexin) and the antistaphylococcal penicillins (such as nafcillin and oxacillin) are not active against *P. multocida* infections.

- Cephalexin and the antistaphylococcal penicillins should not be used to treat cat or dog bite wounds infected with *P. multocida*.
- Typical clinical scenario: A 35-year-old man presents with cutaneous infection after a dog or cat bite. It rapidly progresses to cellulitis and bacteremia.

Capnocytophaga (Formerly DF-2)

These gram-negative bacilli are difficult to grow on routine culture media. They are normal oral flora of domestic animals (especially dogs) and humans. *Capnocytophaga* causes bacteremia and fulminant sepsis, primarily in splenectomized persons. Dog and cat bites are associated with 50% of cases. Occasionally, bacteremia with human oral *Capnocytophaga* species occurs in neutropenic patients with mucositis. Treatment with a penicillin or a cephalosporin is most effective.

- *Capnocytophaga* causes bacteremia and fulminant sepsis, primarily in splenectomized persons.
- Dog and cat bites are associated with 50% of cases.

Bartonella henselae

B. henselae (formerly *Rochalimaea henselae*) is the primary causative agent of cat-scratch disease. The disease is characterized by a papule or pustule at the site of inoculation, followed by tender enlargement of the regional lymph nodes. Low-grade fever and malaise also may be present. Exposure to domestic cats (especially kittens) is the main risk factor. About 10% of patients may have extranodal manifestations. Disseminated infection can occur in patients with acquired immunodeficiency syndrome (AIDS).

Diagnosis of cat-scratch disease is based on the clinical picture and serologic evidence of antibodies to *B. henselae*. In biopsied tissue, the organisms can be seen with Warthin-Starry stain. Because the disease is usually self-limited, treatment is indicated only for patients with significant symptoms or bothersome adenopathy. Azithromycin appears to be the most effective antibiotic for treatment of cat-scratch disease.

Vibrio Species

In the United States, consumption of raw or undercooked shellfish such as oysters is the most common source of infection with pathogenic vibrios (e.g., *Vibrio parahaemolyticus*, *Vibrio vulnificus*). Disease usually manifests as self-limited enteritis. Cholera, caused by *Vibrio cholerae*, continues to cause periodic pandemics, the most recent affecting South and Central America. Although indigenous cases are rare in the United States and Canada, cholera has developed in travelers returning from affected areas.

V. vulnificus is unique in that it causes a distinctive soft tissue infection in compromised hosts, especially those with underlying cirrhosis or hemochromatosis. Disease is usually acquired by the ingestion of raw oysters or through injury sustained in warm salt water. After the abrupt onset of fever and hypotension, multiple hemorrhagic bullae develop. Even with prompt therapy with

ceftazidime or a tetracycline, mortality exceeds 30% for bacteremic *V. vulnificus* infection.

- Consumption of raw oysters is the most common source of *Vibrio* infection in the United States.

Gram-Positive Bacilli

Listeria

Listeria monocytogenes is a small, motile, gram-positive, rod-shaped organism. Meningitis and bacteremia are the most common clinical manifestations of infection. *Listeria* may be difficult to visualize on Gram stain of spinal fluid. The elderly, neonates, pregnant women, and persons taking corticosteroids are at highest risk for disease due to *Listeria*. Epidemics have been associated with consumption of contaminated dairy products. Diarrhea may be a feature of epidemic listeriosis.

Penicillin and ampicillin are the most effective agents against *Listeria*. Combination with an aminoglycoside is often recommended for treatment of severe disease. *Listeria* is always resistant to the cephalosporins. Cotrimoxazole is an effective alternative for the penicillin-allergic patient. Treatment should be continued for 2 to 4 weeks to prevent relapse of disease.

- The elderly, neonates, pregnant women, and persons taking corticosteroids are at highest risk for disease due to *Listeria*.
- Epidemics mainly are associated with consumption of contaminated dairy products.
- Diarrhea may be a feature of epidemic listeriosis.

Corynebacterium diphtheriae

Diphtheria is a classic infectious disease that is easily prevented with vaccination. Epidemics of diphtheria recently occurred in states of the former Soviet Union. Diphtheria causes a focal infection of the respiratory tract (pharynx in 60%-70% of cases, larynx, nasal passages, or tracheobronchial tree). A tightly adherent, gray pseudomembrane is the hallmark of the disease, but disease can occur without pseudomembrane formation. Manifestations depend on the extent of involvement of the upper airway and the presence or absence of systemic complications due to toxin. Toxin-mediated complications include myocarditis (10%-25%), which causes congestive heart failure and arrhythmias, and polyneuritis (bulbar dysfunction followed by peripheral neuropathy). The respiratory muscles may be paralyzed.

- In diphtheria, toxin-mediated complications include myocarditis (10%-25%), which causes congestive heart failure and arrhythmias, and polyneuritis.
- Diphtheria may cause respiratory muscle paralysis.

The diagnosis of diphtheria is definitively established by culture with Löffler medium. Rapid diagnosis sometimes can be made with methylene blue stain or fluorescent antibody staining of pharyngeal swab specimens. Diphtheria is highly contagious. Equine antiserum is still the main therapy. Although there is no evidence that antimicrobial agents alter the course of disease, they may prevent transmission to susceptible hosts. Erythromycin and penicillin G are active against *C. diphtheriae*. Non-immune persons exposed to diphtheria should be evaluated and treated with erythromycin or penicillin G if culture results are positive. They should also be immunized with diphtheria-tetanus toxoid.

- Non-immune persons exposed to diphtheria should be evaluated and treated with erythromycin or penicillin G if culture results are positive.

Cutaneous infection with *C. diphtheriae* can occur in indigent persons and alcoholics. Preexisting dermatologic disease (most often in the lower extremities) is a risk factor. Lesions may appear "punched-out" and filled with a membrane, but they may be indistinguishable from other infected ulcers. Toxin-mediated complications (such as myocarditis and neuropathy) are uncommon. Diagnosis is established with methylene blue staining and culture of the lesion with Löffler medium.

- Cutaneous diphtheria is reported in indigent patients and alcoholics.

Bacillus Species

Bacillus species are increasingly recognized as causes of bacteremia in patients with indwelling catheters or prosthetic devices and in injection drug users. Other syndromes include ocular infections (posttraumatic endophthalmitis) and gastroenteritis. Anthrax (*Bacillus anthracis*) causes cutaneous disease in handlers of animal skins (also called woolsorters' disease).

Although many strains of *Bacillus* are susceptible to penicillins and cephalosporins, infection should be treated with vancomycin or clindamycin while the results of susceptibility tests are awaited.

In 2001, several cases of inhalational and cutaneous anthrax followed the deliberate dissemination of *B. anthracis* spores through the mail. Inhalation anthrax is particularly deadly. It produces hemorrhagic mediastinitis, hemorrhagic meningitis, and bacteremia. Cutaneous anthrax usually manifests as a solitary papule that evolves into an eschar. Culture of blood, pleural fluid, cerebrospinal fluid, or a skin lesion confirms the diagnosis of anthrax. Sputum rarely reveals the organism. Nasal swab culture is useful for epidemiologic purposes but is not sufficiently sensitive to diagnose individual exposures.

B. anthracis is usually susceptible to penicillins, tetracyclines, clindamycin, vancomycin, rifampin, and the fluoroquinolones. Inhalational exposures should be treated for at least 60 days. Combination therapy with multiple active drugs is preferred for inhalational anthrax.

Gram-Negative Cocci

Moraxella

Moraxella catarrhalis (*Branhamella catarrhalis*) is a respiratory tract pathogen primarily causing bronchitis and pneumonia in persons with chronic obstructive pulmonary disease. It also may cause otitis media, sinusitis, meningitis, bacteremia, and endocarditis in

immunosuppressed patients. Ampicillin resistance through β-lactamase production is common. Trimethoprim-sulfamethoxazole, the fluoroquinolones, and amoxicillin-clavulanate are effective for therapy.

Neisseria

Neisseria meningitidis and *Neisseria gonorrheae* are discussed in the section Clinical Syndromes (Part II of this chapter).

Anaerobic Bacteria

Bacteroides and *Prevotella*

Bacteroides species are anaerobic gram-negative rods that are normal colonic flora (*Bacteroides fragilis* group). Related organisms also reside in the mouth (such as *Prevotella melaninogenica*). Infections caused by these organisms are often polymicrobial and result from disruption or perforation of mucosal surfaces. These anaerobes often produce abscesses containing foul-smelling pus. *Bacteroides* species also are associated with pelvic infections, particularly in women (e.g., septic abortion, tubo-ovarian abscess, or endometritis). Anaerobic bacteremia usually is associated with focal infection elsewhere (such as intra-abdominal abscess). Osteomyelitis due to *Bacteroides* usually results from a contiguous source and is often polymicrobial (such as diabetic foot ulcer or osteomyelitis of the maxilla or mandible after dental infection). Pleuropulmonary infections include aspiration pneumonia and lung abscess, most commonly with *P. melaninogenica* and other oral anaerobes.

- *Bacteroides* species are associated with intra-abdominal and pelvic abscesses.
- Anaerobic bacteremia usually is associated with focal infection elsewhere (such as intra-abdominal abscess).
- Pleuropulmonary infections caused by *Bacteroides* and *Prevotella* species include aspiration pneumonia and lung abscess.

Many strains of *Bacteroides* and *Prevotella* produce penicillinase, making them resistant to penicillin. Metronidazole, ampicillin-sulbactam, and imipenem are active against most anaerobic gram-negative rods. Resistance to clindamycin is increasingly common. The third-generation cephalosporins and fluoroquinolones have little activity against the anaerobic gram-negative bacilli.

Peptococcus and *Peptostreptococcus*

These anaerobic streptococci often are involved in polymicrobial infection. Like *Bacteroides*, they are part of the normal flora of the mouth and colon and are associated with anaerobic pleuropulmonary infection and intra-abdominal abscess.

Both *Peptococcus* and *Peptostreptococcus* are exquisitely sensitive to the penicillins. For patients allergic to penicillin, the effective alternative therapies include clindamycin, vancomycin, and cephalosporins.

Clostridia

Clostridium tetani

C. tetani is a strictly anaerobic gram-positive rod that produces a neurotoxin (tetanospasmin). This neurotoxin, when produced by organisms in infected wounds, is responsible for the clinical manifestations of tetanus. Although rare in the United States, 200 to 300 cases still occur annually, mostly in elderly persons who have never been immunized.

The first muscles affected by tetanus are controlled by cranial nerves, resulting in trismus. Eye muscles (cranial nerves III, IV) rarely are involved. As the disease progresses, other muscles become involved (generalized rigidity, spasms, opisthotonos). Sympathetic overactivity is common (labile hypertension, hyperpyrexia, arrhythmias). The diagnosis of tetanus is based on clinical findings, although a characteristic electromyogram is suggestive.

- The diagnosis of tetanus is based primarily on clinical findings.

Treatment of tetanus includes supportive care, proper wound management, and administration of antiserum (human tetanus immune globulin). Penicillin G or metronidazole should be administered to eradicate vegetative organisms in the wound. Active tetanus does not induce protective immunity. Therefore, a primary tetanus immunization series should be given after an episode of tetanus.

- Active tetanus does not induce protective immunity to subsequent episodes of tetanus.

Clostridium botulinum

C. botulinum produces a heat-labile neurotoxin that inhibits acetylcholine release from cholinergic terminals at the motor end plate. Botulism usually is caused by the ingestion of contaminated food (home-canned products and improperly prepared or handled commercial foods). Wound botulism results from contaminated traumatic wounds. Neonatal botulism can result from consumption of contaminated honey.

- Neurotoxin of *C. botulinum* inhibits acetylcholine release from cholinergic terminals at the motor end plate.

The clinical symptoms of botulism include unexplained diplopia; fixed, dilated pupils; dry mouth; and descending flaccid paralysis with normal sensation. Patients are usually alert and oriented and have intact deep tendon reflexes. Fever is rare.

- Typical clinical scenario: In *C. botulinum* infection (botulism), a patient presents with unexplained diplopia; fixed, dilated pupils; dry mouth; and descending flaccid paralysis with normal sensation.

Treatment of botulism is primarily supportive although an equine antitoxin is available. In food-borne cases, purging the gut with cathartics, enemas, and emetics to remove unabsorbed toxin also may be of value. Antibiotic therapy does not affect the course of illness.

Other Clostridium *Species*

Clostridium perfringens is one of the causes of food poisoning. Illness usually develops 7 to 15 hours after ingestion and manifests as diarrhea with abdominal cramps. *Clostridium difficile* is the primary cause of antibiotic-associated pseudomembranous colitis. Bacteremia

or soft tissue infection with *Clostridium septicum* indicates a high probability of coincident occult colonic malignancy.

- *C. perfringens* may cause a food-associated illness.
- *C. difficile* causes antibiotic-associated diarrhea.
- In patients with *C. septicum* bacteremia, occult bowel carcinoma should be suspected.

Actinomycetes

Actinomyces israelii, an anaerobic, gram-positive, branching, filamentous organism, is the most common cause of human actinomycosis. *A. israelii* is part of the normal flora of the mouth. Infections are associated with any condition that creates an anaerobic environment (such as trauma with tissue necrosis, pus). The pathologic characteristic is formation of "sulfur granules," which are clumps of filaments. Infection is not characterized by granuloma formation.

- The pathologic characteristic of actinomycosis is "sulfur granules" (clumps of filaments).

Lumpy jaw is caused by a perimandibular infection with *A. israelii*. It is characterized by a chronic draining sinus and may follow a dental extraction. Pulmonary actinomycosis develops when aspirated material reaches an area of lung with decreased oxygenation (such as in atelectasis). A chronic suppurative pneumonitis may develop and eventually result in a sinus tract draining through the chest wall. There may be subsequent perforation into the esophagus, pericardium, ribs, and vertebrae. Ileocecal perforation from focal actinomycosis has been reported. Appendicitis may be a predisposing factor.

- Lumpy jaw is caused by a perimandibular infection with *A. israelii*. It is characterized by a chronic draining sinus and may follow a dental extraction.

A. israelii also may be found in culture of tubo-ovarian abscesses and other pelvic infections. It is especially associated with pelvic inflammatory disease developing in a woman with an intrauterine device.

A prolonged course of penicillin is the preferred treatment of actinomycosis.

Mycobacteria

Mycobacterium tuberculosis

Clinical Disease

Pulmonary tuberculosis can manifest as primary infection, reactivation of previously latent infection, or reinfection. Primary infection involves continuous uninterrupted mycobacterial proliferation without a period of involution or quiescence. Primary disease commonly occurs in infants, children, and immunosuppressed adults. The radiographic findings of primary pulmonary disease include mid- or lower-zone parenchymal infiltrates with hilar adenopathy and pleural effusions. Reactivation-type pulmonary tuberculosis is the more common "classic" presentation in adults. Patients often present with symptoms such as prolonged cough (initially dry, later productive), fever, chills, night sweats, general fatigue, and weight loss. Hemoptysis and chest pain may occur. Chest radiographic abnormalities are variable but may include fibronodular infiltrates or cavitary disease, often found in the apical and posterior segments of the upper lobe or superior segments of the lower lobe. With cavitary disease, sputum samples are usually acid-fast bacillus smear-positive. Culture of respiratory specimens remains the standard for diagnosing tuberculosis and allows for drug susceptibility testing. However, in 10% to 15% of tuberculosis cases, the cultures are negative and diagnosis is dependent on radiographic or clinical findings. Nucleic acid amplification through polymerase chain reaction offers a more rapid means for identification of *M. tuberculosis* than traditional culture. Tissue biopsy for histologic review often reveals classic caseating (necrotizing) granulomas with or without acid-fast organisms.

- In adults, reactivation-type pulmonary tuberculosis is the typical presentation.
- Symptoms of tuberculosis include prolonged cough, hemoptysis, fever, chills, night sweats, general fatigue, and weight loss.
- Chest radiographs may show fibronodular or cavitary disease in the apical and posterior segments of the upper lobe or superior segments of the lower lobe.
- Culture is important for *M. tuberculosis* confirmation and susceptibility testing.

Treatment of Pulmonary Tuberculosis

Regimens for the treatment of pulmonary tuberculosis are outlined in Table 14-2. All 6-month regimens must contain isoniazid, rifampin, and an initial 2 months of therapy with pyrazinamide. All 9-month regimens must contain isoniazid and rifampin. Patient compliance is paramount to a successful treatment program, and directly observed therapy should be considered for all patients. Multidrug resistance is defined as resistance to both isoniazid and rifampin, although such strains are often also resistant to other drugs. Infections with multidrug-resistant tuberculosis are very difficult to treat and should be referred to an expert in tuberculosis management.

- Directly observed therapy is strongly recommended for all patients with tuberculosis.

Extrapulmonary Tuberculosis

Lymphatic tuberculosis (scrofula) is most commonly found in the head and neck region, including posterior cervical and supraclavicular chains. Although most cases of mycobacterial lymphadenitis in children are caused by *Mycobacterium avium-intracellulare*, more than 90% of cases in adults are from *M. tuberculosis* infection. Pleural tuberculosis commonly presents with a unilateral effusion. Pleural fluid analysis shows a predominance of mononuclear cells and a low glucose level. Culture of the pleural fluid is usually negative, but pleural biopsy can increase the diagnostic yield to 90% to 95%. Genitourinary tuberculosis can involve the kidneys, ureters, bladder, and reproductive organs. Calcifications of renal parenchyma and ureteral strictures may occur. Vertebral infection with tuberculosis (Pott disease)

Table 14-2 Treatment of Pulmonary Tuberculosis*

Option 1
Initiation: INH, RFP, PZA, EMB daily × 8 wk
Continuation: INH, RFP daily or 2-3 times/wk DOT for 16 wk
Option 2
Initiation: INH, RFP, PZA, EMB daily × 2 wk, then INH, RFP, PZA, EMB 2 times/wk DOT × 6 wk
Continuation: INH, RFP 2 times/wk DOT × 16 wk
Option 3
INH, RFP, PZA, EMB 3 times/wk DOT × 6 mo
Special circumstances
Intolerant to PZA: INH, RFP × 9 mo†
Pregnancy‡: INH, RFP, EMB × 9 mo

DOT, directly observed therapy; EMB, ethambutol; INH, isoniazid; PZA, pyrazinamide; RFP, rifampin.

*Ethambutol or streptomycin should be added to all regimens until susceptibility data are known or unless isoniazid resistance is less than 4% in the geographic area. Pyridoxine (vitamin B_6) should be given with all regimens containing isoniazid and during pregnancy.

†Twice/wk dosing can be given after 1 to 2 months if isolate is sensitive.

‡Streptomycin and pyrazinamide are not recommended during pregnancy; streptomycin may be harmful to the fetus, and pyrazinamide has not been well studied during pregnancy.

causes an anterior wedging and collapse of the vertebral body, producing a gibbus deformity. Tuberculous infection of the central nervous system manifests as a chronic meningitis with basilar arachnoiditis, cranial nerve deficits, hydrocephalus, vascular thrombosis, and tissue necrosis. Findings on cerebrospinal fluid evaluation are mononuclear cell predominance, increased protein value, and decreased glucose value.

Disseminated tuberculosis (simultaneous involvement of multiple organs) can be a progressive form of primary disease or a product of reactivating disease. Young children, the elderly, and immunosuppressed persons are most at risk. Chest radiography may show miliary shadows composed of 1- to 2-mm well-defined nodules throughout both lungs. Tuberculin skin testing commonly results in no reaction (cutaneous anergy), and the diagnosis of disseminated tuberculosis can be difficult. Extrapulmonary tuberculosis is adequately treated with the same regimens as those for pulmonary tuberculosis, with a few exceptions: an extended course of therapy is recommended for vertebral, central nervous system-meningeal, and disseminated tuberculosis. Adjunctive corticosteroids may be indicated in the management of meningeal and pericardial tuberculosis.

- Unlike in children, more than 90% of cases of mycobacterial lymphadenitis in adults are due to *M. tuberculosis*.
- Adjunctive corticosteroids are beneficial in the management of meningeal and pericardial tuberculosis.
- A prolonged course of therapy is recommended for vertebral, central nervous system, and disseminated tuberculosis.

Screening for Tuberculosis

Current guidelines for detection of latent tuberculosis infection emphasize a "targeted" screening approach toward patients at risk for tuberculosis. Only persons at high risk for recent infection or with clinical conditions that increase the risk for tuberculosis should be screened. Criteria to identify persons with latent tuberculosis infection or high-risk contacts are listed in Table 14-3. Tuberculin skin test (TST) conversion is defined as an increase of 10 mm or more in induration within a 2-year period, regardless of age. All persons with a positive result of TST require chest radiography and evaluation to exclude clinical disease. For patients with chest radiographic findings consistent with prior or untreated tuberculosis, an evaluation for active disease, including sputum sample collection, should be performed before therapy is started. If chest radiography or clinical evaluation raises the suspicion for active disease, then combination chemotherapy should be initiated while culture results are awaited. Contacts of persons with infectious cases of tuberculosis should have a baseline TST. If the result is negative, a repeat TST is done 10 to 12 weeks later (a delayed-type hypersensitivity skin test response to *M. tuberculosis* is generally detectable 2-12 weeks after infection). Healthy immunocompetent adults may be observed without initiating medical therapy unless the initial TST result is 5 mm or more; however, immunosuppressed adults, HIV-infected persons, and children should start preventive therapy regardless of the initial TST. Treatment can be discontinued in children if repeat skin testing at 12 weeks is negative.

- Only persons at high risk for latent tuberculosis infection or with clinical conditions that increase the risk for tuberculosis should be screened, regardless of age.
- Tuberculin skin test (TST) conversion is defined as an increase of 10 mm or more in induration within a 2-year period, regardless of age.
- All persons with a positive result of TST require chest radiography and evaluation to exclude clinical disease.

Delayed-type hypersensitivity may wane over time in some individuals infected with *M. tuberculosis*. In these persons, a TST many years after infection may be nonreactive; however, it can stimulate or "boost" hypersensitivity to subsequent skin tests and be misinterpreted as new infection. Two-step testing is designed to identify and distinguish between boosted reactions ("booster effect"), signifying previous infection, and reactions due to new or recent infection. If the first test result is positive, the patient should be considered infected (recent or remote). If the initial TST is negative, a positive repeat skin test 1 to 3 weeks later indicates previous rather than new infection. A negative TST *never* excludes tuberculosis. Although less common in otherwise healthy individuals, the TST result may be falsely negative in 20% to 25% of patients with active tuberculosis. In persons infected with both HIV and tuberculosis, the percentage of false-negative skin tests variably ranges between 30% and 80%, depending on the magnitude of cell-mediated immunity

Table 14-3 Candidates for Treatment of Latent Tuberculosis Infection or Special Contacts,* by Diameter of Induration Produced by Tuberculin Skin Testing

<5 mm	≥5 mm	≥10 mm	≥15 mm
Child <5 y old and recent close contact HIV infection and recent close contact Immunosuppressed and recent close contact	HIV-infected persons Persons with organ transplants and other immunosuppressed patients (receiving the equivalent of ≥15 mg/day of prednisone for ≥1 mo) Recent contact with infectious tuberculosis Fibrotic changes on chest radiograph consistent with prior tuberculosis (if patient not previously fully treated)	Recent tuberculin skin test converters (within past 2 y) Injection drug users who are HIV-negative High-risk medical conditions† Residents and employees of high-risk congregate settings‡ Recent immigrants (within past 5 y) from areas where tuberculosis is common§ Health care workers, depending on individual risk factors Children <4 y old Children or adolescents exposed to adults at high risk	No risk factors (tuberculin skin test not recommended)

HIV, human immunodeficiency virus.
*Recent contacts who are initially negative on tuberculin skin testing should have a repeat test 10 to 12 weeks after last exposure to tuberculosis. Treatment can be discontinued if repeat result is negative.
†Gastrectomy, hematologic malignancies, reticuloendothelial diseases, renal failure, other malignancies, diabetes (insulin-dependent), silicosis, jejunoileal bypass.
‡Nursing homes, long-term care facilities, prisons or jails, homeless shelters.
§Asia, Africa, Latin America.

damage. Therefore, clinical judgment is always required when screening for tuberculosis.

- Two-step testing may help distinguish boosted reactions from new infection.
- If the first test result is positive, the patient should be considered infected (recent or remote).
- If the first test is negative and the repeat skin test 1-3 weeks later is positive (booster effect), the result most likely represents previous infection.

Outside the United States, the bacille Calmette-Guérin (BCG) vaccine is commonly administered to children and infants and can serve as a source of confusion in TST interpretation. Reactivity to the BCG vaccine by tuberculin skin testing generally decreases with time, and previous BCG vaccination generally should be disregarded in TST interpretation. Unless BCG vaccine was recently administered (i.e., within the past year), significant TST reactions should not be attributable to BCG vaccine and probably indicate infection with *M. tuberculosis*.

Treatment of Latent Tuberculosis Infection

Administration of isoniazid for 9 months is preferred for treatment of latent tuberculosis infection for all patients, including those with HIV infection, chest radiographic lesions suggestive of prior inactive disease, and children and adolescents. Treatment with rifampin for 4 months is an alternative for patients intolerant to isoniazid or exposed to isoniazid-resistant tuberculosis. Rifampin plus pyrazinamide for 2 months is no longer recommended for therapy of latent tuberculosis infection because of an increased risk of hepatoxicity. Completion of therapy is defined by the total number of doses administered and not on duration of therapy alone. Therefore, the 9-month daily isoniazid regimen should consist of at least 270 doses administered within 12 months, whereas the twice-weekly isoniazid regimen should consist of at least 76 doses administered within 12 months. Baseline and routine laboratory monitoring during treatment are generally not indicated, except for patients at increased risk of drug toxicity. Active hepatitis and end-stage liver disease are relative contraindications to use of isoniazid for treatment of latent tuberculosis infection. Contrary to the urgency for treatment of active tuberculosis in pregnant women, treatment of latent tuberculosis infection during pregnancy is usually less imperative and more controversial. Most authorities delay treatment of latent tuberculosis infection until after delivery; however, recently infected women and those with HIV co-infection should most likely be treated during pregnancy (preferably with isoniazid) and monitored closely.

- Isoniazid administration for 9 months is the preferred treatment for latent tuberculosis infection for all patients, including those with HIV infection, chest radiographic lesions suggestive of prior inactive disease, and children and adolescents.

- Baseline and routine laboratory monitoring during treatment of latent tuberculosis infection are generally not indicated, except for certain patients at increased risk of drug toxicity.

Diseases Other Than Tuberculosis Which Are Due to Mycobacteria

Mycobacterium marinum causes swimming pool granuloma and may occur after cleaning an aquarium. It presents with a chronic indurated nodule on the finger or hand. *M. marinum* responds to therapy with rifampin plus ethambutol, doxycycline, or trimethoprim-sulfamethoxazole.

- *M. marinum* causes swimming pool granuloma.

Mycobacterium kansasii produces a pulmonary disease resembling that caused by *M. tuberculosis*. *M. kansasii* is more resistant to isoniazid than is *M. tuberculosis*. Standard treatment regimens include isoniazid, rifampin, and ethambutol and continue for 12 to 24 months.

- *M. kansasii* pulmonary disease resembles tuberculosis.

Mycobacterium avium-intracellulare is an important cause of infection in advanced acquired immunodeficiency syndrome (AIDS), in which disseminated disease is common. Although usually only a respiratory tract colonizer, *M. avium-intracellulare* also may cause chronic pulmonary infections. There are four characteristic chest radiographic appearances for *M. avium-intracellulare* pulmonary disease: multiple discrete nodules (71% of patients), bronchiectasis, upper lobe infiltrates, and diffuse infiltrates. The newer macrolides (clarithromycin and azithromycin) are the most active drugs against *M. avium-intracellulare*.

- Chest radiographic findings with *M. avium-intracellulare* pulmonary disease include multiple discrete nodules (71% of patients), bronchiectasis, upper lobe infiltrates, and diffuse infiltrates.

Rapid-growing mycobacteria include *Mycobacterium fortuitum* and *Mycobacterium chelonei*. Typically they cause indolent subcutaneous infections of an extremity. They also are associated with osteomyelitis and nosocomial infection (sternal osteomyelitis after cardiac operation, intramuscular injection). Treatment often requires surgical excision of the lesions. Although resistant to antituberculosis drugs, the rapid growers are usually susceptible to clarithromycin.

Spirochetes

Syphilis is discussed in Part II of this chapter in the section "Sexually Transmitted Diseases."

Leptospirosis

Leptospira interrogans infection is acquired by contact with urine from infected animals (rats, dogs), and it causes a biphasic disease. The infections occur more often after a rainy season. The organism can enter directly through the skin from contaminated water that contains animal urine. Leptospirosis can be diagnosed in persons exposed to contaminated freshwater and in persons who have fever on returning from traveling. The *first phase*, the leptospiremic phase, is characterized by abrupt-onset headache (98%), fever, chills, conjunctivitis, severe muscle aching, gastrointestinal symptoms (50%), changes in sensorium (25%), rash (7%), and hypotension. This phase lasts 3 to 7 days. Improvement in symptoms coincides with disappearance of *Leptospira* organisms from blood and cerebrospinal fluid. The *second phase*, immune stage, occurs after a relatively asymptomatic period of 1 to 3 days, when fever and generalized symptoms recur. Meningeal symptoms often develop during this period. The second phase is characterized by the appearance of IgM antibodies. Most patients recover after 1 to 3 days. However, in serious cases, hepatic dysfunction and renal failure may develop. Death in patients with leptospirosis usually occurs in the second phase as a result of hepatic and renal failure.

- *L. interrogans* infection is acquired by contact with urine from infected animals (rats, dogs).
- Leptospirosis is a biphasic disease.

The diagnosis of leptospirosis is established on the basis of clinical presentation and of cultures of blood and, rarely, cerebrospinal fluid in the first 7 to 10 days of infection. Urine cultures can remain positive in the second week of illness. Serologic testing by IgM detection with enzyme-linked immunosorbent assay or microscopic agglutination test has a low sensitivity, especially in the acute phase, but it increases to 89% and 63% in the second phase of disease, respectively. The specificity of both tests is high (>94%) in all specimens. Treatment with penicillin G is effective *only* if given within the first 1 to 5 days from onset of symptoms. Oral amoxicillin or doxycycline can be used for mild-moderate illness.

- Treatment of leptospirosis with penicillin G is effective only if given within the first 1-5 days from onset of symptoms.

Lyme Disease

Epidemiology

Lyme disease is the most common vector-borne (*Ixodes* ticks) disease reported in the United States. The incidence of disease is highest in the spring and summer, when exposure to the tick vector is most common. Experimental evidence suggests that ticks must be attached for more than 24 hours to transmit infection. Although Lyme disease has been reported from most states, it is most common in coastal New England and New York, the mid-Atlantic states, Oregon, northern California, and the Upper Midwest. The white-footed mouse and the white-tailed deer serve as zoonotic reservoirs for the etiologic agent *Borrelia burgdorferi*. Coinfections with *Babesia* or *Ehrlichia* species can occur in up to 15% and may increase the severity of symptoms.

- *B. burgdorferi* is the etiologic agent of Lyme disease.

Clinical Syndromes

Stage 1 (early) occurs from 3 to 32 days after the tick bite. Erythema

migrans (solitary or multiple lesions) is the hallmark of Lyme disease and occurs in 80% or more of infected persons. It can be associated with fever, lymphadenopathy, and meningismus. The rash of erythema migrans usually enlarges and resolves over 3 to 4 weeks. *B. burgdorferi* disseminates hematogenously early in the course of the illness.

- Erythema migrans develops in 80% or more of patients with Lyme disease.

Stage 2 occurs weeks to months after stage 1. In 10% to 15% of cases, neurologic abnormalities develop (facial nerve palsy, lymphocytic meningitis, encephalitis, chorea, myelitis, radiculitis, and peripheral neuropathy). Carditis (reversible atrioventricular block) occurs in 5% to 10% of patients. Conduction abnormalities are mostly reversible, and permanent heart block is rare. Temporary pacing may be necessary in approximately 30% of patients. Dilated cardiomyopathy has been reported, and conjunctivitis and iritis also occur.

- During stage 2, 10%-15% of patients have neurologic abnormalities.
- Carditis occurs in 5%-10% of patients.

Stage 3, although uncommon, can develop months to years after initial infection. Monarticular or oligoarticular arthritis occurs in 50% of patients who do not receive effective therapy. It becomes chronic in 10% to 20%. Chronic arthritis is more common in those with HLA-DR2 and HLA-DR4. Other manifestations are acrodermatitis chronica atrophicans (primarily with European strains), progressive, chronic encephalitis, and dementia (rare). Most patients will have detectable serum antibodies against *B. burgdorferi*. Magnetic resonance imaging may show demyelination.

Diagnosis

Anti-*B. burgdorferi* antibodies can be detected by enzyme-linked immunosorbent assay after the first 2 to 6 weeks of illness. Response may be diminished by antimicrobial therapy early in the course. Antibody testing is not standardized. False-positive results occur with infectious mononucleosis, rheumatoid arthritis, systemic lupus erythematosus, echovirus infection, and other spirochetal disease. The Western blot test is an adjunct in diagnosis when antibody response is equivocal or when a false-positive result is suspected. It is particularly useful in the first few months of illness.

Treatment

For stage 1 (early) Lyme disease in the absence of neurologic involvement or complete heart block, doxycycline (100 mg twice a day for 10-21 days), amoxicillin (500 mg 3 times a day for 10-21 days), and cefuroxime axetil (500 mg twice a day for 10-21 days) are effective therapeutic agents. Azithromycin, clarithromycin, or erythromycin is less effective than doxycycline or amoxicillin but can be used in penicillin-allergic patients. Because of the risk of vertical transmission, all pregnant women with active Lyme disease should be treated.

In Lyme carditis, the outcome is usually favorable. If first- or second-degree atrioventricular block is present, it should be treated with oral agents, whereas third-degree heart block should be treated with ceftriaxone, 2 g a day for 14 to 21 days, or penicillin G, 20 million units a day for 14 to 21 days. Lyme meningitis, radiculopathy, or encephalitis should be treated parenterally.

- In Lyme carditis, the outcome is usually favorable.

The outcome in patients with facial palsy is also usually favorable. In one series, 105 of 122 affected patients completely recovered. Corticosteroids have no role. If only facial nerve palsy is present (no symptoms of meningitis, radiculoneuritis), oral therapy with doxycycline or amoxicillin is used. The therapy used if other neurologic manifestations are present is described below.

- The outcome in patients with facial palsy due to Lyme disease is usually favorable.

If Lyme meningitis is present, ceftriaxone, 2 g a day for 14 to 28 days, or penicillin G, 20 million units a day for 14 to 28 days, should be given. Radiculoneuritis and peripheral neuropathy may have a greater tendency for chronicity and often occur with meningitis. Treatment is the same as that for Lyme-associated meningitis. The regimens for encephalopathy and encephalomyelitis are identical to those for meningitis.

- Radiculoneuritis and peripheral neuropathy may have a greater tendency for chronicity and often occur with meningitis.

Optimal regimens for Lyme arthritis (oral vs. intravenous) are not established. Intra-articular corticosteroids may cause treatment failures. Joint rest and aspiration of reaccumulated joint fluid are often needed. Response to antibiotics may be delayed. If no neurologic disease is present, doxycycline is given (100 mg orally twice a day for 28 days). An alternative regimen is amoxicillin and probenecid (500 mg each, 4 times a day for 28 days) or ceftriaxone (2 g per day intravenously for 14-28 days).

Prevention

Prophylactic antibiotic therapy after a tick bite is not recommended. Use of single-dose doxycycline is controversial but may be useful in prolonged, engorged nymphal tick attachment. In the vast majority of tick bites, disease is not transmitted. Appropriate use of repellents and protective clothing are recommended.

- Prophylactic antibiotic therapy after a tick bite is not recommended.

Nocardia

Nocardia organisms are aerobic, gram-positive, filamentous, and branching and are visualized with a modified acid-fast stain. *Nocardia asteroides* is the cause of most human infections in the United States (Fig. 14-3). *Nocardia brasiliensis* and *Nocardia madurae* cause mycetomas. Infections are most often opportunistic, occurring in immunosuppressed patients, including those with HIV or AIDS, but infections can occur in normal hosts also.

- *Nocardia* infections are most often opportunistic, occurring in immunosuppressed patients.

The respiratory tract is the usual portal of entry for *Nocardia* infection. Chronic pneumonitis and lung abscess are the most common findings. Hematogenous spread to the brain is relatively common. Spread also can occur to the skin (12%) and joints (3%). In patients with chronic pneumonia who have neurologic symptoms or signs, *Nocardia* brain abscess should be considered.

- In patients with chronic pneumonia who have neurologic symptoms, *Nocardia* brain abscess should be considered.

Nocardiosis is not diagnosed until autopsy in up to 40% of cases. Antemortem diagnosis depends on obtaining appropriate stains and cultures (the organism will grow on fungal media). Because sputum culture is relatively insensitive, bronchoscopically obtained specimens or open lung biopsy may be needed to confirm the diagnosis. The disease must be differentiated from other causes of chronic pneumonia (such as bacterial, actinomycotic, tuberculosis, fungal infections).

Therapy involves drainage of abscesses and high doses of sulfonamide drugs (trimethoprim-sulfamethoxazole is the current drug of choice). Some species of *Nocardia* show evidence of sulfonamide resistance. Other antimicrobial agents used for nocardiosis include imipenem, amikacin, minocycline, and cephalosporins. Therapy depends on antimicrobial susceptibility patterns. Newer drugs such as linezolid have activity against *Nocardia* species.

- Nocardiosis is diagnosed at autopsy in up to 40% of cases.
- Trimethoprim-sulfamethoxazole is the current treatment of choice.

Rickettsiae

All rickettsial infections are transmitted by an insect vector except Q fever (respiratory spread). All are associated with a rash except Q fever and ehrlichiosis. The rash of Rocky Mountain spotted fever may be indistinguishable from that of meningococcemia. Rocky Mountain spotted fever rash begins on the extremities and moves centrally. The rash of typhus (both murine and endemic typhus) begins centrally and moves toward the extremities. Rocky Mountain spotted fever is most common in the mid-Atlantic states and Oklahoma, not the Rocky Mountain states. The pathophysiology of all rickettsial infections includes vasculitis and disseminated intravascular coagulation. Rickettsial pox is a common, although usually unrecognized, disease in urban areas of the United States. It is the only rickettsial disease characterized by vesicular rash. The mouse mite is the vector for rickettsial pox. A small eschar is present at the site of inoculation in 95% of patients.

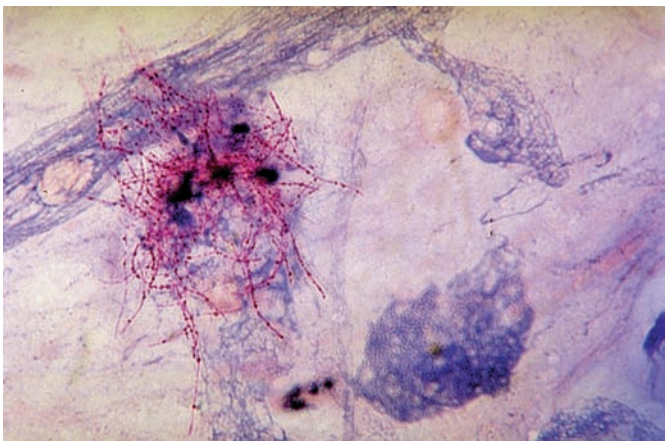

Fig. 14-3. *Nocardia asteroides.* (Modified acid-fast stain; ×450.)

- All rickettsial infections have an insect vector except Q fever.
- All are associated with a rash except Q fever and *ehrlichiosis*.
- Rocky Mountain spotted fever rash begins on the extremities and moves centrally.
- Rocky Mountain spotted fever is most common in the mid-Atlantic states and Oklahoma, not the Rocky Mountain states.

Coxiella burnetii, the cause of Q fever, is acquired by inhalation of contaminated aerosol particles of dust, earth, or feces or after exposure to animal products, especially infected placentas. Sheep are common sources, but other animals, including cats, can harbor the disease (e.g., a small outbreak occurred in a group of poker players after a cat gave birth beneath their card table). Disease manifests most commonly as an isolated febrile illness, most of those cases presenting with pneumonitis; 15% of patients have hepatitis (granulomatous), 1% have endocarditis, and some also present with central nervous system manifestations. Q fever is one of the causes of culture-negative endocarditis. It usually is diagnosed with serologic testing. Treatment is with tetracyclines or chloramphenicol.

- Among persons with Q fever, most have pneumonitis, and 15% have hepatitis.
- Q fever is one of the causes of culture-negative endocarditis.

Ehrlichia species are gram-negative intracellular bacteria that resemble rickettsial organisms and preferentially infect lymphocytes, monocytes, and neutrophils. The species that cause human ehrlichiosis are *Ehrlichia chaffeensis* (which infects monocytes), *Ehrlichia equi*, and *Anaplasma phagocytophilum* (which causes human granulocytic ehrlichiosis).

The disease is seasonal; the peak incidence is from May through July. The vectors are the common dog tick (*Dermacentor variabilis*), the lone star tick (*Amblyomma americanum*) for *E. chaffeensis*, and *Ixodes* ticks for the agent of human granulocytic ehrlichiosis. The incubation period is approximately 7 days, followed by fever, chills, malaise, headache, and myalgia. Less than 50% of patients have a rash. Important laboratory features include leukopenia, thrombocytopenia, and increased levels of hepatic transaminases.

The severity of the disease is variable, but severe complications, including death, can occur. Coinfection with human granulocytic ehrlichiosis and *Borrelia burgdorferi* (Lyme disease) does occur and can be especially severe. Diagnosis depends on serologic analysis

(indirect immunofluorescent assay) or detection by polymerase chain reaction amplification. Treatment is with doxycycline, 100 mg twice a day. Unlike the rickettsial diseases, chloramphenicol is often not effective against *Ehrlichia*.

Mycoplasma pneumoniae

This is one of the smallest microorganisms capable of extracellular replication. *Mycoplasma* organisms lack a cell wall. Therefore, cell-wall-active antibiotics such as penicillins are not effective treatment. *Mycoplasma* infection is spread by droplet inhalation. It primarily infects young, previously healthy persons and presents with rapid onset of headache, dry cough, and fever. Results of physical examination are often unremarkable, with the possible exception of bullous myringitis. Chest radiography usually shows bilateral, patchy pneumonitis. The chest radiographic findings are often out of proportion to the physical findings. Pleural effusion is present in 15% to 20% of cases. Neurologic complications include Guillain-Barré syndrome, cerebellar peripheral neuropathy, aseptic meningitis, and mononeuritis multiplex. Hemolytic anemia may occur late in the illness as a result of circulating cold hemagglutinins.

- Circulating cold hemagglutinins can cause hemolytic anemia.
- *M. pneumoniae* infection is spread by droplet inhalation.
- Chest radiography usually shows bilateral, patchy pneumonitis.
- Pleural effusion is present in 15%-20% of cases.
- Neurologic complications include Guillain-Barré syndrome, cerebellar peripheral neuropathy, aseptic meningitis, and mononeuritis multiplex.

The diagnosis is established by specific complement fixation test. Cold agglutinins are nonspecific and unreliable for diagnosing *Mycoplasma* infections. Fluoroquinolones, macrolides, and tetracyclines are effective therapies. Because immunity to *Mycoplasma* infection is transient, reinfection may occur. Clinical relapse of pneumonia occurs in up to 10% of cases of *Mycoplasma* pneumonia.

Chlamydia pneumoniae (Twar Agent)

This is a relatively new agent, distinct from *Chlamydia trachomatis* and *Chlamydia psittaci*. In young adults, it causes 10% of cases of pneumonia and 5% of cases of bronchitis. It has been a cause of community outbreaks, and nosocomial transmission has occurred. Fifty percent of adults are seropositive for *C. pneumoniae*. Birds are the source of infection with *C. psittaci* (psittacosis), but there is no reservoir for *C. pneumoniae*. Clinical manifestations of infection are usually mild and may resemble those caused by *Mycoplasma pneumoniae*. Pharyngitis occurs 1 to 3 weeks before the onset of pulmonary symptoms, and cough may last for weeks. The diagnosis is based on serologic testing. Treatment is with doxycycline or a macrolide.

- In young adults, *C. pneumoniae* causes 10% of cases of pneumonia and 5% of cases of bronchitis.

Fungi

Coccidioidomycosis

Coccidioides immitis is a dimorphic fungus: in tissue it exists as a spherule, and in culture at room temperature it is mycelial (filamentous). It forms arthrospores that are highly infectious. *C. immitis* is endemic in the southwestern United States, especially the San Joaquin Valley of California and central Arizona. Disseminated disease is most likely to occur in males (especially Filipino and black), pregnant females, and immunocompromised hosts regardless of sex. Nonpregnant white females seem to be more resistant to disseminated disease than white males.

- *C. immitis* is endemic in the southwestern United States.
- Disseminated disease is most likely to occur in males (especially Filipino and black), pregnant females, and immunocompromised hosts.

Half to two-thirds (~60%) of primary infections with *C. immitis* are subclinical. The most common clinical manifestation is pneumonitis that is usually self-limited. Common manifestations are dry cough and fever (valley fever) that may resemble influenza. Associated findings include hilar adenopathy, pleural effusion (12%), thin-walled cavities (5%), and solid "coin" lesions. Disseminated infection predominantly affects the central nervous system, skin, bones, and joints.

- Primary infection with *C. immitis* causes pneumonitis that is usually self-limited.

Coccidioidomycosis is one of the causes of erythema nodosum. When present, it usually indicates an active immune response that will control the infection. Erythema nodosum is more common in females and is often associated with arthralgias, especially of the knees and ankles.

- Coccidioidomycosis is one of the causes of erythema nodosum.

The diagnosis of coccidioidomycosis is based on detecting the organism by culture or biopsy with silver stains. A *C. immitis* serologic (complement fixation) titer more than 1:4 is suggestive of infection. Skin testing is of epidemiologic value only. Detection of cerebrospinal fluid anticoccidioidal antibodies is the usual means for diagnosing coccidioidomycosis meningitis. Laboratory abnormalities may include eosinophilia and hypercalcemia.

Fluconazole and amphotericin B are effective for therapy of coccidioidomycosis. The acute pulmonary form is usually self-limited and observation may be adequate. However, therapy is indicated if a patient is pregnant, is immunocompromised (patients with AIDS or receiving immunosuppressive regimens for organ transplantation or other medical reasons), or has worsening infection without therapy. Amphotericin B is the drug of choice for severe manifestations and for pregnant women with coccidioidomycosis. An alternative to fluconazole is itraconazole (200 mg twice daily). For meningitis, therapy with high-dose fluconazole is preferred and has largely replaced intrathecal amphotericin B. Because of the high

relapse rate of *C. immitis* meningitis, chronic suppressive therapy is necessary, usually with fluconazole. *Coccidioides* meningitis may be complicated by adhesive arachnoiditis. Newer antifungal medications such as voriconazole are active in vitro but clinical studies are not available, and caspofungin has limited in vitro activity against coccidioidomycosis.

Histoplasmosis

Histoplasma capsulatum is also a dimorphic fungus that grows as a small (3 mm in diameter) yeast in tissue. Culture at room temperature produces the mycelial form. Although present in many areas of the world, histoplasmosis is especially prevalent in the Ohio and Mississippi river valleys. Outbreaks have been associated with large construction projects and exposure to bird droppings. Histoplasmosis is acquired by inhalation of spores and also can be transmitted by organ transplantation from an infected donor. The risk of acquisition is increased with certain activities, including caving and bridge or other construction. Although healthy individuals may acquire histoplasmosis, patients with AIDS are particularly susceptible. *H. capsulatum* infection is one of the causes of caseating granulomata.

- Outbreaks of histoplasmosis have been associated with large construction projects and exposure to bird droppings.
- Although healthy individuals may acquire histoplasmosis, patients with AIDS are particularly susceptible.

Primary (acute) histoplasmosis may be clinically indistinguishable from influenza or other upper respiratory tract infections. After resolution, multiple small, calcified granulomas may be seen on subsequent chest radiography. The progressive (disseminated) form of histoplasmosis is uncommon but serious. The disseminated form and reactivation of prior disease are most likely to occur in infants, elderly men, and immunosuppressed persons, including those with HIV or AIDS and those receiving therapy with tumor necrosis factor-α inhibitor. Manifestations may resemble those of lymphoma, with weight loss, fever, anemia, increased erythrocyte sedimentation rate, and splenomegaly. Mucosal surface lesions, especially in the mouth, are not infrequent. As with tuberculosis, the adrenal glands may be infected, with resulting adrenal insufficiency. Chronic cavitary pulmonary disease due to *Histoplasma* may resemble tuberculosis.

- Primary (acute) histoplasmosis may be indistinguishable from influenza or other upper respiratory tract infections.
- As with tuberculosis, the adrenal glands may be infected by *H. capsulatum*, with resulting adrenal insufficiency.

Serologic testing is of limited sensitivity and specificity and plays little role in the diagnosis of active infection unless increasing or markedly increased titers are detected. Biopsy, silver staining, and cultures of infected tissues are the best means of diagnosis. Bone marrow stains and cultures and fungal blood cultures are frequently helpful. Biopsy specimens of mouth lesions can be diagnostic. Detection of *Histoplasma* antigen in urine or serum is promising as a diagnostic test, especially for disseminated disease, but is not widely available yet.

The mild, acute forms of histoplasmosis are usually self-limited and do not require therapy. Amphotericin B in a **total** dose of 35 mg/kg (given over time as 0.5-1 mg/kg per day) is the drug of choice for all severe, life-threatening cases. Itraconazole is effective for most nonmeningeal, non–life-threatening cases and has largely replaced ketoconazole. Itraconazole dosage is 200 to 400 mg per day (guided by serum drug concentrations) for 6 to 12 months. Patients with AIDS require chronic maintenance therapy.

Blastomycosis

Yet another dimorphic fungal pathogen is *Blastomyces dermatitidis*. In tissue, the yeast forms are thick-walled and have broad-based buds (±10 µm in diameter) (Fig. 14-4). In culture at room temperature, a mycelial form is found. Blastomycosis is endemic in the southeastern and upper midwestern United States. Primary pulmonary blastomycosis may be asymptomatic and may disseminate hematogenously to bone, skin, or prostate. Granulomas occur, but calcification is less frequent than with histoplasmosis or tuberculosis.

Blastomycosis affects lung, skin, bone (especially the vertebrae), male genitalia (prostate, epididymis, testis), and the central nervous system. The pulmonary form has no characteristic findings: pleural effusion is rare, hilar adenopathy develops occasionally, and cavitation is infrequent. It often mimics carcinoma of the lung. Cutaneous involvement with blastomycosis is common. Lesions, especially on the face, are characteristically painless and nonpruritic and have a sharp, spreading border. Chronic crusty lesions may occur.

- Blastomycosis affects lungs, skin, bone (especially the vertebrae), and male genitalia (prostate, epididymis, testis).
- The most common clinical forms of blastomycosis are pulmonary and cutaneous.

The diagnosis of blastomycosis is based on the results of biopsy, stains, and cultures. Serologic and skin testing are **rarely** helpful.

Amphotericin B (total dose is 20-25 mg/kg) or itraconazole (200-400 mg per day for 6 months) is effective as therapy for blastomycosis. Amphotericin B is reserved primarily for life-threatening infections. Mild-to-moderate nonmeningeal blastomycosis can be treated with itraconazole (200-400 mg/day) for 6 months.

Sporotrichosis

A fourth dimorphic fungal pathogen, *Sporothrix schenckii*, in tissue is a round, cigar-shaped yeast. In culture at room temperature it is mycelial. Sporotrichosis is transmitted by cutaneous inoculation (rose-gardener's disease) and, rarely, through inhalation. It manifests as a suppurative and granulomatous reaction.

Cutaneous infection produces characteristic crusty lesions ascending the lymphatics of the extremities from the initial site of infection. Similar lesions may be produced by infection with *Mycobacterium marinum*, *Nocardia*, or cutaneous leishmaniasis. Joint spaces rarely are involved. Sporotrichosis occasionally may cause chronic pneumonitis (with cavitation and empyema) or meningitis.

- Cutaneous sporotrichosis produces characteristic crusty lesions ascending the lymphatics of the extremities from the initial site of infection.
- Sporotrichosis occasionally may cause chronic pneumonitis (with cavitation and empyema) or meningitis.

The diagnosis of sporotrichosis may be difficult and depends on clinical recognition of the cutaneous lesions in most instances. Biopsy, culture, or serologic testing may aid in the diagnosis.

For the lymphocutaneous or cutaneous form, itraconazole is the therapy of choice. An effective alternative is supersaturated solution of potassium iodide. Amphotericin B is recommended for disseminated disease (pulmonary, joint), although it may respond poorly to therapy.

Aspergillosis

Aspergillus is an opportunistic pathogen that causes infection in immunocompromised persons. Although any species of *Aspergillus* can cause disease, *Aspergillus fumigatus* is the most common pathogenic species. The organisms have large, septated hyphae (phycomycetes are nonseptated) branching at 45° angles (Fig. 14-5). Especially in neutropenic hosts, they may invade blood vessels, producing a striking thrombotic angiitis similar to phycomycosis. Metastatic foci may cause suppurative abscess formation.

- *Aspergillus* organisms may invade blood vessels, producing a striking thrombotic angiitis.

The form of disease produced by aspergillosis primarily is determined by the nature of the immunologic deficit in the infected individual. Neutropenia predisposes to rapidly invasive bronchopulmonary disease with early dissemination to the brain and other tissues. The longer the duration of neutropenia, the higher the risk for invasive aspergillosis. Prompt therapy with high doses of amphotericin B and resolution of the neutropenia are necessary to control the disease. Diagnosis should be suspected when *Aspergillus* is isolated from any source in a susceptible individual.

T-cell deficiencies (primarily from corticosteroids) predispose to somewhat more indolent, although no less dangerous, forms of aspergillosis. Progressive pulmonary infiltrates, necrotic skin lesions, wound infections, and brain abscesses may result. Sinus infections with *Aspergillus* may be localized or invasive in patients with T-cell deficiencies.

Serologic testing is not helpful for diagnosing invasive *Aspergillus* in the compromised host.

- Neutropenia predisposes to rapidly invasive bronchopulmonary disease with early dissemination to the brain and other tissues.

Aspergillus also can cause localized disease in persons with normal immunologic function. Chronic necrotizing pulmonary aspergillosis occurs in patients with pulmonary emphysema. The chronic, progressive infiltrates of this condition often require tissue sampling for diagnosis. Treatment with surgical resection and systemic antifungal therapy is sometimes curative.

Aspergillus may produce a "fungus ball" in preexisting lung bullae (such as from ankylosing spondylitis, previous tuberculosis, or emphysema). Hemoptysis is the main symptom. Surgical excision may be necessary to prevent lethal hemorrhage.

Localized colonization with *Aspergillus* is common and usually does not produce disease. However, otitis externa (swimmer's ear) and allergic bronchopulmonary aspergillosis are exceptions. The symptoms of allergic bronchopulmonary aspergillosis resemble those of asthma. It is characterized by migratory pulmonary infiltrates, thick, brown, tenacious mucous plugs in the sputum, eosinophilia, and high titers of anti-*Aspergillus* antibodies. Endophthalmitis due to *Aspergillus* may develop after ocular operation or trauma.

Aspergillus frequently colonizes the respiratory tract. Isolating the organism from the sputum of an immunocompetent host usually does not indicate disease and does not require treatment.

- Chronic necrotizing pulmonary aspergillosis occurs in patients with pulmonary emphysema.

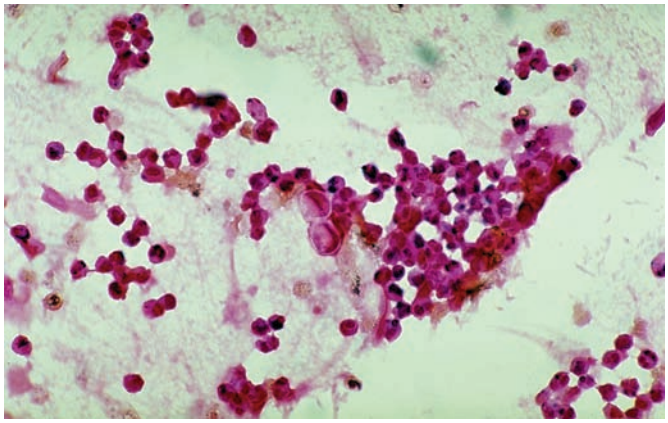

Fig. 14-4. *Blastomyces dermatitidis* in bronchoalveolar lavage. (Silver stain; ×450.)

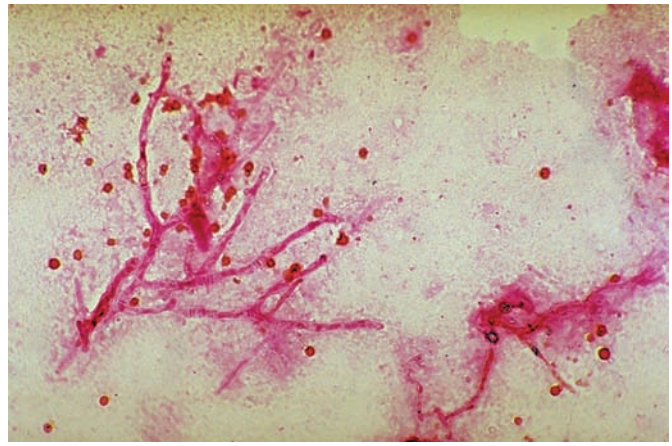

Fig. 14-5. *Aspergillus fumigatus* in bronchoalveolar lavage. (×450.)

- *Aspergillus* may produce a "fungus ball" in preexisting lung bullae (such as from ankylosing spondylitis, previous tuberculosis, or emphysema).

Aspergillus infections may respond poorly to currently available antifungal medications. Amphotericin B products are very effective, but they must be given in high doses. Lipid-based formulations of amphotericin B are advised for patients in whom nephrotoxicity develops with deoxycholate amphotericin B. Itraconazole was the first oral agent with substantial activity against *Aspergillus*. However, recently approved newer drugs such as voriconazole and caspofungin have potent in vitro and in vivo activity against *Aspergillus*. Intravenous voriconazole should be avoided in patients with severe renal insufficiency (glomerular filtration rate, <50 mL/min). Caspofungin is approved by the U.S. Food and Drug Administration for refractory invasive aspergillosis. This has been used alone or in combination with amphotericin B products. Surgical debridement of infected tissues is often necessary for cure. Allergic bronchopulmonary aspergillosis responds to corticosteroid therapy, and itraconazole may be an important adjunctive therapy in decreasing or sparing the use of corticosteroids.

- Typical clinical scenario of *Aspergillus* infection: Fever and lung infiltrates occur in a patient with prolonged neutropenia.

Cryptococcosis

Cryptococcus neoformans is the only species of *Cryptococcus* that is pathogenic for humans. It is a yeast in both tissue and culture, is 4 to 7 μm in diameter, and has thin-walled buds and a capsule (Fig. 14-6). It is an opportunistic pathogen infecting persons with T-cell deficiencies or dysfunction (patients with Hodgkin disease, hematologic malignancy, organ transplantation, exogenous corticosteroids, chronic liver disease, and AIDS). The respiratory tract is the probable portal of entry. Cryptococcosis does not incite much inflammatory reaction, and calcification is rare.

- *C. neoformans* is an opportunistic pathogen.
- *Cryptococcus* primarily infects persons with T-cell deficiencies or dysfunction (Hodgkin disease, hematologic malignancy, organ transplantation, exogenous corticosteroids, chronic liver disease, and AIDS).

C. neoformans is acquired by inhalation. From the lungs it disseminates widely and easily crosses into the central nervous system. Pneumonia and meningitis are the most common forms of cryptococcosis. Meningitis may be insidious, with headache as the only symptom. Cranial nerve involvement may develop (including blindness with involvement of the optic nerve). *Cryptococcus* also may cause an indolent form of cellulitis.

- Pneumonia and meningitis are the most common forms of *C. neoformans* infection.

Cryptococcal infection can be diagnosed with fungal culture (cerebrospinal fluid, blood, sputum, urine), silver staining of biopsy tissue, or detection of *Cryptococcus* antigen in body fluids. The cryptococcal antigen test is the most helpful of all fungal serologic tests. It measures capsular antigen, whereas most other fungal serologic tests measure antibody response. Remember that *Cryptococcus* very commonly spreads to the central nervous system. Therefore, if *C. neoformans* is isolated from any source (such as sputum, urine, blood) in a susceptible patient, simultaneous meningitis should be suspected. India ink preparation largely has been replaced by antigen detection assay.

Cryptococcal infections respond to treatment with amphotericin B or fluconazole. Choice of therapy depends on extent of disease and host immune function. Mild-to-moderate non-central nervous system cryptococcosis can be treated with fluconazole for 6 to 12 months. However, severe presentation, immunocompromised hosts, and central nervous system involvement should be treated with amphotericin B. Combining oral flucytosine (100-150 mg/kg per day) with amphotericin B for 6 weeks allows a lower dose of amphotericin to be used. Unfortunately, relapse rates are high regardless of the treatment regimen given. In a recent study comparing fluconazole (200 mg per day) with amphotericin B for 10 weeks, fluconazole was as effective as amphotericin B ("effective" is defined as clinical improvement or resolution of symptoms with negative results for culture of cerebrospinal fluid). However, mortality in the first 2 weeks of therapy was higher with fluconazole (15% vs. 8%).

Cryptococcosis in patients with AIDS is virtually impossible to cure. The goal of therapy is to control the infection and then suppress it with long-term antifungal agents. A common approach is to initiate therapy with amphotericin B (with or without flucytosine). Amphotericin therapy is continued until cerebrospinal fluid cultures are negative or there is unacceptable toxicity from the drug. Oral fluconazole (200-400 mg per day) is then given indefinitely. Disappointingly, relapse remains frequent even with maintenance therapy. The newly approved caspofungin does not have any activity against *C. neoformans*.

Candidiasis

Candida is a normal part of the human microflora. It grows as both yeast and hyphal forms simultaneously. Although *Candida albicans*

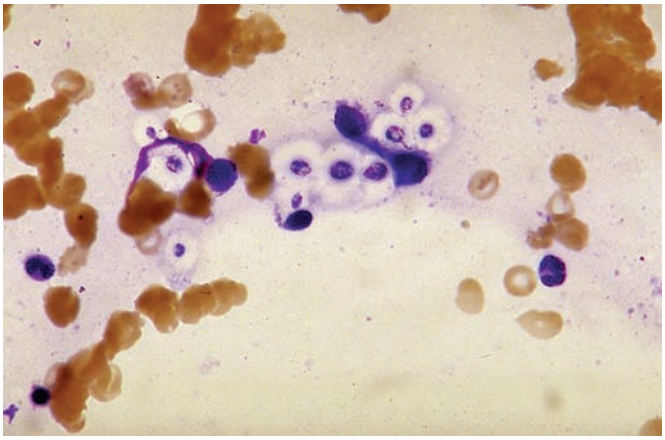

Fig. 14-6. *Cryptococcus neoformans* in cerebrospinal fluid. (×450.)

is the most common species, numerous other species can cause human disease. *Candida* causes mucosal and cutaneous infections in both normal and immunocompromised hosts. Invasive disease primarily occurs in neutropenic hosts and as a nosocomial bloodstream infection.

Examples of candidiasis in the normal host include diaper rash and intertrigo, in which *Candida* growth on moist skin surfaces produces irritation. Vulvovaginal candidiasis is common, especially after a woman takes a course of antibiotics for an unrelated infection. Treatment with topical antifungal agents or a single dose of oral fluconazole is usually curative. Diabetes, corticosteroids, oral contraceptives, obesity, and HIV infection predispose to recurrent vulvovaginal candidiasis. Oral thrush may result from the same conditions.

Candida species cause 5% to 10% of nosocomial bloodstream infections. Candidemia most often occurs in critically ill patients receiving broad-spectrum antibiotics and parenteral nutrition. Neutropenia is another predisposing factor. Current blood culture techniques usually detect *Candida*, but culture results may be delayed. All intravenous catheters should always be removed or replaced when bloodstream infection with *Candida* is discovered. Metastatic abscesses can occur in any site after an episode of candidemia. *Candida* osteomyelitis or joint infections can occur as complications after an episode of line-related fungemia. Endophthalmitis may occur as long as 1 month after initial fungemia. For central venous catheter-related candidemias, catheter removal followed by amphotericin B (250-500 mg) or fluconazole is indicated.

Candida tropicalis, *Candida parapsilosis*, *Candida glabrata*, and multiple other species cause nosocomial illness, especially in immunocompromised patients. Note that these non-*albicans* species of *Candida* are more often resistant to fluconazole therapy.

Injection drug use is a risk factor for *Candida* endocarditis (and joint space infections, especially of the sternoclavicular joint). It is often caused by species other than *C. albicans*.

- Fungemia develops from infected intravenous catheters, especially in the immunosuppressed host.
- Risk factors for *Candida* bloodstream infection include previous antibacterial therapy, cytotoxic or corticosteroid therapy, and parenteral nutrition.
- *Candida* endocarditis occurs most often in injection drug users.
- Diabetes, corticosteroids, oral contraceptives, obesity, and HIV infection predispose to recurrent vulvovaginal candidiasis.

Candida urinary tract infection is common in patients with urinary catheters and those receiving antibacterial drugs. Removal of the catheter is the primary therapy. If necessary, treatment with fluconazole or bladder irrigation with dilute amphotericin B may be curative, although recurrence is common.

Hepatosplenic candidiasis, also called chronic disseminated candidiasis, occurs in patients after prolonged chemotherapy-induced neutropenia. Symptoms of fever and increasing liver enzyme values manifest as the leukocyte count recovers. Typical "bull's-eye lesions" can be seen with ultrasonography, computed tomography, or magnetic resonance imaging of the infected liver. The preferred treatment is with at least 2 g of intravenous amphotericin B, but fluconazole or lipid complex amphotericin B also may be effective.

Candida esophagitis is a common cause of odynophagia in immunosuppressed patients, especially those with AIDS. Endoscopy is necessary to prove the diagnosis. *Candida* esophagitis is clinically indistinguishable from, and may coexist with, cytomegalovirus and herpes simplex virus esophagitis. Fluconazole is effective therapy for oral or esophageal candidiasis. Caspofungin is also active and is approved by the U.S. Food and Drug Administration against *Candida* species, including those that are resistant to azoles such as fluconazole. Caspofungin is available only as an intravenous drug.

- Hepatosplenic candidiasis typically develops as chemotherapy-induced neutropenia resolves.
- *Candida* esophagitis is clinically indistinguishable from, and may coexist with, cytomegalovirus and herpes simplex virus esophagitis.
- Typical clinical scenario for *hepatosplenic candidiasis*: A patient recovering from prolonged chemotherapy-induced neutropenia has fever and increasing liver enzyme values. The diagnosis is made with ultrasonography or computed tomography showing characteristic bull's-eye lesions.
- Typical clinical scenario for *Candida* esophagitis: Odynophagia in immunocompromised patients. Differential diagnosis is herpes simplex virus esophagitis. Diagnosis is made with endoscopy and culture.

Mucormycosis (*Rhizopus* Species, Zygomycetes)

Mucormycosis is another disease of immunocompromised hosts. Pulmonary, nasal, and sinus infections are the most common. Rhinocerebral mucormycosis results from direct extension into the brain. Diabetic ketoacidosis, neutropenia, renal failure, and deferoxamine therapy are all risk factors for this dreaded infection. The diagnosis of mucormycosis depends on finding the typical black necrotic lesions (usually in the nose or on the palate) and is confirmed by biopsy. Treatment involves reversing the predisposing condition as much as possible, surgical debridement of necrotic tissue, and amphotericin B.

- The diagnosis of mucormycosis depends on finding the typical black necrotic lesions (usually in the nose or on the palate) and is confirmed by biopsy.
- Diabetic ketoacidosis, neutropenia, renal failure, and deferoxamine therapy are all risk factors for mucormycosis.

Viruses

Herpesviruses

There are now eight known herpesviruses: *herpes simplex virus* (HSV) *types 1 and 2*, *Epstein-Barr virus* (EBV), *cytomegalovirus* (CMV), *varicella-zoster virus* (VZV), *human herpesvirus 6* (HHV-6), *HHV-7* (not yet known to be associated with clinical disease), and *HHV-8*. All herpesviruses are DNA viruses that share the characteristic of establishing latency after primary infection, whether or not symptomatic.

Serologic evidence of infection is common by adulthood: HSV 1, 87%; HSV 2, 5%; EBV, 95%; CMV, 50%; and VZV, 90%. The rate of infection increases in populations of lower socioeconomic status.

Herpes Simplex Virus

Primary infection with HSV results from exposure of skin or mucous membranes to intact viral particles. Latent infection is then established in sensory nerve ganglia. Genital HSV infection is caused by HSV type 2 in 80% of cases and by HSV type 1 in the remaining 20%. The reverse is true for oral HSV. Genital HSV is more likely to recur when caused by HSV type 2. Recurrence rates can be decreased by 80% with chronic use of antiviral drugs. In normal hosts, this does not promote emergence of acyclovir-resistant strains.

Herpes simplex encephalitis is a nonseasonal, life-threatening illness usually caused by HSV type 1. Herpes simplex encephalitis causes confusion, fever, and, frequently, seizures. Simultaneous herpes labialis is present in 10% to 15% of cases. Antemortem diagnosis may be difficult. Although a definitive diagnosis traditionally requires a brain biopsy, new techniques such as magnetic resonance imaging of the temporal lobes and amplification of HSV DNA from cerebrospinal fluid are often helpful. Detecting periodic lateralized epileptiform discharges with electroencephalography is suggestive of herpes simplex encephalitis. Poor neurologic status, age older than 30 years, and encephalitis of more than 4 days in duration before initiation of therapy are associated with a poor outcome.

Neonatal HSV infection is acquired at the time of vaginal delivery. The mortality rate is high (20%) despite antiviral therapy. In neonates who survive, neurologic sequelae and recurrent HSV lesions are common. Cesarean section is recommended if a woman has active herpetic lesions at the time of delivery.

Acyclovir, famciclovir, valacyclovir, ganciclovir, foscarnet, and vidarabine inhibit replication of both HSV types 1 and 2. Acyclovir resistance may develop in patients with AIDS who are treated with multiple courses of acyclovir. Resistance usually is conferred by a mutation in the thymidine kinase gene, preventing phosphorylation of acyclovir to its active form.

- Recurrence rates of oral HSV can be decreased 80% with chronic suppressive therapy with acyclovir.
- Herpes simplex encephalitis can be diagnosed with magnetic resonance imaging and polymerase chain reaction amplification of HSV DNA from cerebrospinal fluid.
- Delivery by cesarean section is recommended if active genital lesions are present at the end of pregnancy.

HSV pneumonia is rare and usually occurs in immunosuppressed patients. When HSV is isolated from a respiratory source, it most commonly represents shedding from the oral mucosa rather than the lungs. HSV also is associated with visceral disease (such as esophagitis). Biopsy is required to reliably distinguish HSV from CMV or *Candida* esophagitis. *Eczema herpeticum* (Kaposi varicelliform eruption) occurs in areas of eczema. Large areas of skin are involved. *Herpetic whitlow* is a painful HSV infection of a finger, often caused by inoculation with a contaminated needle. Although nosocomial transmission of HSV is rare, recent reports stress the importance of mucous membrane precautions when treating all patients with HSV, particularly those with respiratory infection who undergo invasive procedures.

- *Herpetic whitlow* is a painful HSV infection of a finger, often caused by inoculation with a contaminated needle.

HSV can cause outbreaks among participants in contact sports (in wrestlers it is called *herpes gladiatorum*). The infection is transmitted by skin-to-skin contact. Lesions appear on the head (78%), trunk (28%), and extremities (42%). The rash may be atypical. Large, ulcerative perianal lesions can develop in patients with AIDS. Some of the lesions are mistaken for decubitus ulcers.

- HSV can cause outbreaks among participants in contact sports.
- Large, ulcerative perianal lesions can develop in patients with AIDS.

Epstein-Barr Virus

Most acute EBV infections are asymptomatic. Symptomatic *infectious mononucleosis* causes the clinical triad of fever, pharyngitis (80%), and adenopathy. Splenomegaly occurs in 50% of cases. One of the most serious complications of mononucleosis is splenic rupture. Other complications include hemolytic anemia, airway obstruction, encephalitis, and transverse myelitis. Associated laboratory abnormalities include atypical lymphocytosis, thrombocytopenia, and mild increases in liver enzyme values. Corticosteroids may be beneficial for treatment of hemolytic anemia and acute airway obstruction. Ampicillin or amoxicillin given during infectious mononucleosis commonly causes a diffuse macular rash.

Table 14-4 differentiates EBV from other causes of mononucleosis. The diagnosis of infectious mononucleosis depends on detection of heterophile antibodies (monospot test) or specific EBV IgM antibodies. False-negative results of the monospot test are more likely with increasing age.

- Infectious mononucleosis has the clinical triad of fever, pharyngitis, and adenopathy.
- Splenomegaly occurs in 50% of cases of infectious mononucleosis.
- One of the most serious complications is splenic rupture.
- If ampicillin is given, a rash often develops.

Uncomplicated cases require symptomatic care only. The patient should not participate in contact sports for several months because of the risk for splenic rupture. Corticosteroids are not indicated for uncomplicated infection. Acyclovir and other antiviral drug therapy is not effective.

Chronic fatigue syndrome is a syndrome characterized by various nonspecific symptoms. Studies have definitively shown that EBV does not cause chronic fatigue syndrome.

- No therapy is indicated for uncomplicated cases of infectious mononucleosis.
- EBV does not cause chronic fatigue syndrome.

EBV infection in males with X-linked lymphoproliferative syndrome is a rare disorder of young boys in whom fulminant EBV infections develop and is associated with a 57% mortality rate. Complications include severe EBV hepatitis with liver failure and hemophagocytic syndrome with bleeding. In survivors, hypogammaglobulinemia, malignant lymphoma, aplastic anemia, and opportunistic infections develop. Death occurs by age 40 years in all cases. Acyclovir and corticosteroids do not seem to be beneficial.

In *EBV-associated Burkitt lymphoma and nasopharyngeal carcinoma*, patients have high titers of IgA antibodies to EBV. *Polyclonal and monoclonal B-cell lymphoproliferative syndromes* have been associated with EBV in patients who have had organ transplantation and in patients with AIDS. Oral hairy leukoplakia in patients with AIDS is associated with EBV infection and responds to acyclovir therapy. EBV recently has been associated with leiomyosarcomas in transplant recipients.

- Polyclonal and monoclonal B-cell lymphoproliferative syndromes have been associated with EBV.

Cytomegalovirus

Primary CMV infection is usually asymptomatic in immunocompetent patients, but it can cause a heterophile-negative mononucleosis syndrome. It is a significant cause of neonatal disease. Perinatal infection can occur in utero, intra partum, or post partum and can cause congenital malformations. Primary infection of the mother during pregnancy results in a 15% chance of fetal cytomegalic inclusion disease. Young children in day-care centers commonly shed CMV in their urine and saliva. Their parents are at risk of acquiring primary infection from an asymptomatic child.

CMV can be transmitted by leukocytes in blood transfusions. Use of leukocyte-poor packed red blood cells or blood from CMV-seronegative donors decreases the risk of transmission via this route. Symptomatic infection develops about 4 weeks after transfusion and manifests as fever with atypical lymphocytes in the peripheral blood smear. Serologic testing confirms the diagnosis. Viral cultures are rarely helpful in diagnosing CMV disease in the noncompromised patient.

- CMV can cause heterophile-negative mononucleosis syndrome.
- CMV can be transmitted by blood transfusion.
- Fever and infectious mononucleosis-like picture on peripheral smear are characteristics in postoperative patients who have received blood transfusions.

In persons with impaired cellular immunity (such as those with AIDS or organ and bone marrow transplant recipients), CMV causes serious infections (CMV syndrome, retinitis, pneumonia, gastrointestinal ulcerations, encephalitis, adrenalitis). The diagnosis most often is established by isolation of CMV from blood or from culture, by histopathologic evidence of CMV infection in involved tissue (such as liver, lung, gastrointestinal tract), or from clinical findings alone (CMV retinitis).

- CMV causes serious infections (retinitis, pneumonia, gastrointestinal ulcerations, encephalitis, adrenalitis) in patients who have AIDS or take immunosuppressive medications.

The manifestations of CMV disease in persons with advanced AIDS are protean. Disease is almost always caused by reactivation of latent infection in this setting. Finding CMV in the blood or urine of patients with AIDS is common and has a low predictive value for symptomatic CMV disease. CMV retinitis occurs in 20% to 30% of patients with advanced AIDS. Diagnosis is based on ophthalmologic examination. The relapse rate for CMV retinitis in AIDS is high, even with chronic antiviral therapy.

Solid organ and bone marrow transplant recipients are another group of patients at risk for CMV disease. It is the most common infection after solid organ transplantation (occurring primarily in the first 6 months after transplantation). Those at highest risk are CMV seronegative before transplantation and receive an organ from a seropositive donor. Latent virus is present in almost all tissues and begins replicating shortly after transplantation. Symptomatic disease (CMV syndrome) usually develops in the first 4 to 8 weeks after a solid organ transplantation and causes fever, leukopenia, increases in liver enzyme values, and end-organ involvement. CMV serum antigen testing or CMV detected in blood culture helps confirm the diagnosis. Patients who have had bone marrow transplantation are especially at risk for CMV pneumonia. The mortality rate approaches 50% despite therapy. Prophylactic ganciclovir and, possibly, CMV immune globulin may decrease or delay posttransplantation CMV disease.

Table 14-4 Infectious Mononucleosis-like Syndromes

Disease	Pharyngitis	Adenopathy	Splenomegaly	Atypical lymphocytes	Heterophile	Other test
Infectious mononucleosis	++++	++++	+++	+++	+	Specific EBV antibody + (VCA IgM)
CMV	–	–	+++	++	–	CMV IgM
Toxoplasmosis	–	++++	+++	++		Toxoplasmosis serology

–, absent; +, ++, +++, and ++++, present to varying degrees; CMV, cytomegalovirus; EBV, Epstein-Barr virus; VCA, viral capsid antigen.

- CMV retinitis occurs in 20%-30% of patients with advanced AIDS.
- CMV is the most common infectious complication of organ transplantation.

Ganciclovir is the treatment of choice for most CMV infections in immunocompromised hosts. A randomized, placebo-controlled trial found that foscarnet and ganciclovir are equally efficacious for halting the progression of CMV retinitis in patients with AIDS but that patients taking foscarnet lived longer (12 vs. 8 months). Both drugs are now approved for this indication. Full-dose induction therapy is given for 2 to 3 weeks, followed by chronic suppressive therapy indefinitely (usually as once-daily dosing). Transplant recipients usually do not require suppressive medication after an episode of CMV disease. In patients with CMV pneumonia after bone marrow transplantation, combining ganciclovir with intravenous immune globulin is more effective than ganciclovir alone. Non-immunocompromised patients with CMV do not require treatment.

- Ganciclovir or foscarnet is the treatment of choice for most CMV infections.

Varicella-Zoster Virus

Primary infection with VZV usually occurs in childhood and causes chickenpox. Illness with chickenpox is more likely to be severe in adults and immunocompromised hosts. Varicella pneumonia occurs in 5% to 50% of cases. Pregnant women are especially vulnerable. They should be treated with high-dose acyclovir (10 mg/kg every 8 hours). Acyclovir is not associated with toxicity to the fetus. Pneumonia develops within 1 to 6 days after the onset of illness and usually recedes as the rash does. Encephalomyelitis is another serious complication of varicella infection, occurring predominantly in children. Onset is 3 to 14 days after the appearance of rash.

- Varicella pneumonia occurs in 5% to 50% of adults with chickenpox.
- Pneumonia begins to improve with disappearance of rash.

After primary infection, VZV DNA persists in a latent state in sensory neuron ganglia. Reactivated infection causes zoster (shingles), which manifests as a painful vesicular rash in a dermatomal distribution. Involvement of the fifth cranial nerve, especially the ophthalmic branch, may be sight-threatening. In non-immune persons exposed to zoster, primary VZV infection may develop. Neurologic complications of herpes zoster include motor paralysis (localized to the dermatomal distribution of rash), encephalitis, and myelitis.

- Herpes zoster infection often involves the fifth cranial nerve, especially the ophthalmic branch.

Varicella immune globulin can prevent primary VZV infection, especially when given within 96 hours of exposure. It is indicated for 1) VZV-seronegative immunocompromised hosts who have had close contact with a person with chickenpox and 2) newborns of mothers with varicella infection that occurs 5 days before or 2 days after delivery.

Ten percent of mothers with active varicella will transmit the infection to the fetus. Infection during the first trimester may result in limb hypoplasia, cortical atrophy, and chorioretinitis. During the third trimester, multiple visceral abnormalities can occur, including pneumonia. The fetal and neonatal mortality rate is 31%.

- Among mothers with active varicella, 10% will transmit the infection to the fetus.

Treatment for varicella (*primary varicella-zoster*) infection is based on whether the patient is immunocompetent. Two recent randomized clinical trials showed that oral acyclovir (800 mg 5 times a day or equivalent) reduced the duration of skin lesions and viral shedding in adults and children. Its efficacy for reducing visceral complications (pneumonia) remains unknown. Early treatment (<24 hours) is necessary. The cost of therapy may limit its usefulness, but it is advocated by some to decrease the duration of illness. Acyclovir may reduce the risk of dissemination and of complications in immunocompromised patients. Treatment of zoster ophthalmicus reduces the incidence of uveitis and keratitis. For immunocompetent patients with zoster, three antiviral drugs (acyclovir, famciclovir, and valacyclovir) speed healing and reduce pain. Preliminary data suggest that the new antiviral agent famciclovir might decrease the duration of postherpetic neuralgia. Corticosteroids do not prevent postherpetic neuralgia. For disseminated infections (encephalitis, cranial neuritis), a recent controlled trial showed that high-dose intravenous acyclovir decreases the duration of hospitalization. Acyclovir-resistant VZV infection (which can occur in patients with AIDS) can be treated with intravenous foscarnet or cidofovir.

An effective live virus vaccine for VZV is now available. It is recommended for children and VZV-seronegative adolescent and adult populations. It is contraindicated in pregnancy and in patients with impaired cellular immunity such as AIDS, leukemias, lymphoma, chemotherapy, transplantation, chronic steroid therapy, or other cellular immunodeficiency states. Such immunocompromised patients should avoid contact with persons who have received the vaccine in the past month.

Human Herpesvirus 6

HHV-6 is a recently discovered lymphotropic virus. It causes the mild childhood infectious exanthem known as roseola infantum. Like CMV, reactivation of infection occurs after organ transplantation. HHV-6 has been associated with pneumonitis after bone marrow transplantation.

Human Herpesvirus 8

HHV-8 is also known as Kaposi sarcoma-associated virus. As the name implies, it is thought to be the causative agent of Kaposi sarcoma. It is related to EBV. Most recently, HHV-8 has been linked to body cavity-based lymphomas in patients with AIDS and Castleman disease.

Influenza

Type A is the most common. Epidemics occur every 2 to 4 years; pandemics occur every 20 to 30 years. Epidemics and pandemics

are a result of a major antigenic shift in the influenza virus. About 80% to 90% of deaths due to influenza occur in persons older than 65 years. Complications include 1) primary influenza pneumonia (interstitial desquamative pneumonia) and 2) secondary bacterial infection, which usually is caused by *Streptococcus pneumoniae*, *Haemophilus*, or *Staphylococcus aureus*. Rare cases of toxic shock syndrome have been reported when *S. aureus* pneumonia complicates influenza.

- About 80%-90% of deaths due to influenza occur in persons older than 65 years.
- Secondary infection usually is caused by *S. pneumoniae* or *S. aureus*.
- Typical clinical scenario: An elderly patient, often with chronic obstructive lung disease, has influenza, which may or may not improve; then, the severity of symptoms increases substantially, with high fever, marked leukocytosis, and often respiratory failure.

Amantadine and rimantadine are effective against only influenza A virus, not influenza B. Therapy is most beneficial if begun within 48 hours of onset of symptoms. Vaccine, together with amantadine, can give about 95% protection against influenza A infection. Neuraminidase inhibitors (oseltamivir and zanamivir) are effective against uncomplicated disease caused by both influenza A and B. Both reduce the duration of symptoms by 1 day when started within 48 hours after onset of symptoms.

An inactivated influenza and live attenuated intranasal vaccine (recently approved by the U.S. Food and Drug Administration) are used for the prevention of influenza. Target groups for vaccination are persons older than 50 years, residents of chronic care facilities, persons with cardiopulmonary disorders, healthy children between 6 and 23 months old, children 6 months to 18 years old receiving long-term aspirin therapy (to prevent Reye syndrome), health care personnel, employees of chronic care facilities, providers of home health care, and those sharing the same household as high-risk persons. The live attenuated vaccine is approved only for healthy immunocompetent persons between the ages of 5 and 49 years. Adverse reactions to both vaccines include fever, myalgias, and hypersensitivity. For those who did not receive the vaccine, amantadine, rimantadine, or oseltamivir can be used for influenza prevention and are effective for prophylactic use after exposure to a patient with influenza. Amantadine is given at a dose of 200 mg per day; if the person is older than 65 years, only 100 mg per day is given to decrease the risk of side effects. The decreased dosage also is used for patients with impaired renal function or seizure disorders. Toxicity manifests as dizziness, restlessness, and insomnia. High-risk individuals who have not received the vaccine during the influenza season should be considered for chemoprophylaxis.

- Target groups for influenza vaccine are persons older than 50 years, residents of chronic care facilities, persons with cardiopulmonary disorders, healthy children between 6 and 23 months old, children 6 months to 18 years old receiving long-term aspirin therapy (to prevent Reye syndrome), health care personnel, employees of chronic care facilities, providers of home health care, and household members of high-risk persons.

Hantavirus Infection, *Hantavirus* Pulmonary Syndrome

In May 1993, an outbreak of an acute illness consisting of fever, rapidly progressive respiratory failure, and death was reported in the four-state area of New Mexico, Arizona, Colorado, and Utah. Most of the initial cases occurred in young Navajo Indians. The causative agent is a virus belonging to the genus *Hantavirus* (family Bunyaviridae) and is now called the Sin Nombre virus. Infection is transmitted through inhalation of aerosolized secretions from the common deer mouse (*Peromyscus maniculatus*).

Since the early reports, cases also have been identified in most other states and Canada. The disease begins with a nonspecific prodrome (fever and generalized myalgia) followed in 4 to 5 days by respiratory symptoms (cough, dyspnea, and tachypnea). This progresses rapidly to an adult respiratory distress syndrome. Diagnosis is possible with serologic studies (such as enzyme-linked immunosorbent assay for antivirus IgM and IgG antibodies). Treatment is mainly supportive. Ribavirin, a guanosine analog, has been used effectively for treating hemorrhagic fever with renal syndrome caused by other related types of *Hantavirus*, but its efficacy in *Hantavirus* pulmonary syndrome is not yet established.

Poliovirus

Although wild-type polio has been eliminated from the Western Hemisphere, it remains endemic in parts of Asia and Africa. Disease still can be imported from these areas. There was a recent outbreak in the Netherlands among members of religious groups who were not vaccinated. Remember that polio is most often an asymptomatic infection. The virus affects the nuclei of cranial nerves and anterior motor neurons of the spinal cord, causing a flaccid paralysis. When paralysis develops, it is usually asymmetric. Vaccine-related polio, although rare, can occur with the live virus vaccine. In July 2000, a vaccine-strain polio outbreak occurred in the Dominican Republic and Haiti. Patients traveling to these countries are advised to receive an injectable inactivated polio vaccine booster.

Rabies

Rabies is difficult to diagnose ante mortem. Manifestations are hydrophobia and copious salivation. It should be considered in any case of encephalitis or myelitis of unknown cause, especially in persons who have recently traveled outside the United States. The virus spreads along peripheral nerves to the central nervous system. The most common sources of exposure are dogs, cats, skunks, foxes, raccoons (Florida, Connecticut), wolves, and bats. Spread by other animals is *very rare*. Rodents rarely, if ever, transmit rabies. From 1980 to 1989, 9 of 13 cases in the United States were due to exposure to rabid animals outside the country. Rabies also has been reported to occur in patients after corneal transplantation. Aerosol spread is possible; it is most often due to exposure to bats during spelunking or in medical laboratories. The risk of nosocomial transmission is low. Definitive diagnosis is established by finding Negri bodies on biopsy of the hippocampus. Serum and cerebrospinal fluid can be tested for rabies antibodies when trying to diagnose the disease. Direct fluorescent antibody testing of a skin biopsy specimen from the nape of the neck is used to detect rabies antigen.

- Rabies should be considered in any case of encephalitis or myelitis of unknown cause.
- Most common sources of exposure are dogs, cats, skunks, foxes, raccoons, wolves, and bats.
- Definitive diagnosis is established by the presence of Negri bodies on biopsy of the hippocampus.

Human diploid vaccine is more effective and less toxic than the older duck embryo vaccine. Human rabies immunoglobulin is now widely available, mitigating the need to use horse serum immune globulin. Human rabies immunoglobulin and vaccine are not of benefit after onset of clinical disease. Pre-exposure rabies vaccination is advised for patients likely to be in situations that put them at high risk for rabies, such as prolonged travel to rabies-endemic countries. Pre-exposure vaccination mitigates the need for rabies immunoglobulin and decreases the post-exposure doses to only 2 (days 0 and 3 after bite).

Slow Viruses and Prion-Associated Central Nervous System Diseases

Progressive Multifocal Leukoencephalopathy

Progressive multifocal leukoencephalopathy is associated with AIDS, leukemia, lymphoma, and immunosuppression for organ transplantation. It is caused by a papovavirus (JC virus). It can cause either diffuse or focal central nervous system abnormalities. Despite its name, progressive multifocal leukoencephalopathy usually causes solitary brain lesions, as seen on computed tomography or magnetic resonance imaging. Cerebrospinal fluid is normal in most cases. The diagnosis is based on brain biopsy, although detection of JC virus DNA in the cerebrospinal fluid is suggestive of progressive multifocal leukoencephalopathy. There is no proven effective therapy.

- Progressive multifocal leukoencephalopathy is associated with AIDS, leukemia, lymphoma, and immunosuppression for organ transplantation.
- Progressive multifocal leukoencephalopathy is caused by a papovavirus (JC virus).

Subacute Sclerosing Panencephalitis (Inclusion Body Encephalitis)

This is a progressively fatal disease of children and adolescents. It is thought to be due to rubeola (measles) virus. Patients are younger than 11 years in 80% of cases. Onset is insidious, with progressive mental deterioration. Later, myoclonic jerks and diffuse abnormalities occur. Measles antibody levels in sera and cerebrospinal fluid are markedly increased. Brain biopsy is necessary for diagnosis (inclusion body encephalitis). There is no treatment. The disease is uniformly fatal.

Creutzfeldt-Jakob Disease

This is a rare, fatal, degenerative disease of the central nervous system. It occurs equally in both sexes, usually at older ages. There are both familial and sporadic forms of the disease. Creutzfeldt-Jakob disease usually presents as rapidly evolving dementia with myoclonic seizures. Prions (small proteinaceous infectious particles without nucleic acid) have been proposed as the cause of this disease. Nosocomial transmission of Creutzfeldt-Jakob disease can occur via corneal transplant recipients and exposure to cerebrospinal fluid. Several recent cases in Great Britain were linked to consumption of beef from cattle that had bovine spongiform encephalopathy. There is no treatment.

- Creutzfeldt-Jakob disease presents as rapidly evolving dementia with myoclonic seizures.

Measles (Rubeola)

There was a substantial increase in measles cases in the late 1980s and early 1990s in unvaccinated preschool children and vaccinated high school and college students (1990: 27,786 cases). Prodromal upper respiratory tract symptoms are prominent. Oral lesions (Koplik spots) precede the rash. Both measles infection and measles vaccine cause temporary cutaneous anergy (false-negative purified protein derivative test). Infection may cause more significant immunologic suppression, as exemplified by cases of reactivated tuberculosis in persons with measles.

- In measles, oral Koplik spots precede the rash.
- Measles vaccine may cause temporary cutaneous anergy.

Complications of measles include encephalitis and pneumonia. Encephalitis is often severe. It usually occurs after a period of apparent improvement of measles infection. In primary measles pneumonia, large, multinucleated cells (Warthin-Finkeldey cells) are found on lung biopsy. Secondary bacterial infection is more common than primary measles pneumonia. *S. aureus* and *Haemophilus influenzae* are the most common bacterial pathogens.

- Complications of measles include encephalitis.
- Secondary bacterial infection is more common than primary measles pneumonia.

Atypical measles occurs in patients vaccinated before 1968. After exposure to measles, atypical rash, fever, arthralgias, and headache (aseptic meningitis) may develop. The presence of a high titer of measles antibody in serum helps confirm the diagnosis.

Rubella

The prodromal symptoms of rubella are mild (unlike those of rubeola). Posterior cervical lymphadenopathy, arthralgia (70% in adults), transient erythematous rash, and fever are characteristic. Infection is subclinical in many cases. Central nervous system complications and thrombocytopenia are rare.

- Characteristics of rubella: posterior cervical lymphadenopathy, arthralgia (70% in adults), transient erythematous rash, and fever.

The greatest danger from rubella is to the fetus. When a pregnant female is exposed to rubella, rubella serologic testing should be done. If the titer indicates immunity, there is no danger and no further testing is indicated. If the titer indicates non-immunity, the patient

should be followed for evidence of clinical rubella. The serum titer should be checked again in 2 to 3 weeks to evaluate for evidence of asymptomatic infection. If the titer is not increased and there is no evidence of clinical rubella, then no intervention is indicated. If clinical rubella develops or seroconversion is demonstrated, there is a high risk of congenital abnormalities or spontaneous abortion. The risk varies from 40% to 60% if infection occurs during the first 2 months of gestation to 10% by the 4th month. Intravenous gamma globulin may mask symptoms of rubella, but it does not protect the fetus.

- Gamma globulin does not protect the fetus after exposure to rubella.

From 6% to 11% of young adults remain susceptible to rubella after receiving rubella vaccine. A pregnant female should not be given rubella vaccine because it can cause congenital abnormalities. Females of childbearing age should be warned not to become pregnant within 2 to 3 months from the time of immunization. Transient arthralgias develop in 25% of immunized women. Fever, rash, and lymphadenopathy also may develop. Symptoms may occur as long as 2 months after vaccination. They may be confused with other forms of arthritis.

Viral Meningoencephalitis

Etiologic agents of viral meningitis include mumps, enteroviruses, herpes simplex, and, in summer months, the equine encephalitis viruses. Lymphocytic choriomeningitis is acquired by exposure to rodent urine. Lactate levels in cerebrospinal fluid are normal in viral meningitis. The lactate level usually is increased in bacterial meningitis.

Mumps

Mumps virus commonly affects glandular tissue. Parotitis, pancreatitis, and orchitis are characteristic manifestations. Orchitis occurs in 20% of males with mumps. It is unilateral in approximately 75%. Orchitis often is associated with recrudescence of malaise and chills, fever, headache, nausea, vomiting, and testicular pain. Sterility is uncommon, even after bilateral infection.

Mumps meningoencephalitis is one of the most common nonseasonal viral meningitides. It can cause low glucose values in the cerebrospinal fluid, mimicking bacterial meningitis. Deafness is a rare complication of mumps.

- Mumps meningoencephalitis is one of the most common nonseasonal viral meningitides.

Mumps polyarthritis is most common in men between the ages of 20 and 30 years. Joint symptoms begin 1 to 2 weeks after subsidence of parotitis, and large joints are involved. The condition lasts approximately 6 weeks, and complete recovery is usual. This condition may be confused with other forms of arthritis.

- Mumps polyarthritis is most common in men between the ages of 20 and 30 years.

Parvovirus B19

Parvovirus is a single-stranded DNA virus that infects the erythrocyte precursors in bone marrow, with resulting reticulocytopenia. It is the cause of erythema infectiosum (fifth disease) in children, transient arthritis in adults, and aplastic crisis in persons with hemolytic anemias. Infection during pregnancy results in a 5% chance of hydrops fetalis or fetal death. Serologic testing is the preferred diagnostic method in immunologically competent persons.

Parvovirus B19 infection may persist in immunosuppressed patients, resulting in red blood cell aplasia. Diagnosis is established by demonstration of giant pronormoblasts in bone marrow or identification of viral DNA in bone marrow or peripheral blood. Most patients respond to administration of commercial immune globulin infusions for 5 to 10 days. No treatment is recommended for parvovirus infections in the noncompromised host.

- Parvovirus B19 is the cause of erythema infectiosum (fifth disease) and transient arthritis.
- B19 virus can cause red blood cell aplasia in patients with AIDS.

Human T-Cell Lymphotropic Viruses (HTLV)

HTLV-I and -II are non-HIV human retroviruses. HTLV-I is endemic in parts of Japan, the Caribbean basin, South America, and Africa. It may be transmitted by sexual contact, infected cellular blood products (not clotting factor concentrates), and injection drug use. Vertical transmission (breast-feeding, transplacental) also occurs. HTLV-I is associated with human T-cell leukemia/lymphoma and tropical spastic paraparesis (also known as HTLV-I–associated myelopathy). However, clinical disease never develops in 96% of persons infected with HTLV-I. HTLV-II causes no known clinical disease. The seroprevalence of HTLV-I or -II is as high as 18% in certain high-risk groups (injection drug users, patients attending sexually transmitted disease clinics) (HTLV-II is 2.5 times more prevalent than HTLV-I). Among voluntary blood donors, the seroprevalence in the United States is estimated at 0.016%. With current screening practices, the risk of transmission of HTLV-I or -II through blood transfusion is estimated to be 0.0014% (1/70,000 units).

- HTLV-I may be transmitted by sexual contact, infected blood products, and injection drug use.
- HTLV-I infection is usually asymptomatic but is associated with human T-cell leukemia and chronic myelopathy.

Parasites

Helminths

Neurocysticercosis is an infection of the central nervous system with a larval stage of the pork tapeworm (*Taenia solium*). It is acquired by ingesting tapeworm eggs from fecally contaminated food. It is endemic in Latin America, Asia, and Africa. Recent cases have been reported among household contacts of foreign-born persons (working as domestic employees). The infected persons had not traveled to an affected area. The most common presentation is seizures. Brain imaging reveals cystic or calcified brain lesions. Serum or cerebrospinal fluid serologic testing can aid in the diagnosis. Treatment with

praziquantel or albendazole may be beneficial. Albendazole is considered superior for neurocysticercosis because of better central nervous system penetration. The coadministration of corticosteroids often is used to decrease cerebral inflammation associated with therapy.

- Neurocysticercosis is acquired by ingesting tapeworm eggs from fecally contaminated food.
- Seizures are the most common symptom of neurocysticercosis.

Strongyloides stercoralis is unique among the intestinal nematode infections. Unlike the other helminths, the larvae of this organism can mature in the human host (auto-infection). In immunocompromised hosts (neutropenia, steroids, AIDS), a superinfection can develop with larval migration throughout the body. Gram-negative bacteremia is a common coinfection, resulting from disruption of the intestinal mucosa by the invasive larvae. Treatment is with ivermectin.

Trichinosis is acquired from eating undercooked meat, especially pork or bear. Features include muscle pain (especially diaphragm, chest, and tongue), eosinophilia, and periorbital edema. Treatment is with mebendazole or albendazole.

Hookworm (*Necator americanus*) causes anemia. It is found mainly in tropical and subtropical regions. The larval form penetrates the skin. Walking barefoot is a risk factor. Treatment is with mebendazole or albendazole.

Ascariasis infection may cause intestinal obstruction or pancreatitis (worm migrates up the pancreatic duct). Treatment is with mebendazole or albendazole.

Schistosomiasis is a tropical disease that causes hepatic cirrhosis, hematuria, and carcinoma of the bladder. Transverse myelitis may develop as a result of schistosomiasis. It is acquired by direct penetration of the *Schistosoma cercariae* from contaminated water (lakes, rivers). Praziquantel is the drug of choice for schistosomiasis.

- Trichinosis is acquired from eating undercooked meat, especially pork or bear.
- Transverse myelitis may develop as a result of schistosomiasis.

Protozoan Parasites

Acanthamoeba, a free-living ameba, causes amebic keratitis in persons swimming in fresh water while wearing soft contact lenses. The diagnosis is based on microscopic examination of scrapings of the cornea. Treatment is with topical antifungal agents. Patients often respond poorly to therapy and have progressive corneal destruction.

Symptomatic infection with *Entamoeba histolytica* (amebiasis) may cause diarrhea (often bloody), abdominal pain, and fever. Metronidazole, followed by a lumenocidal agent such as iodoquinol or paromomycin, is the preferred therapy (metronidazole does not kill amebae in the intestinal lumen). Asymptomatic carriage of amebic cysts should be treated with one of the lumenocidal agents.

- Metronidazole, followed by a lumenocidal agent such as iodoquinol or paromomycin, is the preferred therapy for symptomatic amebiasis.

Invasive amebiasis may lead to distant abscesses (primarily the liver, but other organs can be involved). An amebic liver abscess usually is single and is commonly located in the posterior portion of the right lobe of the liver. The anatomical location, the fact that it is usually a single abscess, and the absence of other signs of bacterial infection help to distinguish amebic hepatic abscess from bacterial abscess. Serologic tests (complement fixation) are positive in more than 90% of patients with amebic abscess. Hepatic abscess may rupture through the diaphragm into the right pleural cavity.

- Amebic liver abscess may rupture through the diaphragm into the right pleural cavity.

Giardia lamblia is the parasite most frequently detected in state parasitology laboratories. Infection characteristically produces sudden onset of watery diarrhea with malabsorption, bloating, and flatulence. Prolonged disease that is refractory to standard therapy may occur in patients with IgA deficiency. The organism may be detected in stool specimens, but examination of duodenal aspirates is more sensitive. Treatment with metronidazole usually cures giardiasis.

- *G. lamblia* is the parasite most frequently detected in state parasitology laboratories.
- Giardiasis causes sudden onset of watery diarrhea and malabsorption, bloating, and flatulence.
- Prolonged giardiasis is particularly common in patients with IgA deficiency.

Toxoplasma gondii is acquired from eating undercooked meat or exposure to cat feces. Primary toxoplasmosis is usually asymptomatic. In immunocompetent persons it may cause a heterophile-negative mononucleosis-like syndrome. Toxoplasmosis causes brain lesions and pneumonia in patients with AIDS. Immunocompromised patients with toxoplasmosis can be treated effectively with pyrimethamine in combination with either sulfadiazine or clindamycin.

- Toxoplasmosis is acquired from eating undercooked meat or exposure to cat feces.
- Toxoplasmosis may cause an infectious mononucleosis-like syndrome.

Malaria is endemic and spreading in many parts of the world. Spiking fevers, rigors, and headache are the hallmark of malaria. With falciparum malaria, the fevers may be irregular or continuous. *Plasmodium vivax* and *Plasmodium malariae* infections cause regular episodic fevers (malarial paroxysms). Malaria is diagnosed by examination of thick and thin blood smears (Fig. 14-7).

- Diagnosis of malaria is based on examination of thick and thin blood smears.

Prophylaxis for malaria is increasingly difficult because of drug-resistant *Plasmodium falciparum*. Personal protection should always be used (such as mosquito nets, insect repellents containing DEET [*N*,*N*-diethyl-3-methylbenzamide]). For travelers to chloroquine-sensitive

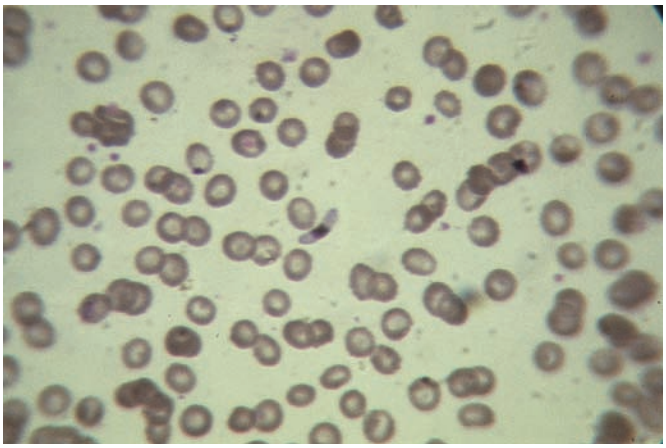

Fig. 14-7. Thin blood smear showing banana-shaped gametocyte of *Plasmodium falciparum*.

areas (Central America [north of Panama], Mexico, Haiti, the Dominican Republic, and the Middle East), chloroquine phosphate is still effective. In chloroquine-resistant areas, mefloquine, doxycycline, or an atovaquone-proguanil hydrochloride combination tablet (Malarone) is suggested. Sulfadoxine-pyrimethamine (Fansidar) or a combination of chloroquine with proguanil is not recommended for prophylaxis for chloroquine-resistant falciparum malaria. Travelers to the mefloquine-resistant areas of the Thai-Myanmar and Thai-Cambodian borders should use doxycycline or atovaquone-proguanil hydrochloride. Mefloquine should be avoided in patients with cardiac conduction abnormalities, depression or other psychiatric disorder, or seizure disorder. No regimen guarantees 100% prophylaxis. While receiving mefloquine, patients should be advised not to take halofantrine for a febrile illness because of the risk of fatal cardiac arrhythmias. All patients should be advised to seek medical attention if fever develops within 1 year after return from an endemic area.

Chloroquine is the preferred treatment of infection caused by *P. vivax*, *P. malariae*, and known chloroquine-susceptible strains of *P. falciparum*. Chloroquine-resistant strains may respond to quinine and doxycycline, atovaquone-proguanil hydrochloride, mefloquine, or artemether (this agent is not available in the United States). For severe *P. falciparum* infections, intravenous quinidine or quinine is effective. In the United States, only parenteral quinidine is available for severe malaria. Primaquine is used to eradicate the exoerythrocytic phase of *Plasmodium ovale* and *P. vivax* infections, preventing later relapses. Be aware that primaquine can cause hemolysis in persons with glucose-6-phosphate dehydrogenase deficiency. Exchange transfusion may be beneficial as treatment for cases with overwhelming parasitemia.

Cryptosporidium parvum is an important cause of diarrhea, especially in persons with AIDS. Cryptosporidiosis is also a cause of self-limited diarrhea in otherwise healthy persons. Waterborne outbreaks (Georgia; Milwaukee, Wisconsin) have been reported. They occur most often in late summer or fall. Thirty-five percent of patients have another pathogen simultaneously, most often *Giardia*. The diagnosis may be missed on standard stool examination for ova and parasites. There is no effective therapy for *Cryptosporidium*, except paromomycin, which shows some efficacy.

- Cryptosporidiosis is an important cause of diarrhea in AIDS.

Cyclospora cayetanensis is a recently described cause of persistent diarrhea, fever, and profound fatigue. First described in travelers to tropical areas of the world, disease due to *Cyclospora* also has been linked to consumption of contaminated food in the United States (raspberries from Guatemala). Like *Cryptosporidium*, the organism may not be detected on routine stool examinations. The illness can be effectively treated with trimethoprim-sulfamethoxazole.

- Infection with *C. cayetanensis* causes persistent diarrhea, fever, and profound fatigue.

Leishmaniasis is a protozoan disease transmitted by the sand fly bite. Visceral leishmaniasis (kala-azar, caused by *Leishmania donovani*) causes fever, hepatosplenomegaly, hypergammaglobulinemia, cachexia, and pancytopenia. It has been reported in patients with AIDS in Spain. Bone marrow examination (Giemsa stain) is often diagnostic. Cutaneous leishmaniasis (caused by *L. tropica*, *L. major*, *L. braziliensis*, and *L. mexicana*) may be self-limited. However, South and Central American forms of cutaneous leishmaniasis are often destructive and should be treated. Treatment is with antimony compounds or with amphotericin B or its liposomal formulations.

Babesia microti is a tick-borne (same vector as Lyme disease, *Ixodes dammini*) parasite that infects erythrocytes and causes fever, myalgias, and hemolytic anemia. Often asymptomatic in normal hosts, severe disease may develop in asplenic individuals. Babesiosis is endemic in the northeastern United States, especially around Nantucket and Cape Cod. Cases of transfusion-transmitted babesiosis have been documented. The diagnosis is established with examination of peripheral blood smear or polymerase chain reaction amplification of *Babesia* DNA from peripheral blood. Treatment is with clindamycin and quinine. Simultaneous infection with babesiosis and Lyme disease may be especially severe.

- Babesiosis infects erythrocytes and causes fever, myalgias, and hemolytic anemia.

Robert Orenstein, DO

Clinical Syndromes

Infective Endocarditis

Native Valve Infective Endocarditis

Native valve infective endocarditis is more common in males and patients older than 65 years. The age- and sex-adjusted incidence rate of infective endocarditis is 4.9 cases per 100,000 person-years. In 60% to 80% of cases, there is a predisposing cardiac lesion. The mitral and aortic valves are most commonly involved. Congenital heart disease is present in 10% to 20% of cases, and rheumatic heart disease is present in less than 15% of cases. The risk of infective endocarditis from mitral valve prolapse is low, but the prevalence of mitral valve prolapse makes it the most common underlying cardiac condition. Infective endocarditis may present with acute or subacute manifestations, depending on the virulence of the infecting organism. The diagnosis of infective endocarditis is often difficult and is based on clinical, microbiologic, and echocardiographic findings (Fig. 14-8). Diagnostic criteria have been developed to aid the clinician in the diagnosis of infective endocarditis (Tables 14-5 and 14-6).

- The risk of infective endocarditis from mitral valve prolapse is low, but the prevalence of mitral valve prolapse makes it the most common underlying cardiac condition.
- Diagnostic criteria have been developed to aid in the diagnosis of infective endocarditis.

Microorganisms causing native valve infective endocarditis include viridans group streptococci (i.e., *Streptococcus sanguis*, *Streptococcus mutans*, and *Streptococcus mitis*), 30% to 40% of cases; enterococci (i.e., *Enterococcus faecalis* and *Enterococcus faecium*), 5% to 18%; other streptococci (i.e., *Streptococcus bovis* and *Streptococcus pneumoniae*), 15% to 25%; *Staphylococcus aureus*, 10% to 27%; coagulase-negative staphylococci, 1% to 3%; gram-negative bacilli, 1.5% to 13%; fungi, 2% to 4%; miscellaneous bacteria, less than 5%; mixed infections, 1% to 2%; and "culture-negative," less than 5% to 24%.

- The organisms most commonly involved in native valve infective endocarditis are viridans group streptococci.

Treatment of native valve infective endocarditis includes an emphasis on short-course therapy in patients with uncomplicated left-sided native valve infective endocarditis caused by penicillin-susceptible viridans group streptococci. For enterococcal endocarditis, combination therapy with penicillin G or ampicillin in addition to gentamicin is recommended. Testing for high-level aminoglycoside resistance (gentamicin, >500 μg/mL; streptomycin, >2,000 μg/mL) and penicillin and vancomycin resistance is mandatory.

Table 14-7 lists the recommended treatment regimens for native valve infective endocarditis.

Prosthetic Valve Infective Endocarditis

Prosthetic valve infective endocarditis occurs in up to 3% to 6% of patients with a prosthetic cardiac valve. Some studies suggest that the aortic valve is affected more often than the mitral valve. Early-onset endocarditis is defined as infection occurring 2 months or less after implantation, and late-onset endocarditis is infection occurring more than 2 months postoperatively. Early infection tends to have a more acute presentation. Microorganisms that cause prosthetic valve endocarditis are outlined in Table 14-8. Treatment regimens for prosthetic valve infective endocarditis are given in Table 14-9.

Additional Information About Infective Endocarditis

- Transthoracic echocardiography and transesophageal echocardiography visualize vegetations in approximately 60% and 90% of patients, respectively. Transesophageal echocardiography is superior to transthoracic for diagnosing complications of infective endocarditis such as cardiac abscesses and perivalvular extension.
- Infective endocarditis in injection drug users is caused by *S. aureus* (60%), streptococci (16%), gram-negative bacilli (13.5%), polymicrobial infection (8.1%), and *Corynebacterium JK* (1.4%). *Candida* spp. endocarditis also occurs in this patient population. Tricuspid valve involvement is common. Short-course (2 weeks) therapy with a penicillinase-resistant penicillin with or without an aminoglycoside or 4-week oral regimens with a fluoroquinolone and rifampin may be as effective as longer courses of therapy in uncomplicated right-sided endocarditis due to methicillin-susceptible *S. aureus* in injection drug users, irrespective of whether the patient has human immunodeficiency virus (HIV).
- "Culture-negative" endocarditis may be the result of previous use of antibiotics (most common) and endocarditis due to the following organisms: HACEK (*Haemophilus* spp., *Actinobacillus actinomycetemcornitans*, *Cardiobacterium hominis*, *Eikenella* spp., *Kingella Kingae*) organisms, nutritionally variant streptococci (i.e., *Abiotrophia* spp.), *Neisseria* spp., *Listeria monocytogenes*, *Brucella* spp., fungi, mycobacteria, *Legionella* spp., *Coxiella burnetii*, *Chlamydia* spp., *Mycoplasma* spp., *Nocardia* spp., *Rothia dentocariosa*, and *Bartonella* spp.

Surgical Therapy

If cardiac valve replacement is needed, it should not be delayed to allow additional days of antimicrobial therapy. Surgical treatment is often indicated in cases of congestive heart failure refractory to medical management. Intractable congestive heart failure is the most common indication for cardiac valve replacement. Other generally accepted indications for cardiac valve replacement include evidence of more than one serious systemic embolic episode, uncontrolled bacteremia despite effective antimicrobial therapy, and inadequate antimicrobial therapy. Other indications include invasive perivalvular infection as manifested by abscess or fistula on echocardiography, new or persistent electrocardiographic changes, persistent unexplained fever, fungal

Table 14-5 Duke Criteria for the Diagnosis of Infective Endocarditis

Definite infective endocarditis
- Pathologic criteria
  - Microorganisms: demonstrated by culture *or* histology in vegetation, *or* in vegetation that has embolized, *or* in an intracardiac abscess, *or*
  - Pathologic lesions: vegetation or intracardiac abscess present, confirmed by histology showing active endocarditis
- Clinical criteria, using specific definitions listed in Table 14-6
  - 2 major criteria, *or*
  - 1 major and 3 minor criteria, *or*
  - 5 minor criteria

Possible infective endocarditis
- Findings consistent with infective endocarditis that fall short of "definite," but not "rejected"

Rejected
- Firm alternative diagnosis for manifestations of endocarditis, *or*
- Resolution of manifestations of endocarditis, with antibiotic therapy for 4 days or less, *or*
- No pathologic evidence of infective endocarditis at surgery or autopsy, after antibiotic therapy for 4 days or less

From Durack DT, Lukes AS, Bright DK, Duke Endocarditis Service. New criteria for diagnosis of infective endocarditis: utilization of specific echocardiographic findings. Am J Med. 1994;96:200-9. Used with permission.

Table 14-6 Definitions of Terminology Used in the Criteria for the Diagnosis of Infective Endocarditis

Major criteria
1. Positive blood culture for infective endocarditis
   a. Typical microorganism for infective endocarditis from two separate blood cultures
      1) Viridans group streptococci,* *Streptococcus bovis*, HACEK† group, *or*
      2) Community-acquired *Staphylococcus aureus* or enterococci, in the absence of a primary focus, *or*
   b. Persistently positive blood cultures, defined as recovery of a microorganism consistent with infective endocarditis from:
      1) Blood cultures drawn more than 12 hours apart, *or*
      2) All of three or a majority of four or more separate blood cultures, with first and last drawn at least 1 hour apart
2. Evidence of endocardial involvement
   a. Positive echocardiogram for infective endocarditis
      1) Oscillating intracardiac mass, on valve or supporting structures, *or* in the path of regurgitant jets, *or* on implanted material, in the absence of an alternative anatomical explanation, *or*
      2) Abscess, *or*
      3) New partial dehiscence of prosthetic valve, *or*
   b. New valvular regurgitation (increase or change in preexisting murmur not sufficient)

Minor criteria
1. Predisposition: predisposing heart condition *or* intravenous drug use
2. Fever: 38.0°C (100.4°F)
3. Vascular phenomena: major arterial emboli, septic pulmonary infarcts, mycotic aneurysm, intracranial hemorrhage, conjunctival hemorrhages, Janeway lesions
4. Immunologic phenomena: glomerulonephritis, Osler nodes, Roth spots, rheumatoid factor
5. Microbiologic evidence: positive blood culture but not meeting major criteria as noted previously‡ *or* serologic evidence of active infection with organisms consistent with infective endocarditis
6. Echocardiogram: consistent with infective endocarditis but not meeting major criteria as noted previously

*Including nutritionally variant strains.
†HACEK, *Haemophilus* spp., *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella* spp., and *Kingella kingae*.
‡Excluding single positive cultures for coagulase-negative staphylococci and organisms that do not cause endocarditis.
From Durack DT, Lukes AS, Bright DK, Duke Endocarditis Service. New criteria for diagnosis of infective endocarditis: utilization of specific echocardiographic findings. Am J Med. 1994;96:200-9. Used with permission.

Table 14-7 Treatment of Native Valve Infective Endocarditis

Microorganisms	Therapy*	Alternative therapy*
Penicillin-sensitive viridans group streptococci and *Streptococcus bovis* (MIC, ≤0.1 μg/mL)	Aqueous crystalline penicillin G, 12-18 × 10^6 U/24 h IV either continuously or in six equally divided doses for 4 wk *Or* Ceftriaxone sodium 2 g IV or IM for 4 wk‡ *Or* Aqueous penicillin G, 12-18 × 10^6 U/24 h IV either continuously or in six equally divided doses for 2 wk *Plus* Gentamicin sulfate,§ 1 mg/kg IV or IM every 8 h for 2 wk	Vancomycin,† 30 mg/kg IV in two equally divided doses, not to exceed 2 g/24 h unless serum levels are monitored for 4 wk Vancomycin therapy is recommended for patients allergic to β-lactams (immediate-type hypersensitivity); serum concentration of vancomycin should be obtained 1 h after completion of the infusion and should be in the range of 30-45 μg/mL for twice-daily dosing
Relatively penicillin-resistant viridans group streptococci (MIC, >0.1 μg/mL and <0.5 μg/mL)	Aqueous crystalline penicillin G, 24 × 10^6 U/24 h IV either continuously or in four to six equally divided doses for 4 wk *Plus* Gentamicin sulfate,§ 1 mg/kg IV or IM every 8 h for 2 wk	Vancomycin,† 30 mg/kg IV in two equally divided doses, not to exceed 2 g/24 h unless serum levels are monitored for 4 wk Vancomycin therapy is recommended for patients allergic to β-lactams (immediate-type hypersensitivity); serum concentration of vancomycin should be obtained 1 h after completion of the infusion and should be in the range of 30-45 μg/mL for twice-daily dosing
Enterococci (gentamicin- or vancomycin-susceptible) or viridans group streptococci with MIC ≥0.5 μg/mL or nutritionally variant streptococci (All enterococci causing endocarditis must be tested for antimicrobial susceptibility in order to select optimal therapy)	Aqueous crystalline penicillin G, 18-30 × 10^6 U/24 h IV either continuously or in six equally divided doses for 4-6 wk *Or* Ampicillin sodium 12 g/24 h IV either continuously or in six equally divided doses *Plus* Gentamicin sulfate,§ 1 mg/kg IV or IM every 8 h for 4-6 wk (4-wk therapy recommended for patients with symptoms ≤3 mo in duration; 6-wk therapy recommended for patients with symptoms >3 mo in duration)	Vancomycin,† 30 mg/kg IV in two equally divided doses, not to exceed 2 g/24 h unless serum levels are monitored for 4-6 wk *Plus* Gentamicin,§ 1 mg/kg IV or IM every 8 h for 4-6 wk Vancomycin therapy is recommended for patients allergic to β-lactams (immediate-type hypersensitivity); serum concentration of vancomycin should be obtained 1 h after completion of the infusion and should be in the range of 30-45 μg/mL for twice-daily dosing Cephalosporins are not acceptable alternatives for patients allergic to penicillin
Enterococcus faecium	Linezolid, 1,200 mg/24 h IV or PO in two divided doses for ≥8 wk *Or* Quinupristin-dalfopristin, 22.5 mg/kg per 24 h IV in three divided doses for ≥8 wk	Patients with endocarditis caused by these strains should be treated in consultation with an infectious diseases specialist Cardiac valve replacement may be necessary for bacteriologic cure Cure with antimicrobial therapy alone may be <50% Severe, usually reversible thrombocytopenia may occur with use of linezolid, especially after 2 wk of therapy Quinupristin-dalfopristin only effective against *E. faecium* and can cause severe myalgias, which may require discontinuation of therapy Only small number of patients have reportedly been treated with imipenem/cilastatin-ampicillin or ceftriaxone + ampicillin

Table 14-7 (continued)

Microorganisms	Therapy*	Alternative therapy*
Enterococcus faecalis	Imipenem/cilastatin, 2 g/24 h IV in four equally divided doses for ≥8 wk *Plus* Ampicillin sodium, 12 g/24 h IV in six divided doses for ≥8 wk *Or* Ceftriaxone sodium, 2 g/24 h IV or IM in one dose for ≥8 wk *Plus* Ampicillin sodium, 12 g/24 h IV in six divided doses for ≥8 wk *Pediatric dose* (should not exceed that of a normal adult): linezolid 30 mg/kg per 24 h IV or PO in three divided doses; quinupristin-dalfopristin 22.5 mg/kg per 24 h IV in three divided doses; imipenem/cilastatin 60-100 mg/kg per 24 h IV in four divided doses; ampicillin 300 mg/kg per 24 h IV in four-six divided doses; ceftriaxone 100 mg/kg per 24 h IV or IM once daily	
Staphylococcus aureus‖		
Methicillin-sensitive	Nafcillin sodium or oxacillin sodium, 2.0 g IV every 4 h for 4-6 wk *Plus* Gentamicin sulfate (optional),§ 1 mg/kg every 8 h IV or IM for first 3-5 days. Benefit of additional aminoglycoside has not been established	Cefazolin (or other first-generation cephalosporins in equivalent dosages), 2 g IV every 8 h for 4-6 wk *Plus* Gentamicin (optional),§ 1 mg/kg every 8 h IV or IM for first 3-5 days Cephalosporins should be avoided in patients with immediate-type hypersensitivity to penicillin Vancomycin,† 30 mg/kg IV in two equally divided doses, not to exceed 2 g/24 h unless serum levels are monitored for 4-6 wk Vancomycin therapy is recommended for patients allergic to β-lactams (immediate-type hypersensitivity); serum concentration of vancomycin should be obtained 1 h after completion of the infusion and should be in the range of 30-45 μg/mL for twice-daily dosing
Methicillin-resistant	Vancomycin,† 30 mg/kg IV in two equally divided doses, not to exceed 2 g/24 h unless serum levels are monitored for 4-6 wk	Consult infectious diseases specialist
HACEK group	Ceftriaxone sodium, 2 g IV or IM for 4 wk‡ *Or* Ampicillin¶-sulbactam 12 g/24 h IV in four divided doses for 4 wk *Or* Ciprofloxacin 1,000 mg/24 h PO or 800 mg/24 h IV in two divided doses if unable to tolerate alternatives Cefotaxime sodium or other third-generation cephalosporins may be substituted	Consult infectious diseases specialist

Table 14-7 (continued)

Microorganisms	Therapy*	Alternative therapy*
Neisseria gonorrhoeae	Ceftriaxone, 1-2 g every 24 h for ≥4 wk	Aqueous crystalline penicillin G, 20 × 10^6 U/24 h IV either continuously or in six equally divided doses for 4 wk, for penicillin-susceptible isolates
Gram-negative bacilli	Most effective single drug or combination of drugs IV for 4-6 wk	
Urgent empiric treatment for culture-negative endocarditis	Vancomycin,† 30 mg/kg IV in two equally divided doses, not to exceed 2 g/24 h unless serum levels are monitored for 6 wk *Plus* Gentamicin sulfate,§ 1.0 mg/kg IV every 8 h for 6 wk	
Fungal endocarditis	Amphotericin B *Plus* Flucytosine (optional) *Plus* Cardiac valve replacement (flucytosine levels should be monitored)	
Suspected *Bartonella*, culture negative	Ceftriaxone sodium, 2 g/24 h IV or IM in one dose for 6 wk *Plus* Gentamicin sulfate, 3 mg/kg per 24 h IV or IM in three divided doses for 2 wk *With or without* Doxycycline 200 mg/kg per 24 h IV or PO in two divided doses for 6 wk	Consult an infectious diseases specialist

HACEK, *Haemophilus* spp., *Actinobacillus actinomycetemcomitans*, *Cardiobacterium hominis*, *Eikenella* spp., and *Kingella kingae*; IM, intramuscularly; IV, intravenously; MIC, minimal inhibitory concentration; PO, orally.

*Dosages recommended are for patients with normal renal function.

†Vancomycin dosage should be reduced in patients with impaired renal function. Vancomycin given on an mg/kg basis produces higher serum concentrations in obese patients than in lean patients. Therefore, in obese patients, dosing should be based on ideal body weight. Each dose of vancomycin should be infused over at least 1 h to reduce the risk of the histamine-release "red man" syndrome.

‡Patients should be notified that IM injection of ceftriaxone is painful.

§Dosing of gentamicin on an mg/kg basis produces higher serum concentrations in obese patients than in lean patients. Therefore, in obese patients, dosing should be based on ideal body weight. (Ideal body weight for men is 50 kg + 2.3 kg per inch over 5 feet, and ideal body weight for women is 45.5 kg + 2.3 kg per inch over 5 feet.) Relative contraindications to the use of gentamicin are age older than 65 years, renal impairment, or impairment of the eighth nerve. Other potentially nephrotoxic agents (such as nonsteroidal anti-inflammatory drugs) should be used cautiously in patients receiving gentamicin.

//For treatment of endocarditis due to penicillin-susceptible staphylococci (MIC, <0.1 μg/mL), aqueous crystalline penicillin G, 12-18 × 10^6 U/24 h IV either continuously or in six equally divided doses for 4-6 wk, can be used instead of nafcillin or oxacillin. Shorter antibiotic courses have been effective in some injection drug users with right-sided endocarditis due to *S. aureus*. The routine use of rifampin is not recommended for the treatment of native valve staphylococcal endocarditis.

¶Ampicillin should not be used if laboratory tests show β-lactamase production.

From Karchmer AW. Infections of prosthetic valves and intravascular devices. In: Mandell GL, Bennett JE, Dolin R, editors. Principles and practice of infectious diseases. Vol 1. 5th ed. Philadelphia: Churchill Livingstone; 2000. p. 903-17. Used with permission.

endocarditis, and relapse of appropriately treated prosthetic valve endocarditis due to penicillin-sensitive streptococci.

- Surgical treatment is indicated in cases of congestive heart failure refractory to medical management.
- Intractable congestive heart failure is the most common indication for cardiac valve replacement.

Prevention

Recommendations for prevention of infective endocarditis have changed considerably. Recent reports have concluded that only a small number of cases of infective endocarditis can be prevented by prophylaxis for dental procedures (Circulation. 2007;115. Epub 2007 Apr 9). Prophylaxis for infective endocarditis is indicated only in patients with prosthetic cardiac valves, previous infective endocarditis, or congenital heart disease and in recipients of a cardiac transplant who have cardiac valvulopathy (Table 14-10). For patients with these underlying cardiac disorders, prophylaxis is indicated before dental procedures, including manipulation of gingival tissue or periapical region of the teeth or perforation of oral mucosa. Current recommendations for antibiotic prophylaxis before a dental procedure are summarized in Table 14-11. Antibiotic prophylaxis is not indicated before genitourinary or gastroenterology procedures. Prophylaxis for infective endocarditis is currently not recommended on the basis of an increased lifetime risk of acquiring infective endocarditis.

- Routine prophylaxis for infective endocarditis is not recommended in patients with cardiac disorders.
- Prophylaxis for infective endocarditis is recommended only for patients with prosthetic cardiac valves, previous infective endocarditis, or congenital heart disease and in recipients of a cardiac transplant who have cardiac valvulopathy.

The changes in the recommendations for prophylaxis are summarized as follows:

- Bacteremia resulting from daily activities is much more likely to cause infective endocarditis than bacteremia associated with a dental procedure.
- Only an extremely small number of cases of infective endocarditis might be prevented by antibiotic prophylaxis even if prophylaxis is 100% effective.
- Antibiotic prophylaxis is not recommended based solely on an increased lifetime risk of acquisition of infective endocarditis.
- Limit recommendations for infective endocarditis prophylaxis to only those conditions listed in Table 14-10.
- Antibiotic prophylaxis is no longer recommended for any other form of congenital heart disease except for the conditions listed in Table 14-10.
- Antibiotic prophylaxis is recommended for all dental procedures that involve manipulation of gingival tissues or periapical region of teeth or perforation of oral mucosa only for patients with underlying cardiac conditions associated with the highest risk of adverse outcome from infective endocarditis (Table 14-10).
- Antibiotic prophylaxis is recommended for procedures on respiratory tract or infected skin, skin structures, or musculoskeletal tissue only for patients with underlying cardiac conditions associated with the highest risk of adverse outcome from infective endocarditis (Table 14-10).
- Antibiotic prophylaxis solely to prevent infective endocarditis is not recommended for genitourinary or gastrointestinal tract procedures.
- The procedures noted in the 1997 prophylaxis guidelines for which endocarditis prophylaxis is not recommended are reaffirmed, and these are extended to other common procedures, including ear and body piercing, tattooing, and vaginal delivery and hysterectomy.

(Summary is from Circulation. 2007;115. Epub 2007 Apr 19.)

Table 14-9 Treatment of Prosthetic Valve Infective Endocarditis

Organism	Therapy*	Alternative therapy/comments*
Staphylococcus aureus or coagulase-negative staphylococci: methicillin-resistant	Vancomycin,† 30 mg/kg IV in two equally divided doses, not to exceed 2 g/24 h unless serum levels are monitored for ≥6 wk *Plus* Rifampin,‡ 300 mg PO every 8 h for ≥6 wk *Plus* Gentamicin sulfate,§ 1 mg/kg IV or IM every 8 h for first 2 wk of therapy (If organism is not susceptible to gentamicin, ciprofloxacin may be substituted if the organism is susceptible in vitro)	Rifampin increases the amount of warfarin sodium required for antithrombotic therapy
Staphylococcus aureus or coagulase-negative staphylococci: methicillin-susceptible	Nafcillin sodium or oxacillin sodium, 2 g IV every 4 h for ≥6 wk *Plus* Rifampin,‡ 300 mg orally every 8 h for ≥6 wk *Plus* Gentamicin sulfate,§ 1 mg/kg IV or IM every 8 h for first 2 wk of therapy (If organism is not susceptible to gentamicin, ciprofloxacin may be substituted if the organism is susceptible in vitro)	Rifampin increases the amount of warfarin sodium required for antithrombotic therapy First-generation cephalosporins or vancomycin should be used in patients allergic to β-lactams Cephalosporins should be avoided in patients with immediate-type hypersensitivity to penicillin or to methicillin-resistant staphylococci
Enterococci (gentamicin- or vancomycin-susceptible) or viridans group streptococci or nutritionally variant streptococci or *Streptococcus bovis* (All streptococci causing endocarditis must be tested for antimicrobial susceptibility in order to select optimal therapy)	Aqueous crystalline penicillin G, 18-30 × 10^6 U/24 h IV either continuously or in six equally divided doses for 6 wk *Or* Ampicillin sodium, 12 g/24 h IV either continuously or in six equally divided doses *Plus* Gentamicin sulfate,§ 1 mg/kg IV or IM every 8 h for 6 wk	Vancomycin,† 30 mg/kg IV in two equally divided doses, not to exceed 2 g/24 h unless serum levels are monitored for 4-6 wk *Plus* Gentamicin sulfate,§ 1 mg/kg IV or IM every 8 h for 4-6 wk Vancomycin therapy is recommended for patients allergic to β-lactams (immediate-type hypersensitivity); serum concentration of vancomycin should be obtained 1 h after completion of the infusion and should be in the range of 30-45 μg/mL for twice-daily dosing Cephalosporins are not acceptable alternatives for patients allergic to penicillin
Enterococcus faecium	Linezolid, 1,200 mg/24 h IV or PO in two divided doses for ≥8 wk *Or*	Patients with endocarditis caused by these strains should be treated in consultation with an infectious diseases specialist Cardiac valve replacement may be necessary for bacteriologic cure Cure with antimicrobial therapy alone may be <50% Severe, usually reversible thrombocytopenia may occur with use of linezolid, especially after 2 wk of therapy

Table 14-9 (continued)

Organism	Therapy*	Alternative therapy/comments
Enterococcus faecium (continued)	Quinupristin-dalfopristin, 22.5 mg/kg per 24 h IV in three divided doses for ≥8 wk	Quinupristin-dalfopristin only effective against *E. faecium* and can cause severe myalgias, which may require discontinuation of therapy Only small number of patients have reportedly been treated with imipenem/cilastatin-ampicillin or ceftriaxone + ampicillin
Enterococcus faecalis	Imipenem/cilastatin, 2 g/24 h IV in four equally divided doses for ≥8 wk *Plus* Ampicillin sodium, 12 g/24 h IV in six divided doses for ≥8 wk *Or* Ceftriaxone sodium, 2 g/24 h IV or IM in one dose for ≥8 wk *Plus* Ampicillin sodium, 12 g/24 h IV in six divided doses for ≥8 wk *Pediatric dose* (should not exceed that of a normal adult): linezolid 30 mg/kg per 24 h IV or PO in three divided doses; quinupristin-dalfopristin 22.5 mg/kg per 24 h IV in three divided doses; imipenem/cilastatin 60-100 mg/kg per 24 h IV in four divided doses; ampicillin 300 mg/kg per 24 h IV in four-six divided doses; ceftriaxone 100 mg/kg per 24 h IV or IM once daily	

IM, intramuscularly; IV, intravenously; PO, orally.

*Dosages recommended are for patients with normal renal function.

†Vancomycin dosage should be reduced in patients with impaired renal function. Vancomycin given on an mg/kg basis produces higher serum concentrations in obese patients than in lean patients. Therefore, in obese patients, dosing should be based on ideal body weight. Each dose of vancomycin should be infused over at least 1 h to reduce the risk of the histamine-release "red man" syndrome.

‡Rifampin plays a unique role in the eradication of staphylococcal infection involving prosthetic material; combination therapy is essential to prevent emergence of rifampin resistance.

§Dosing of gentamicin on an mg/kg basis will produce higher serum concentrations in obese patients than in lean patients. Therefore, in obese patients, dosing should be based on ideal body weight. (Ideal body weight for men is 50 kg + 2.3 kg per inch over 5 feet, and ideal body weight for women is 45.5 kg + 2.3 kg per inch over 5 feet.) Relative contraindications to the use of gentamicin are age older than 65 years, renal impairment, or impairment of the eighth nerve. Other potentially nephrotoxic agents (such as nonsteroidal anti-inflammatory drugs) should be used cautiously in patients receiving gentamicin.

Meningitis

Bacterial Meningitis

The incidence of bacterial meningitis is estimated to be 3.0 cases per 100,000 person-years. The overall case fatality rate was 25% in a report of 443 cases of bacterial meningitis in adults between 1962 and 1988. Forty percent of cases were nosocomial. Common predisposing conditions for community-acquired meningitis include acute otitis media, altered immune states, alcoholism, pneumonia, diabetes mellitus, sinusitis, and a cerebrospinal fluid leak. Risk factors for death among adults with community-acquired meningitis include age 60 years or older, obtundation on admission, and occurrence of seizures within 24 hours of symptom onset. In 66% of patients, fever, nuchal rigidity, and altered mental status are present (N Engl J Med. 1993;328:21-8).

Typical initial cerebrospinal fluid characteristics include a cell count of 1,000 to 5,000/μL (range, <100-10,000) and a glucose value less than 40 mg/dL or a cerebrospinal fluid–serum glucose ratio less than 0.31. The leukocyte differential is more likely to show a predominance of polymorphonuclear neutrophils. The Gram stain is positive in 60% to 90% of cases. Countercurrent immunoelectrophoresis or latex agglutination tests may provide results in 15 minutes and are useful for the detection of *Haemophilus influenzae* type B, *Streptococcus pneumoniae*, and *Neisseria meningitidis* types A, B, C, and Y, *Escherichia coli* K1, and group B streptococci in the absence of a positive Gram stain. Cerebrospinal fluid cultures are positive in 70% to 85% of cases. Blood cultures may be positive. Polymerase chain reaction has been used to diagnose meningitis due to *S. pneumoniae*, *H. influenzae* type B, *Streptococcus agalactiae*, *Listeria monocytogenes*, and *N. meningitidis*.

Organisms most commonly causing community-acquired meningitis in adults are *S. pneumoniae* (38%), *N. meningitidis* (14%), *L. monocytogenes* (11%), streptococci (7%), *Staphylococcus aureus* (5%), *H. influenzae* (4%), and gram-negative bacilli (4%).

Although still somewhat controversial in adults, recent guidelines (Clin Infect Dis. 2004;39:1267-84) do suggest a role for the use of dexamethasone in the early treatment of specific types of bacterial meningitis: suspected pneumococcal meningitis in adults and

Table 14-10 Cardiac Conditions Associated With the Highest Risk of Adverse Outcome From Endocarditis for Which Prophylaxis With Dental Procedures Is Recommended

Prosthetic cardiac valve
Previous infective endocarditis
Congenital heart disease (CHD)*
Unrepaired cyanotic CHD, including palliative shunts and conduits
Completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or catheter intervention, during the first 6 months after the procedure†
Repaired CHD with residual defects at the site or adjacent to the site of a prosthetic patch or prosthetic device (which inhibit endothelialization)
Cardiac transplantation recipients who have cardiac valvulopathy

*Except for the conditions listed above, antibiotic prophylaxis is no longer recommended for any other form of CHD.
†Prophylaxis is recommended because endothelialization of prosthetic material occurs within 6 months after the procedure.
From Wilson W, Taubert KA, Gewitz M, Lockhart PB, Baddour LM, Levison M, et al. Prevention of infective endocarditis. Guidelines from the American Heart Association. A guideline from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group. Circulation. 2007;115. Epub 2007 Apr 19. Used with permission.

H. influenza type B meningitis in children. There is inadequate evidence to support dexamethasone use in other forms of bacterial meningitis. It is important to remember that the benefit occurs with administration before antibiotics. Thus the optimal approach is to obtain a cerebrospinal fluid Gram stain and blood and cerebrospinal fluid cultures and administer dexamethasone and then the appropriate antibiotic. Dexamethasone 0.15 mg/kg should be given 10 to 20 minutes *before* the first dose of antibiotics and the dose repeated every 6 hours for the first 2 to 4 days. If subsequently it is determined that the patient does not have pneumococcal meningitis, use of dexamethasone should be stopped.

- Risk factors for death in bacterial meningitis: age 60 years or older, decreased mental status at admission, seizures within 24 hours of symptom onset.
- Gram stains of cerebrospinal fluid are positive in 60%-90% of cases.
- Organisms most commonly causing community-acquired infection in adults: *S. pneumoniae*, *N. meningitidis*, *H. influenzae*, and *L. monocytogenes*.

The causative organisms, affected age groups, and predisposing factors in bacterial meningitis are shown in Table 14-12, and empiric treatment in various age and patient groups is outlined in Table 14-13.

Although the *Haemophilus influenzae* type B conjugate vaccine has clearly resulted in a decline in meningitis caused by this organism, and the same decline seems to be occurring with invasive pneumococcal disease in children, the impact of the 7-valent conjugate pneumococcal vaccine is not yet clear. Immunocompromised hosts, pregnant women, and elderly patients should receive an empiric antibiotic regimen that includes coverage for *L. monocytogenes*. High-dose ampicillin is the treatment of choice. An aminoglycoside can be added to ampicillin if *L. monocytogenes* meningitis is confirmed. High-dose intravenous trimethoprim-sulfamethoxazole can be used in patients with a penicillin allergy. *L. monocytogenes* can be mistakenly reported as a diphtheroid on cerebrospinal fluid culture and labeled a contaminant.

- Immunocompromised hosts, pregnant women, and the elderly should receive an empiric antibiotic regimen that includes high-dose ampicillin to cover *L. monocytogenes*.

Meningococcal Meningitis

Meningitis often occurs in patients who are carriers of meningococci in the nasopharynx. Terminal component complement deficiencies predispose to repeated episodes of infection. Serotypes B, C, and Y cause most of the endemic disease in the United States. Many patients have a petechial rash. The pathogenesis of Waterhouse-Friderichsen syndrome (i.e., acute hemorrhagic necrosis of the adrenal glands causing primary adrenocortical insufficiency) is related to disseminated intravascular coagulation. Treatment is with penicillin G if the minimal inhibitory concentration is <0.1 μg/mL, otherwise high-dose ceftriaxone or cefotaxime is preferred. In close contacts of the index case (hospital workers with substantial respiratory exposure, roommates, household contacts, day-care center members, persons exposed to patient's oral secretions), chemoprophylaxis should be given within 24 hours of exposure, if possible. Rifampin, ceftriaxone, or ciprofloxacin (use only in patients 18 years or older) have been used. The carrier state is not eliminated by penicillin; thus, affected cases may require one of these drugs for eradication of carriage. Immunization of certain populations (e.g., military recruits, college students living in dormitories, Hajj pilgrims, patients with terminal complement component deficiencies or asplenia) is also of benefit. The meningococcal vaccine contains polysaccharides of groups A, C, Y, and W-135. A new meningococcal vaccine (Menactra) was recently approved and offers longer protection.

Table 14-11 Regimens for a Dental Procedure

Situation	Agent	Regimen: single dose 30 to 60 min before procedure	
		Adults	Children
Oral	Amoxicillin	2 g	50 mg/kg
Unable to take oral medication	Ampicillin	2 g IM or IV	50 mg/kg IM or IV
	Or		
	Cefazolin or ceftriaxone	1 g IM or IV	50 mg/kg IM or IV
Allergic to penicillins or ampicillin—oral	Cephalexin*†	2 g	50 mg/kg
	Or		
	Clindamycin	600 mg	20 mg/kg
	Or		
	Azithromycin or clarithromycin	500 mg	15 mg/kg
Allergic to penicillins or ampicillin and unable to take oral medication	Cefazolin or ceftriaxone†	1 g IM or IV	50 mg/kg IM or IV
	Or		
	Clindamycin	600 mg IM or IV	20 mg/kg IM or IV

IM, intramuscularly; IV, intravenously.
*Or other first- or second-generation oral cephalosporin in equivalent adult or pediatric dosage.
†Cephalosporins should not be used in an individual with a history of anaphylaxis, angioedema, or urticaria with penicillins or ampicillin.
From Wilson W, Taubert KA, Gewitz M, Lockhart PB, Baddour LM, Levison M, et al. Prevention of infective endocarditis. Guidelines from the American Heart Association. A guideline from the American Heart Association Rheumatic Fever, Endocarditis, and Kawasaki Disease Committee, Council on Cardiovascular Disease in the Young, and the Council on Clinical Cardiology, Council on Cardiovascular Surgery and Anesthesia, and the Quality of Care and Outcomes Research Interdisciplinary Working Group. Circulation. 2007;115. Epub 2007 Apr 19. Used with permission.

Table 14-12 Organisms Involved, Affected Age Groups, and Predisposing Factors in Bacterial Meningitis

Organism	Age group	Comment	Predisposing factors
Streptococcus pneumoniae	Any age, but often elderly	Most common cause of recurrent meningitis in adults	Cerebrospinal fluid leak, alcoholism, splenectomy, functional asplenia, multiple myeloma, hypogammaglobulinemia, Hodgkin disease, HIV
Neisseria meningitidis	Infants to 40 y	Petechial rash is common Epidemics occur in closed populations	Terminal component complement deficiency
Haemophilus influenzae, type B	>Neonate to 6 y	Significant decrease in incidence since licensure of *H. influenzae* B vaccine	Hypogammaglobulinemia in adults, HIV, splenectomy, functional asplenia
Escherichia coli, group B streptococci	Neonates		Maternal colonization
Gram-negative bacilli	Any age	*Staphylococcus aureus* and coagulase-negative staphylococci also common after neurosurgical procedure	Neurosurgical procedures, bacteremia due to urinary tract infection, pneumonia, etc., *Strongyloides* hyperinfection syndrome
Listeria monocytogenes	Neonates; immunosuppressed		

HIV, human immunodeficiency virus.

Table 14-13 Empiric Therapy for Bacterial Meningitis

Age group/patient group	Common pathogens	Antimicrobial therapy
Age		
0-4 wk	Group B streptococci, *Escherichia coli*, *Listeria monocytogenes*, *Klebsiella pneumoniae*, *Enterococcus* spp., *Salmonella* spp.	Ampicillin plus cefotaxime or ampicillin plus an aminoglycoside
1-23 mo	Group B streptococci, *E. coli*, *L. monocytogenes*, *Haemophilus influenzae*, *Streptococcus pneumoniae*, *Neisseria meningitidis*	Vancomycin plus cefotaxime or ceftriaxone
2-50 y	*N. meningitidis*, *S. pneumoniae*	Vancomycin plus cefotaxime or ceftriaxone
>50 y*	*S. pneumoniae*, *L. monocytogenes,* aerobic gram-negative bacilli	Vancomycin plus cefotaxime or ceftriaxone plus ampicillin
Basilar skull fracture	*S. pneumoniae*, *H. influenzae*, group A β-hemolytic streptococci	Vancomycin plus cefotaxime or ceftriaxone
Post-neurosurgery	Coagulase-negative staphylococci, *Staphylococcus aureus*, aerobic gram-negative bacilli (including *P. aeruginosa*)	Vancomycin plus cefepime or ceftazidime or meropenem

Modified from Tunkel AR, Hartman BJ, Kaplan SL, Kaufman BA, Roos KL, Scheld WM, et al. Practice guidelines for the management of bacterial meningitis. Clin Infect Dis. 2004;39:1267-84. Used with permission.

- In meningococcal meningitis, terminal component complement deficiencies predispose to repeated episodes of infection.
- If the risk of the carrier state is high (household contacts), rifampin, ceftriaxone, or ciprofloxacin should be used for prophylaxis.

The Acute Aseptic Meningitis Syndrome

This is a syndrome characterized by an acute onset of meningeal symptoms, fever, cerebrospinal fluid pleocytosis (usually lymphocytes), and negative bacterial cultures from the cerebrospinal fluid. A host of pathogens may cause this. Noninfectious causes of aseptic meningitis include medications, such as nonsteroidal anti-inflammatory drugs and trimethoprim-sulfamethoxazole; chemical meningitis; and neoplastic meningitis. Aseptic meningitis is most often caused by viruses. Despite the large number of potential agents, these cases often are differentiated by an accurate exposure history and seasonality. Cases occurring in spring may be associated with tick-borne diseases such as Lyme disease. Cases occurring in the late summer are most often associated with mosquito-borne arboviruses such as West Nile virus. The most frequent viral agents are the enteroviruses (most common in summer) and herpes simplex virus types 1 and 2 (often recurrent). Less frequent pathogens include mumps, lymphocytic choriomeningitis virus (rodents), other human herpesviruses, cytomegalovirus, HIV (acute retroviral syndrome), varicella-zoster virus, Epstein-Barr virus, and Colorado tick fever virus.

- Characteristics of aseptic meningitis: meningeal symptoms, fever, cerebrospinal fluid pleocytosis, negative bacterial cultures.
- The cause is most often viral.

Sexually Transmitted Diseases

Neisseria gonorrhoeae

Common uncomplicated infections include urethritis and cervicitis. Symptoms are indistinguishable from those of nongonococcal disease. Gram stain and culture or molecular detection are required for diagnosis. Both men and women may be asymptomatic, but the asymptomatic carrier state is more common in females. Asymptomatic carriers are primarily responsible for transmission of the infection. In females, concomitant proctitis is common (rectal cultures should be done in all women). Gonococcal pharyngitis is often asymptomatic. Coexistence of chlamydial infection is common (both conditions should be treated). For diagnosis in males, a Gram stain of urethral exudate showing intracellular gram-negative diplococci has high sensitivity and specificity. Gram staining of cervical exudate has a sensitivity of only 50%, but the specificity is high. Definitive diagnosis requires culture on modified Thayer-Martin medium. Chlamydial infections and gonorrhea can be rapidly diagnosed with molecular diagnostic tests such as the ligase chain reaction or polymerase chain reaction assay on urine or swabs of genital secretions.

- *N. gonorrhoeae* commonly causes urethritis, cervicitis, pharyngitis, and proctitis.
- Asymptomatic carrier state occurs in both males and females, but it is more common in females.

The prevalence of multiply resistant gonococcal strains is increasing. Resistance to penicillin and tetracycline is frequent. Quinolone-resistant *N.*

gonorrhoeae has become common in parts of Asia and the Pacific Rim and spread to the United States. Because of the increase in quinolone resistance, quinolones are no longer recommended as initial treatment of gonorrhea in Hawaii, and their use in California is inadvisable. Primary treatment is ceftriaxone (125 mg intramuscularly), ciprofloxacin (500 mg orally in a single dose), or ofloxacin (400 mg orally in a single dose) plus doxycycline (100 mg orally twice a day for 7 days) or azithromycin (a single 1-g dose). Alternative drugs include spectinomycin 2 g in a single intramuscular dose, ceftizoxime 500 mg in a single intramuscular dose, cefoxitin 2 g in a single intramuscular dose with probenecid 1 g orally, cefotaxime 500 mg in a single intramuscular dose, gatifloxacin 400 mg orally in a single dose, norfloxacin 800 mg orally in a single dose, and lomefloxacin 400 mg orally in a single dose. Pharyngeal infection is best treated with ceftriaxone, ciprofloxacin, or ofloxacin. Spectinomycin, ciprofloxacin, and ofloxacin may not be active against incubating syphilis. Therapy recommended for pregnant women includes ceftriaxone (125 mg intramuscularly) plus erythromycin base (500 mg orally four times a day for 7 days). Erythromycin estolate is contraindicated during pregnancy because of drug-related hepatotoxicity. Cefixime, previously recommended as single-dose therapy for gonorrhea, is no longer available. Follow-up gonococcal cultures need to be performed only if nonstandard regimens are used. All patients with sexually transmitted diseases should be considered at risk for HIV infection, and testing should be offered. Sexual partners should be offered evaluation and treatment. A recent study suggested that partner-initiated treatment may reduce transmission rates.

- Primary treatment of *N. gonorrhoeae* includes ceftriaxone (125 mg intramuscularly) plus doxycycline (100 mg orally twice a day for 7 days) or azithromycin (single 1-g dose).

Disseminated gonococcemia occurs in 1% to 3% of infected patients and is most likely to occur during menstruation (sloughing of endometrium allows access to blood supply, enhanced growth of gonococci due to necrotic tissue, and change in pH). There are two distinct phases. The bacteremic phase may manifest as tenosynovitis (often around the wrists or ankles), skin lesions (usually less than 30 in number), and polyarthralgia. Results of synovial fluid testing are usually negative. The nonbacteremic phase follows in approximately 1 week and may present as monarticular arthritis of the knee, wrist, and ankle; results of joint culture are positive in about 50%. Culture specimens should be obtained from the urethra, cervix, rectum, and pharynx.

- Disseminated gonococcemia is most likely to occur during menstruation.
- A bacteremic phase may manifest as tenosynovitis, skin lesions, and arthralgias; joint cultures are usually negative.
- A nonbacteremic phase may present as monarticular arthritis of the knee, wrist, and ankle; results of joint cultures are positive in about 50%.

Treatment is with ceftriaxone (1 g intravenously daily for 7-10 days); alternatives include ceftriaxone (for 3 or 4 days or until improvement is noted) followed by ciprofloxacin to complete a course of 7 to 10 days. If the strain is tested and found to be penicillin-susceptible, treatment includes penicillin G (10 million units intravenously daily) for 7 to 10 days or it is given for 3 or 4 days and then oral amoxicillin is used to finish a 7- to 10-day course. If the patient is allergic to cephalosporins, spectinomycin, ciprofloxacin, or ofloxacin can be given. Chlamydial infection can coexist with gonococcal infection and should be treated. For meningitis, treatment includes ceftriaxone (1-2 g intravenously every 12 hours for at least 10-14 days). Alternative drugs are penicillin, if the strain is susceptible, or chloramphenicol. For endocarditis, ceftriaxone or penicillin is used for at least 28 days.

- Treatment of disseminated gonococcal infection is with ceftriaxone (1 g intravenously daily for 7-10 days).
- Chlamydial infections can coexist with gonococcal infection and should be treated.

Nongonococcal Urethritis and Cervicitis

The most common etiologic agent is *Chlamydia trachomatis*. Infection is often asymptomatic. Diagnosis can be made with culture, antigen detection, or molecular tests. Doxycycline (100 mg twice a day for 7 days) or azithromycin as a single 1-g dose is standard treatment. Women with *C. trachomatis* cervicitis should be rescreened 3 to 4 months after treatment. *Ureaplasma urealyticum*, *Trichomonas vaginalis*, *Mycoplasma genitalium*, and herpes simplex virus are less common causes of nongonococcal urethritis. If urethritis does not resolve and reinfection or relapse of a chlamydial infection has been excluded, *Trichomonas* or tetracycline-resistant *Ureaplasma* infection should be considered. Treatment consists of metronidazole (2 g orally in a single dose) plus erythromycin base (500 mg orally four times a day for 7 days) or erythromycin ethylsuccinate (800 mg orally four times a day for 7 days).

- Nongonococcal urethritis and cervicitis are most commonly caused by *C. trachomatis*.

Herpes Genitalis

Seventy percent to 90% of cases are caused by herpes simplex virus type 2. For the first episode, therapy with acyclovir (400 mg orally three times a day or 200 mg orally five times a day for 7-10 days), famciclovir (250 mg orally three times a day), or valacyclovir (1 g orally twice a day) shortens the duration of pain, viral shedding, and systemic symptoms. If symptoms are severe, acyclovir at a dosage of 5 mg/kg intravenously every 8 hours for 5 to 7 days is used. Topical acyclovir has marginal benefit for decreasing viral shedding and has no effect on symptoms or healing time. For recurrent episodes with severe symptoms, therapy can be started at prodrome onset or within 1 day of the onset of symptoms (acyclovir, 400 mg orally three times a day, 200 mg orally five times a day, or 800 mg orally twice a day, or famciclovir, 125 mg orally twice a day, or valacyclovir, 500 mg orally twice a day, all for 5 days). Recurrence after therapy is usually *not* related to the development of in vitro resistance of herpes simplex to acyclovir. For suppression, in selected patients with more than six recurrences a year, acyclovir (400 mg twice a day), famciclovir (250 mg orally twice a day), or valacyclovir (250 mg, 500 mg, or 1 g orally

twice a day) is used for up to 1 year. (The recommended dosages for HIV-infected patients are different from the doses listed above.)

Syphilis

The etiologic agent of syphilis is *Treponema pallidum*. It is estimated that half of cases are not reported. The incidence of syphilis is increased in large cities among sexually active persons, particularly among inner city minority populations and men who have sex with men.

The fluorescent treponemal antibody absorption (FTA-ABS) test is the most helpful serologic test for the diagnosis of syphilis (Table 14-14). Results of this test are positive before those on VDRL testing, and thus they may be positive without a positive VDRL result in primary syphilis. VDRL results may be negative in 30% of patients with primary syphilis.

- FTA-ABS is the most helpful serologic test for the diagnosis of syphilis.
- VDRL results may be negative in 30% of patients with primary syphilis.

A chancre (clean, indurated ulcer) is the main manifestation of *primary syphilis*. It occurs at the site of inoculation and is usually painless. The incubation period is 3 to 90 days. It should be distinguished from herpes simplex virus and chancroid (painful exudative ulcer, *Haemophilus ducreyi*). Diagnosis is made by darkfield examination.

The manifestations of *secondary syphilis* result from hematogenous dissemination and usually occur 2 to 8 weeks after appearance of the chancre. Constitutional symptoms occur, in addition to rash, mucocutaneous lesions, alopecia, condylomata lata (i.e., a broad and flat verrucous syphilitic lesion located in warm, moist intertriginous areas, especially about the anus and genitals), lymphadenopathy, and various other symptoms and signs. The diagnosis is based on the clinical picture and serologic testing. The condition resolves spontaneously without treatment.

Latent syphilis is the asymptomatic stage after symptoms of secondary syphilis subside. Those that occur after 1 year are classified as late. The diagnosis is based on serologic testing. For latent syphilis, a cerebrospinal fluid examination is indicated before treatment in patients with neurologic or ophthalmologic abnormalities, in patients with other evidence of active syphilis, at baseline in patients treated with a non-penicillin regimen, before re-treatment of relapses, and in patients with HIV infection.

Tertiary syphilis can involve all body systems (cardiovascular—aortitis involving the ascending aorta, which can cause aneurysms and aortic regurgitation; gummatous osteomyelitis; hepatitis). However, neurosyphilis is the most common manifestation in the United States.

Neurosyphilis is often asymptomatic. Symptomatic disease is divided into several clinical syndromes that may overlap and occur at any time after primary infection. The diagnosis is made from cerebrospinal fluid examination; abnormalities include mononuclear pleocytosis and an increased protein value. VDRL testing of cerebrospinal fluid is only 30% to 70% sensitive. The FTA-ABS test on cerebrospinal fluid is highly sensitive but not specific. Any cerebrospinal fluid abnormality in a patient who is seropositive for syphilis must be investigated. Syndromes include 1) meningovascular syphilis (occurs 4-7 years after infection and presents with focal central nervous system deficits such as stroke or cranial nerve abnormalities) and 2) parenchymatous syphilis (general paresis or tabes dorsalis). Parenchymatous syphilis occurs decades after infection and may present as general paresis (chronic progressive dementia) or as tabes dorsalis (sensory ataxia, lightning pains, autonomic dysfunction, and optic atrophy).

- Neurosyphilis is the most common manifestation in tertiary disease in the United States.
- The diagnosis is made from cerebrospinal fluid examination.
- VDRL testing of cerebrospinal fluid is only 30%-70% sensitive.

Treatment of syphilis is based on whether the disease is early or late. For early syphilis (primary, secondary, or early latent [<1 year]), benzathine penicillin is used—2.4 million units intramuscularly; follow-up serologic testing is done. (Some experts recommend completing three weekly 2.4 million-unit intramuscular doses in patients with HIV infection.) Alternatives are doxycycline (100 mg twice a day for 14 days) or tetracycline (500 mg orally four times a day for 14 days). Erythromycin (500 mg orally four times a day) is less effective.

Treatment for late disease (>1 year in duration, cardiovascular disease, gumma, late latent syphilis) is with benzathine penicillin, 2.4 million units intramuscularly weekly for 3 weeks. Alternatives are doxycycline (100 mg orally twice a day) or tetracycline (500 mg orally four times a day) for 4 weeks.

Treatment of neurosyphilis is with aqueous penicillin G (12-24 million units intravenously per day) for 10 to 14 days or procaine penicillin (2.4 million units intramuscularly per day) plus probenecid (500 mg four times a day) for 10 to 14 days.

Pregnant patients should receive a penicillin-based regimen for treatment of all stages of syphilis. If a pregnant patient has a penicillin allergy, she should be desensitized to penicillin.

For early and secondary syphilis, follow-up clinical and serologic testing should be performed at 6 and 12 months. Re-treatment with three weekly injections of 2.4 million units of benzathine penicillin G should be given to patients with signs or symptoms that persist or whose VDRL result has a sustained fourfold increase in titer.

Table 14-14 Laboratory Diagnosis of Syphilis

	Test, % positive		
Syphilis	VDRL	FTA-ABS	MHA-TP
Primary	70	85	50-60
Secondary	99	100	100
Tertiary	70	98	98

FTA-ABS, fluorescent treponemal antibody absorption; MHA-TP, microhemagglutination assay for *Treponema pallidum*.

From Hook EW III. Syphilis. In: Bennett JE, Plum F, editors. Cecil textbook of internal medicine. 12th ed. Philadelphia: WB Saunders; 1996. p. 1705-14. Used with permission.

HIV testing should be performed if not done previously. If the VDRL titer does not decrease fourfold by 6 months, consideration also should be given to re-treatment.

Patients with latent syphilis should have a follow-up examination at 6, 12, and 24 months. If the VDRL result increases fourfold, if a high titer (>1:32) fails to decrease fourfold within 12 to 24 months, or if signs or symptoms attributable to syphilis occur, the patient should be examined for neurosyphilis and re-treated.

Follow-up in cases of neurosyphilis should include testing of cerebrospinal fluid every 6 months if cerebrospinal fluid pleocytosis was present initially; this testing is done until results are normal. If the cell count is not decreased at 6 months or if the cerebrospinal fluid is not entirely normal at 2 years, re-treatment should be considered.

Pelvic Inflammatory Disease

In this condition, proximal spread of infection from the endocervix causes endometritis, salpingitis, tubo-ovarian abscess, or pelvic peritonitis in various combinations. Organisms responsible are *N. gonorrhoeae*, *C. trachomatis*, *Mycoplasma hominis*, and various aerobic gram-negative rods and anaerobes. Fitz-Hugh-Curtis syndrome is an acute perihepatitis caused by direct extension of *N. gonorrhoeae* or *C. trachomatis* to the liver capsule. Occasionally, a friction rub can be auscultated over the liver and "violin string" adhesions between the liver capsule and parietal peritoneum can be observed with laparoscopy. *Actinomyces israelii* can be a pathogen in patients with an intrauterine device. Tuberculosis in older women, including postmenopausal women, should be considered. Clinical signs and symptoms include lower abdominal tenderness, adnexal tenderness, cervical motion tenderness, oral temperature more than 38.3°C, abnormal cervical discharge, increased erythrocyte sedimentation rate, and evidence of *N. gonorrhoeae* or *C. trachomatis* infection. Laboratory evidence includes laparoscopic or ultrasonographic documentation. The emphasis on early diagnosis is meant to decrease the incidence of infertility as a complication of pelvic inflammatory disease.

- In pelvic inflammatory disease, responsible organisms are *N. gonorrhoeae*, *C. trachomatis*, and anaerobes.
- Fitz-Hugh-Curtis syndrome is an acute perihepatitis caused by direct extension of *N. gonorrhoeae* or *C. trachomatis* to the liver capsule.
- The emphasis on early diagnosis is meant to decrease the incidence of infertility as a complication of pelvic inflammatory disease.

Treatment for inpatients includes cefoxitin (2 g intravenously every 6 hours) plus doxycycline (100 mg intravenously every 12 hours followed by 100 mg orally twice a day) for 14 days. Alternative parenteral regimens are clindamycin (900 mg intravenously every 8 hours) and gentamicin (2 mg/kg intravenously then 1.5 mg/kg every 8 hours) or moxifloxacin, gatifloxacin (400 mg), or levofloxacin (500 mg) (intravenously once daily).

For outpatients, treatment is with levofloxacin (500 mg orally once a day), moxifloxacin (400 mg once daily), gatifloxacin (400 mg once daily) with or without metronidazole (500 mg orally twice a day) for 14 days. Alternatives include ceftriaxone (250 mg intramuscularly once) or cefoxitin (2 g intramuscularly) plus probenecid (1 g orally as a single dose), or another third-generation cephalosporin plus doxycycline (100 mg orally twice a day) for 14 days.

Hospitalization is indicated when the outpatient therapy is precluded by severe nausea and vomiting, the diagnosis is uncertain, pelvic abscess or peritonitis is present, the patient is pregnant, the patient is an adolescent, HIV infection is present, or noncompliance is suspected.

Tubo-ovarian abscess may be characterized by an adnexal mass on physical examination or radiographic examination or by failure of antimicrobial therapy. Most abscesses 4 to 6 cm in diameter respond to medical therapy alone with the preferred regimen of ampicillin, gentamicin, and clindamycin. Larger abscesses (>10 cm) most often necessitate operation.

- Tubo-ovarian abscess is characterized by an adnexal mass on physical examination or radiographic examination or by failure of antimicrobial therapy.

Trichomonas vaginalis

Infection with this organism produces a yellow, purulent discharge in 5% to 40% of cases. Dysuria and dyspareunia occur in 30% to 50% of cases. Petechial lesions on the cervix are noted with colposcopy (strawberry cervix) in 50% of cases. The vaginal pH is usually more than 4.5. The diagnosis is established with wet mount preparation of vaginal secretions (70%-80% sensitive). Culture is done in difficult cases. Treatment is with metronidazole (2 g as a single dose or 500 mg twice a day for 7 days) or tinidazole (2 g: 4 500-mg tabs as a single dose). Gastrointestinal tolerance may be better with tinidazole, although there is less clinical experience with this agent. All partners should be examined and treated if necessary. Although treatment in asymptomatic pregnant women is controversial, treatment in symptomatic pregnant women should be a one-time dose of 2 g of metronidazole.

- *T. vaginalis* infection often is characterized by yellow, purulent discharge.
- Diagnosis is established with wet mount of vaginal secretion.
- Treatment of *T. vaginalis* is with metronidazole or tinidazole orally.

***Gardnerella vaginalis* (Bacterial Vaginosis)**

This condition is characterized by a malodorous "fishy" smell and a grayish white discharge that is homogeneous and coats the vaginal walls. Dysuria and pain are relatively uncommon. Organisms associated with the syndrome are *Mobiluncus* spp., *M. hominis*, *G. vaginalis*, and *Prevotella* spp. The diagnosis is determined by excluding *Candida* and *Trichomonas* infections and other sexually transmitted diseases. The following are characteristics of the vaginal secretion: "clue" cells on wet mount examination, pH more than 4.5 and often more than 6.0, and a "fishy" smell when secretion is mixed with 10% KOH (positive "whiff" test). Recommended treatment regimens include metronidazole (500 mg orally twice a day for 7 days) or topical clindamycin cream or metronidazole gel (the clindamycin cream appears less efficacious than the metronidazole regimens). A single

2-g dose of metronidazole or clindamycin, 300 mg orally twice a day for 7 days, is an alternative. Bacterial vaginosis has been associated with adverse pregnancy outcomes. All symptomatic pregnant women should be treated. In pregnant patients, systemic therapy with metronidazole (250 mg orally three times a day for 7 days) or clindamycin (300 mg orally twice a day for 7 days) is recommended rather than topical agents in order to treat organisms in the upper genital tract. Treatment of asymptomatic nonpregnant carriers is not recommended. Some experts recommend treatment of asymptomatic pregnant women at high risk for preterm delivery. Routine treatment of sex partners is not recommended.

- Diagnosis of *G. vaginalis* is established by excluding *Candida* and *Trichomonas* infections and other sexually transmitted diseases.
- Vaginal discharge has "clue" cells, a "fishy" smell when mixed with 10% KOH (positive "whiff" test), and a pH more than 4.5.
- Routine treatment of sex partners is not recommended.

Vulvovaginal Candidiasis

The predominant symptom of this condition is pruritus. It is typically caused by *Candida albicans*. Seventy-five percent of women will have one episode and 40% to 45%, two or more episodes. Usually there is no odor, and discharge is scant, watery, and white. "Cottage cheese curds" may adhere to the vaginal wall. The diagnosis is made by the addition of 10% KOH to the discharge to demonstrate pseudohyphae. Culture may detect an asymptomatic carrier. Treatment is with various topical agents from 1 to 7 days, depending on the dose and agent. Single-dose fluconazole (150 mg for one dose) therapy may be more convenient and less costly. Multiple-dose oral azole therapy also is used for severe, refractory cases. In severe or recurrent cases, consider HIV infection or drug-resistant candidal species.

- In vulvovaginal candidiasis, "cottage cheese curds" may adhere to the vaginal wall.
- In severe or recurrent cases, consider HIV infection.

Epididymitis

This condition usually presents as a unilateral, painful scrotal swelling. It should be distinguished from testicular torsion. In young, sexually active men, *C. trachomatis* and *N. gonorrhoeae* are the common pathogens. In older men, aerobic gram-negative rods and enterococci predominate. Urologic abnormality is more common in this population than in younger men. Doxycycline (100 mg orally twice a day for 7 days) plus ceftriaxone (250 mg intramuscularly) is the treatment of choice in young males. In older men, treatment is individualized on the basis of results of urine Gram stain, results of culture, local susceptibility patterns, and presence of recent instrumentation.

- Epididymitis is usually unilateral; it should be distinguished from testicular torsion.
- In young, sexually active men, *C. trachomatis* and *N. gonorrhoeae* are the common pathogens.

Gastrointestinal Infection

Bacterial Diarrhea

The principal causes of toxigenic diarrhea are listed in Table 14-15, and those of invasive diarrhea are listed in Table 14-16. Fecal leukocytes usually are absent in toxigenic diarrhea. In invasive diarrhea, fecal leukocytes usually are present. The travel history is often important.

Campylobacter jejuni is being recognized with increasing frequency as a common cause of bacterial diarrhea. Approximately 10% to 30% of cases of Guillain-Barré syndrome are preceded by *C. jejuni* infection. Outbreaks are associated with consumption of unpasteurized dairy products and undercooked poultry. The incidence of disease peaks in summer and early fall. Diarrhea may be bloody. Fever usually is present. The diagnosis is established by isolation of the organism from stool; a special medium is required. Treatment is with erythromycin. Alternatives are ciprofloxacin and norfloxacin (emergence of resistance to fluoroquinolones has been reported). Supportive care also is needed.

- Outbreaks of bacterial diarrhea caused by *C. jejuni* are associated with consumption of unpasteurized milk and undercooked poultry.
- Approximately 10%-30% of cases of Guillain-Barré syndrome are preceded by *C. jejuni* infection.

Table 14-15 Bacterial Diarrhea: Toxigenic

Organism	Onset after ingestion, h	Preformed toxin	Fever present	Vomiting predominates
Staphylococcus aureus	2-6	Yes	No	Yes
Clostridium perfringens	8-16	No	No	No
Escherichia coli	12	No	No	No
Vibrio cholerae	12	No	Due to dehydration	No
Bacillus cereus				
a.	1-6	Yes	No	Yes
b.	8-16	No	No	No

Table 14-16 Bacterial Diarrhea: Invasive

Organism	Fever present	Bloody diarrhea present	Antibiotics effective
Shigella species	Yes	Yes	Yes
Salmonella (non-*typhi*)	Yes	No	No
Vibrio parahaemolyticus	Yes	Yes (occasional)	No
Escherichia coli O157:H7	Yes	Yes	No
Campylobacter	Yes	Yes	Yes
Yersinia	Yes	Yes (occasional)	±

In bacterial diarrhea caused by *Staphylococcus aureus*, preformed toxin is ingested in contaminated food. Onset is abrupt, with severe vomiting (often predominates), diarrhea, and abdominal cramps. The duration of infection is 8 to 24 hours. Diagnosis is based on rapid onset, absence of fever, and history. Treatment is supportive.

- Bacterial diarrhea due to *S. aureus* is caused by ingestion of preformed toxin in contaminated food.

Bacterial diarrhea caused by *Clostridium perfringens* is associated with ingestion of bacteria that produce toxin in vivo, often in improperly prepared or stored precooked foods (meat and poultry products). Food is precooked and toxin is destroyed but spores survive; when food is rewarmed, spores germinate. When food is ingested, toxin is produced. Diarrhea is worse than vomiting, and abdominal cramping is prominent. Onset of symptoms is later than with *S. aureus* infection. Duration of illness is 24 hours. The diagnosis is based on the later onset of symptoms, a typical history, and Gram staining or culture of incriminated foods. Treatment is supportive.

- In diarrhea caused by *C. perfringens*, ingested bacteria produce toxin in vivo in precooked food.
- Diarrhea is worse than vomiting; abdominal cramping is prominent.

Two types of food poisoning are associated with *Bacillus cereus* infection. Profuse vomiting follows a short incubation period (1-6 hours); this is associated with the ingestion of a preformed toxin (usually in fried rice). A disease with a longer incubation occurs 8 to 16 hours after consumption; profound diarrhea develops and usually is associated with eating meat or vegetables. The diagnosis is confirmed by isolation of the organism from contaminated food. The illness is self-limited and treatment is supportive.

Diarrhea caused by *Escherichia coli* can be either enterotoxigenic (ETEC) or enterohemorrhagic. Enterohemorrhagic *E. coli* should not be treated with antibiotics. Enterotoxigenic *E. coli* is the most common etiologic agent in traveler's diarrhea. Treatment consists of fluid and electrolyte replacement along with loperamide plus a fluoroquinolone or rifaximin. Medical evaluation should be sought if fever and bloody diarrhea occur. For prophylaxis, water, fruits, and vegetables need to be chosen carefully. Routine prophylactic use of trimethoprim-sulfamethoxazole, ciprofloxacin, and doxycycline is not recommended because the risks outweigh the benefits in most travelers. Bismuth subsalicylate reduces the incidence of enterotoxigenic *E. coli*-associated diarrhea by up to 60%.

- Enterotoxigenic *E. coli* is the most common etiologic agent in traveler's diarrhea.

E. coli O157:H7 causes a relatively uncommon form of bloody diarrhea. This agent has been identified as the cause of waterborne illness, outbreaks in nursing homes and child care centers, and sporadic cases. It also has been transmitted by eating undercooked beef and other contaminated food products. Bloody diarrhea, severe abdominal cramps, fever, and profound toxicity characterize this enterohemorrhagic illness. It may resemble ischemic colitis. At extremes of age (old and young), the infection may produce hemolytic-uremic syndrome and death. This organism should be considered in all patients with hemolytic-uremic syndrome. Antibiotics are not known to be effective and may increase the likelihood of hemolytic-uremic syndrome.

- *E. coli* O157:H7 has been identified as the cause of waterborne illness, outbreaks in nursing homes and child care centers, and sporadic cases.
- Eating undercooked beef also transmits *E. coli* O157:H7.
- Bloody diarrhea, severe abdominal cramps, and profound toxicity characterize *E. coli* O157:H7 infection; it may resemble ischemic colitis.
- Infection should be considered in all patients with hemolytic-uremic syndrome.
- Antibiotic therapy is not recommended.

Vibrio cholerae causes a toxigenic bacterial diarrheal disease in which antibiotics (tetracycline) clearly shorten the duration of disease. However, fluid replacement therapy is the mainstay of management. It is associated with consumption of undercooked shellfish.

Diarrhea caused by *Shigella* species is often acquired outside the United States. It often is spread by person-to-person transmission but also has been associated with eating contaminated food or water. Bloody diarrhea is characteristic, bacteremia may occur, and fever is present. The diagnosis is based on results of stool culture and blood culture (occasionally positive). Treatment is with ampicillin (ampicillin-resistant strains are common), trimethoprim-sulfamethoxa-

zole (in some countries, increasing resistance is being reported), norfloxacin, or ciprofloxacin. The illness may precede the onset of Reiter syndrome in persons with HLA-B2 and group B *Shigella flexneri*.

- Diarrhea caused by *Shigella* species is associated with person-to-person transmission and the consumption of contaminated food or water.
- Bloody diarrhea is characteristic, bacteremia may occur, and fever is present.
- Illness caused by *Shigella* species may precede the onset of Reiter syndrome.

Salmonella (non-*typhi*)-associated illness most commonly is caused by *Salmonella enteritidis* and *Salmonella typhimurium* in the United States. It is associated with consumption of contaminated foods or with exposure to reptiles and snakes, pet turtles, ducklings, and iguanas. *Salmonella* infection is a common cause of severe diarrhea and may cause septicemia in patients with sickle cell anemia or acquired immunodeficiency syndrome (AIDS). *Salmonella* bacteremia can lead to the seeding of abdominal aortic plaques resulting in mycotic aneurysms. In *Salmonella* enteritis, fever is usually present, and bloody diarrhea is often absent (a characteristic distinguishing it from *Shigella* infection). The diagnosis is based on stool culture. Treatment is supportive. Antibiotics only prolong the carrier state and do not affect the course of the disease. Antibiotics are used if results of blood culture are positive. Reactive arthritis may be a complication of this illness.

- *Salmonella* infection is a common cause of severe diarrhea.
- *Salmonella* infection may cause septicemia in patients with sickle cell anemia or AIDS.
- Bloody diarrhea is often absent (a feature distinguishing it from *Shigella* infection).

Vibrio parahaemolyticus infection is acquired by eating undercooked shellfish. It is a common bacterial cause of acute food-borne illness in Japan and is appearing with increasing frequency in the United States (Atlantic Gulf Coast and on cruise ships). Acute onset of explosive, watery diarrhea and fever are characteristic. The diagnosis is determined with stool culture. Antibiotic therapy is not required.

- Typical clinical scenario of *V. parahaemolyticus* infection: acute onset of watery diarrhea and fever after eating undercooked shellfish.
- Antibiotic therapy is not required.

Clinical syndromes associated with *Vibrio vulnificus* include bacteremia, gastroenteritis, and cellulitis. Most patients with bacteremia have distinctive bullous skin lesions and underlying hepatic disease (cirrhosis). The condition is associated with consumption of raw oysters. The mortality rate is high. Wound infections occur in patients who have had contact with seawater, such as with fishing injuries or contamination of a wound with seawater. Affected patients have intense pain and cellulitis in the extremities. Gastrointestinal illness is associated with consumption of raw oysters. The incubation period is approximately 18 hours. Vomiting, diarrhea, and severe abdominal cramps are features of this illness. Treatment of uncomplicated gastroenteritis is supportive. Bacteremia or cellulitis is treated with tetracycline, cefotaxime, or ciprofloxacin. *V. vulnificus* is not uniformly susceptible to the aminoglycosides.

- *V. vulnificus* bacteremia can cause distinctive bullous skin lesions and occurs in patients who are immunocompromised or have cirrhosis.
- It is associated with consumption of raw oysters or seawater contact.

Yersinia enterocolitica is the etiologic agent of several major clinical syndromes: enterocolitis, mesenteric adenitis, erythema nodosum, polyarthritis, Reiter syndrome, and bacteremia associated with contaminated blood products. Approximately 20% of infected patients have sore throat. Infection with *Y. enterocolitica* causing mesenteric adenitis can mimic acute appendicitis. Acquisition of infection is thought to be associated with eating contaminated food products. The organism has been cultured from chocolate milk, meat, mussels, poultry, oysters, and cheese.

- In adults with *Y. enterocolitica* infection, erythema nodosum, polyarthritis, and Reiter syndrome can develop.
- Infection with *Y. enterocolitica* causing mesenteric adenitis can mimic acute appendicitis.

Colitis caused by *Clostridium difficile* should be distinguished from other forms of antibiotic-associated diarrhea (watery stools, no systemic symptoms, and negative tests for *C. difficile* toxin). Symptoms often occur 2 to 4 weeks after stopping use of antibiotics. The illness is associated with antibiotic exposure in 99% of cases (any antibiotic can cause it). Nosocomial spread has been documented. Typical features are profuse, watery stools; crampy abdominal pain; constitutional illness; unexplained leukocytosis; the presence of fecal leukocytes; and a positive *C. difficile* toxin. In toxin-negative disease, proctoscopy or flexible sigmoidoscopy can be used to look for pseudomembranes. Disease can be localized to the cecum (postoperative patient with ileus) and can present as fever of unknown origin. A recent toxigenic strain associated with a binary toxin has been associated with earlier onset, marked leukocytosis, and severe disease refractory to medical therapy, often requiring colectomy. Treatment in mild-moderate disease consists of metronidazole (250-500 mg orally three or four times a day for 7-10 days) or vancomycin (125 mg orally four times a day for 7-10 days). The emergence of vancomycin-resistant enterococci and cost differences favor the use of metronidazole as a first-line agent. Antiperistalsis drugs should not be used. If a patient is unable to take drugs orally, intravenous metronidazole (not vancomycin) or vancomycin enemas can be used. Relapse is frequent (about 15% of cases) and necessitates re-treatment. Treatment of asymptomatic carriers to decrease the nosocomial spread of infection or to reduce the risk of pseudomembranous colitis is not recommended.

- Colitis caused by *C. difficile* often occurs 2-4 weeks after stopping use of antibiotics.
- Illness is associated with antibiotic exposure in 99% of cases (any antibiotic can cause it).
- Features of colitis caused by *C. difficile* are profuse, watery stools; crampy abdominal pain; constitutional illness; fecal leukocytes;

leukocytosis; and a positive *C. difficile* toxin.
- Treatment of colitis caused by *C. difficile* is with metronidazole (250-500 mg orally three or four times a day for 7-10 days) or vancomycin (125 mg orally four times a day for 7-10 days). Severe cases may require colectomy.
- Relapse is frequent (about 15% of cases).

Viral Diarrhea

Many types of viral diarrhea can be defined by their seasonal epidemiology. *Rotavirus infection* is the most common cause of sporadic mild diarrhea in children. It may be spread from children to adults. It usually occurs during the winter. Vomiting is a more common early manifestation than watery diarrhea. Hospitalization for dehydration is common in young children. Diagnosis is made by detection of antigen in stool. Treatment is symptomatic. A vaccine was available in the United States but was withdrawn from the market because of a temporal association between the use of the vaccine and the development of intussusception.

Noroviruses are a common cause of epidemic diarrhea and "winter vomiting disease" in older children and adults. They occur in families, communities, and institutions. Outbreaks have been associated with eating shellfish, undercooked fish, cake frosting, and salads, and with drinking contaminated water. They are the cause of up to 10% of gastroenteritis outbreaks. These viruses have caused community-wide outbreaks and outbreaks of gastroenteritis on cruise ships. Nausea, vomiting, and watery diarrhea characterize this illness. It is a mild, self-limited (<36 hours) illness. Currently, no commercial diagnostic test is available. Treatment is symptomatic.

- Outbreaks of norovirus are associated with eating shellfish, undercooked fish, cake frosting, and salads, and with drinking contaminated water.
- Numerous outbreaks of noroviruses have occurred on cruise ships.
- Illness is mild and self-limited (<36 hours).

Bacteremia, Sepsis, and Septic Shock

Bacteremia, or bloodstream infection in general, is defined as the presence of living bacteria or other organisms in the blood and is established by a positive blood culture or other microbiologic techniques. The systemic inflammatory response syndrome is characterized by a group of physiologic responses due to several infectious and noninfectious causes. If systemic inflammatory response syndrome is caused by an infection, then sepsis is said to be present. Some of the common manifestations of this syndrome or sepsis include tachypnea, tachycardia, irritability, lethargy, fever or hypothermia, hypoxemia, and leukocytosis. Septic shock is sepsis with hypotension (blood pressure <90 mm Hg or a reduction of 40 mm Hg from baseline) despite adequate fluid replacement.

Severe sepsis and septic shock are characterized by impaired tissue perfusion, hypotension, and multiorgan dysfunction in the setting of infection (blood cultures positive in 50%-60% of cases). Endotoxin activates endogenous mediators of inflammation with catastrophic consequences. The result can be increased vascular permeability, a decrease in peripheral vascular resistance, profound hypotension with progressive lactic acidosis, and death.

Common causative organisms of community-acquired bloodstream infections include *Escherichia coli*, *Staphylococcus aureus*, and *Streptococcus pneumoniae*. Nosocomial infections most often are due to gram-negative aerobic bacilli, coagulase-negative staphylococci, *S. aureus*, enterococci, and *Candida* spp. The frequency of any one organism depends on the host (i.e., neutropenia is associated with *Pseudomonas aeruginosa*, central lines are associated with coagulase-negative staphylococci, *S. aureus*, and *Candida* spp.). The overall mortality rate is 20% to 30%. Management involves maintaining intravascular volume, administering appropriate bactericidal antimicrobials, and correcting any problems that lead to infection (such as draining abscesses). Adjunctive corticosteroids are of no proven benefit. Recombinant human activated protein C (drotrecogin alfa) has been approved by the U.S. Food and Drug Administration for treatment of adults with septic shock.

- In septic shock, blood cultures are positive in 50%-60% of cases.
- Most frequent blood isolates: *E. coli*, *S. aureus*, *S. pneumoniae*.
- Endotoxin activates endogenous mediators of inflammation with catastrophic consequences.

Neutropenia

This condition is characterized by an absolute polymorphonuclear neutrophil value less than 0.5×10^9/L, most often in the setting of chemotherapy for malignancy. Bacteremia is documented in approximately 20% of neutropenic fever episodes. If ecthyma gangrenosum is present, *Pseudomonas* infection should be considered. Other gram-negative aerobic rods (such as *Escherichia coli*) also cause bacteremia. The frequency of bacteremia due to aerobic gram-positive organisms is increasing. Bloodstream infection with these organisms (*Staphylococcus aureus*, coagulase-negative staphylococci, enterococci, viridans streptococci, and *Corynebacterium jeikeium*) often is associated with central venous catheters or quinolone antibacterial prophylaxis. *Candida* species should be considered in cases associated with nodular skin lesions, fluffy white chorioretinal exudates, and fever unresponsive to empiric antibacterial agents. Anaerobic organisms are uncommon, except in cases of perirectal abscess and gingivitis. Empiric antimicrobial therapy after an attempt to identify the source of the infection is required for fever of 38.3°C or higher. Monotherapy with ceftazidime, cefepime, or imipenem alone is the preferred initial empiric antibacterial regimen. Alternative therapy with antipseudomonal penicillin plus an aminoglycoside is also acceptable. Vancomycin can be added to the initial regimen if there is severe mucositis, quinolone prophylaxis has been utilized, the patient is known to be colonized with methicillin-resistant *S. aureus* or penicillin-resistant *Streptococcus pneumoniae*, an obvious catheter-related infection is present, or the patient is hypotensive. If subsequent cultures show the presence of aerobic gram-positive organisms, vancomycin therapy can be continued. If there is no response after 5 to 7 days of treatment and the patient remains neutropenic, empiric therapy with an antifungal agent such as amphotericin, voriconazole, or caspofungin should be considered.

Urinary Tract Infection

Females

Because urethritis or cystitis can occur with low colony counts of bacteria (10^3 colony-forming units), routine urine cultures in young women with dysuria are not recommended. Urinalysis should be done with or without a Gram stain. If pyuria and uncomplicated urinary tract infection (UTI) are present, short-course treatment (3 days) should be initiated. Only if occult upper urinary tract disease, a complicated UTI, or sexually transmitted disease is suspected should appropriate culture and sensitivity testing be performed. Risk factors for occult infection and complications include emergency department presentation, low socioeconomic status, hospital-acquired infection, pregnancy, use of Foley catheter, recent instrumentation, known urologic abnormality, previous relapse, UTI at age less than 12 years, acute pyelonephritis or three or more UTIs in 1 year, symptoms for more than 7 days, recent antibiotic use, diabetes mellitus, and immunosuppression. Causative organisms include *Escherichia coli* and *Staphylococcus saprophyticus* (susceptible to ampicillin and trimethoprim-sulfamethoxazole), *Proteus mirabilis*, or *Klebsiella pneumoniae*. *S. saprophyticus* may be reported on urine culture as "coagulase-negative staphylococcus."

- Routine urine cultures are not recommended in young women with dysuria.
- Associated organisms of UTI include: *E. coli*, *S. saprophyticus* (susceptible to ampicillin and trimethoprim-sulfamethoxazole), *P. mirabilis*, or *K. pneumoniae*.

For the first episode of cystitis or urethritis, treatment is given but no investigation is needed. Trimethoprim-sulfamethoxazole or an oral fluoroquinolone is more effective than ampicillin or other β-lactams. Short-course treatment (single-dose) has fewer side effects than standard (7-10 days) therapy, but the risk of relapse (due to retention of viable organisms in the vaginal or perivaginal area) is higher. Three-day therapy may be associated with relapse rates equal to those with treatment for 7 to 10 days and with less toxicity. In patients who fail to improve within 48 hours of treatment with trimethoprim or trimethoprim-sulfamethoxazole, drug resistance should be suspected and an oral fluoroquinolone should be considered. Rates of trimethoprim-sulfamethoxazole resistance may approach 20% in some communities. If recurrence develops after 3-day therapy, subclinical pyelonephritis or resistance should be considered and treatment is then given for 14 days. Urologic evaluation is usually not necessary. It should be performed in patients with multiple relapses, painless hematuria, a history of childhood UTI, renal lithiasis, and recurrent pyelonephritis.

- For first episode of cystitis or urethritis, trimethoprim-sulfamethoxazole or an oral fluoroquinolone is more effective than ampicillin.
- Short-course treatment (3 days) has fewer side effects than standard (7-10 days) therapy, and risk of relapse of infection may be the same.
- Urologic evaluation should be pursued in patients with multiple relapses, painless hematuria, history of childhood UTI, renal lithiasis, and recurrent pyelonephritis.

For acute pyelonephritis, 2 weeks of therapy is equal in efficacy to 6 weeks of therapy. Recent data suggest that 1 week of treatment with a fluoroquinolone may be sufficient for uncomplicated pyelonephritis due to susceptible organisms in women. Most patients are sufficiently ill to require hospitalization. Many are bacteremic. Unless gram-positive cocci are seen on Gram stain (suggesting enterococci), a third-generation cephalosporin, trimethoprim-sulfamethoxazole, or a fluoroquinolone can be used as empiric therapy. If enterococci are suspected, ampicillin or piperacillin with or without gentamicin should be used. Enterococci are resistant to cephalosporins. Enterococci appear susceptible to trimethoprim-sulfamethoxazole in vitro (and may be reported as such on a susceptibility report), but trimethoprim-sulfamethoxazole fails in the therapy of enterococcal infections because the organism is able to circumvent the block of folate synthesis by using exogenous folinic acid, dihydrofolate, and tetrahydrofolate from the in vivo environment. Oral regimens can be substituted quickly as the patient improves. A urine culture is recommended 1 to 2 weeks after completion of therapy only in pregnant women, children, and patients with recurrent pyelonephritis in whom suppressive therapy is being considered. If relapse occurs, treatment is given for 6 weeks and a urologic evaluation is done. For recurrent lower UTI (more than two episodes per year), single-dose therapy, 3-day therapy, or 6-week therapy is used. For treatment failure, chronic suppressive therapy may be used; however, the risk of resistant organisms must be weighed. Asymptomatic bacteriuria (>10^5 colony-forming units/mL) in a midstream urine specimen should be treated only in pregnant women, patients undergoing urinary tract instrumentation, and renal transplant recipients.

- For acute pyelonephritis, 2 weeks of therapy is equal in efficacy to 6 weeks of therapy.
- A follow-up urine culture is not usually recommended.
- Cephalosporins and trimethoprim-sulfamethoxazole should not be used to treat enterococcal UTI.

Males

UTI is less common in males than females. Urologic abnormalities (such as benign prostatic hyperplasia) are common. Symptoms are unreliable for localization. Physical examination should include prostate examination, retraction of the foreskin to look for discharge, and palpation of the testicles and epididymis. When a UTI is suspected, urine culture and sensitivity testing should always be done. Causative organisms include *E. coli* in 50% of cases, other gram-negative organisms in 25%, enterococci in 20%, and others in 5%. If signs and symptoms of epididymitis, acute prostatitis, and pyelonephritis are present, treat accordingly. If uncomplicated lower UTI is present, treatment duration is 10 to 14 days. If symptoms persist or relapse, the urine culture should be repeated. If results are positive, treat for a minimum of 6 weeks. If culture results are negative, consider further evaluation for one of the chronic prostatitis/chronic pelvic pain syndromes.

- Causes of UTI in males include *E. coli* in 50%, other gram-negative organisms in 25%, enterococci in 20%, and others in 5%.
- Men with UTI should *not* receive short-course therapy.

Soft Tissue Infection

Cellulitis is a skin infection that involves the dermis and subcutaneous fat. The most common causes are β-hemolytic streptococci and *Staphylococcus aureus*. Community-acquired methicillin-resistant *S. aureus* infections are an emerging problem. These infections are typically resistant to β-lactams and erythromycin but are susceptible to trimethoprim-sulfamethoxazole, rifampin, and sometimes clindamycin. These isolates have a different genetic mechanism of resistance (staphylococcal chromosomal cassette 4) from hospital-acquired methicillin-resistant *S. aureus*. Many of the community-acquired methicillin-resistant *S. aureus* isolates contain the Panton-Valentine leukocidin gene, which is associated with significant local toxicity. The optimal management of these community-acquired methicillin-resistant *S. aureus* infections is not yet clear but agents such as dicloxacillin or cephalosporins are associated with clinical failure and should not be used. Abscesses, boils, or furuncles should be incised, drained, and sent for culture. Currently, combinations of trimethoprim-sulfamethoxazole or clindamycin with rifampin are recommended for outpatient therapy. Inpatients may be treated with these parenterally or with therapies including vancomycin or linezolid.

Patients with lymphedema, patients who have had saphenous vein harvesting for coronary artery bypass grafting, or patients who have tinea pedis are predisposed to cellulitis, often due to streptococci. Treatment is typically with an antistaphylococcal penicillin or first-generation cephalosporin. Unusual causes of soft tissue infection are *Eikenella corrodens* and oral anaerobes after human bites, *Pasteurella multocida* and *Capnocytophaga canimorsus* after animal bites, *Aeromonas hydrophila* after freshwater exposure or exposure to leeches, *Vibrio vulnificus* after saltwater exposure, *Erysipelothrix rhusiopathiae* and *Streptococcus iniae* after fish exposure, and *Pseudomonas aeruginosa* after hot tub exposure.

Bone and Joint Infections

Acute Bacterial Arthritis (Nongonococcal)

This is most commonly due to hematogenous spread of bacteria. The hip and knee joints are commonly involved. Bacteria involved are gram-positive aerobic cocci (about 75% of cases): *Staphylococcus aureus* (most common) and β-hemolytic streptococci. Gram-negative aerobic bacilli also can cause infection (about 20% of cases); *Pseudomonas aeruginosa* is a common cause in injection drug users. Anaerobes, fungi, and mycobacteria are unusual. Clinical features include involvement usually of monarticular, large joints. Fever, pain, swelling, and restriction of motion are the most frequent signs and symptoms. The synovial fluid is usually turbid, and the leukocyte count generally exceeds 40 × 10^9/L (=75% polymorphonuclear neutrophils). The condition may overlap and be confused with other inflammatory arthropathies. Gram stain is 50% to 95% sensitive. Culture results are positive unless antibiotics have been used previously or the pathogen is unusual. Blood culture results are often positive. Radiographs are not helpful in routine cases because destructive changes have not had time to occur. Specific antimicrobial therapy is based on results of Gram stain, culture, and sensitivity testing. The duration of therapy is dependent on individual circumstances, such as the presence of complicating osteomyelitis. Usually, treatment is given for 2 to 4 weeks. Empiric therapy should include agents directed against *S. aureus* and gram-negative bacilli. Drainage is essential. Percutaneous, arthroscopic, or open procedures are used. Hip, shoulder, and sternoclavicular joint involvement, development of loculations, and persistently positive culture results (not due to resistant organisms) are the usual indications for arthroscopy or open debridement.

- Acute bacterial arthritis (nongonococcal) is most commonly due to hematogenous spread of bacteria.
- Bacteria most commonly involved are gram-positive aerobic cocci (about 75% of cases): *S. aureus* is most common.
- Monarticular, large joints usually are involved.
- Fever, pain, swelling, and restriction of motion are frequent.
- Synovial fluid is turbid; leukocyte count generally exceeds 40 × 10^9/L.
- Blood culture results are often positive.
- Drainage is essential.

Viral Arthritis

This is usually transient, self-limited polyarthritis. It may be caused by rubella (also may occur after vaccination), hepatitis B, mumps, coxsackievirus, adenovirus, parvovirus B19, and HIV, among others.

Chronic Monarticular Arthritis

Organisms involved include Mycobacteria (*Mycobacterium tuberculosis* is more common than *Mycobacterium avium-intracellulare*, *Mycobacterium kansasii*, *Mycobacterium marinum*), fungi (*Coccidioides immitis* and *Sporothrix schenckii* are more common than *Histoplasma capsulatum*, *Blastomyces dermatitidis*–acute, and *Candida* spp.–acute), and others (*Brucella*, *Nocardia*).

- *M. tuberculosis*, *C. immitis*, and *S. schenckii* often are involved in chronic monarticular arthritis.

Osteomyelitis

Acute *hematogenous osteomyelitis* is more common in infants and children than in adults. The metaphysis of long bones (femur, tibia) most commonly is affected. *S. aureus* is the most common organism. Acute onset of pain and fever are typical features. The illness can present with pain only. Compatible radiographic changes and bone biopsy for culture and pathologic examination are used to establish the diagnosis. Results of blood culture may be positive. Specific parenteral antibiotic therapy is used for 3 to 6 weeks on the basis of culture and sensitivity test results. Debridement is usually not necessary unless a sequestrum is present.

- *S. aureus* is the most common organism in acute hematogenous osteomyelitis.
- Acute onset of pain and fever are typical features.

Chronic osteomyelitis is more common in adults. It results from direct inoculation caused by trauma or adjacent soft tissue infection, for

example. Open fractures and diabetic foot ulcers are common predisposing factors. *S. aureus* is the most common organism. Coagulase-negative staphylococci are often pathogens if a foreign body (such as plate, screws) is present. Often, osteomyelitis complicating a foot ulcer is polymicrobial, including aerobic gram-positive and gram-negative organisms and anaerobes. Local pain, tenderness, erythema, and draining sinuses are common. Fever is atypical unless there is concurrent cellulitis. The condition can present with pain only. Compatible radiographic changes (often vague) and bone biopsy for culture and pathologic examination are used to establish the diagnosis. Results of blood culture are rarely positive. Adequate debridement, removal of dead space, soft tissue coverage, and fixation of infected fractures are essential. Specific parenteral antibiotic therapy is given for 4 to 6 weeks on the basis of culture and sensitivity test results.

- *S. aureus* is the most common organism in chronic osteomyelitis.
- Coagulase-negative staphylococci are common pathogens if a foreign body is present.
- Local pain, tenderness, erythema, and draining sinuses are common.
- Specific parenteral antibiotic therapy is given for 4-6 weeks.

Vertebral Osteomyelitis

This condition often results from hematogenous dissemination from a focal source of infection (such as urinary tract, pneumonia). *S. aureus* and gram-negative bacilli are the major pathogens. Only 10% of cases have positive results of blood culture. Symptoms include pain and local tenderness. Fever may be present. The leukocyte count may be normal or increased. The sedimentation rate often is increased. Plain radiographs do not show destruction early in the course of disease. Gallium scanning is approximately 80% sensitive. Magnetic resonance imaging is the diagnostic test of choice because it is sensitive and specific and shows anatomical detail (coexistent epidural abscess). Percutaneous needle biopsy (computed tomography-guided) or open biopsy of bone or disk tissue is usually needed to define the microbiology of the infection. Treatment includes appropriate parenteral antimicrobial therapy for 4 to 6 weeks. Drainage may be necessary if a concomitant epidural abscess is present.

- In vertebral osteomyelitis, *S. aureus* and gram-negative bacilli are major pathogens.
- Gallium scanning is about 80% sensitive; magnetic resonance imaging is the diagnostic test of choice.

Sinusitis in Adults

The physician's overall impression as to the presence or absence of sinusitis is the best clinical predictor of sinusitis. Independent clinical predictors of disease are maxillary toothache, poor transillumination, poor response to decongestants, and a history or examination finding of purulent discharge. Limited computed tomography scanning of the sinuses is the radiographic method of choice. Organisms that are usually involved are *Haemophilus influenzae*, *Streptococcus pneumoniae*, and oral anaerobes. Treatment is with oral trimethoprim-sulfamethoxazole, amoxicillin, amoxicillin-clavulanate, and levofloxacin, among other options.

- Organisms involved in sinusitis in adults are *H. influenzae*, *S. pneumoniae*, and oral anaerobes.

Hepatic (Bacterial) Abscess

Mechanisms of bacterial abscess include portal vein bacteremia resulting from, for example, appendicitis and diverticulitis, bacteremia caused by a primary focus elsewhere in the body, ascending cholangitis, direct extension (subphrenic abscess), or trauma. Fever is common. Right upper quadrant pain, tenderness on percussion, and increased values on liver function tests may or may not be present. Computed tomography and ultrasonography are helpful in diagnosis. Bacteriology depends on the mechanism of abscess formation. Infection is often polymicrobial and is due to aerobic gram-negative rods, anaerobic streptococci, and *Bacteroides* species. Blood cultures should be obtained, and empiric therapy should be initiated pending drainage. Drainage of the abscess usually can be performed percutaneously, and material is obtained for Gram stain, culture, and susceptibility testing. Empiric options include ampicillin plus gentamicin, a fluoroquinolone plus metronidazole, or a third-generation cephalosporin plus metronidazole, a β-lactam/β-lactamase inhibitor combination, or a carbapenem. If hematogenous route is suspected, an agent that is active against staphylococci should be used in the regimen.

Toxic Shock Syndrome

This syndrome is caused by the establishment or growth of a toxin-producing strain of *Staphylococcus aureus* in a nonimmune person. Clinical scenarios associated with this syndrome include young menstruating women with prolonged, continuous use of tampons, postoperative and nonoperative wound infections, localized abscesses, and *S. aureus* pneumonia developing after influenza. It is a multisystem disease. Clinical criteria include fever, hypotension, erythroderma (often leads to desquamation, particularly on palms and soles), and involvement in three or more organ systems. Onset is acute; blood culture results are usually negative. The condition is caused by production of staphylococcal toxin (TSST-1). Treatment is supportive; subsequent episodes are treated with a β-lactam antibiotic, which decreases the frequency and severity of subsequent attacks. The relapse rate may be as high as 30% to 40% (menstruation-related disease). The mortality rate is 5% to 10%.

- Toxic shock syndrome is caused by a toxin-producing strain of *S. aureus* in a nonimmune person.
- Toxic shock syndrome is a multisystem disease: fever, hypotension, erythroderma (often leads to desquamation, particularly on palms and soles).
- Onset is acute; results of blood culture are usually negative.
- Toxic shock syndrome is caused by production of staphylococcal toxin (TSST-1).

Streptococcal Toxic Shock Syndrome

This syndrome is similar to staphylococcal toxic shock syndrome. Patients have invasive group A streptococcal infections with associated hypotension and two of the following: renal impairment, coagulopathy, liver impairment, adult respiratory distress syndrome, rash (may desquamate), or soft tissue necrosis. Symptoms are caused by production of streptococcal toxin (pyrogenic exotoxin A). Most patients have skin or soft tissue infection, are younger than 50 years, and are otherwise healthy compared with patients with invasive group A streptococcal infections without the toxic streptococcal syndrome. Most patients are bacteremic (different from toxic shock syndrome due to *Staphylococcus aureus*). Treatment includes early aggressive antiobiotic therapy, supportive care, and surgical debridement if needed. The case-fatality rate is 30%. Although there is no reported resistance to penicillin, clindamycin plus high-dose penicillin G is the preferred regimen because clindamycin may suppress exotoxin and M-protein production in addition to its activity against group A streptococci. In severe cases, consideration should be made for the use of early intravenous immunoglobulin therapy.

- Symptoms of toxic streptococcal syndrome are caused by production of streptococcal toxin.
- Most patients are bacteremic (different from toxic shock syndrome due to *S. aureus*).
- Clindamycin plus high-dose penicillin G is the preferred antibiotic regimen.

Infections in Solid Organ Transplantation and Immunodeficiency States

The spectrum of potential pathogens in patients after solid organ transplantation is diverse. The individual risk of specific infection can be classified according to the following: symptoms and signs of illness at presentation (i.e., meningitis vs. pneumonia), post-transplantation time course, serologic status of recipient and donor for certain infections (such as cytomegalovirus, toxoplasmosis), type of organ transplantation, type and duration of immunosuppression, type of antimicrobial prophylaxis patient has received, and travel history and previous exposure to pathogens (such as tuberculosis, coccidioidomycosis). The majority of infections in the first month after transplantation are not opportunistic infections but instead are common nosocomial infections such as wound infections, UTIs, and line infections. Cytomegalovirus is an important pathogen in patients who have had transplantation. Presentations can include febrile illness with viremia, hepatitis, colitis, gastritis, retinitis, myocarditis, and pneumonitis. Cytomegalovirus-seronegative recipients of organs from a seropositive donor are at highest risk for cytomegalovirus disease. The time of occurrence of opportunistic infections after solid organ transplantation is given in Table 14-17. Pathogens associated with various immunodeficiency states are shown in Table 14-18.

- The majority of infections in the first month after transplantation are not opportunistic infections but instead are common nosocomial infections such as wound infections, UTIs, and line infections.
- Cytomegalovirus is an important pathogen in patients who have had transplantation. Presentations can include febrile illness with viremia, hepatitis, colitis, gastritis, retinitis, myocarditis, and pneumonitis. Cytomegalovirus-seronegative recipients of organs from a seropositive donor are at highest risk for cytomegalovirus disease.

Bioterrorism

After the September 11, 2001, terrorist attacks and the subsequent deaths from anthrax sent in the mail, it is imperative for physicians to be familiar with likely bioterrorism agents. The Centers for Disease Control and Prevention classified the following diseases as category A, high-priority diseases that pose a risk to national security: smallpox, anthrax, botulism, plague, tularemia, and viral hemorrhagic fevers.

The incubation period, lethality, chemotherapy, and chemoprophylaxis for each agent are described in Table 14-19. These agents cause high mortality rates, can be easily disseminated or transmitted from person to person, and have the potential to have a major public health impact.

Severe Acute Respiratory Syndrome

Severe acute respiratory syndrome (SARS) is a rapidly progressive pneumonia that first developed in the Guangdong province of southern China in November 2002. The number of worldwide cases topped 8,000 by July 2003. The infection is caused by a novel coronavirus named SARS-associated coronavirus (SARS-CoV). Symptoms include fever often associated with myalgia, headache, dry cough, and dyspnea. The infection can progress to respiratory failure and death; the case fatality ratio is almost 10%.

The infection is suspected in a patient who has documented fever (>38°C) and lower respiratory tract symptoms and has had contact with a person believed to have had SARS or a history of travel to an area of documented transmission. Serum antibody tests and reverse-transcription polymerase chain reaction tests have been developed. The infection is highly contagious, and health

Table 14-17 Opportunistic Infections in Solid Organ Transplantation

Month	Type of infection after transplantation
1	Bacterial infections (related to wound, intravenous lines, urinary tract), herpes simplex virus, hepatitis B
1-4	Cytomegalovirus, *Pneumocystis carinii*, *Listeria monocytogenes*, *Mycobacterium tuberculosis*, *Aspergillus*, *Nocardia*, *Toxoplasma*, hepatitis B, *Legionella*
2-6	Epstein-Barr virus, varicella-zoster virus, hepatitis C, *Legionella*
>6	*Cryptococcus neoformans*, *Legionella*

care workers are particularly at risk of exposure. Infected patients must be isolated. Infection control precautions for hospitalized patients include standard precautions of good hand hygiene together with airborne isolation and the use of gowns, gloves, and eye protection. No specific treatment recommendations are available.

- SARS is a highly contagious, rapidly progressive respiratory infection caused by a novel coronavirus, SARS-associated coronavirus (SARS-CoV).
- No specific treatment is recommended, although infection control precautions need to be observed to minimize transmission.

Table 14-18 Pathogens Associated With Immunodeficiency

Immunodeficiency	Usual conditions	Pathogens
Neutropenia (<0.5 × 10^9/L)	Cancer chemotherapy, adverse drug reaction, leukemia	**Bacteria**: Aerobic gram-negative bacilli (coliforms and pseudomonads, *Staphylococcus aureus*, *Viridans streptococci*, *Staphylococcus epidermidis*) **Fungi**: *Aspergillus*, *Candida* spp.
Cell-mediated immunity	Organ transplantation, human immunodeficiency virus infection, lymphoma (especially Hodgkin disease), corticosteroid therapy	**Bacteria**: *Listeria*, *Salmonella*, *Nocardia*, *Mycobacteria* (*M. tuberculosis* and *M. avium*), *Legionella* **Viruses**: CMV, *Herpes simplex*, varicella-zoster, JC virus **Parasites**: *Pneumocystis carinii*, *Toxoplasma*, *Strongyloides stercoralis*, *Cryptosporidium* **Fungi**: *Candida*, *Cryptococcus*, *Histoplasma*, *Coccidioides*
Hypogammaglobulinemia or dysgammaglobulinemia	Multiple myeloma, congenital or acquired deficiency, chronic lymphocytic leukemia	**Bacteria**: *Streptococcus pneumoniae*, *Haemophilus influenzae* (type B) **Parasites**: *Giardia* **Viruses**: Enteroviruses
Complement deficiencies C2, 3 C5 C6-8 Alternative pathway	Congenital	**Bacteria**: *S. pneumoniae*, *H. influenzae*, *S. aureus*, Enterobacteriaceae *Neisseria meningitidis*, *S. pneumoniae*, *H. influenzae*, *Salmonella*
Hyposplenism	Splenectomy, hemolytic anemia	*S. pneumoniae*, *H. influenzae*, DF-2
Defective chemotaxis	Diabetes, alcoholism, renal failure, lazy leukocyte syndrome, trauma, SLE	*S. aureus*, streptococci, *Candida*
Defective neutrophilic killing	Chronic granulomatous disease, myeloperoxidase deficiency	Catalase-positive bacteria: *S. aureus*, *Escherichia coli*, *Candida* spp.

CMV, cytomegalovirus; SLE, systemic lupus erythematosus.

Table 14-19 Treatment for Infections Potentially Caused by Bioterrorism

Variable	Disease					
	Smallpox (variola major)	Anthrax (*Bacillus anthracis*)	Botulism toxin (*Clostridium botulinum*)	Plague (*Yersinia pestis*)	Tularemia (*Francisella tularensis*)	Viral hemorrhagic fevers
Incubation period, days	7-17	1-14 (cutaneous); 1-42* (inhalational)	1-5	2-3	1-21	2-21
Lethality	High to moderate	Very high	High without respiratory support	High without treatment	Moderate if untreated	Variable
Chemotherapy†	Cidofovir (in vitro)	Cutaneous: Ciprofloxacin 500 mg PO every 12 h *or* Doxycycline 100 mg PO every 12 h Duration: 60 days Inhalational: Ciprofloxacin 500 mg IV every 12 h *or* Doxycycline 100 mg IV every 12 h *Plus* 1 or 2 antimicrobials with demonstrated susceptibility Duration: 60 days	CDC bivalent equine antitoxin for serotypes A, B (licensed) and monovalent for serotype E (investigational)	Streptomycin 1 g IM twice daily *or* gentamicin 5 mg/kg IV once daily *or* ciprofloxacin 400 mg IV every 12 h or 750 mg PO twice daily *or* chloramphenicol 25 mg/kg IV four times daily *or* doxycycline 100 mg IV twice daily Duration: 10 days	Streptomycin 1 g IM twice daily *or* gentamicin 5 mg/kg a day IV *or* ciprofloxacin 400 mg IV twice daily Duration: 10 days Doxycycline 100 mg IV twice daily *or* chloramphenicol 15 mg/kg IV four times daily Duration: 14-21 days	Supportive care. Ribavirin (arena viruses or bunyaviruses) 30 mg/kg IV initial dose, then 16 mg/kg every 6 h × 4 days, then 8 mg/kg every 8 h for 6 days. Passive antibody for AHF, BHF, Lassa fever, and CCHF
Chemoprophylaxis	Vaccinia immune globulin 0.6 mL/kg IM (within 3 d of exposure)	Ciprofloxacin 500 mg PO twice daily *or* Doxycycline 100 mg PO twice daily Duration: 60 days‡	NA	Doxycycline 100 mg PO twice daily *or* Ciprofloxacin 500 mg PO twice daily *or* Chloramphenicol 25 mg/kg PO four times daily Duration: 7 days	Doxycycline 100 mg PO twice daily *or* Ciprofloxacin 500 mg PO twice daily Duration: 14 days	NA
Vaccine	Calf lymph vaccina vaccine: 1 dose by scarification	Anthrax vaccine: 0.5 mL SC at 0, 2, 4 wk, 6, 12, 18 mo, with annual boosters	DOD pentavalent toxoid for serotypes A-E (IND): 0.5 mL deep SC at 0, 2, 12 wk, then annual booster	Greer inactivated vaccine (FDA licensed). Not effective for aerosol exposure. No longer available	Live attenuated vaccine (IND). Recommended for laboratory personnel, not for postexposure prophylaxis	AHF candidate #1 vaccine (cross-protection for BHF) (IND). RVF inactivated vaccine (IND)

Table 14-19 (continued)

Variable	Disease					
	Smallpox (variola major)	Anthrax (*Bacillus anthracis*)	Botulism toxin (*Clostridium botulinum*)	Plague (*Yersinia pestis*)	Tularemia (*Francisella tularensis*)	Viral hemorrhagic fevers
Specimen[§]						
Postexposure (0-24 h)	Nasal swab, sputum, induced sputum for culture and PCR	Nasal swab, sputum, induced sputum for culture, FA, and PCR	Nasal swabs, respiratory secretions for PCR and toxin assays. Serum for toxin assays	Nasal swab, sputum, induced sputum for culture, FA, and PCR	Nasal swab, sputum, induced sputum for culture, FA, and PCR	Nasal swabs and induced respiratory secretions for RT-PCR and viral culture
Clinical illness and convalescence	Serum for viral culture. Drainage from skin lesions, scrapings, tissue for microscopy, EM, viral culture, PCR	Blood for culture and PCR. CSF for Gram stain, culture, and PCR. Tissue for Gram stain, culture, IHC, and PCR. Acute and convalescent sera for toxin and antibody studies	Nasal swabs, respiratory secretion for PCR and toxin assays. Usually no IgM or IgG	Blood, sputum, and tissue for Gram stain, culture, FA, F-1 antigen assays, IHC, and PCR. Acute and convalescent sera for antibody assays	Blood for culture and PCR. Sputum and tissue for Gram stain, culture, FA, IHC, and PCR. Acute and convalescent sera for antibody assays	Serum for viral culture, acute and convalescent antibody assays. Tissue for microscopy, EM, IHC, PCR

AHF, Argentine hemorrhagic fever (Junin virus); BHF, Bolivian hemorrhagic fever; CCHF, Congo-Crimean hemorrhagic fever; CDC, Centers for Disease Control and Prevention; CSF, cerebrospinal fluid; DOD, U.S. Department of Defense; EM, electron microscopy; FA, fluorescent antibody; FDA, U.S. Food and Drug Administration; IgG, immunoglobulin G; IgM, immunoglobulin M; IHC, immunohistochemistry; IM, intramuscularly; IND, investigational drug; IV, intravenously; NA, not applicable; PO, orally; PCR, polymerase chain reaction; RT-PCR, reverse transcription-polymerase chain reaction; RVF, Rift Valley fever; SC, subcutaneously.

[*]A human case of inhalational anthrax developed at 42 days after exposure to the accidental release of *B anthracis* in Sverdlosk, Russia. This long incubation period may have been due, in part, to the use of postexposure prophylaxis in that setting or to inaccuracies in information regarding the date of the release (or if there was more than one). The incubation period for inhalational cases acquired outside this setting (millworkers and others) ranges from 1 to 7 days.

[†]Dosages are for adult patients only. See agent-specific recommendations for children and immunocompromised populations.

[‡]Increased duration because of possibility of concomitant aerosol exposure.

[§]Should be obtained only in coordination with infection control, public health, and Laboratory Response Network.

Antimicrobials

The mechanisms of action, spectrum of activity, clinical uses, route of excretion, and toxic effects of various antimicrobial agents are emphasized. Some of this information is given in Tables 14-20 through 14-31.

Specific Antibacterial Agents

Penicillins

Natural Penicillins

Agents include penicillin G (intravenous, IV), penicillin V (oral), procaine penicillin (intramuscular, IM), and benzathine penicillin (IM, repository formulation).

Their **spectrum of activity** includes non–penicillinase-producing staphylococci (rare), β-hemolytic streptococci (group A, B, C, G), susceptible viridans streptococci, group D streptococci, penicillin-susceptible *Streptococcus pneumoniae* (incidence of penicillin resistance is increasing), most *Neisseria meningitidis* organisms, non–penicillinase-producing *Neisseria gonorrhoeae*, and susceptible anaerobes (*Clostridium* species, most oral *Bacteroides* and *Fusobacterium* species, and *Peptostreptococcus*). Susceptible enterococci are inhibited but not killed by the natural penicillins. Other microbes that these agents are active against include Erysipelothrix, *Listeria monocytogenes*, *Pasteurella multocida*, *Streptobacillus*, *Spirillum*, *Treponema pallidum*, *Borrelia burgdorferi*, and *Actinomyces israelii*. Most staphylococci and gram-negative organisms produce β-lactamase that inactivates the natural penicillins.

Pharmacokinetics: These agents have short half-lives necessitating frequent administration or continuous infusions (except long-acting IM formulations such as benzathine and procaine penicillin). They are renally eliminated and require dosage adjustment with renal dysfunction. IV penicillin penetrates the central nervous system when inflammation is present. Oral penicillin V is preferred to penicillin G because it is more acid-stable and attains higher systemic concentrations (but considerably lower than with IV penicillin).

Clinical uses of the natural penicillins include treatment of infections caused by group A streptococci, including streptococcal pharyngitis and skin or soft tissue infections (when staphylococci are not suspected). Additionally, these agents can be used to treat susceptible *S. pneumoniae* infections (e.g., respiratory tract infections) and susceptible enterococcal infections, often with an aminoglycoside if bactericidal activity is needed. Penicillin (benzathine or IV) is the drug of choice for all stages of syphilis. Less common uses of natural penicillins include treatment of Lyme disease (*Borrelia*) and IV penicillin for treatment of meningitis caused by *N. meningitidis*, susceptible *S. pneumoniae*, and *Listeria*. Table 14-22 lists the pathogens for which a penicillin is the drug of choice.

- Natural penicillins are effective treatment of infections caused by susceptible *S. pneumoniae*, group A streptococci, and susceptible *Enterococcus*.

Aminopenicillins

Agents are ampicillin (IV and oral) and amoxicillin (oral). The advantages of amoxicillin over oral ampicillin are increased gastrointestinal absorption, decreased incidence of diarrhea, and dosing three times a day instead of four.

Their **spectrum of activity** extends the antibacterial spectrum of the natural penicillins to include certain strains of *Escherichia coli*, *Proteus mirabilis*, *Salmonella*, *Shigella* (amoxicillin less active than ampicillin), β-lactamase–negative *Haemophilus influenzae* (60%-70%), and β-lactamase–negative *Moraxella catarrhalis* (<20%). Production of β-lactamase by the organism or alterations in binding to the penicillin-binding proteins has resulted in increasing resistance by some of these organisms.

Pharmacokinetics properties are similar to those of natural penicillins. These agents have short half-lives and are renally excreted.

Clinical uses of aminopenicillins include otitis media caused by *S. pneumoniae* or β-lactamase–negative *Haemophilus*, infections caused by susceptible enterococci, endocarditis prophylaxis for gastrointestinal or genitourinary procedures, and *Listeria* meningitis (IV ampicillin). Aminopenicillins also can be used to treat susceptible *E. coli* infections. However, resistance to this organism has increased to the extent that these agents are no longer empiric drugs of choice for the treatment of urinary tract infections.

- Aminopenicillins are front-line agents for treatment of otitis media, susceptible enterococcal infections, and *Listeria* meningitis.

Penicillinase-Resistant Penicillins

Agents include methicillin (IV), oxacillin (IV), nafcillin (IV), dicloxacillin (oral), and cloxacillin (oral).

The **spectrum of activity** is narrow and includes methicillin-susceptible *Staphylococcus aureus* and group A streptococci. Penicillinase-resistant penicillins have no gram-negative, enterococcal, or anaerobic activity.

The **pharmacokinetic properties** of these penicillins differ from the others in that they are the only penicillins that are not cleared renally. The penicillinase-resistant penicillins have hepatobiliary elimination and do not require dosage adjustment for renal function. Similar to the natural penicillins, they have short half-lives and require frequent administration or continuous infusions. The IV agents penetrate the central nervous system in the presence of inflammation.

Clinical uses include treatment of skin or soft tissue infections because of good activity for group A streptococci and methicillin-susceptible staphylococci. In addition, these are the drugs of choice for treatment of serious infections (e.g., bacteremia, endocarditis)

caused by methicillin-susceptible staphylococci. They are more active than vancomycin in this setting.

- Penicillinase-resistant penicillins primarily are used for treatment of infections caused by group A streptococci and methicillin-susceptible *S. aureus*. Thus, they are useful agents for skin or soft tissue infections caused by these organisms and also are used for treatment of serious methicillin-susceptible staphylococcal infections (e.g., endocarditis).

Table 14-20 Routes of Excretion of Antimicrobial Agents

Antimicrobial	Major route of excretion
Abacavir	Liver
Acyclovir, valacyclovir, famciclovir	Renal
Amantadine	Renal
Aminoglycosides	Renal
Azithromycin	Liver
Aztreonam	Renal
Carbapenems (imipenem, meropenem, ertapenem)	Renal
Caspofungin, micafungin	Liver
Cephalosporins*	Renal
Chloramphenicol	Liver
Clarithromycin	Liver/renal
Clindamycin	Liver
Cotrimoxazole (sulfamethoxazole-trimethoprim)	Renal
Cytomegalovirus agents: foscarnet, ganciclovir, valganciclovir, cidofovir	Renal
Doxycycline	Liver/intestine
Erythromycin, dirithromycin	Liver
Fluconazole	Renal
Flucytosine	Renal
Fluoroquinolones†	Renal
Itraconazole, ketoconazole, voriconazole	Liver
Linezolid	Liver
Metronidazole	Liver
Oseltamivir	Liver
Penicillins‡	Renal
Quinupristin/dalfopristin (Synercid)	Liver
Rifamycins (rifampin, rifabutin, rifapentine)	Liver
Rimantadine	Liver
Tetracycline	Renal
Tigecycline	Biliary
Vancomycin	Renal

*Ceftriaxone has renal and biliary excretion; cefoperazone is excreted primarily in the bile.
†Moxifloxacin and sparfloxacin have liver metabolism; ciprofloxacin and enoxacin have hepatic and renal elimination.
‡Nafcillin and oxacillin are excreted by the liver.

- These agents are the only penicillins that are not cleared renally. They have hepatobiliary elimination.
- These agents are more active than vancomycin for methicillin-sensitive staphylococci and are drugs of choice for infections caused by these organisms.

Carboxypenicillins and Ureidopenicillins

Agents include carbenicillin and ticarcillin (carboxypenicillins) and piperacillin (ureidopenicillin).

The carboxypenicillins have a broader gram-negative **spectrum of activity** than ampicillin. When used as antipseudomonal agents, they generally should be used in combination with an aminoglycoside or ciprofloxacin. They lack good activity against staphylococci and streptococci and have little or no activity against enterococci or *Klebsiella* species.

Piperacillin has a broad **spectrum of activity** against gram-negative bacteria. Compared with penicillin G and ampicillin, it is slightly less active against streptococci and enterococci but more active against *H. influenzae* and *M. catarrhalis*. Piperacillin is more active than carbenicillin and ticarcillin against Enterobacteriaceae, including most strains of *Klebsiella*. In addition, it is somewhat more active than ticarcillin against *Bacteroides fragilis*. Against *Pseudomonas aeruginosa*, piperacillin should be given in a higher dosing format, and combination therapy with an aminoglycoside or ciprofloxacin has been suggested for serious infections caused by *Pseudomonas* and *Enterobacter* species.

Clinical uses of carboxypenicillins and piperacillin include polymicrobial and nosocomial gram-negative infections.

- Carboxypenicillins have improved gram-negative activity compared with the natural penicillins or aminopenicillins. However, they lack good activity against staphylococci and streptococci and have little or no activity against enterococci or *Klebsiella* species.
- Piperacillin has good gram-negative activity that includes *Klebsiella* and other Enterobacteriaceae, *Pseudomonas*, some gram-positive activity (less than natural or aminopenicillins), and some anaerobic activity against *B. fragilis*.

β-Lactamase Inhibitors

Agents in this group are amoxicillin-clavulanate (Augmentin), ampicillin-sulbactam (Unasyn), ticarcillin-clavulanate (Timentin), and piperacillin-tazobactam (Zosyn).

The **spectrum of activity** of the parent drug is increased by the addition of β-lactamase inhibitors. This results in enhanced activity against β-lactamase–producing organisms such as *S. aureus* (methicillin-susceptible), *B. fragilis*, most *Klebsiella pneumoniae*, *H. influenzae*, and *M. catarrhalis*. Similar to other β-lactam agents, they are not active against methicillin-resistant *S. aureus*. The addition of the β-lactamase inhibitor usually does not change the activity of the parent compound against most strains of *Pseudomonas* or *Enterobacter*.

Because they have good activity against methicillin-susceptible staphylococci and group A streptococci, anaerobes, and some gram negative organisms, **clinical uses** of amoxicillin-clavulanate (Augmentin) and ampicillin-sulbactam (Unasyn) include

Table 14-21 Mechanisms of Action of Antimicrobials

Cell wall	Protein synthesis	Cell membrane	Cell synthesis	RNA synthesis
Penicillins	Macrolides, ketolide	Amphotericin	Nalidixic acid	Rifampin
Cephalosporins	Clindamycin	Azoles*	Fluoroquinolones	Rifabutin
	Aminoglycosides		Flucytosine	Rifapentine
Carbapenems	Tetracyclines, glycylcyclines			
Vancomycin	Chloramphenicol			
Aztreonam	Metronidazole			
Glucan synthesis inhibitors (i.e., caspofungin)	Linezolid			
	Quinupristin/dalfopristin			

*Ketoconazole, fluconazole, itraconazole, voriconazole.

polymicrobial skin or soft tissue infections (e.g., bite wounds, infected ulcers, cellulitis, and oropharyngeal infections). They also are used for treatment of otitis media, sinusitis, and aspiration pneumonia. They are alternatives for community-acquired pneumonia, community-acquired intra-abdominal infections, and urinary tract infections.

Clinical uses of piperacillin-tazobactam (Zosyn) and ticarcillin-clavulanate (Timentin) include coverage for mixed gram-negative, gram-positive, and anaerobic infections (including intra-abdominal infections, complicated skin or soft tissue infections, and nosocomial respiratory tract infections) and empiric broad-spectrum therapy for polymicrobial infections. Their activity against *Enterobacter*, *P. aeruginosa*, and other gram-negative organisms provides enhanced coverage over ampicillin-sulbactam or amoxicillin-clavulanate for nosocomial infections.

- β-Lactamase inhibitors have good activity against β-lactamase–producing strains of *S. aureus*, *B. fragilis*, *K. pneumoniae*, *H. influenzae*, and *M. catarrhalis*. Thus, their good gram-positive, gram-negative, and anaerobic activity provides good coverage for polymicrobial infections.
- The addition of the β-lactamase inhibitor usually does not change the activity of the parent compound against most strains of *Pseudomonas* or *Enterobacter*. Thus, piperacillin-tazobactam and ticarcillin-clavulanate have activity similar to that of piperacillin and ticarcillin, respectively. Ampicillin-sulbactam and amoxicillin-clavulanate do not have significant activity for these pathogens.
- β-Lactamase inhibitors are not active against methicillin-resistant staphylococci. No currently available β-lactam is active against these organisms.

Adverse Reactions to Penicillins

Hypersensitivity reactions are fairly common (3%-10% of cases). These reactions include maculopapular rash, urticaria, angioedema, serum sickness, and anaphylaxis. True anaphylaxis occurs in 0.004% to 0.015% of patients receiving penicillin. Skin testing in difficult cases can be used to predict subsequent severe (type I) penicillin allergy but will not predict maculopapular drug eruptions. Patients allergic to one penicillin agent should be considered allergic to all penicillins. Furthermore, there is a cross-allergenicity rate of 3% to 7% with cephalosporin compounds, and cross-allergenicity also may occur with the carbapenems. Cephalosporins and carbapenems should be avoided when possible in patients who have had a severe, immediate penicillin allergy (type I anaphylaxis or urticarial eruption). Rash is common when aminopenicillins (ampicillin and amoxicillin) are given to patients with infectious mononucleosis—this is usually not a true allergy.

Gastrointestinal side effects to penicillins include nausea, vomiting, and diarrhea—including *Clostridium difficile* colitis. The clavulanic acid component of amoxicillin-clavulanate (Augmentin) increases the incidence of diarrhea. Rare hematologic side effects include neutropenia, platelet dysfunction, and hemolytic anemia. Drug fever also can occur with penicillin therapy. Electrolyte disturbances, especially hyperkalemia, can occur when high doses of penicillin potassium are used in patients with renal dysfunction. Central nervous system side effects with penicillin G, when given in high doses, may include tremors, lowered seizure threshold, and neuromuscular irritability.

With penicillinase-resistant penicillins, interstitial nephritis, phlebitis, hepatitis, and transient neutropenia can occur with prolonged use.

Additional side effects for the carboxypenicillins include sodium overload, hypokalemia, and platelet dysfunction. These are more pronounced for carbenicillin than ticarcillin.

- A person who is allergic to one penicillin agent should be considered allergic to all penicillins. Additionally, there is a cross-allergenicity rate of 3%-7% with cephalosporin compounds and some cross-allergenicity with carbapenems.
- Transient neutropenia with prolonged use can occur with penicillinase-resistant penicillins (e.g., nafcillin).
- Additional side effects for the carboxypenicillins (carbenicillin and ticarcillin) include sodium overload, hypokalemia, and platelet dysfunction. These occur less commonly with ureidopenicillins (piperacillin).

Table 14-22 Microorganisms for Which a Penicillin Is the Drug of Choice

Microorganism	Penicillin
Gram-positive cocci	
Enterococcus faecalis (non-penicillinase strains)	Ampicillin or penicillin G (often with an aminoglycoside*)
E. faecium	Ampicillin or penicillin G (often with an aminoglycoside*)
Staphylococcus aureus	
Non-penicillinase strain (rare)	Penicillin
Penicillinase-producing strain	Nafcillin, oxacillin†
S. epidermidis‡	
Non-penicillinase strain	Penicillin
Penicillinase-producing strain	Nafcillin, oxacillin
Streptococcus pyogenes (group A, B, C, G)	Penicillin
Viridans streptococci	Penicillin§
Streptococcus bovis	Penicillin
Anaerobic streptococci or peptostreptococci	Penicillin
Streptococcus pneumoniae (pneumococcus), "penicillin susceptible"	Penicillin§
Gram-negative cocci	
Neisseria meningitidis	Penicillin//
Gram-positive bacilli	
Bacillus anthracis (anthrax)	Penicillin
Clostridium perfringens	Penicillin
Clostridium tetani	Penicillin
Erysipelothrix rhusiopathiae	Penicillin
Listeria monocytogenes	Ampicillin plus an aminoglycoside
Gram-negative bacilli	
Proteus mirabilis	Ampicillin
Eikenella corrodens	Ampicillin
Fusobacterium spp.	Penicillin
Leptotrichia buccalis	Penicillin
Pasteurella multocida	Penicillin
Pseudomonas aeruginosa	Ureidopenicillin (high dose) plus an aminoglycoside
Spirillum minus	Penicillin
Streptobacillus moniliformis	Penicillin
Other	
Actinomyces israelii	Penicillin
Borrelia burgdorferi (Lyme disease)	Amoxicillin¶
Leptospira spp.	Penicillin
Treponema pallidum (syphilis)	Penicillin
T. pallidum subsp. *pertenue* (yaws)	Penicillin

*Aminoglycoside used in combination with penicillin for treatment of enterococcal endocarditis and other serious enterococcal bacteremias.
†Penicillins (and other β-lactams) are not active against methicillin-resistant *S. aureus*.
‡Between 70% and 80% of *S. epidermidis* organisms are methicillin-resistant (and resistant to other β-lactams).
§Resistance to penicillin is increasing.
//Resistance to penicillin is uncommon but has been found (especially outside the United States).
¶Oral doxycycline or intravenous ceftriaxone also can be used as first-line therapy against Lyme disease.

Table 14-23 The Cephalosporins

1st Generation	2nd Generation	3rd Generation	4th Generation
Cefazolin	Cefaclor	Cefotaxime	Cefepime
Cephalexin	Cefamandole	Ceftriaxone	
Cefadroxil	Cefmetazole	Ceftazidime	
Cephalothin	Cefonicid	Cefoperazone	
Cephradine	Cefotetan	Cefixime	
	Cefuroxime	Cefpodoxime	
	Cefprozil	Moxalactam	
	Loracarbef	Ceftizoxime	
	Cefoxitin	Ceftibuten	
		Cefdinir	

Cephalosporins

Cephalosporins have been divided into four generations according to spectrum of activity (Table 14-23). In general, first-generation agents have good gram-positive activity; second-generation agents have better gram-negative and somewhat less gram-positive activity; third-generation agents have improved gram-negative activity and variable gram-positive activity; and fourth-generation agents have good gram-negative and fairly good gram-positive activity.

First-Generation Cephalosporins

Representative agents include the injectable agents cefazolin (long serum half-life allows dosing every 8 hours) and cephalothin and the oral agents cephalexin and cefadroxil.

The **spectrum of activity** of the first-generation agents includes good activity against methicillin-susceptible staphylococci, β-hemolytic streptococci, and many strains of *P. mirabilis*, *E. coli*, and *Klebsiella* species. Similar to all cephalosporins, the first-generation agents are not active against methicillin-resistant staphylococci, enterococci, *L. monocytogenes*, *Legionella* species, *Chlamydia pneumoniae*, *Mycoplasma pneumoniae*, and *C. difficile*. These agents have fairly minimal gram-negative anaerobic activity.

Pharmacokinetics: The first-generation cephalosporins are renally eliminated and require dosage adjustment for renal dysfunction. They do not penetrate the blood-brain barrier and should not be used to treat meningitis or other central nervous system infections.

Clinical uses of the first-generation agents include activity for treatment of skin or soft tissue infections caused by most streptococci or methicillin-susceptible staphylococci. Similar to nafcillin, cefazolin is often used to treat serious infections caused by methicillin-susceptible staphylococci, including bacteremias and endocarditis. They are also commonly used for surgical prophylaxis and for community-acquired urinary tract infections caused by susceptible organisms. Cephalosporins are not active against methicillin-resistant staphylococci or enterococci.

- First-generation cephalosporins are active against methicillin-susceptible staphylococci and most streptococci.
- Cephalosporins are not active against methicillin-resistant staphylococci or enterococci.

Second-Generation Cephalosporins

Representative IV agents include cefamandole, cefoxitin, cefuroxime, cefmetazole, cefonicid, and cefotetan. Oral second-generation agents include cefuroxime, cefprozil, cefaclor, and loracarbef.

The **spectrum of activity** of the second-generation agents is, in general, improved gram-negative activity but slightly less gram-positive activity than the first-generation agents. Of the second-generation agents, cefuroxime has the best activity against *S. aureus* and β-lactamase–producing *H. influenzae* and *M. catarrhalis*.

Cefamandole has limited advantage over cefazolin. It has some increase in activity against *E. coli*, *Klebsiella*, indole-positive *Proteus*, *Enterobacter*, and non-β-lactamase–producing *H. influenzae*. It contains the methylthiotetrazole (MTT) side chain, which can produce hypoprothrombinemia (increased international normalized ratio), resulting in bleeding problems and a disulfiram-like reaction when ethanol is consumed. Cephalosporins possessing an MTT side group are listed in Table 14-24.

Cefoxitin has some increase in activity over first-generation agents against *E. coli*, *Klebsiella*, indole-positive *Proteus*, and *Serratia*. It is less active against *S. aureus* and streptococci than first-generation cephalosporins. It is active against most strains of *B. fragilis*.

Table 14-24 Cephalosporins With Methylthiotetrazole (MTT) Side Group

Agents:	Cefoperazone	Cefamandole
	Cefotetan	Cefmetazole
	Moxalactam (also decreased platelet aggregation)	
Interactions:	1. Hypoprothrombinemia (↑INR) via competitive inhibition by MTT side group	
	2. Disulfiram-like reaction (with ethanol consumption)	

INR, international normalized ratio.

Table 14-25 Major Clinical Indications for Use of Tetracyclines

Genital infections or sexually transmitted diseases
Chlamydia trachomatis (nongonococcal urethritis, pelvic inflammatory disease, epididymitis, prostatitis, LGV)
Granuloma inguinale (donovanosis)
Alternative agent for *Ureaplasma urealyticum*, *Treponema pallidum* (syphilis)
"Atypical" respiratory tract pathogens
Mycoplasma pneumoniae
Chlamydia pneumoniae
Chlamydia psittaci (psittacosis)
Alternative agent for *Legionella pneumophila*
Systemic infections
Rickettsia spp. (Rocky Mountain spotted fever, endemic and epidemic typhus, Q fever)
Brucellosis (in combination with rifampin or streptomycin)
Ehrlichiosis (HME, HGE)
Early Lyme disease
Vibrio infections
Other indications
Tularemia (*Francisella tularensis*)
Bacillary angiomatosis (*Bartonella* spp.)
Leptospirosis
Helicobacter pylori (in combination therapy)
Mycobacterium marinum
Pasteurella multocida (in patients allergic to β-lactam agents)
As prophylaxis against mefloquine-resistant *Plasmodium falciparum* malaria

HGE, human granulocytic ehrlichiosis; HME, human monocytic ehrlichiosis; LGV, lymphogranuloma venereum.

The activity of cefotetan is fairly similar to that of cefoxitin. It has somewhat better activity than cefoxitin against aerobic gram-negative rods. It also has a longer half-life so can be given less frequently than cefoxitin (every 12 hours, compared with every 6). It has the MTT side chain with the associated toxicities described for cefamandole.

The oral second-generation agents have improved gram-negative activity over first-generation agents. Their activity generally includes β-lactamase–producing *H. influenzae* and *M. catarrhalis*, penicillin-sensitive streptococci, and many community-acquired strains of *E. coli*, *Klebsiella* species, and *P. mirabilis*. Cefprozil and cefuroxime have the greatest gram-positive activity of the oral second-generation agents.

Pharmacokinetics: The second-generation cephalosporins are renally eliminated. Cefuroxime penetrates the central nervous system with inflammation but has been shown to be less effective for meningitis treatment than ceftriaxone or cefotaxime (slower activity and more long-term sequelae).

The most common **clinical uses** of cefuroxime, cefamandole, loracarbef, and cefonicid are for community-acquired respiratory tract infections and urinary tract infections. Cefotetan and cefoxitin have somewhat improved anaerobic activity and are used for community-acquired intra-abdominal infections, pelvic inflammatory infections (usually in combination with doxycycline), and surgical prophylaxis for obstetric, gynecologic, and colorectal procedures.

- Cefuroxime and the oral second-generation cephalosporins often are used for community-acquired respiratory tract infections.
- Cefoxitin and cefotetan have enhanced anaerobic and gram-negative activity. They are used for community-acquired intra-abdominal or pelvic inflammatory infections and surgical prophylaxis for obstetric, gynecologic, and colorectal procedures.
- Cefotetan and cefamandole have the MTT side chain, which is associated with hypoprothrombinemia (increased international normalized ratio), resulting in bleeding problems and a disulfiram-like reaction when ethanol is consumed.

Third-Generation Cephalosporins

Representative agents are IV cefotaxime, ceftizoxime, ceftriaxone, cefoperazone, and ceftazidime and oral cefixime, cefpodoxime, ceftibuten, and cefdinir.

Spectrum of activity: The third-generation cephalosporins have improved gram-negative activity versus the first- and second-generation agents. The gram-positive activity varies, as described below.

Some organisms, most notably *Enterobacter*, have developed an inducible resistance to these agents. Because resistance can occur during therapy, these agents generally should not be used alone for treatment of *Enterobacter* infections, even if shown to be susceptible initially. Extended-spectrum β-lactamases also have been found in some strains of *Klebsiella* and *E. coli* and can cause resistance to ceftazidime and the other cephalosporins. Widespread use of ceftazidime may be more likely to select for these resistant organisms. Some hospitals have had success in reducing resistance rates by restricting use of this agent.

Ceftazidime and cefoperazone are less active against staphylococci and streptococci than most other third-generation cephalosporins. However, they have activity against *P. aeruginosa* (ceftazidime greater than cefoperazone). Penetration into cerebrospinal fluid for cefoperazone is less than that of other available third-generation cephalosporins, and it has the MTT side chain with the associated potential toxic effects. Thus, this agent is rarely used.

Cefotaxime, ceftriaxone, and ceftizoxime have very similar spectra. The primary difference among these agents is their pharmacokinetics. These agents have enhanced gram-negative activity compared with the second-generation agents but in contrast to ceftazidime and cefoperazone, they are not active against *Pseudomonas*. However, they have better activity against methicillin-susceptible staphylococci and streptococci (including *S. pneumoniae* organisms, which are intermediately resistant to penicillin and viridans group streptococci) than ceftazidime and cefoperazone. Cefotaxime and ceftriaxone have good cerebrospinal fluid penetration in the presence of inflammation and have a primary role in the treatment of community-acquired bacterial meningitis and other central nervous system infections.

Oral agents in this class include cefpodoxime proxetil, cefdinir, cefixime, and ceftibuten. They have improved gram-negative activity over the second-generation oral cephalosporins, but they are not as

Table 14-26 Situations in Which the Use of Vancomycin Should Be Discouraged

- Routine surgical prophylaxis
- Empiric antimicrobial therapy for a febrile neutropenic patient without high likelihood that infection is due to gram-positive organisms
- Treatment in response to a single blood culture positive for coagulase-negative *Staphylococcus* (i.e., if contamination of the culture is likely)
- Continued empiric use for presumed infections in patients whose cultures are negative for β-lactam–resistant gram-positive microorganisms
- Prophylaxis for infection or colonization of vascular catheters
- Selective decontamination of the digestive tract
- Eradication of methicillin-resistant *Staphylococcus aureus* colonization
- Primary treatment of *Clostridium difficile* colitis (should use metronidazole)
- Routine prophylaxis for infants with very low birth weight
- Routine prophylaxis for patients receiving continuous ambulatory peritoneal dialysis
- Treatment (chosen for convenience) of infections caused by β-lactam–susceptible gram-positive microorganisms in patients with renal dysfunction
- Use of vancomycin for topical application or irrigation

Data from Centers for Disease Control and Prevention. Preventing the spread of vancomycin resistance. Fed Register. 1994;59:25758-63.

Table 14-27 Therapeutic Indications for Vancomycin

- Serious infections caused by methicillin-resistant strains of *Staphylococcus aureus*, coagulase-negative staphylococci, and enterococci (resistant to penicillin/ampicillin)*
- Serious infections caused by *Staphylococcus aureus*, enterococci, or streptococci in patients intolerant of β-lactam antibiotics
- Infections caused by multiply resistant gram-positive organisms (e.g., *Corynebacterium jeikeium* and resistant strains of *Streptococcus pneumoniae*)
- *Clostridium difficile* colitis (oral administration) only if metronidazole therapy fails or in seriously ill patients
- Endocarditis prophylaxis for selected genitourinary or gastrointestinal procedures in penicillin-intolerant patients
- Surgical prophylaxis for major procedures involving implantation of prosthetic materials at institutions with high incidence of methicillin-resistant *Staphylococcus aureus* or methicillin-resistant *Staphylococcus epidermidis*

*Vancomycin may be less rapidly bactericidal than β-lactam agents for β-lactam–susceptible staphylococci.
Data from Centers for Disease Control and Prevention. Preventing the spread of vancomycin resistance. Fed Register. 1994;59:25758-63.

active as the injectable third-generation agents against nosocomial gram-negative infections. None of the oral agents are effective against *Pseudomonas*. Cefixime and ceftibuten have the best gram-negative activity of any oral cephalosporins. However, neither is very active against staphylococci, and ceftibuten has poor streptococcal activity. Cefpodoxime proxetil and cefdinir have better gram-positive activity than the other oral third-generation cephalosporins, particularly against staphylococci and streptococci. Although they have somewhat less gram-negative activity than cefixime or ceftibuten, they are active against *H. influenzae*, *M. catarrhalis*, *N. gonorrhoeae*, and many other gram-negative organisms.

Pharmacokinetics: These agents are renally eliminated except ceftriaxone, which has dual renal and hepatobiliary elimination, and cefoperazone, which is primarily excreted in the bile. Cefotaxime, ceftazidime, and ceftizoxime are usually given every 8 hours, whereas the long half-life of ceftriaxone allows for dosing every 24 hours in most circumstances. Cefotaxime, ceftriaxone, and ceftazidime cross the blood-brain barrier in the presence of inflammation.

Clinical uses: Cefotaxime, ceftriaxone, and ceftizoxime are commonly used for community-acquired respiratory tract infections, urinary tract infections, and pyelonephritis. Cefotaxime and ceftriaxone are used for the treatment of community-acquired meningitis and other central nervous system infections. Additionally, ceftriaxone is used for the treatment of susceptible viridans group streptococcal endocarditis. The long half-life of ceftriaxone permits convenient treatment of susceptible outpatient infections that necessitate IV antibiotics.

The enhanced gram-negative activity of ceftazidime (and less commonly cefoperazone) makes this agent useful for the treatment of nosocomial gram-negative infections. Ceftazidime is useful for the treatment of pseudomonal infections—often in combination with another agent such as an aminoglycoside. Ceftazidime also has been used for the treatment of febrile neutropenia.

Third-generation cephalosporins can be used for nosocomial gram-negative infections or in combination with an anti-anaerobic agent (e.g., metronidazole) for polymicrobial infections.

- Ceftazidime is more active than any other third-generation cephalosporin against *Pseudomonas* and is often used for nosocomial infections or treatment of febrile neutropenia.

Table 14-28 First-Line Antituberculosis Medications

Variable	Isoniazid	Rifampin*	Pyrazinamide	Ethambutol	Streptomycin†

ANA, antinuclear antibody; CBC, complete blood count; CNS, central nervous system; WBC, white blood cell.
*Alternative rifamycins include rifabutin 300 mg daily (dose adjustment may be needed with some antiretroviral agents) and rifapentine 600 mg weekly.
†Streptomycin is no longer considered a first-line drug because of increased rates of global resistance.
‡Dosing (daily and intermittent) is listed for adults only; maximum recommended doses in parentheses.

- Cefotaxime, cefuroxime, ceftizoxime, and the oral third-generation agents provide good coverage of community-acquired respiratory and urinary tract pathogens.
- Third-generation cephalosporins can be used in combination with anti-anaerobic agents such as metronidazole for intra-abdominal and other polymicrobial infections.
- Inducible resistance to ceftazidime and other cephalosporins can develop in *Enterobacter* organisms, and extended-spectrum β-lactamase–producing *E. coli* and *Klebsiella* are an increasing problem.

Fourth-Generation Cephalosporins

Cefepime is the first of the fourth-generation cephalosporins. Its **spectrum of activity** includes gram-positive activity (methicillin-susceptible *S. aureus* and *Streptococcus* species) similar to that of cefotaxime. Its gram-negative activity (including *P. aeruginosa*) is similar

Azole antifungals	Efavirenz	Propranolol
Calcium channel blockers	Haloperidol	Protease inhibitors
Corticosteroids	Imidazoles	Quinidine
Cyclosporine	Opioids/methadone	Theophylline
Dapsone	Oral contraceptives	Tolbutamide
Diazepam	Oral hypoglycemic agents	Warfarin

*The list is not all-inclusive; review drug interactions thoroughly when prescribing.

to or better than that of ceftazidime. In addition, cefepime has a lower potential for inducing resistance and may have more durable activity against some gram-negative organisms, such as *Enterobacter*, that may become resistant to third-generation agents. However, cefepime and other cephalosporin agents should not be used against extended-spectrum β-lactamase–producing gram-negative bacilli.

Pharmacokinetics: Cefepime is renally cleared and does penetrate into the cerebrospinal fluid in the presence of inflammation.

Clinical uses: Cefepime has gained widespread popularity because of a broadened spectrum of activity and decreased potential for development of resistance compared with ceftazidime. It is useful for the treatment of nosocomial infections, including respiratory tract, urinary tract, bloodstream, soft tissue, and intra-abdominal infections, in combination with an anaerobic agent. It is also a preferred agent for treatment of febrile neutropenia.

- Cefepime has gram-positive activity similar to cefotaxime and gram-negative activity similar to or better than ceftazidime. Its spectrum includes *Pseudomonas* and *Enterobacter* species.

Adverse Reactions to Cephalosporins

Cephalosporins usually are well tolerated. The most common **toxic effects** include adverse reactions related to the gastrointestinal tract (such as nausea, vomiting, diarrhea). Hypersensitivity reactions, primarily rashes, occur in 1% to 3% of patients taking cephalosporins. Anaphylaxis is rare. Cross-allergenicity may occur with penicillins. Other adverse reactions associated with cephalosporins include drug fever and *C. difficile* colitis.

The MTT side chain can produce hypoprothrombinemia (increased international normalized ratio), resulting in bleeding problems and a disulfiram-like reaction when ethanol is consumed. Cephalosporins possessing an MTT side group are listed in Table 14-24.

Ceftriaxone has been reported to cause pseudocholelithiasis, cholelithiasis, biliary colic, and cholecystitis as a result of biliary precipitation of ceftriaxone as the calcium salt in up to 2% of cases, especially in children. This effect usually resolves with discontinuation of therapy.

Carbapenems

Imipenem, Meropenem, and Ertapenem

Spectrum of activity: The carbapenems have the broadest antibacterial activity of any antibiotics currently available. The gram-positive spectrum includes β-hemolytic streptococci, *S. pneumoniae*, and methicillin-susceptible *S. aureus*. Imipenem and, to a lesser extent,

Table 14-31 Selected Pharmacologic Properties of Azole Antifungal Agents

Factor	Antifungal agent			
	Fluconazole	Itraconazole	Voriconazole	Ketoconazole
Route of administration	Oral, IV	Oral, IV	Oral, IV	Oral
Requires gastric acidity for absorption	No	Yes for oral capsules	No	Yes
Protein binding, %	12	99	60	91-99
Cerebrospinal fluid concentrations	High	Minimal (but some clinical efficacy noted)	High	Minimal
Half-life, h	25-30	24-64	6	8
Clearance route	Renal	Hepatic	Hepatic	Hepatic
Urinary levels of active drug	High	Low	Low	Low
Dose reduction for renal dysfunction	Yes	No for oral*	No for oral*	No

IV, intravenous.
*The manufacturer warns against use of intravenous itraconazole in patients with creatinine clearance <30 mL/min and of voriconazole with creatinine clearance <50 mL/min because of the possible accumulation of the vehicle.

meropenem provide coverage for susceptible *Enterococcus* species (inhibited only). However, ertapenem is not active against enterococci. These agents are more active than ceftriaxone or cefotaxime against *S. pneumoniae* organisms, which have intermediate resistance to penicillin (minimal inhibitory concentration, 0.1-1.0 μg/mL), and retain some activity against strains with high-level penicillin resistance (minimal inhibitory concentration, >2.0 μg/mL). They are alternative agents against *Nocardia*.

Regarding gram-negative organisms, the carbapenems have good coverage for Enterobacteriaceae, *H. influenzae*, and *M. catarrhalis*. The carbapenems remain active against most extended-spectrum β-lactamase–producing *Klebsiella* species and *E. coli* as well as ampC-producing organisms such as *Enterobacter*. Meropenem and imipenem cover most strains of *P. aeruginosa* and *Acinetobacter* species; however, ertapenem lacks good coverage of these organisms.

The spectrum of each of these agents also includes excellent activity against anaerobes, including *Bacteroides*, *Clostridium*, *Eubacterium*, *Fusobacterium*, *Peptostreptococcus*, *Porphyromonas*, and *Prevotella* species.

Organisms to which carbapenems are not active include methicillin-resistant *Staphylococcus*, *Legionella*, *Chlamydia* species, *Mycoplasma* species, *Pseudomonas cepacia*, and *Stenotrophomonas maltophilia*.

Differences in spectra between imipenem and meropenem are minimal but may include slightly better gram-positive activity for imipenem (probably only clinically significant for *Enterococcus faecalis*) and slightly better gram-negative activity for meropenem (including *P. aeruginosa*). In contrast to imipenem and meropenem, ertapenem lacks good coverage for *Enterococcus*, *P. aeruginosa*, and *Acinetobacter*.

Pharmacokinetics: Imipenem is administered intravenously and is hydrolyzed in the kidney by a peptidase located in the brush border of renal tubular cells. Administration with cilastatin, a dehydropeptidase inhibitor, solves this problem and allows imipenem to have activity in the urine. Meropenem and ertapenem do not require the addition of cilastatin. These agents are renally eliminated and require dosage adjustment for renal dysfunction. Ertapenem has a longer half-life than the other carbapenems and can be given once daily, which may be beneficial for outpatient therapy.

Clinical Uses: Carbapenems are commonly used when broad-spectrum empiric therapy is needed in patients with sepsis and for treatment of polymicrobial infections, including intra-abdominal, pelvic, pulmonary, and necrotizing soft tissue infections. Additionally, carbapenems often can be used for the treatment of aerobic gram-negative bacilli that are resistant to the other β-lactam agents (including *Enterobacter* and extended-spectrum β-lactamase–producing Enterobacteriaceae). Imipenem and meropenem also are used for febrile neutropenia, especially when anaerobic and antipseudomonal activity is needed. Ertapenem is considerably less costly than the other carbapenems and provides cost-effective therapy for mixed infections, for example, intra-abdominal, complicated respiratory tract, and complicated skin or soft tissue infections when *P. aeruginosa*, *Acinetobacter* species, or *Enterococcus* are not likely to be serious pathogens. For mixed intra-abdominal infections, it is often not necessary to specifically cover *Enterococcus*.

Toxic effects of carbapenems include nausea and vomiting, diarrhea, hypersensitivity, drug fever, and overgrowth of resistant organisms (yeast, *S. maltophilia*, *C. difficile*). Seizures occur rarely with these agents; affected patients are those with a history of previous seizures, renal insufficiency without proper dosage adjustment, or structural central nervous system defects.

- The carbapenems have the broadest spectrum of activity of any antibiotic, including gram-positive, gram-negative, and anaerobic

organisms. They commonly are used as broad-spectrum empiric therapy, but the spectrum often can be narrowed when results of cultures and sensitivities are known.
- Ertapenem is considerably less costly than the other carbapenems yet still provides a broad spectrum of activity. However, it does not provide good coverage of *Enterococcus*, *P. aeruginosa*, or *Acinetobacter* species.

Aztreonam

Aztreonam is the only commercially available monobactam and is a derivative of naturally occurring monocyclic β-lactam compounds. Aztreonam is administered intravenously and is excreted by the kidneys. Unlike other β-lactams, cross-reactivity with aztreonam in patients with a penicillin or cephalosporin allergy is rare. However, because of a similar side chain, there may be some cross-allergenicity with ceftazidime.

Its **spectrum of activity** includes most aerobic gram-negative bacteria, including *P. aeruginosa*. However, it has no activity against gram-positive anaerobic bacteria, and it is not synergistic with penicillins against the enterococci (in contrast to gentamicin and streptomycin). The **toxic effects** of aztreonam are similar to those of other β-lactams.

Clinical uses of aztreonam include the treatment (as an alternative agent) of aerobic gram-negative infections, especially in penicillin-allergic patients. It may be used in combination with other agents in the treatment of mixed polymicrobial infections.

- Aztreonam is active only against gram-negative aerobes.
- Aztreonam may be useful in cases of penicillin or cephalosporin allergy because cross-reactivity is uncommon.

Aminoglycosides

Agents in this group are gentamicin, tobramycin, amikacin, streptomycin, kanamycin, and neomycin.

The **spectrum of activity** of these agents includes most aerobic gram-negative bacilli, mycobacteria (*Mycobacterium tuberculosis*, streptomycin, amikacin, kanamycin; *Mycobacterium avium-intracellulare*, amikacin; *Mycobacterium chelonei*, amikacin; *Mycobacterium fortuitum*, tobramycin), *Brucella* (streptomycin), *Nocardia* (amikacin), *Francisella tularensis* (streptomycin), and *Yersinia pestis* (streptomycin). They are synergistic with certain β-lactams and vancomycin in the treatment of serious infections due to susceptible enterococci (gentamicin, streptomycin), staphylococci, and several aerobic gram-negative species.

Pharmacokinetics: The aminoglycosides are not absorbed orally and are therefore sometimes used for oral bowel decontamination. They are available as IV or IM preparations, except neomycin, which is available only as a bladder irrigant because of toxicities when given parenterally. Tobramycin is also available as an inhalation formulation for local bronchial distribution. They are renally eliminated through glomerular filtration, and the half-life in patients with normal renal function is 1.5 to 4 hours. These agents have minimal protein binding and are distributed to extracellular fluid. When administered systemically, they do not achieve adequate penetration to the central nervous system, lungs, eyes, or prostate. In addition, they are less active in a low pH environment (e.g., abscess).

The major **adverse reactions** to aminoglycosides include nephrotoxicity and auditory or vestibular toxicity. Neuromuscular blockade is uncommon and can occur with rapid administration of large doses. The risk of nephrotoxicity varies among the different aminoglycosides; neomycin is the most nephrotoxic, and streptomycin is the least nephrotoxic. Risk factors include increased serum trough levels, total cumulative dose, advanced age, hypotension, concomitant use of other nephrotoxic drugs, and liver disease. Aminoglycoside nephrotoxicity is almost always reversible with discontinuation of the drug therapy, and it can be minimized if dosages are adjusted to achieve desired serum concentrations and if renal function is carefully monitored. Nephrotoxicity may be delayed or decreased when the entire daily dose is administered at once (single daily dosing of aminoglycosides). Other nephrotoxic drugs such as cisplatin, amphotericin B, vancomycin, and cyclosporine may potentiate nephrotoxicity.

Unlike nephrotoxicity, ototoxicity caused by aminoglycosides is almost always irreversible. Streptomycin, gentamicin, and tobramycin are preferentially toxic to the vestibular system, whereas amikacin and neomycin are primarily toxic to the auditory nerve. Advanced age and concomitant use of ethacrynic acid or furosemide seem to be risk factors for ototoxicity. Because of the imprecision of bedside testing for auditory and vestibular toxicity, routine audiologic and vestibular function evaluation should be considered when prolonged administration is anticipated and in patients predisposed to ototoxicity. Patients also should be routinely questioned about symptoms of ototoxicity.

Single daily dosing (also known as pulse dosing) is a simplified, efficacious, and cost-effective method of aminoglycoside administration. For most infections with gram-negative bacteria, single daily dosing is as effective as the more traditional multiple daily dosing format and may lower the risk of nephrotoxicity. Single daily dosing takes advantage of three basic principles: 1) aminoglycosides display concentration-dependent bactericidal action—that is, higher doses and serum concentrations result in more rapid bacterial killing; 2) aminoglycosides have a long post-antibiotic effect, resulting in persistent bacterial suppression even after serum concentrations decline below the minimal inhibitory concentration (allowing for less frequent drug administration); and 3) large, single daily doses result in periods with negligible serum concentrations, reducing renal cortical and auditory accumulation of the drug. Single daily dosing should not be used for enterococcal endocarditis and requires further evaluation in select patient groups, including pregnant women, children, and persons with cystic fibrosis, severe renal insufficiency, and neutropenic fever.

Although the **clinical uses** of aminoglycosides against gram-negative infections have largely been replaced with alternative, less toxic agents, the aminoglycosides continue to play an important role for some infections. They commonly are used in combination with other agents for the treatment of endocarditis caused by *Enterococcus* spp. or viridans group streptococci. In addition, they may be used in combination for serious pseudomonal and other gram-negative infections, *Listeria*, mycobacterial infections, *nocardiosis*, and *brucellosis*. The aminoglycosides are first-line drugs to treat tularemia and *Yersinia* infections.

- Aminoglycosides are active against most aerobic gram-negative bacilli and are synergistic with β-lactams or vancomycin against susceptible enterococci.
- Major adverse reactions to aminoglycosides are nephrotoxicity and auditory or vestibular toxicity.
- Aminoglycoside nephrotoxicity is almost always reversible with discontinuation of the drug therapy.
- Ototoxicity is almost always irreversible.
- Single daily dosing is a cost-effective, efficacious, and potentially less toxic form of administration than traditional multiple daily dosing.

Tetracyclines

Agents are short-acting (tetracycline, chlortetracycline, oxytetracycline), intermediate-acting (demeclocycline, methacycline), and long-acting (doxycycline, minocycline).

In regard to **spectrum of activity**, these agents are drugs of choice for *Rickettsia*, *Chlamydia* species (including pelvic inflammatory disease), *M. pneumoniae*, *Vibrio cholerae*, *Vibrio vulnificus*, *Brucella* species (with streptomycin or rifampin), *B. burgdorferi* (early stages), and *Borrelia recurrentis*. These agents are also effective therapy or alternatives for *Actinomyces*, anthrax, *Campylobacter*, *P. multocida*, *Spirillum minus*, *Streptobacillus moniliformis*, *T. pallidum*, *F. tularensis*, Whipple disease, *Y. pestis*, *Nocardia* (minocycline), and *Mycobacterium marinum*. Minocycline also may be active against methicillin-resistant staphylococci (for mild disease in patients who cannot tolerate vancomycin) and *Stenotrophomonas*. The tetracyclines also may be used for the treatment of *Helicobacter pylori* infection (as part of combination therapy) and for respiratory tract infections with susceptible *S. pneumoniae*. Although the tetracyclines are active in vitro against many other aerobic gram-positive and gram-negative organisms as well as some anaerobes, they are usually not the drugs of choice to treat the infections caused by these organisms because of the presence or emergence of resistant strains. Further information on the clinical indications for tetracyclines is given in Table 14-25.

Toxic effects include gastrointestinal upset, rash, and photosensitivity. The incidence of uremia may be increased in patients with renal failure. Other, more rare side effects include acute fatty liver of pregnancy, Fanconi syndrome (old tetracycline), or pseudotumor cerebri. The tetracyclines are not used in pregnant females or in children because they impair bone growth of the fetus and stain the teeth of children. Coadministration of milk, antacids, iron, calcium, or calcium-, magnesium-, or aluminum-containing compounds substantially decreases the enteric absorption of the tetracycline.

In addition to its **clinical use** in treating respiratory, genital, soft tissue, tick-borne, and systemic infections with the aforementioned organisms, the tetracyclines have certain non-antimicrobial therapeutic roles. Demeclocycline inhibits antidiuretic hormone-induced water reabsorption in the renal tubule and collecting duct and therefore is used in treatment of the syndrome of inappropriate antidiuretic hormone. The tetracyclines also are a useful sclerosing agent for the treatment of refractory or malignant pleural effusions.

- The tetracyclines should not be used during pregnancy or in children because they impair bone growth of the fetus and stain the teeth of children.

Tigecycline

Tigecycline is a novel glycylcycline antimicrobial that is structurally related to minocycline but with expanded activity. It is available only as an intravenous preparation.

The **spectrum of activity** of tigecycline is wide and includes several multidrug-resistant organisms, including those that are tetracycline-resistant. Its gram-positive activity includes methicillin-sensitive and methicillin-resistant staphylococci, streptococci (including tetracycline- and penicillin-resistant strains of *S. pneumoniae*), and vancomycin-susceptible and vancomycin-resistant enterococci. Tigecycline also has broad gram-negative activity, including *E. coli*, *Klebsiella* species, *Enterobacter*, *Citrobacter*, *Acinetobacter*, *Stenotrophomonas*, *Hemophilus*, and *Moraxella*. It does not have appreciable activity against *Proteus*, *Morganella*, or *Pseudomonas*. It seems to have good anaerobic activity and also displays good in vitro activity against rapid-growing mycobacterial organisms.

Pharmacokinetics: Tigecycline has a large volume of distribution, indicating extensive tissue distribution. It has a long half-life with a mean of 42 hours after multiple doses. It is primarily excreted into the bile, and renal clearance accounts for only 15% to 20% of total clearance. Dosage adjustment is not required for renal dysfunction, hemodialysis, or mild-moderate hepatic impairment.

The most pronounced **adverse effect** is a high incidence of nausea and vomiting. Similar to the tetracyclines, it can cause permanent tooth discoloration if given to children younger than 8 years.

Clinical uses: This agent currently is approved by the U.S. Food and Drug Administration for complicated skin and intra-abdominal infections. In the future, it will likely find use for multiresistant pathogens such as methicillin-resistant staphylococci, staphylococci with reduced susceptibility to vancomycin, vancomycin-resistant enterococci, and multidrug-resistant gram-negative organisms such as *Acinetobacter* or *Stenotrophomonas*. However, further clinical studies are needed to confirm efficacy for these pathogens.

Chloramphenicol

The **spectrum of activity** of this agent is broad and includes inhibition of most strains of clinically important aerobic and anaerobic bacteria. Exceptions are methicillin-resistant *S. aureus*, many *Klebsiella* isolates, *Enterobacter*, *Serratia*, indole-positive *Proteus*, and *P. aeruginosa*. It is active against *H. influenzae*, *N. meningitidis*, *N. gonorrhoeae*, *Salmonella typhi*, *Brucella* species, and *Bordetella pertussis*. In addition, chloramphenicol is also active against *Rickettsia*, *Chlamydia*, *Mycoplasma*, and spirochetes.

Toxic effects include two types of hematologic manifestations: idiosyncratic aplastic anemia (dose-independent; severe, often fatal; incidence approximately 1/24,000 to 1/40,000) and dose-related, reversible bone marrow suppression (much more common, especially with a dose >4 g/day or increased serum levels). Gray baby syndrome (abdominal distention, cyanosis, vasomotor collapse) can occur in premature infants and possibly in patients with profound liver failure who cannot conjugate chloramphenicol and who have

high serum levels. Rare toxic effects are hemolytic anemia, retrobulbar neuritis, peripheral neuritis, and potentiation of oral hypoglycemic agents.

The **clinical use** of chloramphenicol has largely been curbed by the availability of potent, less toxic alternative agents. Although chloramphenicol is no longer the drug of choice for any specific infection, it still remains widely used for typhoid fever in parts of the world where cost and availability limit other drug options. Chloramphenicol remains a useful alternative agent for central nervous system infections and rickettsial infections in patients allergic to β-lactams and tetracyclines, respectively.

- Toxicities with chloramphenicol include two main types of hematologic manifestations: idiosyncratic aplastic anemia (very rare and usually fatal) and dose-related bone marrow suppression.

Clindamycin

Clindamycin is active against aerobic and anaerobic gram positive organisms. Its anaerobic activity includes *Actinomyces* species, *Clostridium* (except *C. difficile*), *Peptococcus*, *Peptostreptococcus*, and most *Bacteroides* species. However, 10% to 20% of *B. fragilis* organisms (a gram-negative aneorobe) are resistant. Clindamycin is active against gram-positive anaerobes such as staphylococci and group A streptococci, but emergence of resistance by staphylococci can occur during treatment. Double-disk diffusion testing is suggested for streptococcal or staphylococcal strains resistant to erythromycin to rule out inducible clindamycin resistance. Gram-negative aerobic bacteria and enterococci are resistant to clindamycin. Clindamycin does not penetrate well into the central nervous system.

Toxic effects most commonly include rash and gastrointestinal side effects. Antibiotic-associated diarrhea can occur in up to 20% of patients, and *C. difficile* colitis occurs in 1% to 10%.

The **clinical uses** of clindamycin encompass the treatment of anaerobic infections and infections outside the central nervous system. Examples include anaerobic and mixed pulmonary, head and neck, and pelvic infections. For the treatment of polymicrobial infections, clindamycin is commonly combined with a gram-negative active agent. Because of increasing resistance with *Bacteroides* species, metronidazole may be a better choice for anaerobic activity in intra-abdominal infections. Clindamycin is a useful alternative in the treatment of soft tissue infections. Through the inhibition of protein synthesis, clindamycin may reduce pyogenic toxin production. The combination of clindamycin and penicillin for necrotizing group A streptococcal or clostridial infections may be superior to either drug alone.

- Clindamycin has activity against aerobic and anaerobic gram-positive organisms.
- About 10% to 20% of *B. fragilis* organisms are resistant to clindamycin.
- Antibiotic-associated diarrhea can occur in up to 20% of patients, including *C. difficile* colitis in 1% to 10% of patients.

Metronidazole

Metronidazole is quite active against most anaerobic microorganisms, including *Bacteroides* species. The exceptions include some anaerobic gram-positive organisms including *Peptostreptococcus*, *Actinomyces*, and *Propionibacterium acnes*. The agent is also effective against infections due to *Entamoeba histolytica*, *Giardia lamblia*, and *Gardnerella vaginalis*. Metronidazole is cleared hepatically.

Toxic effects include nausea, vomiting, reversible neutropenia, metallic taste, a disulfiram reaction when coadministered with alcohol, and potentiation of the effects of oral anticoagulants. Major adverse reactions are rare and include central nervous system effects (seizures, cerebellar ataxia, peripheral neuropathy).

Clinical uses of metronidazole are broad because of its anaerobic bactericidal activity and excellent penetration into tissues (including the central nervous system). Metronidazole is an effective drug for the treatment of serious anaerobic and mixed infections (usually in combination with an agent active against aerobic organisms), including intra-abdominal infections, central nervous system abscesses, and some skin and soft tissue infections. Oral metronidazole is the treatment of choice for pseudomembranous colitis from *C. difficile*, giardiasis, amebiasis (followed by a luminal agent), bacterial vaginosis, and trichomoniasis. For polymicrobial infections, additional agents may be necessary for coverage of aerobes and certain gram-positive anaerobes.

- Metronidazole is quite active against most anaerobic bacteria. It is often used in combination with agents active against aerobes for mixed infections including intra-abdominal infections.
- Oral metronidazole is the treatment of choice for pseudomembranous colitis from *C. difficile*, giardiasis, amebiasis (followed by a luminal agent), bacterial vaginosis, and trichomoniasis.

Macrolides

Erythromycin

Erythromycin is available as IV and oral preparations and is active against group A β-hemolytic streptococci, most other β-hemolytic streptococci (including groups B, C, F, and G), and *S. pneumoniae* (although resistance is increasing). Most methicillin-sensitive *S. aureus* isolates are also sensitive to erythromycin, but resistance can develop. Additionally, erythromycin is active against *B. pertussis*, *Campylobacter jejuni*, *T. pallidum*, *Ureaplasma urealyticum*, *M. pneumoniae*, *Legionella pneumophila*, and *Chlamydia* species.

Toxic effects include gastrointestinal upset (dose-related), cholestatic jaundice (especially the erythromycin estolate compound), and transitory deafness (especially with large doses, such as 4 g/day). Erythromycin is hepatically cleared and can increase the serum levels of several drugs that are metabolized through the P-450 system, including theophylline, carbamazepine, and cyclosporine. High doses (usually of the IV formulation) can prolong the QT interval. A recent study indicated an increased incidence of sudden cardiac death in patients taking erythromycin, especially in combination with another drug that inhibits the P-450 3A4 isoenzyme, thus decreasing the metabolism of erythromycin.

Clinical uses: Erythromycin is a drug of choice for *M. pneumoniae* infections, diphtheria, pertussis, *C. jejuni* gastroenteritis, and bacillary angiomatosis. It remains an active drug for pneumonia caused by *Chlamydia* and *Legionella* species. Erythromycin is an

alternative agent for patients allergic to β-lactams for treatment of mild-to-moderate soft tissue infections caused by susceptible staphylococcal and nonenterococcal streptococcal infections. Additionally, erythromycin can treat and eradicate the carrier state of *Corynebacterium diphtheriae* and shorten the duration of *B. pertussis* disease (whooping cough). Erythromycin is safe during pregnancy. Erythromycin is commonly used as a promitility agent (unrelated to antimicrobial activity) in some gastrointestinal disorders.

- Erythromycin can increase the serum levels of several drugs that are metabolized through the hepatic P-450 system.
- Erythromycin, especially in combination with other drugs that can inhibit its metabolism, has been reported to increase risk of sudden cardiac death.
- Clinical uses include treatment of atypical respiratory pathogens (such as *Mycoplasma*, *Chlamydia*, and *Legionella*), pertussis, diptheria, and *Campylobacter* gastroenteritis.

Clarithromycin

This agent provides good **activity** against most *S. pneumoniae* (resistance is increasing), β-hemolytic streptococci, viridans streptococci, methicillin-sensitive *S. aureus*, *M. catarrhalis*, *L. pneumophila*, *M. pneumoniae*, *C. pneumoniae*, *Chlamydia trachomatis*, *B. burgdorferi*, and several non-tuberculosis mycobacterial species. It is superior to erythromycin for *S. pneumoniae* and β-hemolytic streptococci. It is moderately effective against *H. influenzae*.

In regard to **pharmacokinetics**, excellent concentrations are achieved in many body fluids. The drug penetrates macrophages and polymorphonuclear neutrophils. It is available only as an oral formulation, and food has no effect on absorption. Excretion is through the liver and kidneys.

Adverse effects include nausea and other gastrointestinal complaints (less often than erythromycin). As with erythromycin, reversible hearing loss may occur at high dosages. Similar to erythromycin, drug interactions due to inhibition of cytochrome P-450 enzymes can occur and close scrutiny for possible drug interactions should be performed before prescribing this agent.

Clinical uses of clarithromycin include the treatment of mild-to-moderate upper and lower respiratory tract infections, including sinusitis, pharyngitis, acute and chronic bronchitis, and community-acquired pneumonia. Other indications include *M. avium-intracellulare* complex and other atypical mycobacterial infections, in combination with other active agents.

Azithromycin

The **spectrum of activity** is similar to that of clarithromycin. However, it is more active against *H. influenzae* than clarithromycin. Azithromycin is the most active macrolide against *Legionella* species and remains active against *M. pneumoniae*, *C. pneumoniae*, *C. trachomatis*, and *U. urealyticum*.

Pharmacokinetics: Oral bioavailability is approximately 37%. Azithromycin achieves excellent concentrations in many body fluids. The agent penetrates macrophages and polymorphonuclear neutrophils. Food decreases absorption of the capsules but not the tablets or suspension. Its half-life is 68 hours, which allows once-daily dosing. In addition, for many mild-to-moderate infections, a 5-day course of oral azithromycin is as effective as a 10-day course with an alternative drug. Additionally, a single-dose, extended-release formulation is now available. Azithromycin is hepatically metabolized.

Adverse effects are similar to those for clarithromycin. Intravenous azithromycin can cause pain at the injection site. Unlike erythromycin and clarithromycin, azithromycin has minimal drug interactions with the P-450 metabolic pathway.

Clinical uses of azithromycin include oral azithromycin for treatment of community-acquired mild-to-moderate upper and lower respiratory tract infections and skin and soft tissue infections. Because of activity against *Mycoplasma*, *Chlamydia*, and *Legionella* species and the availability in an intravenous form, azithromycin IV also is commonly used with a β-lactam agent as empiric therapy for severe community-acquired pneumonia. It is theorized that there may be beneficial anti-inflammatory activity of macrolides.

Azithromycin is a first-line sexually transmitted disease agent against *C. trachomatis* and chancroid, and in high doses it has activity against *N. gonorrhoeae*. It is also first-line agent for prophylaxis (in patients with human immunodeficiency virus [HIV]) against *M. avium* complex and is used as alternative treatment in combination therapy against *M. avium* complex, other atypical *Mycobacteria*, and *Toxoplasma gondii* infections.

Ketolides

Telithromycin is the first ketolide antimicrobial agent and is available only as an oral formulation.

Spectrum of activity: The ketolides differ from the macrolides by the replacement of the cladinose moiety with a ketone group. The mechanism remains the same; however, because of dual binding sites, it has improved activity against macrolide-resistant *S. pneumoniae*. Telithromycin also has good activity against other community-acquired respiratory pathogens including *H. influenzae*, *M. catarrhalis*, *Mycoplasma*, *Legionella*, and *Chlamydia* pneumonia. It has similar activity to macrolides for *Staphylococcus*, *Bordetella*, and *Streptococccus pyogenes*.

Pharmacokinetics: Telithromycin has good penetration into the middle ear, paranasal sinus, tonsil, pulmonary tissue, leukocytes, and extracellular inflammatory fluids. About 70% of the dose is hepatically eliminated, with the CYP3A4 isoenzyme being responsible for about half. Telithromycin is also a potent inhibitor of CYP3A4, and concomitant administration results in increased plasma concentrations of other drugs metabolized by this pathway, including cisapride, simvastatin, lovastatin, and midazolam. Routine dosage adjustments in patients with hepatic impairment are not recommended by the manufacturer; however, a dose decrease should be considered in subjects with creatinine clearance less than 30 mL/min.

Adverse effects most commonly include diarrhea, nausea, vomiting, headache, dizziness, abdominal pain, and vaginal candidiasis. Gastrointestinal effects may be more common than with clarithromycin, cephalosporins, or quinolones. Other adverse effects reported less frequently include taste perversion, flatulence, and vision problems, including blurred vision, difficulty focusing, and diploplia. Telithromycin can prolong the QT interval and should be avoided in patients with congenital QT prolongation, patients

with ongoing proarrhythmic conditions, or patients receiving class IA or class III antiarrhythmic agents. Other potential drug interactions should be reviewed closely before using telithromycin. It is not recommended for use in patients with myasthenia gravis unless no other therapeutic alternatives are available because acute, severe exacerbations have been reported.

Clinical uses: Telithromycin is comparable to the macrolides in activity against respiratory pathogens but has enhanced activity against some penicillin- and erythromycin-resistant strains of *S. pneumoniae*. It is as effective as other oral therapies routinely used for community-acquired pneumonia, acute exacerbation of chronic bronchitis, and acute sinusitis.

- Telithromycin is an oral option for community-acquired respiratory infections and may be more active than macrolides against some strains of *S. pneumoniae*.
- Drug interactions are similar to those of erythromycin and clarithromycin and need to be reviewed closely.
- Telithromycin can cause visual disturbances, particularly in slowing the ability to accommodate and the ability to release accommodation. Visual disturbances have included blurred vision, difficulty focusing, and diplopia.
- Telithromycin should be avoided in patients with risk factors for QT interval prolongation or myasthenia gravis.

Vancomycin

IV vancomycin, a glycopeptide antibiotic, has a **spectrum of activity** against most aerobic and anaerobic gram-positive organisms. However, it is not active against certain strains of *Lactobacillus*, *Leuconostoc*, *Actinomyces*, and vancomycin-resistant *Enterococcus* species. Vancomycin is a drug of choice for infections caused by methicillin-resistant *S. aureus*, methicillin-resistant coagulase-negative staphylococci, highly penicillin-resistant *S. pneumoniae*, *Bacillus* species, *Rhodococcus equi*, and other multiply resistant gram-positive organisms such as *Corynebacterium jeikeium*. It is also an alternative agent for infections caused by methicillin-sensitive staphylococci, enterococci (synergistic with aminoglycosides), or streptococci in patients intolerant of β-lactam antimicrobials. Although vancomycin is an active agent, it is less effective than antistaphylococcal β-lactams for treatment of methicillin-susceptible *S. aureus* infections and is not the drug of choice in this setting.

Oral vancomycin is not systemically absorbed and is used for treatment of *C. difficile* colitis after failure, or due to intolerance, of metronidazole.

Vancomycin-resistant strains of *Enterococcus* are becoming a serious problem. Additionally, of considerable concern is that staphylococcal organisms with reduced susceptibility or resistance to vancomycin have been reported. Fortunately, these are currently rare. The widespread use of vancomycin poses a substantial risk for the development of vancomycin-resistant organisms, and the Centers for Disease Control and Prevention has developed guidelines designed to limit the unnecessary use of this drug (Table 14-26).

Pharmacokinetics: Vancomycin is renally eliminated and has a half-life of 4 to 6 hours in patients with normal renal function. Dosing nomograms are available for empiric dosage adjustment for renal function, and serum levels often are monitored for further adjustments. Vancomycin has been used for treatment of central nervous system infections, but its penetration is less than that of β-lactam agents. This agent is not orally absorbed.

Adverse effects: Although rare, ototoxicity is the major toxic effect with vancomycin. This side effect is more common in the elderly and when vancomycin and aminoglycosides are administered concurrently and may not readily be reversible. Infusion-related pruritus and the production of an erythematous rash or flushing reaction involving the face, neck, and upper body ("red man" or "red neck" syndrome) are due to a non–immunologic-related release of histamine. Its frequency can be reduced by slowing the rate of infusion and by the administration of antihistamines before vancomycin infusion.

In its early years, vancomycin contained impurities that were nephrotoxic and sometimes was called "Mississippi Mud." However, with the current preparation, nephrotoxicity is uncommon, except when vancomycin and aminoglycosides (or other nephrotoxic agents) are administered concurrently. With appropriate monitoring, it can be used in patients with underlying renal impairment or those receiving dialysis. Chemical thrombophlebitis, hypersensitivity, and reversible neutropenia are also known side effects.

The **clinical uses** for vancomycin outlined by the Centers for Disease Control and Prevention are listed in Table 14-27.

- Vancomycin is bactericidal against most aerobic and anaerobic gram-positive organisms.
- Vancomycin is a drug of choice for infections caused by methicillin-resistant *S. aureus*, methicillin-resistant coagulase-negative staphylococci, ampicillin-resistant enterococci, highly penicillin-resistant *S. pneumoniae*, and *Bacillus* sp.
- Oral vancomycin is not absorbed and should not be used to treat systemic infections.
- The major toxic effect is ototoxicity. Nephrotoxicity can occur when vancomycin is coadministered with other nephrotoxic agents.
- "Red man" syndrome is due to non–immunologic-related release of histamine. This is not a true allergy.

Cotrimoxazole (Trimethoprim-Sulfamethoxazole)

Cotrimoxazole consists of two separate antimicrobials, trimethoprim and sulfamethoxazole, combined in a fixed (1:5) ratio. Both trimethoprim and sulfamethoxazole inhibit microbial folic acid synthesis and act synergistically when used in combination.

The **spectrum of activity** of cotrimoxazole includes a wide variety of aerobic gram-positive cocci and gram-negative bacilli, including *S. aureus* (moderate activity), many coagulase-negative staphylococci, most *S. pneumoniae*, *H. influenzae*, *M. catarrhalis*, *L. monocytogenes*, and many Enterobacteriaceae. It is active against *Pneumocystis carinii*, *S. maltophilia*, and *Nocardia asteroides*, *Shigella* species (although resistant strains are reported), *Isospora belli*, and *Cyclospora cayetanensis*. It is not active against anaerobic bacteria, *P. aeruginosa*, *Enterococcus*, or many strains of *Citrobacter freundii*, *Proteus vulgaris*, and *Providencia*.

Toxic effects with cotrimoxazole commonly include nausea and vomiting and rash. Hypersensitivity reactions are more common

in patients with acquired immunodeficiency syndrome (AIDS), but desensitization often can be done effectively for mild hypersensitivity. Nephrotoxicity, myelosuppression, hepatitis, and hyperkalemia are less frequent but may occur, especially when high-dose therapy (e.g., 15-20 mg/kg per day of trimethoprim) is used for *Pneumocystis* or *Nocardia*. Caution or avoidance should be considered during the last trimester of pregnancy (to minimize risk of fetal kernicterus) and in patients with known glucose-6-phosphatase dehydrogenase deficiency. Cotrimoxazole has several known drug interactions, including increasing the activity of oral anticoagulants, increasing plasma phenytoin concentrations, enhancing hypoglycemia in patients taking oral hypoglycemics, and contributing to myelosuppression when coadministered with immunosuppressive agents.

Clinical uses of cotrimoxazole include the treatment of selected respiratory tract infections, urinary tract infections (although resistance for *E. coli* is increasing), prostatitis, and gastrointestinal bacterial infections with susceptible organisms. It is the drug of choice for treatment of *P. carinii* pneumonia, nocardiosis, and infections caused by *Stenotrophomonas*. It is also the drug of choice for prophylaxis against *P. carinii* pneumonia and toxoplasmosis in HIV-infected patients. It is an alternative in penicillin-allergic patients with *Listeria* meningitis.

- The spectrum of activity of cotrimoxazole includes a wide variety of gram-positive and gram-negative aerobic organisms.
- It is the drug of choice for treatment of *P. carinii* pneumonia, nocardiosis, and *Stenotrophomonas* infections and for prophylaxis against *P. carinii* pneumonia and toxoplasmosis in HIV-infected patients.
- With cotrimoxazole, hypersensitivity reactions are common in patients with AIDS.

Fluoroquinolones

Agents include norfloxacin, ciprofloxacin, ofloxacin, levofloxacin, gatifloxacin, moxifloxacin, and gemifloxacin.

The **spectrum of activity** of fluoroquinolones varies from drug to drug. In general, they are active against most aerobic gram-negative bacilli, including the Enterobacteriaceae, *H. influenzae*, and some staphylococci. Gram-positive and anaerobic activity varies. Of concern is that bacterial resistance to fluoroquinolones is increasing, particularly among *P. aeruginosa*, staphylococci, and *N. gonorrhoeae*.

The fluoroquinolone agents have been divided into "generations" on the basis of spectra and drug age. These vary slightly according to the reference source but are somewhat helpful for discussing the differences in spectra among the various agents.

The first-generation agent, nalidixic acid, is no longer used. Second-generation agents include ciprofloxacin, ofloxacin, and norfloxacin. Of these, ciprofloxacin is the primary agent used systemically. These agents achieve good tissue and fluid concentrations and can be used for infections at numerous sites. Ciprofloxacin has the best activity against *P. aeruginosa* of the currently available fluoroquinolones. Ciprofloxacin does not have good activity against *S. pneumoniae*, and clinical failures have been reported. Thus, it should not be used empirically for treatment of community-acquired respiratory tract infections.

The third-generation agent levofloxacin has improved activity against *S. pneumoniae* and other gram-positive organisms. It also retains good gram-negative coverage. It has good activity against atypical pneumonia pathogens such as *C. pneumoniae*, *M. pneumoniae*, and *Legionella*.

The currently available fourth-generation agents include gatifloxacin, moxifloxacin, and gemifloxacin. These agents have appreciable activity against anaerobes, including *B. fragilis*, and enhanced activity against gram-positive organisms, such as *S. pneumoniae*, other streptococcal species, and *Staphylococcus*. These agents also remain quite active against aerobic gram-negative bacilli and have enhanced activity against atypical pneumonia organisms (e.g., *C. pneumoniae*, *M. pneumoniae*, and *Legionella*). However, they are less active than ciprofloxacin against *P. aeruginosa*.

IV formulations of ciprofloxacin, ofloxacin, levofloxacin, moxifloxacin, and gatifloxacin are currently available. In general, oral formulations should be used whenever possible because they attain plasma levels similar to the IV formulations and are much less costly.

Clinical uses of the fluoroquinolones are quite broad. They are useful for treatment of gram-negative aerobic infections such as complicated urinary tract infections (not moxifloxacin because it does not achieve optimal urinary concentrations), prostatitis, and many resistant gram-negative organisms (e.g., nosocomial pneumonia).

The newer agents, moxifloxacin, gatifloxacin, gemifloxacin, and levofloxacin, are particularly well suited to treatment of community-acquired respiratory tract infections. Other uses of fluoroquinolones include infectious diarrhea, osteomyelitis, and mycobacterial infections (second-line).

Pharmacokinetics: Fluoroquinolones are very well absorbed; thus, oral therapy often can be used in place of IV therapy. Norfloxacin, ofloxacin, levofloxacin, ciprofloxacin, and gatifloxacin are renally eliminated; doses should be adjusted for renal function. Moxifloxacin is primarily hepatically metabolized. Gemifloxacin has dual fecal and urinary elimination. The fluoroquinolones (except norfloxacin) generally penetrate well into most tissues and fluids.

Fluoroquinolones are generally fairly well tolerated. The more common **toxic effects** are gastrointestinal and include nausea, vomiting, abdominal pain, and diarrhea. *C. difficile* colitis is rare. Rash appears to be most frequent with gemifloxacin.

Central nervous system effects are rare (incidence is somewhat variable among the agents) but can include headache, dizziness, lightheadedness, confusion, hallucinations, restlessness, tremors, and seizures. Seizures are uncommon and usually are associated with an underlying seizure disorder or central nervous system structural defect and high doses relative to organ function.

Fluoroquinolones can cause erosions in cartilage in animals and thus are not recommended in pregnant women or in patients younger than 18 years (exceptions exist where alternatives are scarce). Tendinitis and tendon rupture are rare complications of fluoroquinolones.

Levofloxacin, gatifloxacin, gemifloxacin, and moxifloxacin all have warnings about prolongation of the QT interval in their package inserts. This adverse effect is quite rare, but these agents generally should be avoided in patients at increased risk of arrhythmias. Gatifloxacin may cause disturbances in glucose homeostasis in some patients, resulting in hyperglycemia or hypoglycemia.

There are several important **drug interactions** with fluoroquinolones. Gastrointestinal absorption of the fluoroquinolones is decreased by coadministration of divalent or trivalent cations, which are found in aluminum- and magnesium-containing antacids, multivitamin preparations that include zinc, and oral iron preparations. Calcium decreases absorption of norfloxacin, levofloxacin, and ciprofloxacin. Concurrent administration of sucralfate also inhibits their absorption. Spacing the administration of the fluoroquinolone and interacting drug by several hours can minimize these absorption interactions. Some fluoroquinolones, particularly ciprofloxacin and to a lesser extent, ofloxacin increase serum theophylline and caffeine concentrations. They can also enhance the effects of warfarin and close monitoring of the international normalized ratio is recommended if used in combination.

- Coadministration of aluminum-, calcium-, and magnesium-containing antacids, oral iron preparations, sucralfate, and multivitamin preparations with minerals decreases gastrointestinal absorption of the fluoroquinolones.
- Ciprofloxacin has the best activity against *Pseudomonas*, whereas gatifloxacin, moxifloxacin, and gemifloxacin have enhanced activity against community-acquired respiratory pathogens.

Other Antibacterial Agents

Linezolid is an oxalodinone that possesses activity against gram-positive bacteria, including methicillin-resistant *S. aureus*, methicillin-resistant *Staphylococcus epidermidis*, vancomycin-resistant enterococci (some resistance reported), and penicillin-resistant *S. pneumoniae*. Additionally, it has activity against *Nocardia* (second line) and some *Mycobacteria* species, including *M. tuberculosis* and many other mycobacterial species. Linezolid is not active against gram-negative bacteria.

Pharmacokinetics: Linezolid can be administered either orally or intravenously. Linezolid is rapidly and extensively absorbed after oral dosing; its bioavailability approaches 100%. Thus, oral administration is the preferred route whenever possible. It is well distributed throughout the body and penetrates into the cerebrospinal fluid. It is hepatically metabolized with predominantly inactive metabolites excreted through the kidneys.

The most prominent **adverse effect** is myelosuppression, especially with prolonged use. Headache, diarrhea, and peripheral or optic neuropathy also can occur. Linezolid is also a weak monoamine oxidase inhibitor that can interact with some medications, such as selective serotonin reuptake inhibitor or monoamine oxidase inhibitor antidepressants. Rare cases of serotonin syndrome have been reported when linezolid is used in combination with antidepressants.

Clinical uses of linezolid include the treatment infections caused by resistant gram-positive bacteria. Many clinicians advise cautious use of this agent because of its high cost and to preserve its activity against resistant gram-positive pathogens when there are few other available options. It is an alternative agent for the treatment of susceptible gram-positive infections in patients intolerant to first-line agents.

Dalfopristin-quinupristin (**Synercid**) acts synergistically to produce good activity against gram-positive cocci, including vancomycin-resistant *Enterrococcus faecium*. However, activity against *Enterococcus faecalis* is substantially decreased. This agent is also active against staphylococci, including methicillin-resistant strains.

Pharmacokinetics: Dalfopristin-quinuprostin is available only for intravenous administration and is hepatically metabolized. Because it can inhibit the metabolism of other medications metabolized by way of the cytochrome P-450 isoenzyme, close attention to potential drug interactions is advised.

Adverse reactions include a relatively high rate of inflammation and irritation at the infusion site, arthralgias, myalgias, and hyperbilirubinemia.

For **daptomycin**, the **spectrum of activity** includes *S. aureus* (including methicillin-resistant strains), *Streptococcus pyogenes*, *Streptococcus agalactiae*, and *Enterococcus* (including vancomycin-resistant strains). It also has shown in vitro activity against *Corynebacterium* species, *Peptostreptococcus*, and *Eubacterium*, *Propionibacterium*, and *Clostridium* species.

Pharmacokinetics: Daptomycin is 92% bound to serum albumin in healthy adults. It has a 7- to 11-hour plasma elimination half-life. Excretion is primarily renal.

Toxicities of daptomycin include gastrointestinal effects, hypersensitivity reactions, headache, insomnia, myalgias, and increase in creatine phosphokinase value. The manufacturer suggests stopping use of hydroxymethylglutaryl coenzyme A reductase inhibitors (statins) during daptomycin therapy and monitoring creatine phosphokinase values once weekly.

Clinical uses: This agent is approved by the U.S. Food and Drug Administration for complicated skin and skin structure infections caused by gram-positive pathogens. A recent study found noninferiority for treatment of staphylococcal bacteremia and endocarditis, and the manufacturer is applying to the U.S. Food and Drug Administration for an indication. It may find use for treatment of vancomycin-resistant enterococci, but clinical data are currently scant. It should not be used for treating pneumonia because it may be inactivated by surfactant and has poor penetration.

Antituberculosis Agents

First- and second-line drugs are summarized in Tables 14-28 and 14-29.

For the past 50 years, isoniazid (INH) has been the cornerstone of combination drug therapy against *M. tuberculosis* and for treatment of latent tuberculosis infections. It is rapidly absorbed and readily diffuses across all body fluids and tissues. It penetrates into the cerebrospinal fluid and is effective for treatment of central nervous system disease. INH is metabolized by the liver and excreted in the urine, mostly as inactive metabolites. Although the rate of metabolism is determined by genetic acetylation phenotype, the acetylation status of an individual has not been shown to influence the outcome with daily therapy. INH is safe during pregnancy. Hepatitis is uncommon but is the most notable INH-related toxicity. When it occurs, it usually develops during the first 4 to 8 weeks of therapy. INH can increase the elimination of pyridoxine (vitamin B_6), resulting in peripheral neuropathy. Malnutrition, alcoholism, diabetes, pregnancy, and uremia increase the risk of peripheral neuropathy. It usually develops in a "stocking-glove" fashion and can be prevented by

adding supplemental pyridoxine 5 to 50 mg/day. Hypersensitivity reactions, positive antinuclear antibody titers, and lupus-like reactions also can occur with INH therapy.

- Hepatotoxicity is the most serious adverse effect of INH.
- Peripheral neuropathy can be prevented with the coadministration of pyridoxine.
- Hypersensitivity reactions, positive antinuclear antibody titers, and lupus-like reactions can occur with INH.

Rifampin is a potent, bactericidal antimycobacterial agent and a vital component in 6- and 9-month combination treatment regimens for active infection. It is rapidly absorbed and widely distributed throughout the body and achieves moderate cerebrospinal fluid penetration. It is predominantly hepatically metabolized with enterohepatic circulation; lesser amounts are excreted in the urine. It is safe in pregnancy. Hepatitis with an increase in transaminase value can occur with rifampin; however, increased bilirubin and alkaline phosphatase levels are more characteristic. Anemia, thrombocytopenia, orange discoloration of body fluids (including permanent staining of soft contact lenses), light-chain proteinuria, and hypersensitivity reactions can occur with rifampin. Rifampin will induce the hepatic cytochrome P-450 metabolic pathway, causing a substantial decrease in the serum concentration of drugs metabolized by this pathway (Table 14-30). The maximal effect of these drug interactions may be delayed 1 to 2 weeks. Drug-to-drug interactions should be kept in mind when prescribing rifampin.

Rifabutin has activity similar to that of rifampin against *M. tuberculosis*. Rifabutin induces the hepatic cytochrome P-450 pathway to a lesser extent than rifampin. This allows for rifabutin use by HIV-coinfected patients taking certain protease inhibitors. Rifabutin has a side effect profile similar to that of rifampin and may additionally produce uveitis, arthritis or arthralgias, leukopenia, and bronze skin pigmentation. Of note, *M. tuberculosis* isolates resistant to rifampin are usually resistant to rifabutin. Both rifampin and rifabutin have activity against *M. avium* complex.

Rifapentine is another rifamycin antibacterial agent like rifampin and rifabutin but has a much longer half-life. This allows for less frequent dosing, reduced total number of doses to complete treatment, and easier administration of directly observed therapy. Once-weekly rifapentine and INH may be used in the continuation phase of therapy for select non-HIV infected patients.

Two fixed-dose combination drugs are currently available in the United States for the treatment of tuberculosis: INH plus rifampin (**Rifamate**) and INH plus rifampin plus pyrazinamide (**Rifater**). Typical daily doses are 2 tablets of Rifamate (300 mg INH, 600 mg rifampin) or 6 tablets of Rifater (300 mg INH, 720 mg rifampin, 1,800 mg pyrazinamide); however, individualized dosing adjustments may be needed.

- Increased bilirubin and alkaline phosphatase values may occur with rifampin.
- Rifampin and (to a lesser extent) rifabutin induce the hepatic cytochrome P-450 system, decreasing the serum concentration of many coadministered drugs.
- Rifabutin may cause uveitis, arthritis or arthralgias, and bronze skin pigmentation.

Pyrazinamide (PZA) is more active in an acidic environment and exerts potent bactericidal activity within cavitary or suppurative disease. PZA is an essential initial component of a 6-month combination drug regimen; the benefit of PZA is less clear beyond the first 2 months of therapy. PZA is readily absorbed and diffuses throughout all body fluids and tissues. It achieves good cerebrospinal fluid penetration for the treatment of central nervous system disease. Because data are insufficient regarding the potential teratogenicity of PZA, the Centers for Disease Control and Prevention recommends it should generally be avoided during pregnancy. As with INH and rifampin, hepatitis also can occur with PZA. Hyperuricemia is common, although clinical gout is rare.

- PZA is most active during the first 2 months of therapy and within an acidic medium.
- Hepatitis and hyperuricemia may occur with PZA, but clinical gout is rare.
- PZA is an important initial component of a 6-month combination treatment program for active disease.

Ethambutol is readily absorbed, with variable cerebrospinal fluid penetration. It is predominantly excreted in the urine and is safe in pregnancy. Retrobulbar or optic neuritis is the most noteworthy toxic effect of ethambutol. It usually manifests as a decrease in red-green color discrimination, visual acuity, and visual field. Caution must be used in young children because visual testing may be unreliable.

Streptomycin is one of the oldest antituberculosis and aminoglycoside agents in use today. However, because of increased global resistance, streptomycin is no longer considered a first-line agent. It requires IV or IM injection and is renally excreted. Notable toxic effects are vestibular, auditory, and renal. Appropriate drug dosing should be based on serum drug concentrations. Vestibular, auditory, and renal function should be closely monitored.

- Retrobulbar or optic neuritis is the most noteworthy toxic effect of ethambutol.
- Vestibular, auditory, and renal toxicity can occur with streptomycin.

Drug intolerance and microbial resistance are common in the management of tuberculosis and may require the addition of one or more "second-line" antituberculosis agents (Table 14-29). The widespread use of these agents for mycobacterial disease is curbed by reduced activity or increased toxicity or both. **Amikacin**, **kanamycin**, and **capreomycin** are injectable agents with moderate antituberculosis activity. Auditory (high-frequency hearing loss), vestibular, and renal dysfunction are the most common toxic effects. Amikacin and kanamycin are aminoglycosides, whereas capreomycin is a polypeptide antibiotic. **Ethionamide** is highly absorbed and penetrates well into the cerebrospinal fluid. Its use is usually limited by gastrointestinal intolerance (nausea, vomiting, and dysgeusia). Additional

side effects include arthralgias and certain endocrine disorders (hypothyroidism, glucose abnormalities, sexual and menstrual abnormalities). **Para-aminosalicylic acid** (PAS) has been in use for the past 50 years and is formulated in delayed-release granules with an acid-resistant outer coating (Paser granules). Rash is common with PAS use, as are gastrointestinal intolerance (nausea, vomiting, and abdominal discomfort), hepatitis, and hypothyroidism. Moxifloxacin, gatifloxacin, and levofloxacin are the preferred fluoroquinolones and are commonly used as second-line agents. They have moderate antituberculosis activity and are usually better tolerated than other second-line agents. **Cycloserine** is not as commonly used because of its high side-effect profile, but it has a role against multidrug-resistant tuberculosis. Notable side effects include psychosis, confusion, depression, and headaches. Coadministration of pyridoxine may help decrease the incidence of central nervous system-related side effects.

- Amikacin, streptomycin, kanamycin, capreomycin, levofloxacin, gatifloxacin, moxifloxacin, ethionamide, cycloserine, and PAS are second-line antituberculosis agents.
- They usually have reduced activity and increased toxicity.

Antifungal Therapy

Azole Antifungal Agents

The azole antifungal agents produce their fungistatic effect by interfering with the synthesis and permeability of fungal cell membranes. They do this through inhibition of the fungal cytochrome P-450 enzyme responsible for conversion of lanosterol to ergosterol, which is a major constituent of fungal cell membranes. The azole antifungal agents are less toxic alternatives to amphotericin for many types of fungal infections.

Selected pharmacologic properties of azole antifungal agents are listed in Table 14-31.

Fluconazole

Spectrum of activity: Fluconazole has good activity against most *Candida* species (less activity for *Candida glabrata* and *Candida krusei*), *Cryptococcus*, *Coccidioides*, *Histoplasma*, *Blastomyces*, and *Paracoccidioides* infections.

Pharmacokinetics: Because of the long half-life of fluconazole, it can be administered in a once-per-day dose. It is available in oral tablet, oral suspension, and IV formulations. Because of its excellent oral absorption and the considerably higher expense of IV therapy, fluconazole should be given orally whenever possible. Fluconazole achieves good penetration into the cerebrospinal fluid and is primarily renally eliminated.

Clinical uses include treatment of many types of susceptible candidal infections. The drug also may be used for prophylaxis of candidal infection in patients undergoing bone marrow transplantation and in AIDS patients with chronic, recurrent mucocutaneous candidiasis. A concern is emergence or selection of resistant fungi, such as *C. krusei*, *C. glabrata*, and more rarely, resistant *Candida albicans* (especially in HIV). In serious infections, speciation and susceptibility testing of candidal organisms should be considered.

Fluconazole is also used for treatment of cryptococcal meningitis. For this infection, most experts recommend initial therapy for serious infections with amphotericin B and flucytosine, followed by maintenance therapy with fluconazole. Additionally, fluconazole has been used successfully for treatment of *Coccidioides* meningitis. It is second-line therapy for non–life-threatening cases of histoplasmosis and blastomycosis (after itraconazole and amphotericin).

Adverse effects: This agent is generally well tolerated, and discontinuation of therapy is rarely necessary. The most common effects are gastrointestinal symptoms, rash, and headache. Mild increases in liver function values are occasionally found, but fatal hepatic necrosis is rare. There is no interference with adrenocortical function or synthesis of testosterone, which can occur with ketoconazole.

Drug interactions: Although to a lesser degree than other azoles, fluconazole, through inhibition of the cytochrome P-450 isoenzyme 3A4, inhibits metabolism of several drugs, including phenytoin, oral hypoglycemic agents, carbamazepine, cyclosporine, tacrolimus, dihydropyridine calcium channel blockers, and warfarin. It also can increase concentrations of rifabutin, leading to potential uveitis. Coadministration with rifampin or INH decreases serum concentrations of fluconazole.

Itraconazole

Spectrum of activity: A major advantage of itraconazole over fluconazole is its greater activity against *Aspergillus*, *Sporothrix schenckii*, *Histoplasma capsulatum*, and *Blastomycosis dermatitidis*. It also has activity against *Coccidioides immitis* and *Candida* species (cross-resistance can occur).

Pharmacokinetics: Itraconazole is available in capsule and oral solution formulations and an IV preparation. The two oral formulations are not bioequivalent; the oral solution produces considerably higher serum concentrations and higher area under the curve. For optimal absorption, the capsule should be taken with food, and the liquid on an empty stomach. Because oral absorption (especially with the capsule formulation) is erratic, serum levels should be checked to document adequate systemic levels when itraconazole is used for serious infections. The IV formulation produces higher systemic levels than equivalent doses of oral itraconazole. Itraconazole is extensively metabolized and has an active metabolite, hydroxyitraconazole.

The IV formulation contains the excipient hydroxypropyl-(β)-cyclodextrin, which produced pancreatic adenocarcinomas in a rat carcinogenicity study. The clinical significance in humans is unknown. Because the excipient is renally eliminated and can accumulate with renal dysfunction, caution should be used in prescribing IV itraconazole in patients with renal insufficiency (i.e., creatinine clearance <30 mL/min).

Clinical uses include mild-moderate histoplasmosis, blastomycosis, coccidioidomycosis, sporotricosis, invasive aspergillosis, and onychomycosis. Itraconazole is an alternative for treatment of many *Candida* species, although cross-resistance with fluconazole can occur. Itraconazole also has been studied as a corticosteroid-sparing agent in allergic bronchopulmonary aspergillosis.

The most common **side effects** involve the gastrointestinal tract and rash. Similar to fluconazole, hepatitis can occur but is rare. At

lower doses, there is typically little or no effect on glucocorticoid or testosterone synthesis (as can be seen with ketoconazole). With higher doses or systemic levels, edema, hypokalemia, nausea, and vomiting can occur. Congestive heart failure has rarely been reported in patients with cardiac disease.

Drug interactions: Itraconazole inhibits metabolism and increases serum levels of many drugs, such as cyclosporine, tacrolimus, digoxin, midazolam, triazolam, and cisapride. Cyclosporine, tacrolimus, and digoxin levels should be monitored if concomitant therapy is used. Coadministration with rifampin, isoniazid, phenytoin, and carbamazepine can decrease itraconazole levels. Itraconazole capsules require gastric acid for absorption; thus, absorption is decreased with concomitant use of histamine$_2$ blockers, antacids, proton pump inhibitors, and didanosine chewable tablets (contain an antacid buffer). These gastric pH interactions are not substantial with the oral liquid formulation of itraconazole.

Voriconazole

Voriconazole has enhanced activity against *Aspergillus* species and *Scedosporium apiospermum* (*Pseudallescheria boydii*). It also has activity against *Candida* (including many fluconazole-resistant strains), *Fusarium* species, *Cryptococcus*, *Blastomyces*, and *Trichophyton*. It also has some activity against *Histoplasma*, but it is inactive against the Zygomycetes.

Pharmacokinetics: Voriconazole is well absorbed and penetrates tissues well (including central nervous system penetration with inflammation). It undergoes hepatic metabolism through P-450 enzymes. It inhibits the cytochrome P-450 3A4 enzyme and thus interacts with drugs metabolized through this pathway. In patients with creatinine clearance less than 50 mL/min, IV voriconazole should be used only if the benefit outweighs the risk because of potential accumulation of the intravenous vehicle (sulfobutyl ether β-cyclodextrin sodium). Similar to itraconazole, the clinical significance is unknown.

Clinical uses: Voriconazole has good activity against *Aspergillus* and *Candida* and is a welcome addition to the antifungal agents for immunocompromised patients. Voriconazole is not approved by the U.S. Food and Drug Administration for the empiric treatment of neutropenic fever; however, its performance and measured outcomes were closely similar to those of amphotericin. Its activity against *Scedosporium*, *Fusarium*, and *Candida* species makes this agent a useful alternative in treating infections caused by these pathogens.

Toxic effects include transient visual disturbances, which have been reported in up to 10% to 20% of patients, and rash. Similar to other azoles, voriconazole can cause increased liver enzyme values and can cause hepatotoxicity.

- Voriconazole has good activity against *Aspergillus* and has become a drug of choice for this infection.
- Voriconazole frequently causes transient visual disturbances, including blurred vision, changes in color vision, photophobia, and other visual perception changes. These are generally mild and typically do not cause discontinuation of therapy.

Posaconazole

Posaconazole is a new triazole antifungal that is structurally related to itraconazole. Posaconazole is undergoing review by the U.S. Food and Drug Administration for treatment of invasive fungal infections in refractory cases or when patients are intolerant of alternatives.

The **spectrum of activity** includes *Candida* (including species that are resistant to fluconazole), *Aspergillus*, *Histoplasma*, *Blastomyces*, *Coccidioides*, *Cryptococcus*, and *Scedosporium*. Importantly, it is the first azole antifungal to have activity against the Zygomycetes.

Pharmacokinetics: Posaconazole is available only as an oral suspension and absorption is significantly enhanced with food, especially a high-fat meal. It has a half-life of about 20 hours and is extensively protein-bound with wide tissue distribution. It is metabolized primarily by glucuronidation, with elimination in feces. Unlike other azole antifungals, it is not a substrate of CYP450 enzymes. However, it inhibits CYP3A4 and can decrease metabolism of other drugs metabolized by this isoenzyme so drug interactions should be reviewed prior to prescribing posaconazole.

Adverse reactions include gastrointestinal disturbances, dry mouth, headache, somnolence, increased liver function values, and possibly neutropenia.

- Posaconazole is the first azole antifungal to have significant activity against the Zygomycetes. It also has a wide spectrum of activity for other fungal pathogens.
- Posaconazole is available only as an oral preparation and absorption is enhanced by administration with food.

Ketoconazole

Ketoconazole was the first of the azole antifungals. It has a broad **spectrum of activity**; however, because of its toxicities and the improved pharmacologic characteristics of newer agents, ketoconazole is typically no longer an antifungal drug of choice.

Ketoconazole is available only as an oral agent and requires gastric acid for absorption. It has numerous drug interactions through inhibition of the P-450 cytochrome system. The most common **toxic effect** of ketoconazole is dose-related gastrointestinal upset. Decreased synthesis of adrenal corticosteroids, most notably androgenic corticosteroids, is a dose-related effect that may occur with ketoconazole. This may lead to gynecomastia, menstrual irregularities, and loss of libido with impotence. A mineralocorticoid effect can occur, producing arterial hypertension, edema, and hypokalemia. This effect has been used therapeutically for treatment of Cushing syndrome.

- Ketoconazole requires gastric acid for absorption and has serious drug interactions with medications that are metabolized through the P-450 isoenzyme CYP3A4.
- Because of anti-androgenic effects, gynecomastia, menstrual effects, and loss of libido are fairly common side effects.

Polyenes

Amphotericin B Products

Amphotericin binds to ergosterol in the cell membrane and alters permeability, resulting in leakage of select intracellular contents and cell death. The **spectrum of activity** of amphotericin is the broadest of currently available agents and includes most yeasts, *Aspergillus*,

the Zygomycetes, dimorphic fungi, and most dematiaceous molds. It is commonly used for serious or life-threatening fungal infections, especially in immunocompromised patients. Organisms that might exhibit resistance include *P. boydii*, *Candida lusitaniae*, *Candida guilliermondii*, *Fusarium* species, *Trichosporon* species, some of the species that cause chromoblastomycosis, and phaeohyphomycosis.

Toxic effects include infusion-related reactions such as fever, chills or rigors, nausea, and vomiting. Pretreatment options (such as diphenhydramine, acetaminophen, and meperidine) may lessen these adverse reactions if a patient experiences problems. Nephrotoxicity (usually reversible) is the other major side effect of amphotericin B. This can be reduced by saline hydration, every-other-day dosing, or use of a lipid formulation of amphotericin B. Nephrotoxicity is increased with concomitant use of cyclosporine or other nephrotoxic agents. Other adverse effects include hypokalemia, hypomagnesemia, reversible anemia, and phlebitis. More rarely, changes in blood pressure, bradycardia, neurologic effects, and pulmonary decompensation can occur.

Three lipid formulations of amphotericin B are available: amphotericin B lipid complex (Abelcet), amphotericin B cholesteryl sulfate (Amphotec), and liposomal amphotericin (AmBisome). These agents have considerably less renal toxicity than amphotericin B. The incidence of infusion-related adverse effects varies among these agents; liposomal amphotericin (AmBisome) seems to have the least infusion-related adverse effects and has a lower incidence of electrolyte disturbances. Unfortunately, lipid amphotericin preparations are very expensive; however they are increasingly prescribed because of improved patient tolerability.

Clinical uses of amphotericin include the treatment of deep-seated or life-threatening fungal infections. It is often used for serious candidal infections, fever not responding to antimicrobials in neutropenic patients, invasive *Aspergillus* infections, initial treatment of cryptococcal meningitis (often in combination with flucytosine), and life-threatening or disseminated histoplasmosis, blastomycosis, and coccidioidomycosis. It is the drug of choice for treatment of infections caused by the Zygomycetes.

- Amphotericin has a broad spectrum of activity against fungal pathogens including *Candida*, *Aspergillus*, and Zygomycetes.
- The most significant adverse effects are nephrotoxicity and electrolyte disturbances. The incidence of nephrotoxicity is less with the lipid formulations of amphotericin and liposomal amphotericin has a lower incidence of electrolyte abnormalities.

Echinocandins

Caspofungin

Caspofungin was the first agent available in the glucan synthesis inhibitor class of antifungal agents. These agents inhibit the synthesis of β-(1,3)-D-glucan, an integral part of the cell wall.

Spectrum of activity: Caspofungin has activity against *Aspergillus* and *Candida* species, including most azole-resistant strains. However, it has reduced activity against *Histoplasma*, *Blastomyces*, and possibly *Candida parapsilosis* and *C. guilliermondi*. It is not active against *Cryptococcus*, *Fusarium*, or the Zygomycetes). Caspofungin is available only in an IV formulation and currently is not approved for use in patients younger than 18 years.

Pharmacokinetics: Caspofungin is slowly metabolized by hepatic acetylation and hydrolysis and also undergoes spontaneous chemical degradation. Only a small amount is excreted unchanged in the urine, and dose adjustment is not necessary for renal impairment.

Clinical uses: Caspofungin is a first-line antifungal agent for treatment of serious *Candida* infections and has activity at least equal to that of amphotericin. It is an alternative agent for treatment of *Aspergillus* infections and recently was approved for neutropenic fever not responding to antibacterial agents.

Adverse effects: Caspofungin is generally well tolerated. Possible histamine-mediated effects such as rash, facial swelling, a sensation of warmth, increased eosinophils, and, rarely, anaphylaxis have been reported. Other adverse effects that have uncommonly been reported include fever, phlebitis, gastrointestinal effects, flushing, increased liver function values, and hypokalemia. Concomitant cyclosporine therapy increases caspofungin serum levels and may result in transient increases in liver function values.

- Caspofungin is useful for serious candidal infections and is an alternative for treatment of aspergillosis and neutropenic fever.

Micafungin

Micafungin is the newest echinocandin approved by the U.S. Food and Drug Administration. Similar to caspofungin, it is available only as an intravenous preparation and shares a similar **spectrum of activity** and **adverse effect** profile. It is metabolized by the liver but not significantly through the P-450 cytochrome system. Micafungin does not appear to have drug interactions with tacrolimus or cyclosporine.

Clinical Uses: Micafungin is currently approved by the U.S. Food and Drug Administration only for esophageal candidiasis and candidal prophylaxis for stem cell transplantation.

Other Antifungal Agents

Flucytosine

The **modes of action** of this agent involve conversion to 5-fluorouracil triphosphate, intracellularly, which causes miscoding of fungal RNA, and the conversion to 5-fluorodeoxyuridine monophosphate, which inhibits DNA synthesis. It has **activity** against *Cryptococcus*, *Candida* species, and chromoblastomycosis.

Toxicity is often associated with high serum levels (>100 μg/mL). Side effects include neutropenia, thrombocytopenia, diarrhea, nausea, gastrointestinal upset, and reversible increases in liver function values. Because flucytosine is eliminated renally, it requires dose adjustment with renal dysfunction. Serum levels should be monitored and appropriate dose adjustments made to minimize toxicity.

Clinical uses include combination therapy for cryptococcal meningitis (usually used in combination with amphotericin B), *Candida* meningitis, and disseminated candidal infections (usually in combination with amphotericin). Generally, flucytosine should not be used as monotherapy because of rapid development of resistance.

Antiviral Agents

Current agents are virustatic and have no activity against nonreplicating or latent viruses. Antiretroviral agents are discussed in the chapter on HIV infection, and agents used in treatment of hepatitis are discussed in the gastroenterology chapter. Other antiviral agents are discussed below.

Acyclovir

Acyclovir is a nucleoside analogue of guanosine. It is phosphorylated by virus-specific thymidine kinase to monophosphate and further phosphorylated to the triphosphate form by cellular enzymes. Acyclovir triphosphate inhibits viral DNA polymerase and also acts as a DNA chain terminator.

Acyclovir has good **activity** against herpes simplex viruses 1 and 2 and varicella-zoster virus. It has considerably less activity against Epstein-Barr virus and cytomegalovirus. Resistance to acyclovir can develop through mutations of either viral thymidine kinase or DNA polymerase.

Oral acyclovir is poorly absorbed (bioavailability of 15%-30%). Thus, patients with severe disease or who are immunocompromised should receive IV therapy. Acyclovir generally is well tolerated.

Toxic effects include gastrointestinal distress, headaches, and phlebitis (IV form). Reversible renal dysfunction resulting from crystalline nephropathy can occur with high-dose IV therapy. The risk can be decreased by saline hydration and appropriate dose adjustment for renal function. Confusion, delirium, lethargy, and seizures can occur with high-dose IV therapy in patients with high serum concentrations.

Clinical uses for acyclovir include herpes simplex virus infections (noncurative). It is effective for treatment of primary and recurrent episodes of herpes genitalis and for chronic suppression in patients with frequent recurrences. Topical acyclovir is less effective than oral therapy in genital herpes simplex virus infection. In immunocompromised patients, oral or IV acyclovir is effective in the suppression and treatment of oral-labial disease. High-dose IV acyclovir is the drug of choice for herpes simplex virus encephalitis.

Acyclovir also is used for varicella-zoster virus. In immunocompetent patients with primary varicella, it can shorten the healing time (about 1 day) and decrease the number of lesions if given early (within 24 hours). IV acyclovir in immunocompromised patients can halt progression and prevent dissemination of varicella-zoster. Varicella-zoster responds to oral acyclovir but at higher doses than those required for herpes simplex virus 1 or herpes simplex virus 2. Treatment of varicella-zoster virus decreases viral shedding and time to healing. However, it is effective only if given within 72 hours of the onset of symptoms. Early administration may also decrease postherpetic neuralgia.

- Crystalline nephropathy can occur with high-dose IV therapy. Its incidence can be reduced by saline hydration and appropriate dose adjustment for renal function.
- IV acyclovir is the drug of choice for herpes simplex virus encephalitis.
- Effective therapy of varicella-zoster virus requires higher doses of acyclovir than herpes simplex virus 1 or 2.

Valacyclovir

Valacyclovir is an oral prodrug of acyclovir that is converted extensively and almost completely to acyclovir (the active drug) and L-valine. Approximately 54% to 60% of the valacyclovir dose is available as active acyclovir, representing a twofold to fivefold increase in bioavailability over that achieved after administration of oral acyclovir. The higher bioavailability of valacyclovir also allows for less frequent administration than with oral acyclovir. Like acyclovir, valacyclovir generally is well tolerated.

Toxic effects with valacyclovir are very similar to those with acyclovir. However, when valacyclovir was studied in very high doses (8 g/day) in immunosuppressed patients (patients who had transplantation and patients with HIV), thrombotic thrombocytopenic purpura and hemolytic-uremic syndrome were reported.

Clinical uses of valacyclovir include the treatment of varicella-zoster infections and the treatment and suppression of recurrent genital herpes infections (noncurative). Like acyclovir, valacyclovir may decrease postherpetic neuralgia.

- Valacyclovir is an oral prodrug of acyclovir that increases bioavailability twofold to fivefold. For most indications it can be given less frequently than oral acyclovir.

Famciclovir

Famciclovir is an oral prodrug that is converted to its active form, penciclovir, through tissue and hepatic enzymatic processes. A prolonged intracellular half-life allows for dosing three times daily. It has good bioavailability and is well tolerated.

Clinical uses are similar to those of valacyclovir. It is useful for herpes simplex and varicella-zoster virus infections. It may reduce the duration of postherpetic neuralgia when given early in varicella-zoster infections. Similar to acyclovir and famciclovir, it is not effective against cytomegalovirus or Epstein-Barr virus.

Ganciclovir

This agent inhibits DNA polymerase and is dependent on phosphorylation by viral thymidine kinase. Like acyclovir, valacyclovir and famciclovir, ganciclovir is active against herpes simplex viruses and varicella-zoster. However, it is about 10 times more potent than acyclovir against cytomegalovirus and Epstein-Barr virus and also has activity against human herpesvirus 6. It is available as oral, IV, and ocular preparations. The oral formulation is poorly absorbed, and thus IV therapy is needed for serious disease. Valganciclovir (see below) is an oral prodrug of ganciclovir that achieves significantly higher levels than oral ganciclovir.

Toxic effects include neutropenia and thrombocytopenia. The incidence of neutropenia may be increased when ganciclovir is used in combination with other immunosuppressive drugs. Cytopenias are reversible after use of the drug is stopped. It is teratogenic, carcinogenic, and mutagenic in animals. Less common side effects include fever, rash, anemia, and increased values on liver function tests. Like acyclovir, it is renally eliminated and close monitoring of renal function is required. Dosage adjustment for IV ganciclovir is needed even in the presence of mild renal impairment.

Clinical uses for ganciclovir include treatment of cytomegalovirus

retinitis in patients with AIDS. Studies also have shown beneficial results in other cytomegalovirus infections (colitis, esophagitis, gastritis, and pneumonia) and in immunocompromised hosts. In patients with AIDS, maintenance therapy may be necessary to prevent relapse. Used in combination with hyperimmune globulin, ganciclovir reduces mortality from cytomegalovirus pneumonitis in patients who have had allogeneic bone marrow transplantation. Oral and IV ganciclovir therapy may be given to at-risk patients before transplantation to prevent cytomegalovirus infection.

Although in vitro activity is seen for Epstein-Barr virus and human herpesvirus 6, clinical efficacy remains unclear.

Oral ganciclovir is an alternative to IV maintenance therapy for cytomegalovirus retinitis in patients who have only peripheral cytomegalovirus lesions. Unfortunately, the oral formulation has poor bioavailability levels.

Ganciclovir ocular implants provide the drug directly to the site of the infection in patients with cytomegalovirus retinitis. Vitrasert implants are surgically implanted into the pars plana and deliver a slow release of drug over 7 to 8 months. Possible disadvantages include the spread of infection to the contralateral eye (thus it is often given with a systemic agent), a low incidence of endophthalmitis, and the need to replace the inserts.

- Ganciclovir is used for cytomegalovirus infections in immunocompromised patients.
- Bone marrow suppression is the most serious adverse effect. The incidence may be increased when ganciclovir is used in combination with other immunosuppressive drugs.

Valganciclovir

Valganciclovir is an oral prodrug of ganciclovir with 60% bioavailability. Once absorbed, it is rapidly converted to ganciclovir and achieves a similar area under the curve as IV ganciclovir. It is not a substitute on a "one-for-one" basis with ganciclovir (IV or oral) because valganciclovir has its own dosing platform. Its toxicity profile is similar to that of ganciclovir.

Clinical uses are directed against cytomegalovirus infection. It is approved for treatment of cytomegalovirus retinitis in HIV-infected patients, and the efficacy of valganciclovir has been shown to be similar to that of IV ganciclovir for induction therapy. Oral valganciclovir also has been used for treatment of cytomegalovirus disease in transplant and other immunocompromised patients.

Foscarnet

Foscarnet is a noncompetitive inhibitor of viral DNA polymerase and reverse transcriptase. It does not require phosphorylation and is often active against acyclovir-resistant and ganciclovir-resistant strains. It has in vitro activity against all human herpesviruses, HIV, and hepatitis B.

Toxic effects include nephrotoxicity, which usually develops during the second week and is reversible. Substantial renal impairment develops in about a third of patients. The risk of nephrotoxicity is increased with concurrent use of nephrotoxic drugs (e.g., amphotericin B, aminoglycosides, and cyclosporine). Saline hydration may decrease the risk of nephrotoxicity.

Foscarnet is renally eliminated, and close renal monitoring is required to reduce adverse effects. Like IV ganciclovir, foscarnet requires dose adjustment with mild renal impairment.

Electrolyte disturbances, such as hypocalcemia, hyperphosphatemia, hypophosphatemia, hypokalemia, and hypomagnesemia, also commonly occur. Central nervous system side effects, fever, nausea, vomiting, anemia, fatigue, headache, leukopenia, pancreatitis, and genital ulceration also have been reported.

Clinical uses of foscarnet include treatment of ganciclovir-resistant cytomegalovirus disease and acyclovir-resistant herpes simplex virus or varicella-zoster virus. Occasionally, foscarnet has been used in combination with ganciclovir for severe cytomegalovirus retinitis.

- Foscarnet is effective for cytomegalovirus infections, including most strains that are resistant to ganciclovir.
- Nephrotoxicity is the major dose-limiting side effect. It usually develops during the second week and is reversible.

Cidofovir

Cidofovir is a nucleotide analogue with activity against herpesviruses, including cytomegalovirus, herpes simplex virus, varicella-zoster virus, and Epstein-Barr virus. Its Food and Drug Administration indication is for the treatment of cytomegalovirus retinitis in patients with AIDS. Conversion of cidofovir to its active intracellular metabolite is performed by host (rather than viral) cellular phosphorylating enzymes. Thus, cidofovir may retain activity against ganciclovir-resistant strains of cytomegalovirus and acyclovir resistant strains of HSV. The long intracellular half-life of cidofovir-active metabolites allows for weekly intravenous dosing during induction therapy and every-other-week IV administration during maintenance therapy.

The dose-limiting **toxic effect** of cidofovir is nephrotoxicity. Administration with probenecid and saline hydration decreases the incidence and severity of nephrotoxicity. Cidofovir is contraindicated in patients with preexisting renal dysfunction (serum creatinine >1.5 mg/dL, estimated creatinine clearance <55 mL/min, or urine protein ≥100 mg/dL), and renal function must be monitored closely during therapy. Optimally, it should not be given with other nephrotoxic drugs. Neutropenia also has been reported in up to 20% of patients. More rare adverse reactions include ocular hypotony and metabolic acidosis. Adverse effects to probenecid are also fairly common.

Amantadine and Rimantadine

Amantadine and rimantadine inhibit the activity of influenza A virus. They do not have activity against influenza B virus. Most current influenza A viruses are susceptible to these agents, but resistance can develop. Cross-resistance is shared between amantadine and rimantadine.

Pharmacokinetics: Amantadine is well absorbed after oral administration. It is eliminated unchanged in the urine, and the dose should be decreased in elderly patients and in patients with renal dysfunction. Rimantadine is well absorbed and is also usually given twice daily. In contrast to amantadine, it undergoes substantial hepatic metabolism.

Central nervous system side effects are the most important **adverse effects** with these agents. They are more considerable with

amantadine (particularly if the dose has not been appropriately adjusted for age or renal function) than rimantadine. Central nervous system effects most commonly include nervousness, anxiety, impaired concentration, insomnia, and light-headedness. Psychotic episodes, seizures, tremor, and even coma have been reported less commonly (typically with very high concentrations of amantadine). Gastrointestinal side effects and rash have occurred with both agents, and anticholinergic effects can occur with amantadine.

Clinical uses for these agents include the prevention and treatment of influenza A infections. Treatment is effective only if given early (within 1-2 days) after the onset of symptoms. Disease severity and duration may be reduced by 1 to 2 days. For prevention, amantadine and rimantadine can be an important adjunct to immunization during influenza outbreaks. They can be used until the vaccine takes full effect or to augment the vaccine (particularly in immunocompromised patients who may not have optimal vaccine response). They also may be useful in patients in whom the vaccine is contraindicated.

Oseltamivir and Zanamivir

These agents are selective inhibitors of viral neuraminidase. Unlike amantadine and rimantadine, the newer agents—oseltamivir and zanamivir—have activity against both influenza A and influenza B viruses. They may convey some protective effect against avian flu, but they have not been highly tested for this use. Resistance is also much more difficult to induce with the newer agents than with amantadine or rimantadine.

Pharmacokinetics: Oseltamivir is available as oral tablets and is dosed twice daily. It is eliminated renally, and dose adjustment is necessary in patients with renal impairment. Zanamivir is available as an inhaled preparation and is dosed as 2 puffs given twice daily. It is dispensed with a special inhalation device called a Diskhaler. Demonstration of the use of this device needs to be provided to patients when this agent is prescribed. Some elderly patients or patients without good manual dexterity may find it difficult to use the device.

Oseltamivir is generally well tolerated. The primary **adverse effects** are nausea and vomiting. These occur in about 10% of patients and are usually not severe. Zanamivir is also generally well tolerated. However, it should not be prescribed for patients with underlying airway disease because they may experience bronchospasm or serious breathing problems. In addition, the drug has not been proved efficacious in this patient population. Elderly patients or patients with poor dexterity may have difficulty with the manipulation required for zanamivir inhalation.

Clinical uses for zanamivir and oseltamivir include the treatment and prophylaxis of influenza A virus and influenza B virus. They are considerably more expensive than amantadine or rimantadine. However, in comparison with the older agents, zanamivir and oseltamivir have the advantages of providing coverage against influenza B (which is less common than influenza A) and of having less resistance induction potential (clinical implications unclear). No studies have been done to compare these newer antiviral agents with the older agents. With both oseltamivir and zanamivir, treatment needs to be started very early after onset of symptoms (within 24-48 hours). These agents can reduce the severity and duration of symptoms (usually by about 1 day). They have not been highly tested in critically ill patients. Oseltamivir and zanamavir may convey some protective effect against avian flu.

Infectious Diseases Pharmacy Review

Lynn Estes, PharmD, Eric Matey, PharmD, Lisa K. Buss, PharmD

Drug	Primary toxic/adverse effects	Primary drug interactions
Penicillins	Hypersensitivity reactions, GI effects (nausea, vomiting, diarrhea), interstitial nephritis, hematologic effects (anemia, neutropenia, thrombocytopenia, platelet dysfunction)	Probenecid
Natural penicillins		
Penicillin G		
Penicillin V		
Aminopenicillins		
Amoxicillin		
Amoxicillin-clavulanate	Clavulanate may cause diarrhea	
Ampicillin	Higher incidence of diarrhea than with amoxicillin	Allopurinol
Penicillinase-resistant penicillins		
Cloxacillin		
Dicloxacillin		
Nafcillin	Thrombophlebitis, hepatitis, neutropenia	
Oxacillin	Thrombophlebitis, hepatitis, neutropenia	
Extended-spectrum penicillins		
Ticarcillin	Hypokalemia, hypernatremia, bleeding	
Ticarcillin-clavulanate	Clavulanate may cause diarrhea, hypokalemia, hypernatremia, bleeding	
Piperacillin	Neutropenia, thrombocytopenia	
Piperacillin-tazobactam	Neutropenia, thrombocytopenia	
Cephalosporins	Hypersensitivity reactions, GI effects, hematologic effects, interstitial nephritis; cephalosporins with MTT side chains can cause hypoprothrombinemia and disulfiram-like reactions with alcohol	Anticoagulants, loop diuretics, probenecid
First-generation		
Cefadroxil		
Cefazolin		
Cephalexin		
Cephapirin		
Cephradine		
Second-generation		
Cefaclor		
Cefmetazole	MTT side chain	Alcohol, anticoagulants
Cefonicid		
Cefotetan	MTT side chain	Alcohol, anticoagulants
Cefoxitin		
Cefprozil		
Cefuroxime		
Cefuroxime axetil		Drugs that increase gastric pH
Loracarbef		
Third-generation		
Cefdinir		Antacids, iron supplements
Cefixime		
Cefoperazone	MTT side chain	Alcohol
Cefotaxime		
Cefpodoxime		Drugs that increase gastric pH
Ceftazidime		
Ceftibuten		
Ceftizoxime		
Ceftriaxone	Biliary sludge, gallstones	

Infectious Diseases Pharmacy Review (continued)

Drug	Primary toxic/adverse effects	Primary drug interactions
Cephalosporins (continued)		
Fourth-generation		
Cefepime		
Carbapenems	Nausea, vomiting, diarrhea, rash, hematologic effects, hypersensitivity reactions	Probenecid
Ertapenem		
Imipenem-cilastatin		
Meropenem		
Aztreonam	Rash, diarrhea, nausea, vomiting	Probenecid
Aminoglycosides	Nephrotoxicity, auditory toxicity, vestibular toxicity, neuromuscular blockade	Other nephrotoxic drugs, loop diuretics
Amikacin		
Gentamicin		
Kanamycin		
Neomycin		
Streptomycin		
Tobramycin		
Tetracyclines	Photosensitivity, permanent staining of developing teeth, GI upset, rash	Antacids, anticoagulants, digoxin, isotretinoin, iron
Demeclocycline		
Doxycycline		Phenytoin, carbamazepine
Minocycline	Vestibular toxicity	
Tetracycline		
Chloramphenicol	Aplastic anemia, bone marrow suppression, gray baby syndrome, optic and peripheral neuritis	Anticoagulants, phenytoin
Clindamycin	Diarrhea, Clostridium difficile colitis, nausea, vomiting	Neuromuscular blockers
Metronidazole	Nausea, diarrhea, disulfiram-like reaction, metallic taste, reversible neutropenia	Alcohol, anticoagulants
Macrolides		
Erythromycin	GI effects, cholestatic jaundice, transient hearing loss, ventricular arrhythmias, allergic reaction	Benzodiazepines, carbamazepine, cyclosporine, pimozide, theophylline, warfarin, digoxin, ergot alkaloids, cisapride, drugs that prolong QT interval
Clarithromycin	Nausea, diarrhea, metallic taste	Similar to erythromycin
Azithromycin	Diarrhea, nausea	Warfarin, pimozide
Ketolides		
Telithromycin	Prolong QTc interval, nausea, diarrhea, dizziness, headache, visual effects	Azole antifungals, rifampin, phenytoin, carbamazepine, phenobarbital, digoxin, HMG CoA reductase inhibitors, drugs that prolong QT interval, CYP 3A4 inhibitor; prescribing info should be checked for full interactions
Vancomycin	Ototoxicity, red man syndrome, nephrotoxicity, chemical thrombophlebitis, reversible neutropenia	Aminoglycosides and other nephrotoxic or ototoxic drugs

Infectious Diseases Pharmacy Review (continued)

Drug	Primary toxic/adverse effects	Primary drug interactions
Trimethoprim-sulfamethoxazole	Nausea, vomiting, hypersensitivity reactions (especially common in patients with AIDS)	Antihyperglycemics, methotrexate, phenytoin, warfarin
Fluoroquinolones	GI effects, CNS effects, photosensitivity, arthropathy, tendon rupture	Antacids, calcium, iron, warfarin, sucralfate
Second-generation		
Ciprofloxacin		Theophylline, caffeine
Lomefloxacin		
Norfloxacin		
Ofloxacin		
Third-generation		
Levofloxacin	QT interval prolongation	Antiarrhythmic agents
Fourth-generation		
Gatifloxacin	QT interval prolongation, hyperglycemia, hypoglycemia	Antiarrhythmic agents
Moxifloxacin	QT interval prolongation	Antiarrhythmic agents
Gemifloxacin	QT interval prolongation	Antiarrhythmic agents
Trovafloxacin	Limited to inpatient use because of risk of hepatotoxicity	
Linezolid	Thrombocytopenia, headache, diarrhea, nausea, rash, optic neuritis, peripheral neuropathy	MAO inhibitors, tyramine-containing foods, pseudoephedrine, SSRI antidepressants
Quinupristin/dalfopristin	Pain or inflammation at infusion site, arthralgia, myalgia, hyperbilirubinemia	Carbamazepine, cycloserine, delavirdine, diltiazem, HMG-CoA reductase inhibitors, methylprednisolone, midazolam, nevirapine, nifedipine, paclitaxel, tacrolimus, verapamil
Rifamixin	Nausea, vomiting, flatulence, rash	
Antituberculosis agents		
Isoniazid	Hepatitis, hypersensitivity reactions, lupus-like reactions, peripheral neuropathy	Carbamazepine, cycloserine, phenytoin, levodopa, prednisone, theophylline, warfarin
Rifampin and rifapentine	Orange discoloration of body fluids, leukopenia, thrombocytopenia, proteinuria, hypersensitivity reactions, hepatitis	Anticoagulants, azole antifungals, barbiturates, benzodiazepines, corticosteroids, cyclosporine, digoxin, estrogens, macrolides, protease inhibitors, tacrolimus, thyroid replacements, protease inhibitors, potent CYP inducer; prescribing info should be checked for full interactions
Rifabutin	Neutropenia, body fluid discoloration, GI intolerance, rash, uveitis, increased values on liver function tests	Antigoagulants, azole antifungals, cyclosporine, hydantoins, macrolides, methadone, quinine, theophylline, protease inhibitors, CYP inducer; prescribing info should be checked for full interactions

Infectious Diseases Pharmacy Review (continued)

Drug	Primary toxic/adverse effects	Primary drug interactions
Antituberculosis agents (continued)		
Pyrazinamide	Hepatitis, hyperuricemia, nausea, anorexia, polyarthralgia	Ethionamide, probenecid
Ethambutol	Optic neuritis, hyperuricemia	Aluminum salts
Capreomycin	Ototoxicity, tinnitus, nephrotoxicity	Nephrotoxic agent such as aminoglycosides
Ethionamide	Anorexia, nausea, vomiting, gynecomastia, postural hypotension, drowsiness, asthenia, hepatitis, hypothyroidism	Isoniazid, cycloserine
Para-aminosalicylic acid	Rash, GI intolerance, hypersensitivity	
Cycloserine	CNS toxic effects (somnolence, headache, tremor, psychosis, seizures)	Ethionamide, isoniazid, alcohol
Antifungal agents		
Amphotericin B	Infusion-related reactions (fever, chills, rigors, nausea, hypertension, hypotension), nephrotoxicity, hypokalemia, hypomagnsemia, reversible anemia	Nephrotoxic agents such as aminoglycosides and cyclosporine
Flucytosine	Bone marrow suppression, GI effects, increased values on liver function tests	
Azole antifungal	GI upset, rash, pruritus, increased values on liver function tests, QT prolongation	Carbamazpine, cyclosporine, dihydropyridine, calcium channel blockers, barbiturates, phenytoin, rifampin, tacrolimus, warfarin, drugs that prolong the QT interval, potent CYP 3A4 inhibitors and substrates; prescribing info should be checked for full interactions
Ketoconazole	Gynecomastia, diminished libido, impotence, menstrual irregularities, adrenal suppression, hypokalemia, edema	Antacids, corticosteroids, H_2-receptor blockers, HMG-CoA reductase inhibitors, proton pump inhibitors
Fluconazole	Headache	
Itraconazole	Headache, dizziness, hypokalemia, hypertension, edema, congestive heart failure	Antacids, corticosteroids, digoxin, H_2-receptor blockers, proton pump inhibitors, sucralfate
Voriconazole	Visual disturbances, nausea, vomiting	Sirolimus, tacrolimus, HMG-CoA reductase inhibitors, vinca alkaloids
Caspofungin	Facial swelling, rash, vomiting, proteinuria, hypokalemia	Tacrolimus cyclosporine
Antiviral agents		
Amantadine	Nausea, dizziness, light-headedness, insomnia, delirium	
Rimantadine	Insomnia, dizziness, nervousness, nausea, vomiting	
Oseltamivir	Nausea, vomiting, diarrhea, bronchitis, abdominal pain, dizziness	
Zanamivir	Nausea, diarrhea, nasal symptoms, bronchospasm	
Acyclovir	Malaise, nausea, vomiting, diarrhea, phlebitis (IV)	
Famciclovir	Headache, dizziness, nausea, diarrhea, fatigue	
Ganciclovir	Diarrhea, nausea, anorexia, vomiting, leukopenia, neutropenia, anemia	Probenecid, zidovudine

Infectious Diseases Pharmacy Review (continued)

Drug	Primary toxic/adverse effects	Primary drug interactions
Antiviral agents (continued)		
Valacyclovir	Nausea, headache, dizziness, diarrhea	
Valganciclovir	Headache, insomnia, diarrhea, nausea, leukopenia, neutropenia, anemia	Probenecid, zidovudine
Foscarnet	Renal impairment, leukopenia, electrolyte disturbances, seizures, fever, anemia, headache, nausea, vomiting	Nephrotoxic drugs, antiarrhythmics, pentamidine
Cidofovir	Renal impairment, neutropenia, ocular hypotonia, headache, asthenia, alopecia, rash, GI distress	Nephrotoxic drugs

AIDS, acquired immunodeficiency syndrome; CNS, central nervous system; GI, gastrointestinal; H_2, histamine$_2$; HMG-CoA, 3-hydroxy-3-methylglutaryl coenzyme-A; IV, intravenous; MAO, monoamine oxidase; MTT, methylthiotetrazole; SSRI, selective serotonin reuptake inhibitor.

Medical Ethics

C. Christopher Hook, MD
Paul S. Mueller, MD

Medicine is first and foremost a relationship. It is the coming together of one individual, the patient, who is ill or has specific needs and a second individual, the physician, whose goal is to help the patient and who possesses a unique set of knowledge and skills to pursue that goal. Because medicine is fundamentally a relationship, it is at heart an ethical endeavor. Physicians have a long history of creating codes or oaths to provide the ethical norms and framework to support and protect the underlying relationship. Medical ethics consists of a set of principles and systematic methods that attempt to guide physicians on how they ought to act in their relationships with patients and others. These principles and methods are based on moral values shared by both the lay society (may vary from culture to culture) and the medical profession.

- Medical ethics consists of a set of principles and systematic methods that attempt to guide physicians on how they ought to act in their relationships with patients and others.

The Hippocratic Oath is foundational for much of Western medical ethics. Its principles form the framework for many of our current ethical standards, including beneficence and nonmaleficence (the duties to do good and avoid or prevent harm), confidentiality, and the prohibition of active euthanasia. Contemporary articulations of these core principles include the Declaration of Geneva (1983), World Medical Association International Code of Medical Ethics (1983), The American College of Physicians Ethics Manual (2005), and The American Medical Association Code of Medical Ethics (2004-2005).

Ethical Dilemmas

Advances in medical science and the ever-changing social and legal milieu are responsible for dynamic changes, challenges, and dilemmas in medical ethics. An ethical dilemma is a predicament caused by conflicting moral principles and for which there is no clear course to resolve a problem (i.e., credible evidence exists both for and against a certain action). Even when ethically challenging situations and dilemmas are resolved, physicians may still experience ethical distress because of conflicting values and personal conscience.

- Advances in medical science and the ever-changing social and legal milieu are responsible for dynamic changes, challenges, and dilemmas in medical ethics.
- An ethical dilemma is a predicament caused by conflicting moral principles and for which there is no clear course to resolve a problem.

Principles of Medical Ethics

Today, there are several different philosophical frameworks for deriving the rules or particulars of medical ethics. Historically the foremost ethical principle of medicine has been beneficence and its corollary, nonmaleficence, from which we understand our duty to do good for the patient and to avoid and prevent harm. One contemporary framework is principalism. Proposed by Beauchamp and Childress, principalism, although not necessarily providing bedside guidance for each ethical dilemma, provides a useful delineation of four prima facie (at face value) principles that encompass most of the ethical concerns in the physician-patient relationship. These principles are: 1) autonomy, 2) beneficence, 3) nonmaleficence, and 4) justice.

- Four prima facie principles of medical ethics: autonomy, beneficence, nonmaleficence, and justice.

Autonomy

Autonomy derives from two Greek words: *autos* ("self") and *nomes* ("rule"). The principle of autonomy, or respect for persons, is the concept that persons have the right to establish, pursue, and maintain their values and goals (the right to self-determination). For autonomy to have meaningful expression, however, two requirements must be present: agency and liberty.

Agency is the capability to establish one's own values and goals and be able to make appropriate decisions based on those values and goals. From the requirement of agency is derived the clinically important concept of decision-making capacity. Decision-making capacity is not the same as the legal term "competence." Capacity is the physician's clinical determination of the patient's ability to understand his or her situation and make appropriate decisions for treatment, and competence is the legal determination and status that an individual has the right to make life-affecting decisions (not only health-related decisions but also, for example, financial decisions). Notably, a judge's or court's determination of competence is based in significant part on the clinical assessment of decision-making capacity.

- Autonomy, or respect for persons, is the concept that persons have the right to establish, pursue, and maintain their values and goals (the right to self-determination).
- Autonomy requires decision-making capacity.
- Competence is the legal determination and status that an individual has the right to make life-affecting decisions.

In clinical practice, the lack of decisional capability should be proved and not presumed. Confusion, disorientation, psychosis, and other cognitive changes caused by diseases, metabolic disturbances, and medical interventions can affect decision-making ability. Decisionally capable patients have the right to refuse all medical interventions, even at the risk of death.

- The lack of decisional capability should be proved and not presumed.

Several clinical standards are used to assess decision-making capacity: 1) the patient can make and communicate a choice; 2) the patient understands the medical situation and prognosis, the nature of the recommended care, available alternative options, and the risks, benefits, and consequences of each; 3) the patient's decisions are stable over time; 4) the decision is consistent with the patient's values and goals; and 5) the decision is not due to delusions.

Liberty, the second major element required in autonomy, allows the patient the freedom and opportunity to influence the course of his or her life and medical treatments. Recent court decisions, from the Quinlan case in 1976 to the Quill, Lee decision in 1997 (Table 15-1), along with strong support from the bioethical community, have established the right of patients to refuse any form of medical treatment, even if such refusal will lead to the patient's death.

- Liberty: the freedom and opportunity to influence the course of one's life and medical treatments.

The principle of autonomy, particularly as it affects the right of an individual to refuse life-sustaining treatments, has been affirmed by ethicists and the courts (Table 15-1). Nevertheless, a survey of physicians published in 1995 reported that 34% of physicians had, at least once in the preceding 12 months, declined to withdraw life-sustaining mechanical ventilation despite being requested to do so by a decisionally capable patient or by the surrogates of patients lacking decision-making capacity. Nearly 20% of physicians engaged in this practice because of the fear of malpractice litigation. Unfortunately, many physicians in the United States have a poor understanding of the laws regarding patient autonomy for the states in which they practice. For example, the 1995 survey found that 46% of the respondents from New York incorrectly believed that withdrawal of mechanical ventilation was illegal.

- Many physicians have a poor understanding of the laws regarding patient autonomy for the states in which they practice.

Preserving Patient Autonomy

It is not uncommon for physicians to care for patients who lack or lose decision-making capacity. Can a patient who now is unconscious or lacks decision-making capacity prevent unwanted treatment? Who speaks for the patient when he or she no longer possesses decision-making capacity? Because autonomy is based on a respect for persons, caregivers should endeavor to provide treatment in accordance with what the patient would have desired if he or she were still able to interact capably with the caregivers. To preserve the patient's autonomy, patients may communicate through two means to express their wishes: advance directives and surrogate decision making.

- The patient's autonomy is preserved by 1) advance directives and 2) surrogate decision making.

Advance Directive

An advance directive is a document in which a person either states choices for medical treatments or designates an individual who should make treatment choices when the patient does not possess decision-making capacity. The term also can apply to oral statements from the patient to the caregivers, given at a time when the patient was decisionally capable. Advance directives can take several forms: 1) the living will, 2) the durable power of attorney for health care, 3) a document appointing a health care surrogate (in jurisdictions that do not formally recognize a durable power of attorney for health care), and the advance medical care directive. Notably, the laws concerning advance directives vary from jurisdiction to jurisdiction (e.g., the form of advance directive authorized and the required contents of the advance directive). Therefore, each physician should be familiar with the local statutes concerning advance directives.

- An advance directive is a document in which a person either states choices for medical treatments or designates an individual who should make treatment choices when the patient does not possess decision-making capacity.
- Legal requirements for advance directives vary from state to state.

The traditional *living will* requires that two conditions be present before it takes effect: 1) the patient must be terminally ill, and 2) the patient must lack decision-making capacity. Like the laws concerning advance directives, the determination of "terminal" varies from jurisdiction to jurisdiction. Because of the requirement that the

Table 15-1 Pertinent Legal Rulings

Case, yr	Legal issue	Court	Decision
Salgo, 1957	Informed consent	California Court of Appeals	First used term "informed consent"
Brooks, 1965	Jehovah's Witness refusal of blood	Illinois District Court	Patients have right to personal treatment on religious grounds
Canterbury, 1972	Degree of disclosure required for adequate informed consent	U.S. District Court	Established "prudent patient test"
Quinlan, 1976	PVS—discontinuation of mechanical ventilation, previously articulated directive	New Jersey Supreme Court	Discontinuation (based on right to privacy)
Brophy, 1986	PVS—discontinuation of gastrostomy feedings, previously articulated directive	Massachusetts Supreme Court	Discontinue feedings (based on autonomy)
Bouvia, 1986	Severely impaired, refusal of nasogastric tube feedings by a decisionally capable patient	California Court of Appeals	Removal of nasogastric tube (based on autonomy)
Corbett, 1986	PVS—discontinuation of nasogastric tube feedings, no predefined directive(s)	Florida Court of Appeals	Discontinue feedings (based on right to privacy)
Cruzan, 1990	PVS—state of Missouri required "clear and convincing" evidence of individual's wishes before allowing withdrawal of life support	U.S. Supreme Court	States have right to restrict exercise of right to refuse treatment by surrogates; decisionally capable patients may refuse life-sustaining therapy, including hydration, nutrition, and mechanical ventilation
Wanglie, 1991	PVS—family wished continued support despite objections to continued life-sustaining therapy by the physicians and institution	Minnesota District Court	Continuation (based on autonomy, substituted judgment)
Quill, Lee, 1997	Assisted suicide	U.S. Supreme Court	States have the right to make laws prohibiting or allowing physician-assisted suicide and euthanasia

PVS, persistent vegetative state.

patient must be terminally ill, the living will is restricted in its use and may not be useful in many circumstances in which the patient lacks decision-making capacity but cannot necessarily be described as terminally ill. When activated, the living will provides guidance to the caregivers about what treatments the patient does or does not desire. It is, however, ineffective if vaguely written or applied to patients with uncertain prognoses.

- The living will requires that a patient be terminally ill before it takes effect.

The *durable power of attorney for health care* is a document that designates a surrogate decision maker should the patient lose decision-making capacity. It does not require that the patient be terminally ill, and therefore it is an advance directive that is more useful. Within the durable power of attorney for health care, the patient can make specific directives concerning different types of treatments such as cardiopulmonary resuscitation and artificial nutrition and hydration. The major value of the durable power of attorney for health care, however, is that it identifies an individual who can dynamically interact with the health care team regarding the great breadth of medical decisions.

- The durable power of attorney for health care designates a surrogate decision maker should the patient lose decision-making capacity.

Some patients have specific desires never to receive certain forms of therapy. For instance, many Jehovah's Witnesses do not want to receive blood or blood products under any circumstances. Other individuals may refuse dialysis or some other intervention regardless of the circumstance. The *specific advance medical care directive* states this categorical refusal for a specific treatment. It may take the form of a no-transfusion card or a bracelet or necklace that provides information about a patient's medical condition or instructions (MedicAlert).

- The specific advance medical care directive typically addresses one medical intervention.

In response to the Cruzan decision (Table 15-1), the U.S. Congress passed the *Patient Self-Determination Act* of 1990. This law attempts to ensure that patients are informed of their rights to accept or refuse medical interventions and to create and execute an advance directive. The Patient Self-Determination Act requires that hospitals, nursing homes, hospices, managed care organizations, and home health care agencies provide this information to patients at the time of admission or enrollment. The organizations are required to 1) document whether patients have advance directives, 2) establish policies to implement the advance directives, and 3) educate their staff and community about advance directives and these policies.

- The Patient Self-Determination Act requires that all health care providers, at the time of patient admission, dispense information to patients about their rights to accept or refuse interventions and to create an advance directive.

Surrogate Decision Making

A surrogate is a person who represents the patient's interests and previously expressed wishes. The surrogate is optimally designated by the patient before critical illness. One type of surrogate is the durable power of attorney for health care, in which a legally binding proxy directive authorizes a designated individual to speak on behalf of the patient. The second type of surrogate is the patient's family or the court. The third type is a moral surrogate (usually a family member) who best knows the patient and has the patient's interests at heart. Difficulties may arise when the moral surrogate is not the legal surrogate.

- A surrogate represents the patient's interests and previously expressed wishes in the context of the medical issues.
- Optimally, a surrogate is designated by the patient before critical illness.

How should the surrogate make decisions for the patient's health care? If the patient has issued explicit directives (written or oral), the surrogate should follow those instructions, unless it clearly can be demonstrated that the patient did not understand the nature of the information or choices made in that explicit directive. This situation unfortunately occurs when advance directives are completed without discussing the nature of the questions addressed with a health care provider. In the absence of such directives, the surrogate should use "substituted judgment," that is, the surrogate should decide to the best of his or her ability, based on the beliefs and values of the patient, what the choices would be if the patient were able to speak for himself or herself. In some circumstances the surrogate has not had enough communication about health care and life issues with the patient to be able to project how the patient would decide. There simply is not enough information to be able to specifically "substitute" for the patient. In these circumstances, the surrogate's obligation is to try to decide the best interests of the patient given the clinical scenario.

- In the absence of explicit directives (written or oral), surrogates should use substituted judgment (what the choices would be if the patient were able to speak for himself or herself).
- If substituted judgment is not possible, the surrogate should make choices in the best interest of the patient.

Several studies have shown that surrogates often choose courses that are not what patients would have chosen for themselves in specific circumstances. Because of this, physicians should stress the importance of having patients discuss their values and health care goals with their family members or surrogates. It is also the duty of each physician to discuss these issues with her or his patients. This practice allows physicians to understand their patients' values to ensure that their choices are not made on the basis of misinformation.

Although it is always helpful when a patient has an advance directive that appoints a surrogate, most patients do not have an advance directive. If a patient lacks decision-making capacity and there is no advance directive, who speaks for the patient? The underlying principle is to find a person, or persons, who best knows and

can share with the physician and other caregivers the patient's values and health care goals and how the patient would most likely choose if he or she could speak for himself or herself. The most common approach recognizes the following individuals in descending order of authority: 1) the spouse, 2) an adult child or the majority of adult children, 3) a parent or parents, 4) an adult sibling or the majority of adult siblings, 5) an adult relative who has shown special care and concern, and 6) if no relative can be located, a close friend. Notably, some jurisdictions have different hierarchies of who may serve as surrogates (in this context, some states refer to surrogates as "proxies"), and some have no hierarchy at all.

- A surrogate decision maker is helpful for directing or enforcing a specific advance directive.

Sometimes conflicts in surrogate decision making arise when a surrogate's decisions or instructions to physicians conflict with the patient's previously expressed directive or with those of other family members. Because the primary responsibility of the physician is to the patient, the physician should determine as best as possible what the patient would choose for himself or herself. In these circumstances, it may be helpful to involve an independent third-party arbitrator, such as an ethics consultant or committee or legal counsel, to help work through the issues. This option is useful only if the physician is unable to resolve the conflict. Once it has been established what the patient would want, it is the obligation of the treating physician(s) to comply with those wishes, even in the face of disagreement with surrogates. Only if clear evidence can be provided that the advance directive does not reflect what the patient really desired can the directive be overruled.

- The primary responsibility of the physician is to serve the patient's interest.

Informed Consent

A derivative of the principle of autonomy (and nonmaleficence) is informed consent. Informed consent is the voluntary acceptance of physician recommendations for interventions (clinical and research settings) by decisionally capable patients, or their surrogates, who have been provided sufficient information regarding the risks, benefits, and alternatives of the proposed interventions. Hence, there are three required elements of informed consent: 1) patient decision-making capacity, 2) patient voluntariness, and 3) accurate and sufficient information. The amount of information shared with the patient should not be guided only by what the physician believes is adequate (professional practice standard) but that which the average, prudent person would need to have in order to make an appropriate decision (reasonable person standard). Included within this information is a discussion of available alternatives to the proposed treatment, including doing nothing. For example, a patient with a cancer amenable to surgical resection, chemotherapy, or radiation therapy, all associated with a similar long-term outcome, should receive a thorough discussion of each of the options and their potential complications and side effects, even if the physician may be biased toward one of the three treatments. It is the duty of the physician to set aside personal bias and provide detailed information on each treatment to allow the patient to make a well-informed decision. The patient can then take the information and consider it within the context of her or his own values, health care goals, and quality-of-life considerations.

- Informed consent requires patient decision-making capacity, voluntariness, and accurate and sufficient information.
- Reasonable person standard: amount of information needed by a patient is that which the average prudent person would need to have in order to make a decision.

After a discussion of the available alternatives, the physician should present the patient with a single recommendation that the patient can accept or reject. Patients come to their physicians expecting the caregivers to use their knowledge and experience in providing them with a recommendation. Simply laying out a menu of choices before the patient may lead to confusion or the perception by the patient that the physician is unconcerned with his or her welfare. If the patient refuses the recommended treatment and chooses one of the alternatives, the physician should respect the patient's choice. The final plan should reflect an agreement between a well-informed patient and a well-informed, sympathetic, and unbiased physician.

In certain circumstances, a patient may require more information than what the average reasonable person might desire. For instance, some religious belief systems may specifically preclude certain forms of medical intervention that might not trouble another individual in the least. It is important to ensure that patients receive sufficient information within the context of the factors that are most important to them to help make an appropriate choice.

- The physician should provide all alternatives, followed by a single recommendation.
- If the patient refuses the recommended treatment, the physician should respect the patient's choice.

In rare exceptions, the physician can treat a patient without truly informed consent (e.g., in an emotionally unstable patient who requires urgent treatment, when informing the patient of the details may produce further problems).

Informed consent from surrogates is necessary to perform an autopsy (except in certain instances such as coroners' cases, in which the decision is made by outside authorities) or to practice intubation, placement of intravascular lines, or other procedures on the newly dead.

- Informed consent from surrogates is necessary to perform an autopsy.

Implied Consent

The principle of implied consent is invoked when true informed consent is not possible because the patient (or surrogate) is unable to express a decision regarding treatment, specifically, in emergency situations in which physicians are compelled to provide medically necessary therapy, without which harm would result. This principle

clarifies the duty to assist a person in urgent need of care. Implied consent has been legally accepted (e.g., Good Samaritan laws) and provides the physician a legal defense against battery (although not negligence).

- Implied consent is invoked when true informed consent is not possible, such as in emergency situations.

Truth Telling

Truth telling is an integral aspect of autonomy. The physician must provide decisionally capable patients with truthful information on which to base medical decisions. Without the receipt of sufficient truthful information, patients cannot make truly autonomous decisions about their life plans. Occasionally, however, the physician may withhold part or all of the truth if it is believed that telling the truth is likely to cause significant injury. This is the concept of therapeutic privilege. For example, if it can be well ascertained that a patient will attempt harm to himself or herself or others if certain information is received, such as the diagnosis of cancer, then the information may be withheld. However, there is a *high* burden of proof on the withholding physician to establish the likelihood of injury. This decision for intentional nondisclosure must be fully recorded in the medical record.

Some decisionally capable patients may forgo complete disclosure, deferring the receipt of information and decision making to others. Forgoing complete disclosure may occur by individual preference or in the context of cultural norms. Regardless, this preference should be respected as the patient's autonomous choice.

- Truth telling on the part of the physician is an integral aspect of respecting patient autonomy.

Confidentiality

Privacy is an integral part of the respect for persons and protection of an individual's autonomy. Confidentiality respects that right to privacy and provides the patient the right to keep medical information solely within the realm of the physician-patient relationship. The physician is ethically and legally obliged to maintain a patient's medical information in strict confidence, a tradition dating back to the Hippocratic Oath. Ensuring confidentiality encourages complete communication of all relevant information that may have an impact on the patient's health.

However, "the obligation to safeguard patient confidences is subject to certain exceptions that are justified because of overriding ethical and social concerns. When a patient threatens to inflict serious bodily harm on another individual, and there is reasonable probability that the patient will carry out the threat, the physician is obligated to take reasonable precautions for the protection of the intended victim, including notification of law enforcement authorities if necessary" (American Medical Association Council on Ethical and Judicial Affairs, 1997). Also, in some instances, a patient's data must be shared with public health care agencies, such as in the case of human immunodeficiency virus (HIV), *Mycobacterium tuberculosis*, and other infectious diseases and in cases of physical abuse, gunshot wounds, and other concerns to the public health and welfare. There are state-to-state differences in reporting requirements, and each physician should be aware of local statutes.

A growing area of concern in maintaining confidentiality is in regard to heritable genetic traits. This concern is undergoing significant ethical and legal scrutiny.

An example that challenges the principle of confidentiality is the patient with HIV infection who refuses to inform third parties who have been or will be engaged in high-risk activities with the patient. A functional solution is the following: 1) attempt to persuade the infected patient to cease endangering the third party or to notify the third party of the risk; 2) if persuasion fails, notify an authority who can intervene; 3) if the authority takes no action or is not available (e.g., the state does not pursue contact tracing after report of HIV), notify the endangered party of the risk (American Medical Association Council on Ethical and Judicial Affairs, 1988). It must be clearly stated that this approach still may be open to legal liabilities and is based on the medical profession's obligation to prevent harm. Public policy trends have been moving toward stronger protection of patient confidentiality.

- A physician is obliged to maintain medical information in strict confidence.
- The obligation to safeguard patient confidences is subject to certain exceptions that are justified because of overriding ethical and social concerns (e.g., mandatory reporting requirements).

Futility

It has been clearly established, both ethically and legally, that patients have the right to refuse any and all medical therapies. But does the principle of autonomy give patients, or their surrogates, the right to demand treatments? This question particularly arises when patients or families request that cardiopulmonary resuscitation, mechanical ventilation, and other aggressive treatment be performed on patients with little chance of recovery or survival to dismissal. Can physicians unilaterally withhold or withdraw medical interventions if, in their opinion, the intervention is futile? The conflict seemingly is between the autonomy of the patients and the moral autonomy and integrity of the caregivers. Physicians are moral agents, just as much as patients, and should not be forced to violate their ethical beliefs and principles.

- Patients have the right to refuse any and all medical therapies.

The Oxford English Dictionary defines futility as "leaky, hence untrustworthy, vain, failing of the desired end through intrinsic defect." Therefore, a futile intervention is one that cannot achieve specified goals no matter how many times it is repeated. From this definition, it can clearly be stated that physicians are not required to provide treatments that have no pathophysiologic rationale, have already failed in a given patient in the past, or cannot achieve the goals of care already agreed on by the physician and patient or surrogate. However, many so-called futility conflicts arise in clinical situations in which it is not impossible, but it is unlikely, that an intervention will benefit the patient or there is a conflict about the goals of treatment (such as maintaining physiologic life vs. restoration

of independent functioning or survival to dismissal). Many have tried to create functional definitions of futility that would cover these circumstances, but all have the flaw of establishing arbitrary thresholds that are value-laden in themselves.

- A futile intervention is one that cannot achieve the goals of intervention no matter how many times it is repeated.

When a futility conflict arises in a clinical situation, the solution should be one of "due process," which attempts to negotiate consensus and resolve the conflict. The American Medical Association Council on Ethical and Judicial Affairs endorsed such a program ("Houston Policy," JAMA. 1996;276:571-4), which requires the following:

1. Earnest attempts to deliberate over and negotiate prior understanding among patient, surrogate, and physician about what constitutes "futile" care for the patient and what falls within acceptable limits for those involved. Many times the disagreement is based on inappropriate expectations of the patient or surrogate. When appropriate data about outcomes are shared, many requests for treatments such as cardiopulmonary resuscitation decrease.
2. Joint decision making should occur to the maximal extent possible.
3. Attempts should be made to negotiate and resolve disagreements (such as through ethics consultation).
4. If disagreements are irresolvable, a consultant or end-of-life decisions committee should become involved.
5. If the committee agrees with the patient and the physician remains unpersuaded, intra-institutional or inter-institutional transfer may be arranged.
6. If the committee agrees with the physician and the patient or surrogate remains unpersuaded, intra-institutional or inter-institutional transfer may be arranged.
7. If transfer is not possible, the intervention need not be offered.

- Resolution of futility conflicts should be attempted by using a due process approach.

Beneficence

Beneficence is acting to benefit patients by preserving life, restoring health, relieving suffering, and restoring or maintaining function. The physician (acting in good faith) is obligated to help patients attain their own interests and goals as determined by the patient, *not* the physician.

When we think of benefitting the patient, we must remember that there are several levels of defining benefit for a given situation, some objective and some subjective. The first level concerns the biomedical or physiologic benefit of a proposed intervention, is usually the least controversial area, and requires the most physician input. As physicians we often tend to stop at this first level, but the next two patient-defined levels are often of great importance to how a patient defines "benefit."

The second level is personal benefit: how the patient interprets the situation in the context of her values and goals. This level may sometimes seem in conflict with the biomedical benefit. For example, a patient with end-stage cancer and ventilator-dependent respiratory failure will not derive any long-term biomedical benefit from continuing the intensive care. However, that patient may have the goal of living for another 48 hours in order to say good-bye to a child who is going to be arriving from a great distance. That specific goal enables the intervention to be understood as benefitting the patient.

The third level has been described as "ultimate" benefit, but it refers to the patient's belief system and world view. Does the patient's faith make claims as to the obligation to preserve life to the last breath? Here the patient's ultimate framework of beliefs may have a specific impact on the definition of benefit. As the patient's advocate, we must consider all three levels as we define benefit.

- Beneficence is acting to benefit patients by preserving life, restoring health, relieving suffering, and restoring or maintaining function.

Nonmaleficence

Nonmaleficence requires that one should not do evil or harm. This principle has roots in the Hippocratic saying of "as to diseases, help, but at least do no harm." This principle also addresses unprofessional behavior, such as the verbal, physical, and sexual abuse of patients or uninformed and undisclosed interventions or experimentation on patients.

- Nonmaleficence: "as to diseases, help, but at least do no harm."

Nonabandonment

Abandonment is the act of leaving the patient (for whom the physician has provided health care in the past) without providing for immediate or future medical care. This action has been "universally condemned as a serious and punishable infraction of both the legal and ethical obligations that physicians owe patients" (Ann Intern Med. 1995;122:377-8). In contrast, nonabandonment denotes a requisite ethical obligation of physicians to provide ongoing medical care once the patient and physician mutually concur to enter into an alliance. Nonabandonment is closely related to the principles of beneficence and nonmaleficence and is fundamental to the long-term physician-patient relationship. This principle has several drawbacks and limitations. The degree of physician involvement in the relationship cannot be measured as to its quantity or quality. Furthermore, the extent of the relationship is dictated by the underlying medical condition. For instance, an annual examination may require a single visit to the physician, whereas a complicated disease process may bring the physician and patient closer to each other over a long period. It would be improper for the physician to force a patient to maintain a long-term physician-patient relationship if the latter is unwilling, for whatever reason. Noncompliance, in terms of taking medications or following a physician's instructions, by the patient is not grounds for abandonment. Physicians should strive to respond to the needs of their patients over time, but they should not trespass their own values in the process.

- Nonabandonment: a requisite ethical obligation of physicians to provide ongoing care once the patient and physician mutually concur to enter into an alliance.

Conflict of Interest

The principle of beneficence requires that the physician not engage in activities that are not in the patient's best interest. This is considered to be a significant problem in medicine today. Some studies have suggested that physicians' prescribing practices are influenced by financial and other significant rewards from drug companies. If the physician does not ardently avoid areas of potential conflict of interest (because of the principle of beneficence), the result may be maleficence. Authorship of scientific papers and editorials to promote drugs and appliances solely for immediate or future personal financial gains also constitutes conflict of interest (Ann Intern Med. 1997;126:986-8).

- Conflict of interest is contrary to the principle of beneficence.

The Impaired Physician

According to the American Medical Association, the impaired physician is one who is "unable to practice medicine with reasonable skill and safety to patients because of physical or mental illness, including deteriorations through the aging process, or loss of motor skill, or excessive use or abuse of drugs including alcohol." Impairment is distinct from competence, which specifically concerns the physician's knowledge and skills to adequately perform his or her duties as a physician. Impairment and incompetence both may seriously compromise patient care and safety. Under the obligation to protect patients from harm, physicians must protect patients from impaired and incompetent colleagues. Physicians have a moral, professional, and legal obligation to report impaired and incompetent colleagues to the appropriate authority. Different states vary in the specifics of reporting, but all have a reporting requirement. Typical authorities to contact include the institutional chief of staff or impairment program, local or state medical society impairment programs, or the state licensing body. It is important that reporting the behavior of a colleague be based on objective evidence rather than supposition.

- Physicians have an obligation to report impaired behavior in colleagues.

The Rule of Double Effect (Beneficence Vs. Nonmaleficence)

In the medical management of patients, sometimes the pursuit of a beneficent outcome risks the potential for serious injury or death. Consequently, the moral obligations for beneficence and nonmaleficence conflict. The classic example of such a situation is the terminally ill patient who may require high doses of narcotics for adequate analgesia, but such doses also have the potential for respiratory depression and an earlier death. The rule of double effect is a means of trying to resolve the conflict. This principle states that 1) the act itself must be good or morally neutral, 2) the actor or agent intends only the good effect, 3) the bad effect must not be a means to the good effect (e.g., death is the only way to achieve the desired outcome), and 4) the good effect must outweigh the bad effect. By the reasoning of double effect, and the high requirement of beneficence to address the suffering of patients, adequate analgesia for the relief of suffering should always be given even if death is hastened. The analgesics are to be given, however, in such a way as to relieve the pain and not specifically to hasten the death of patients, even terminally ill patients.

- Adequate analgesia, particularly in patients with incurable disease, is the responsibility of the physician.
- The physician has not performed immorally if death in a terminally ill patient is a result of respiratory depression from analgesic therapy; euthanasia is not the goal.

Justice

Every patient deserves and must be provided optimal care as warranted by the underlying medical condition. Allocation of medical resources fairly and according to medical need is the basis for this principle. The decision to provide optimal medical care should be based on the medical need of each patient and the perceived medical benefit to the patient. The patient's social status, ability to pay, or perceived social worth should not dictate the quality or quantity of medical care. The physician's clear-cut responsibility is to the patient's well-being (beneficence). Physicians should not make decisions about individual care of their patients based on larger societal needs. The bedside is not the place to make general policy decisions.

- Justice: allocation of medical resources fairly and according to medical need.
- Physicians should not make decisions about individual care of patients based on larger societal needs.

Ethical Considerations at the End of Life

Incurable Disease and Death

Probably the most distressing aspect of medical practice is the encounter with a patient who has an incurable disease and in whom death is inevitable. The physician and patient (or surrogate) must formulate appropriate goals of therapy, choose what measures should be taken to maintain life, and decide how aggressive these measures ought to be. It is important to remind oneself that the patient is under enormous mental anguish and physical stress and that the ability to make solid decisions may be clouded. Furthermore, the decision(s) made by the patient may be guided by his or her understanding (whether adequate or not) of the medical condition and prognosis, religious beliefs, financial status, and other personal wishes. The patient may seek counsel from family, friends, and clergy as well as the attending physician.

- In incurable disease, recognize that the patient is under enormous mental anguish and physical stress.
- The ability of the patient to make solid decisions may be clouded.

The following guidelines are suggested in caring for patients with incurable diseases or who are dying. The patient and family (if the

patient so desires) must be provided ample opportunity to talk with the physician and ask questions. An unhurried openness and willing-to-listen attitude on the part of the physician are critical for a positive outcome.

- The patient and family must be provided every opportunity to talk with the physician and ask questions.
- An unhurried openness and willing-to-listen attitude on the part of the physician are critical for a positive outcome.

The physician should assume the responsibility to furnish or arrange for physical, emotional, and spiritual support. Adequate control of pain, respect for human dignity, and close contact with the family are crucial. The emotional and spiritual support available through hospital chaplains or local clergy (as appropriate, given the patient's personal beliefs) should not be underestimated. At no other time in life is the reality of human mortality so real as in the terminal phases of disease. It is always preferable to allay the anxiety of the dying patient through adequate emotional and spiritual support rather than by sedation. The physician should constantly remind herself or himself that despite all the medical technology that surrounds the patient, the patient must not be dehumanized.

- Adequate pain control, respect for human dignity, and close contact with the family are crucial.
- It is better to allay the anxiety of the dying patient through adequate emotional and spiritual support rather than by sedation.

Physician-Assisted Death

All four principles of medical ethics have an impact on the issue of physician-assisted death, that is, physician-assisted suicide and euthanasia. Historically, the medical profession has taken a strong stand against physicians directly killing patients, but this prohibition has been challenged on the basis of patient autonomy, beneficence or compassion, and other grounds. Numerous opinion polls have shown that significant portions of the general population and the medical community now favor some legalization of physician-assisted suicide, if not euthanasia. The American Medical Association and other large professional medical groups have maintained their stance against these practices.

In 1997, the U.S. Supreme Court ruled that states may maintain laws prohibiting euthanasia and assisted suicide but also may pass laws allowing these practices. Although the Court did not find a right to physician-assisted death, it emphasized the patient's right to adequate, aggressive pain control, even if it might shorten the patient's life. In the election of 1997, the people of the state of Oregon reiterated their support for physician-assisted suicide by reapproving a referendum first passed in 1994 legalizing assisted suicide but still prohibiting euthanasia. The Oregon law requires that the patient 1) be terminally ill, 2) be decisionally capable, 3) has initiated two verbal requests and one written request for a prescription for a lethal overdose, 4) undergo a second-opinion consultation, 5) receive appropriate psychiatric intervention if perceived to be depressed, and 6) undergo a 15-day waiting period after the request has been made to allow the patient to change his or her mind. Currently, assisted suicide and euthanasia remain illegal in the other 49 states.

- Euthanasia and physician-assisted suicide are legally prohibited in the United States with the exception of the state of Oregon, which permits physician-assisted suicide.

Regardless of one's position on this difficult issue, physicians are obligated to address the underlying concerns that lead patients and physicians to believe that assisted suicide and euthanasia are necessary (the New York State Task Force on Life and the Law, 1994). Physicians should be acquainted with appropriate means of pain management and palliative care and be willing to be aggressive in the relief of a patient's symptoms. Physicians also are obligated to recognize and appropriately treat depression. Furthermore, physicians should strive to address the other issues that may lead patients to desire assisted death, such as fear of abandonment and loss of control.

Withholding and Withdrawing Life-Sustaining Treatments

The decision to withhold or withdraw life-sustaining treatments may be compatible with beneficence, nonmaleficence, and autonomy. Granting a patient's requests to withhold or withdraw unwanted medical treatments is legal and ethical. Granting a request to refuse or withdraw a medical intervention is not the same as physician-assisted suicide or euthanasia. In assisted suicide, the patient personally terminates his or her life by using an external means provided by a clinician (e.g., lethal prescription). In euthanasia, the clinician directly terminates the patient's life (e.g., lethal injection). In assisted suicide and euthanasia, a new intervention is introduced (e.g., drug), the sole intent of which is the patient's death. In contrast, when a patient dies after an intervention is withheld or withdrawn, the underlying disease is the cause of death. The intent is freedom from interventions that are perceived as burdensome.

Notably, there is no ethical or legal distinction between withholding treatment in the first place, or choosing to withdraw a treatment once begun. The right of a decisionally capable person to refuse lifesaving hydration and nutrition was upheld by the U.S. Supreme Court (Table 15-1), but a surrogate decision maker's right to refuse treatment for decisionally incapable persons has been restricted by some states. Currently, the states of New York, Missouri, and Florida require "clear and convincing evidence" that withdrawing and withholding of life-supporting treatment would be the patient's desire. Other states have lesser evidentiary standards for surrogates to withhold or withdraw life support. Brain death is not a necessary requirement for withdrawing or withholding life support. The value of each medical therapy (risk:benefit ratio) should be assessed for each patient. When appropriate, the withholding or withdrawal of life support is best accomplished with input from more than one experienced clinician.

- Withholding or withdrawing life support does not conflict with the principles of beneficence, nonmaleficence, and autonomy.
- Brain death is not a necessary requirement for withdrawing or withholding life support.

Do-Not-Resuscitate Orders

Do-not-resuscitate (DNR) orders affect administration of cardiopulmonary resuscitation (CPR) only; other therapeutic options should not be influenced by the DNR order. A DNR order can be compatible with maximal forms of treatment (e.g., elective intubation, elective cardioversion, surgery). Every person whose medical history is unclear or unavailable should receive CPR in the event of cardiopulmonary arrest.

Of paramount importance are the patient's knowledge of the extent of disease and the prognosis, the physician's estimate of the potential efficacy of CPR, and the wishes of the patient (or surrogate) regarding CPR as a therapeutic tool. The appropriateness of a DNR order should be reviewed frequently because clinical circumstances may dictate other measures (e.g., a patient with terminal cardiomyopathy who had initially turned down heart transplantation and had a DNR order may change her or his mind and now opt for the transplantation). Physicians should discuss the appropriateness of CPR or DNR with patients at high risk for cardiopulmonary arrest and with the terminally ill. The discussion should optimally take place in the outpatient setting, during the initial period of hospitalization, and periodically during hospitalization, if appropriate. DNR orders (and rationale) should be entered in the patient's medical records.

- DNR orders affect CPR only.
- A DNR order may be compatible with maximal forms of treatment.
- In the absence of a DNR order, universal consent for CPR is presumed.
- DNR orders should be reviewed frequently.

Persistent Vegetative State

Persistent vegetative state is a chronic state of unconsciousness (loss of self-awareness) lasting for more than a few weeks, characterized by the presence of wake-sleep cycles but without behavioral or cerebral metabolic evidence of cognitive function or of being able to respond in a willful manner to external events or stimuli. The body retains functions necessary to sustain physiologic survival (e.g., respiration, circulation, endocrine function) if provided nutritional and other supportive measures. Many patients in a persistent vegetative state require only artificially administered nutrition and hydration, in addition to routine nursing care to continue to survive physically. The U.S. Supreme Court has ruled that there is no distinction between artificially administered nutrition and hydration compared with mechanical ventilation or other interventions in terms of being medical treatments that can be withheld or withdrawn (Table 15-1).

- Persistent vegetative state: unconsciousness (loss of self-awareness) lasting for more than a few weeks.
- U.S. Supreme Court ruling states that there is no distinction between artificially administered nutrition and hydration compared with mechanical ventilation or other interventions in terms of being medical treatments.

Definition of Death

Death is the irreversible cessation of circulatory and respiratory function or the irreversible cessation of all functions of the entire brain, including the brain stem. Clinical criteria (at times supported by electroencephalographic testing or assessment of cerebral perfusion) permit the reliable diagnosis of "brain death."

The family should be informed of the brain death but should not be asked to decide whether further medical therapy should be continued. One exception is when the patient's surrogate (or the patient, through an advance directive) permits certain decisions, such as organ donation, in the case of brain death.

Once it is ascertained that the patient is "brain dead" and that no further therapy can be offered, the primary physician, preferably after consultation with another physician involved in the care of the patient, may withdraw supportive measures. This approach is accepted throughout the United States, with the exception of the states of New Jersey and New York, which have modified their definition of death statutes to allow a religious exemption for groups (such as Orthodox Jews) that do not accept brain death as a valid criterion for death. In these states, continued care may be requested of the caregivers until circulatory and respiratory function collapses.

The imminent possibility of harvesting organs for transplantation should in no way affect any of the aforementioned decisions. When organ and tissue donation is possible after the determination of brain death, the family should be approached, preferably before cessation of cardiac function, regarding organ donation.

- Death: irreversible cessation of circulatory and respiratory function or irreversible cessation of all functions of the entire brain, including the brain stem.

Authors' Note

Laws concerning ethical issues in medicine continue to evolve, reflecting changing attitudes of society. Certainly, legal decisions will continue to influence the practice of medicine. Many states have no directly applicable statutes or court cases relating to difficult ethical issues in medical practice. This review is meant as a guide; the individual practitioner is referred to the appropriate state medical society for further information regarding state-specific mandates.

Men's Health

Thomas J. Beckman, MD
Haitham S. Abu-Lebdeh, MD

The most common diagnoses in a men's health practice are benign prostatic hyperplasia (BPH) and erectile dysfunction.

Benign Prostatic Hyperplasia

This section is modified from Beckman TJ, Mynderse LA. Evaluation and medical management of benign prostatic hyperplasia. Mayo Clin Proc. 2005;80:1356-62. Erratum in: Mayo Clin Proc. 2005;80:1533. Used with permission of Mayo Foundation for Medical Education and Research.

BPH is common among older men. The prostate is the size of a walnut (20 cm^3) in men younger than 30 years, and it gradually increases in size, leading to BPH in most men older than 60 years. BPH results from epithelial and stromal cell growth, which begins in the transitional zone of the prostate and causes urinary outflow resistance. Over time, this resistance leads to detrusor muscle dysfunction, urinary retention, and lower urinary tract symptoms (LUTS). There is evidence that BPH progresses when left untreated. This progression is manifested as worsening prostate symptom scores, declining urinary flow rates, and increased risk of acute urinary retention. Other complications of BPH include urinary tract infections, obstructive nephropathy, and recurrent hematuria.

Diagnosing BPH is challenging because prostate size correlates poorly with LUTS, and numerous conditions other than BPH cause LUTS (Table 16-1). Nonetheless, assessing symptom severity, identifying prostatic enlargement on digital rectal examination (DRE), and documenting decreased urinary flow rates with increased postvoid residuals yield accurate diagnoses in most cases.

- BPH exists in most men age 60 or older.
- Prostate size correlates poorly with symptoms of BPH.
- Conditions other than BPH associated with LUTS include urinary tract infections, obstructive nephropathy, and recurrent hematuria.

History and Physical Examination

When obtaining a history, consider the patient's age. Because prostate size increases with age, LUTS are most likely due to BPH in men older than 50 years, and LUTS are most likely due to other conditions in men younger than 40 years. Reviewing medications is also essential because many medications cause LUTS by affecting detrusor muscle and urinary sphincter function: 1) anticholinergic and antimuscarinic medications decrease detrusor muscle tone; 2) sympathomimetic medications increase urethral sphincter tone; and 3) diuretics increase urinary frequency (Table 16-1). Additionally, over-the-counter cold medications may cause LUTS by various mechanisms. When older men with subclinical BPH simply discontinue taking new medications, LUTS often resolve. Finally, a focused review of systems should identify fever, hematuria (indicating urothelial malignancy), urethral instrumentation or sexually transmitted diseases (suggesting the possibility of urethral stricture), sleep disturbances, patterns of fluid intake, and use of alcohol and caffeine.

The American Urological Association International Prostate Symptom Score (AUA/IPSS) is an objective measure of LUTS associated with BPH. The AUA/IPSS aids in diagnosing BPH and following the progression of BPH over time (Fig. 16-1). Numerous studies have shown the reliability and validity of the AUA/IPSS. The AUA/IPSS asks seven questions about the following symptoms: frequency, nocturia, weak stream, hesitancy, intermittency, incomplete bladder emptying, and urgency. Each of these questions is rated on a five-point scale. When the responses to the seven questions are summed, a score of 0 to 7 represents mild symptoms of BPH, 8 to 19 represents moderate symptoms, and 20 to 35 represents severe symptoms.

- Diuretics and sympathomimetic and anticholinergic medications cause LUTS.
- Numerous over-the-counter medications cause LUTS.
- The AUA/IPSS is a reliable and valid assessment of bothersome prostate symptoms.

Patients with LUTS should be evaluated for neurologic deficits, especially if the patients have a history or presenting symptoms that

Table 16-1 Differential Diagnosis for Benign Prostatic Hyperplasia

Category	Examples	Comments
Malignant	Adenocarcinoma of the prostate	Men should be offered PSA testing in conjunction with DRE
	Transitional cell carcinoma of the bladder	With microhematuria on urinalysis, consider urothelial malignancies
	Squamous cell carcinoma of the penis	
Infectious	Cystitis	Urinalysis and urinary Gram stain are useful in evaluating for cystitis
	Prostatitis	Prostatic massage specimens (VB3) assist in diagnosis of prostatitis
	Sexually transmitted diseases (e.g., chlamydial infection and gonorrhea)	Sexually transmitted diseases may cause LUTS from urethral scarring and stricture
Neurologic	Spinal cord injury	Primary mechanisms for neurologic causes of LUTS are detrusor weakness or uninhibited detrusor contractions (or both)
	Cauda equina syndrome	
	Stroke	Alzheimer disease can cause functional urinary incontinence
	Parkinsonisn	
	Diabetic autonomic neuropathy	
	Multiple sclerosis	
	Alzheimer disease	
Medical	Poorly controlled diabetes mellitus	Medical conditions associated with urinary frequency are often overlooked causes of LUTS
	Diabetes insipidus	
	Congestive heart failure	
	Hypercalcemia	
	Obstructive sleep apnea	
Iatrogenic	Prostatectomy	Surgery sometimes causes neurologic impairment
	Cystectomy	Traumatic urethrocystoscopic procedures can cause scarring and urethral strictures
	Traumatic urethrocystoscopic procedures	
	Radiation cystitis	
Anatomical	Ureteral and bladder stones	Hematuria may be seen on urinalysis
		Consider urinary cytologic, cystoscopic, and renal imaging studies
Behavioral	Polydipsia	Consider assessing serum sodium
	Excessive alcohol or caffeine consumption	A voiding diary may provide useful information about fluid intake
Pharmacologic	Diuretics (e.g., furosemide, hydrochlorothiazide)	Diuretics increase urinary frequency
	Sympathomimetics (e.g., ephedrine, dextroamphetamine)	Sympathomimetic medications increase urethral resistance
	Anticholinergics (e.g., oxybutynin, amantadine)	Anticholinergic and muscarinic medications decrease detrusor contractility
	Antimuscarinics (e.g., diphenhydramine, amitriptyline)	Over-the-counter medications may cause LUTS by various mechanisms
	Over-the-counter decongestants	
Other	Overactive bladder	UDS can help distinguish BPH from isolated detrusor dysfunction

BPH, benign prostatic hyperplasia; DRE, digital rectal examination; LUTS, lower urinary tract symptoms; PSA, prostate-specific antigen; UDS, urodynamic studies; VB3, voiding bottle 3 (postprostatic massage) urine specimen.

From Beckman TJ, Mynderse LA. Evaluation and medical management of benign prostatic hyperplasia. Mayo Clin Proc. 2005;80:1356-62. Used with permission of Mayo Foundation for Medical Education and Research.

suggest a neurologic disorder. In such cases, useful findings include saddle anesthesia, decreased rectal sphincter tone, absent cremasteric reflex, or lower extremity neurologic abnormalities. On examination of the abdomen, masses resulting from a renal tumor, hydronephrosis, or bladder distention may be detected. The penis should be examined for stricture or other pathologic changes. DRE findings most consistent with BPH are symmetric enlargement and firm consistency, often likened to the thenar muscle or the tip of the nose. In contrast, findings consistent with adenocarcinoma of the prostate are prostate asymmetry, induration, and nodularity, which is likened to the consistency of a knuckle or the forehead.

- It is important to identify neurologic deficits on physical examination.
- It is important to identify urethral stricture on physical examination.
- Prostate asymmetry, induration, and nodularity are consistent with prostate carcinoma.

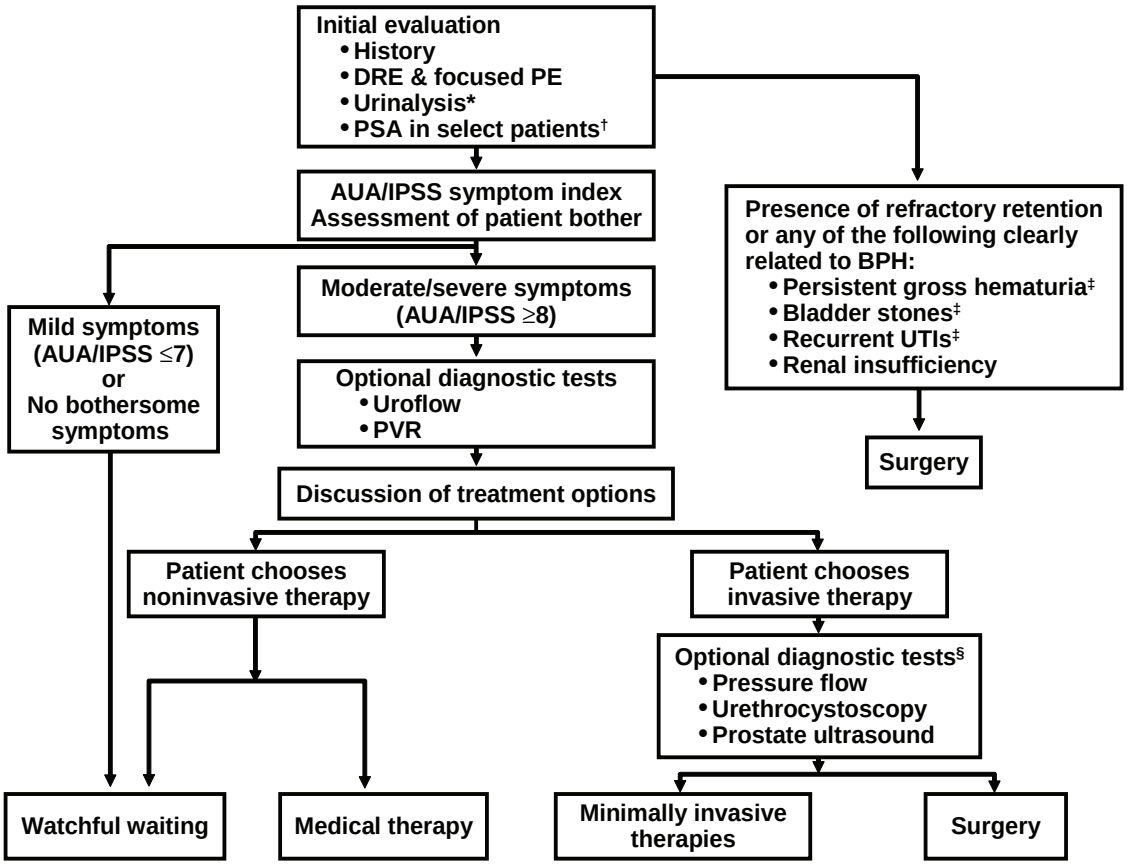

Fig. 16-1. A treatment algorithm for benign prostatic hyperplasia, demonstrating treatment decisions based partly on patient symptom severity as determined by the American Urological Association (AUA) Symptom Score. DRE, digital rectal examination; IPSS, International Prostate Symptom Score; PE, physical examination; PSA, prostate-specific antigen; PVR, postvoid residual urine; UTI, urinary tract infection. *In patients with clinically significant prostatic bleeding, a course of a 5 α-reductase inhibitor may be used. If bleeding persists, tissue ablative surgery is indicated. †Patients with at least a 10-year life expectancy for whom knowledge of the presence of prostate cancer would change management or patients for whom the PSA measurement may change the management of voiding symptoms. ‡After exhausting other therapeutic options. §Some diagnostic tests are used in predicting response to therapy. Pressure-flow studies are most useful in men prior to surgery. (From AUA Practice Guidelines Committee. AUA guideline on management of benign prostatic hyperplasia [2003]. Chapter 1. Diagnosis and treatment recommendations. J Urol. 2003;170:530-47. Used with permission.)

Evaluation

A specimen for urinalysis should be obtained routinely when evaluating men with LUTS. Urinalysis findings may include pyuria and bacteruria, which suggest infection; hematuria, which suggests inflammation or urothelial malignancy; and active urinary sediment, which suggests a possible postobstructive nephropathy.

Optional studies include measuring serum creatinine and prostate-specific antigen (PSA) concentrations. The PSA measurement is optional because the results do not help discriminate BPH from adenocarcinoma of the prostate. Nevertheless, because LUTS may indicate prostate cancer, it is appropriate to routinely offer PSA testing. Additionally, annual screening for prostate cancer with DRE and PSA is appropriate for men aged 50 to 75 years, and sometimes older than 75, depending on the patient's preference and anticipated life expectancy.

- Urinalysis is routinely used to evaluate men with symptoms of BPH.
- Measurement of serum creatinine and PSA levels is optional.

Serum PSA levels strongly correlate with prostate volumes in men with BPH. Other causes of increased PSA levels are prostate carcinoma, bacterial prostatitis, acute urinary retention, instrumentation, prostate incision, and ejaculation. Conditions generally not believed to increase serum PSA levels are routine DRE, transrectal ultrasonography without biopsy, cystoscopy, and nontraumatic bladder catheterization.

- Other causes of increased PSA levels are prostate carcinoma, bacterial prostatitis, acute urinary retention, instrumentation, prostate incision, and ejaculation.
- Routine DRE does not cause significant PSA elevations.

- Conditions that generally do not increase serum PSA levels are routine DRE, transrectal ultrasonography without biopsy, cystoscopy and nontraumatic bladder catheterization.

There are different methods for interpreting serum PSA levels:

1. The traditional cutoff is 4 ng/mL.
2. Age-adjusted normal limits are commonly used because prostate volume increases with age.
3. The level of free (unbound) PSA is lower in men with adenocarcinoma of the prostate; therefore, a low ratio of free-to-total PSA is more consistent with prostate carcinoma than with BPH.
4. A rapidly rising PSA is more suggestive of carcinoma than BPH; in particular, an annual PSA velocity greater than 0.75 ng/mL is considered abnormal.

A uroflow study with ultrasonographic measurement of residual urine volume is an objective, noninvasive way to evaluate men presenting with LUTS. An accurate study requires urine volumes of at least 150 mL. Men with BPH often have peak flow rates less than 15 mL/s and increased urine residuals (Fig. 16-2). Notably, men with detrusor dysfunction also have abnormal results. Consequently, as with any test, interpreting results of uroflow studies depends on the pretest probability of disease. If the pretest probability of BPH is high, an abnormal test result is useful for confirming the diagnosis. But if the pretest probability is intermediate, an abnormal uroflow result is less useful. In such cases, patients may need to undergo complete urodynamic studies to further distinguish BPH from other causes of LUTS.

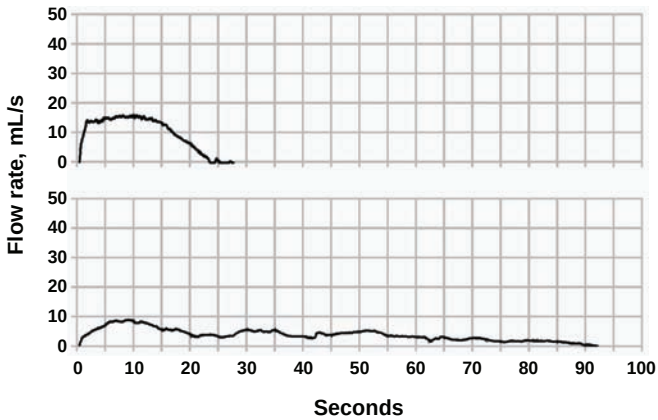

Fig. 16-2. *Top*, Uroflow tracing from a young, asymptomatic male. Note the parabolic flow curve and peak flow rate >15 mL/s. This patient's ultrasonographically measured residual urine volume was 9 mL. *Bottom*, Uroflow tracing from an elderly man with benign prostatic hyperplasia. Note the prolonged voiding time and peak flow rate <10 mL. This patient's ultrasonographically measured residual urine volume was 100 mL. (From Beckman TJ, Mynderse LA. Evaluation and medical management of benign prostatic hyperplasia. Mayo Clin Proc. 2005;80:1356-62. Used with permission of Mayo Foundation for Medical Education and Research.)

- Different methods for assessing PSA include cutoff of 4 ng/mL, age-adjusted limits, free-to-total ratios, and PSA velocity.
- Uroflow is an objective, noninvasive assessment of LUTS.

Medical Management of BPH

Although this chapter focuses on the medical management of BPH, clinicians should recognize the indications for urologic referral and consideration of invasive therapy. These indications are moderate or severe symptoms, persistent gross hematuria, urinary retention, renal insufficiency due to BPH, recurrent urinary tract infections, and bladder calculi.

Watchful waiting is reasonable for patients with mild or moderate symptoms. These patients are monitored at least yearly or when new symptoms arise. In addition, these patients may be advised to practice scheduled voiding (every 3 hours during the day), to avoid excess evening fluid intake, and to be aware of potential adverse effects of over-the-counter decongestants.

Nearly all patients presenting with BPH are candidates for medical therapy. Moreover, medical therapy has replaced interventional therapy as the most common treatment of BPH. Prescription medications available for treating BPH are α_1-adrenergic antagonists (e.g., tamsulosin) and 5α-reductase inhibitors (e.g., finasteride). The most widely used alternative medication is saw palmetto (*Serenoa repens*).

- Watchful waiting is reasonable for patients with mild or moderate BPH.
- Available prescription medications are α_1-adrenergic antagonists and 5α-reductase inhibitors.

The α_1-adrenergic antagonist medications work on the dynamic component of bladder outlet obstruction by decreasing prostatic smooth muscle tone. They are the first line of medical therapy for most men with BPH. Although all α_1-adrenergic antagonist medications are equally efficacious in treating BPH, terazosin and doxazosin are more likely to cause side effects (mainly orthostatic hypotension) than other medications in this class. Other common side effects of α_1-adrenergic antagonists include dizziness, hypotension, edema, palpitations, erectile dysfunction, and fatigue.

The second class of prescription medications for treating BPH, the 5α-reductase inhibitors, act on the static (anatomical) component of bladder outlet obstruction. These medications decrease the conversion of testosterone to dihydrotestosterone in the prostate, thereby limiting prostate growth. The two 5α-reductase inhibitors currently available are finasteride and dutasteride.

The following points about finasteride are important: it is most useful in men with severe BPH and large prostates (>40 cm^3), it may need to be taken for more than 6 months before an optimal drug effect is apparent, and it can significantly decrease serum PSA. For this reason, experts recommend correcting the serum PSA value in men taking finasteride by multiplying the value by two. Side effects with finasteride are uncommon. The most frequent side effects are related to sexual dysfunction and include decreased libido, ejaculatory dysfunction, and ED. Finally, evidence supports the combined use of α_1-adrenergic antagonists and 5 α-reductase inhibitors in men with inadequate responses to either drug alone.

- The α_1-adrenergic antagonists work on the dynamic component of bladder outlet obstruction.
- The 5α-reductase inhibitors work on the static component of bladder outlet obstruction.
- Combining α_1-andrenergic antagonists with 5α-reductase inhibitors is often effective in patients with inadequate responses to monotherapy.
- Correct the serum PSA value in patients taking finasteride by multiplying the value by two.

Herbal medications used to treat BPH include derivatives from African star grass, African plum tree bark, rye grass pollens, stinging nettle, and cactus flower. The most commonly used alternative treatment for BPH is saw palmetto (*Serenoa repens*). Many mechanisms for saw palmetto have been entertained, yet none are proven. Saw palmetto is considered safe, and studies including randomized trials and a meta-analysis have shown that it compares favorably with finasteride and that, compared with placebo, saw palmetto improves flow and decreases symptoms.

Erectile Dysfunction

This section is modified from Beckman TJ, Abu-Lebdeh HS, Mynderse LA. Evaluation and medical management of erectile dysfunction. Mayo Clin Proc. 2006;81:385-90. Used with permission of Mayo Foundation for Medical Education and Research.

Male sexual dysfunction includes erectile dysfunction (ED), decreased libido, anatomical abnormalities (e.g., Peyronie disease), and ejaculatory dysfunction. ED, defined as the inability to achieve erections firm enough for vaginal penetration, affects millions of men in the United States. The Massachusetts Male Aging Study showed that the prevalence of ED increased by age: approximately 50% of men experienced ED at age 50, and nearly 70% at age 70.

- ED is defined as the inability to achieve erections firm enough for vaginal penetration.

Erectile physiology includes hormonal, vascular, psychologic, neurologic, and cellular components. Testosterone is primarily responsible for maintaining sexual desire (libido), and hypogonadism is sometimes associated with ED. Other hormonal causes of ED include hyperthyroidism and prolactinomas. The penile blood supply begins at the internal pudendal artery, which branches into the penile artery, ultimately giving rise to the cavernous, dorsal, and bulbourethral arteries. Psychogenic erections, triggered by fantasy or visual stimulation, are mediated by sympathetic input from the thoracolumbar chain (T11-L2). Reflex erections are caused by tactile stimulation and are mediated by the parasympathetic nervous system (S2-S4). Overall, parasympathetic signals are responsible for erection, and sympathetic signals are responsible for ejaculation.

- Testosterone is primarily responsible for maintaining libido.
- Psychogenic erections are mediated by the thoracolumbar chain, whereas reflex erections are mediated by sacral nerve roots S2-S4.
- Parasympathetic signals control erection, and sympathetic signals control ejaculation.

Sexual arousal and parasympathetic signals to the penis initiate intracellular changes necessary for erection (Fig. 16-3). Endothelial cells release nitric oxide, which in turn increases cyclic guanosine monophosphate (cGMP). Increased levels of cGMP cause relaxation of arterial and cavernosal smooth muscle and increased penile blood flow. As the intracavernosal pressure rises, penile emissary veins are compressed, thus restricting venous return from the penis. The combination of increased arterial flow and decreased venous return results in erection. This process is reversed by the activity of cGMP phosphodiesterase (PDE) type 5, which breaks down cGMP, resulting in cessation of erection.

Although ED is rarely an indicator of serious diseases, it is strongly associated with cardiovascular risk factors. In fact, the Health Professionals Follow-up Study showed that risk factors for ED and cardiovascular disease were nearly identical and that physically active men had a 30% lower risk of ED than inactive men. Therefore, men with diabetes, hypertension, and coronary artery disease are at increased risk of ED. Not surprisingly, randomized controlled trial data show that erectile function significantly improves in obese men who lose weight through diet and exercise.

- Nitric oxide increases cGMP levels, which in turn causes cavernosal smooth muscle relaxation and erection.
- ED is strongly associated with cardiovascular risk factors.
- Weight loss may lead to improved erectile function.

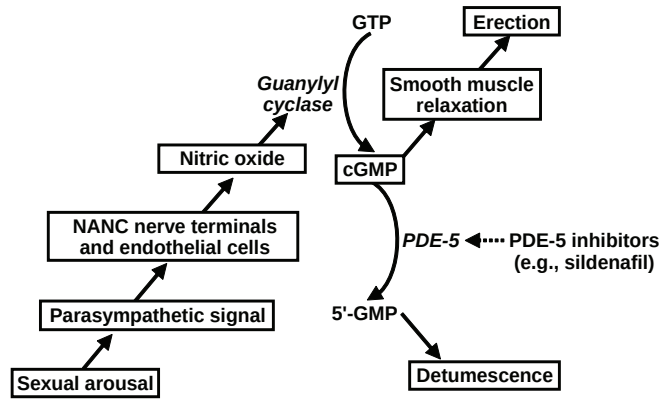

Fig. 16-3. Mechanism for penile erection and the molecular activity of phosphodiesterase type 5 inhibitor medications. cGMP, cyclic guanosine monophosphate; GMP, guanosine monophosphate; GTP, guanosine triphosphate; NANC, nonadrenergic noncholinergic; PDE-5, phosphodiesterase type 5. (From Beckman TJ, Abu-Lebdeh HS, Mynderse LA. Evaluation and medical management of erectile dysfunction. Mayo Clin Proc. 2006;81:385-90. Used with permission of Mayo Foundation for Medical Education and Research.)

Evaluating Patients With Erectile Dysfunction

History and Physical Examination

Certain questions should be asked routinely when taking a history from patients with ED (Table 16-2). Especially important are questions about common ED risk factors such as cardiovascular disease, smoking, diabetes, hypertension, hyperlipidemia, prescription medications, recreational drug use, and mood disorders. In addition, validated questionnaires, such as the International Index of Erectile Function (IIEF), are useful for monitoring patients' responses to ED treatments.

A complete multisystem examination may identify indicators of cardiovascular disease (e.g., obesity, hypertension, or femoral arterial bruits), endocrinopathies (e.g., visual field defects, thyromegaly, or gynecomastia), or neurologic abnormalities (e.g., decreased sphincter tone, absent bulbocavernosus reflex, or saddle anesthesia). The penis should be palpated in the stretched position to detect fibrous plaques consistent with Peyronie disease, which may be present on the dorsum and base of the penis. The testicles should be evaluated for masses (indicating malignancy) and decreased size and soft consistency (indicating hypogonadism). Finally, examining patients with ED is often a good opportunity to screen for prostate cancer and to assess for benign glandular enlargement.

- A careful history should identify ED risk factors, including cardiovascular disease.
- Fibrous plaques in the penis most likely indicate Peyronie disease.
- Small, soft testicles may indicate hypogonadism.

Laboratory Testing

Although disease-specific testing is favored, serum testosterone levels are frequently measured in a men's health practice. If a patient is hypogonadal, serum prolactin and luteinizing hormone (LH) levels should be assessed. If the prolactin level is elevated or the LH level is not elevated, magnetic resonance imaging (MRI) of the brain should be used to rule out a pituitary adenoma. Additional useful testing that pertains to ED risk factors includes measuring the levels of fasting glucose, fasting lipids, and thyrotropin.

- If the prolactin level is elevated or the LH level is not elevated, MRI of the brain should be used to rule out a pituitary adenoma.

Medical Management of Erectile Dysfunction

Phosphodiesterase Type 5 Inhibitors

PDE-5 inhibitor medications are the first line of therapy for most men with ED. PDE-5 inhibitors have revolutionized the treatment of ED since the introduction of sildenafil in 1998, and experts have observed that these medications have considerably affected (both positively and negatively) the sexual culture of older people. After initial concerns about cardiovascular risks associated with PDE-5 inhibitors, studies have shown that these medications are generally safe, even in patients with stable coronary artery disease who are not taking nitrate therapy.

Three PDE-5 inhibitors are currently available: sildenafil (Viagra), vardenafil (Levitra), and tadalafil (Cialis). These medications inhibit cGMP PDE-5, thereby increasing cGMP levels and shifting the physiologic balance in favor of erection (Fig. 16-3). In the absence of comparative clinical trials and meta-analyses, it appears that each of these medications is equally efficacious. Tadalafil has a longer half-life than sildenafil or vardenafil, which affords more spontaneity to tadalafil users (up to 36 hours). Patients should be instructed to take PDE-5 inhibitors at least 1 hour before sexual activity, and sildenafil should be taken on an empty stomach. Patients should also realize that PDE-5 inhibitors will not cause erections in the absence of sexual arousal (unlike intraurethral alprostadil and penile injection therapy).

- PDE-5 inhibitors are safe in patients with stable coronary artery disease who are not taking nitrate therapy.
- The PDE-5 inhibitor medications are likely equally efficacious.
- PDE-5 inhibitors will not cause erections in the absence of sexual arousal.

Common side effects of the PDE-5 inhibitors, which are due to the presence of PDE throughout the body, are headache, flushing, gastric upset, diarrhea, nasal congestion, and light-headedness. A unique reaction to sildenafil is blue-tinged vision, probably related to the activity of sildenafil on PDE-6 in the retina. This reaction resolves with discontinuation of therapy. It is noteworthy that some varieties of retinitis pigmentosa have a PDE-6 gene defect. Consequently, patients with retinitis pigmentosa should not be prescribed medications from the PDE-5 inhibitor class.

- A unique reaction to sildenafil is blue-tinged vision, probably related to the activity of sildenafil on PDE-6 in the retina.
- Patients with retinitis pigmentosa should not be prescribed medications from the PDE-5 inhibitor class.

A contraindication to use of PDE-5 inhibitors is nitrate therapy. Indeed, patients treated for acute coronary syndromes should not receive nitrate therapy within 24 hours of taking sildenafil or vardenafil and within 48 hours of taking tadalafil. Physicians should also be cautious about prescribing PDE-5 inhibitors for patients with poorly controlled blood pressure or multidrug antihypertensive regimens. In patients with known or suspected ischemic heart disease, cardiac stress testing is useful for stratifying the risk of PDE-5 inhibitor therapy; patients who achieve 5 to 6 metabolic equivalents without ischemia probably have low risk of complications from engaging in sexual activity.

- Common side effects of PDE-5 inhibitors are due to the presence of PDE throughout the body.
- Nitrate therapy is an absolute contraindication to use of PDE-5 inhibitor medications.
- Cardiac stress testing helps stratify the risk of PDE-5 inhibitor therapy.

Treatment options for patients who have not had a response to PDE-5 inhibitors or who cannot take PDE-5 inhibitors include intraurethral alprostadil and penile injection therapy. These

Table 16-2 Questions To Ask When Taking a History From Patients With Erectile Dysfunction

Question	Comment
Do you have difficulty achieving erections or difficulty with orgasms and ejaculation?	Sexual dysfunction includes various diagnoses, and it is important to determine whether the patient's primary complaint is ED
How often do you achieve erections? Are your erections firm enough for vaginal penetration?	Often patients are not satisfied with the quality of their erections, yet if patients can achieve erections adequately firm for vaginal penetration most of the time, their complaints are not classically defined as ED
Did your ED occur suddenly? Do you have nocturnal erections? Do you feel anxious depressed? Do you and your partner have a satisfactory relationship?	The sudden onset of ED and the persistence of nocturnal erections indicate an inorganic (psychogenic) cause; in such cases, physicians should explore the psychosocial context of the patient's sexual history, such as whether the patient feels anxious or depressed or whether the patient is experiencing difficulties in his interpersonal relationship(s)
Do you have a desire to engage in sexual activity?	Decreased sexual desire may indicate hypogonadism; if patients are not interested in sexual activity, serum testosterone levels should be assessed and mood disorders should be considered
Do you have penile curvature or pain with erections?	A positive response to this question may indicate Peyronie disease, which is sometimes detected on physical examination; identifying Peyronie disease is important because it precludes intraurethral alprostadil and penile injection therapy
Can you engage in vigorous physical activity without chest pain or unusual dyspnea?	PDE-5 inhibitor medications will be considered in most patients, and sexual activity is associated with cardiovascular stress; hence, a history should be obtained to identify undiagnosed ischemic heart disease or to assess the stability of known ischemic heart disease
What medications are you taking?	Numerous medications are associated with ED, especially antihypertensives and psychotropics; identify medications inhibiting cytochrome P-450 (e.g., ritonavir) because these medications increase plasma levels of PDE-5 inhibitor medications; an absolute contraindication to PDE-5 inhibitor medications is the concurrent use of nitrates (e.g., isosorbide mononitrate)
How much alcohol do you consume? Do you use illegal drugs?	Substance abuse, including alcoholism, is commonly overlooked as a cause of ED
Which treatments for ED have you already tried?	Knowing which medications patients have tried will help physicians decide the next best therapeutic plan
Do you have a history of diseases involving your heart, blood vessels, nervous system, or hormones? Do you have a history of hypertension, hyperlipidemia, diabetes, or tobacco abuse? Do you have a history of penile trauma or genitourinary surgery?	Identify common risk factors for ED
Do you ride a bicycle regularly?	Prolonged and frequent bicycle riding can cause excessive pudendal pressure, leading to ED

ED, erectile dysfunction; PDE-5, phosphodisterase type 5.

From Beckman TJ, Abu-Lebdeh HS, Mynderse LA. Evaluation and medical management of erectile dysfunction. Mayo Clin Proc. 2006;81:385-90. Used with permission of Mayo Foundation for Medical Education and Research.

medications are generally more effective than PDE-5 inhibitors, but their obvious drawbacks are inconvenience. Contraindications for these treatments include blood cell dyscrasias (e.g., sickle cell disease, leukemia, or multiple myeloma) and penile deformity, especially Peyronie disease. Anticoagulation is an additional contraindication to penile injection therapy. There is inadequate information on the safety of combining PDE-5 inhibitors and injection therapy, and hence, their coadministration is not advised.

Intraurethral Alprostadil

Intraurethral alprostadil (commercially available as MUSE, a medicated urethral system for erection) is effective in men of all ages who have various causes of ED. Intraurethral alprostadil is inserted into the tip of the penis with an applicator. Patients should be instructed on the application technique. Additionally, owing to the risk of syncope, administration of the first dose should be supervised by a health care provider. The most common side effect is urethral and genital burning, and hypotension can occur. As for all medical ED treatments, patients are educated about priapism, and they are instructed to go to an emergency department if they have erections for more than 4 hours.

- The most common side effect of intraurethral alprostadil is urethral and genital burning.
- Hypotension and syncope may occur with alprostadil.

Intracavernosal Penile Injections

Intracavernosal penile injection, an efficacious and generally safe therapy, is the most effective medical therapy for ED. In practice, a triple-therapy combination of alprostadil, papaverine, and phentolamine is usually used. The mechanism of action of these medications is to increase penile blood flow. Specifically, alprostadil and papaverine cause relaxation of cavernosal smooth muscle and penile blood vessels, and phentolamine antagonizes α-adrenoreceptors. Triple therapy is available in different concentrations. Doses within each concentration are increased by 0.05-mL intervals from 0.2 mL to a maximum of 0.7 mL. A patient who has no response to the maximal dose at a given concentration is given the next highest concentration. The use of intraurethral alprostadil requires patient instruction, and the initial dose is administered under the supervision of a health care provider. Although many patients are hesitant to attempt penile injection, this method is associated with minimal discomfort.

- Intracavernosal injections are the most effective medical therapy for ED.
- Initial doses of intraurethral and intracavernosal injections should be supervised by a health care provider.

Testosterone

Various hormonal therapies, including testosterone, were once widely used to treat ED. The penile nitric oxide pathway is testosterone dependent, and for this reason it is necessary to screen for low serum testosterone in men who have no response to medical therapy with sildenafil or whose presentation suggests hypogonadism. Hypogonadism is diagnosed by the presence of hypogonadal symptoms (such as decreased libido, cognitive decline, and generalized muscle weakness), and by morning fasting total testosterone levels less than 200 ng/mL on at least two separate occasions. In hypogonadal men, combining PDE-5 inhibitor therapy with testosterone is often effective. Moreover, testosterone replacement alone increases sexual interest, nocturnal erections, and frequency of sexual intercourse. Nevertheless, testosterone replacement has not been shown to improve erectile function in men with normal serum testosterone levels.

- Hypogonadism is diagnosed by the presence of hypogonadal symptoms and morning fasting total testosterone levels <200 ng/mL on at least two separate occasions.
- Testosterone replacement has not been shown to improve erectile dysfunction in men with normal serum testosterone levels.

Testosterone is available by injection, skin patch, topical gel, or buccal oral tablets. Testosterone therapy is associated with potential risks. For example, prolonged use of high-dose, orally active 17α-alkyl androgens (e.g., methyltestosterone) is associated with hepatic neoplasms, fulminant hepatitis, and cholestatic jaundice. Other risks of exogenous testosterone therapy include gynecomastia, alterations in the lipid profile (mainly decreased high-density lipoprotein cholesterol), erythropoietin-mediated polycythemia, edema, sleep apnea, hypertension, infertility (through suppression of spermatogenesis), and benign prostatic hyperplasia. Exogenous testosterone also increases the risk of developing prostate carcinoma. Although testosterone replacement may not cause prostate carcinoma, it may stimulate the growth of existing occult prostate cancer. For this reason, all men should have screening for prostate cancer with DRE and serum PSA before beginning use of exogenous testosterone.

- Risks of testosterone therapy include hepatitis, cholestatic jaundice, hepatic neoplasms, gynecomastia, polycythemia, sleep apnea, and hypertension.
- Screening for prostate cancer is necessary before prescribing testosterone replacement.

The goal of testosterone replacement is to increase serum testosterone levels to the low or middle portion of the reference range. A recommended treatment is to apply topical testosterone, 1% gel at a starting dose of 5 g daily, to the shoulders, upper parts of the arms, or abdomen. A total testosterone level may be reassessed as soon as 14 days after starting treatment. The patient's therapeutic response and testosterone level are reassessed at 3 months, and decisions are then made about whether to continue using testosterone and whether to adjust the dose.

Although patients who receive testosterone replacement and have normal serum testosterone levels should not be at risk of adverse effects, monitoring patients during testosterone therapy is essential. Baseline determinations include whether the patient has a history of prostate cancer, benign prostatic hyperplasia, obstructive sleep apnea, liver disease, hypertension, or hyperlipidemia. Baseline testing includes a complete blood count and levels of serum PSA, lipids, and liver transaminases. PSA levels and prostate-related symptoms should be assessed at 6 months and then annually, and patients with elevated or increasing PSA levels should not be treated with testosterone. The

hematocrit and levels of lipids should be monitored biannually for the first 18 months and annually thereafter; the testosterone dose should be decreased or therapy discontinued if hematocrit values are greater than 50%. Finally, patient response to therapy and side effects are monitored quarterly during the first year of treatment.

- Patients receiving testosterone replacement require regular monitoring.
- Elevated or increasing PSA levels are an indication to stop therapy.
- Hematocrit values >50% are an indication to decrease the dose of testosterone or stop therapy.

Nonmedical Treatments

Other treatments for ED include topical vacuum pump devices and surgically inserted inflatable penile implants. Penile pumps work by creating a vacuum around the penis, thus drawing blood into the penis. When the penis is engorged with blood, an elastic ring is placed over the base of the penis and the pump is removed. Importantly, patients should use vacuum pump devices with vacuum limiters, which prevent negative pressure injury to the penis. Penile implants are generally not offered unless patients have no response to medical treatments, including maximal-strength injection therapy.

Glomerular Disease: Clinical Presentations

Clinical manifestations of glomerular injury can vary from the finding of isolated hematuria or proteinuria, or both, in an asymptomatic patient on a routine medical examination to the more florid presentation as nephritic syndrome, nephrotic syndrome, or rapidly progressive glomerulonephritis. In addition, some patients who present with advanced renal insufficiency, hypertension, and shrunken, smooth kidneys are presumed to have chronic glomerulonephritis. In this situation, renal biopsy is more likely to show nonspecific features of end-stage renal disease (ESRD).

Asymptomatic proteinuria is defined as urinary protein excretion of more than 300 mg/1.73 m^2 per 24 hours and less than 3.5 g/1.73 m^2 per 24 hours. *Normoalbuminuria* is defined as urinary albumin excretion of less than 30 mg/1.73 m^2 per 24 hours, *microalbuminuria* as urinary albumin of 30 to 300 mg/1.73 m^2 per 24 hours, and *overt proteinuria* as urinary albumin of more than 300 mg/1.73 m^2 per 24 hours. *Glomerular proteinuria* can be classified as *transient* or *hemodynamic* (functional) (e.g., after fever, with exercise, or orthostatic) or as *persistent* (fixed). *Functional proteinuria* is benign. The diagnosis of orthostatic proteinuria can be made by obtaining two 12-hour urine collections for protein: one supine and one upright. In this condition, proteinuria is usually less than 1 g/1.73 m^2 per 24 hours. Fixed nonnephrotic proteinuria is usually secondary to glomerular diseases, but tubulointerstitial diseases can also be associated with proteinuria (usually <1,500 mg/1.73 m^2 per 24 hours). Overflow low-molecular-weight proteinuria is due to increased excretion of light chain (myeloma) or to lysozyme release (leukemic cells). The urine dipstick test (which detects albumin only) is negative, but proteinuria can be detected easily by other tests, including the bedside sulfasalicylic acid test. *Hematuria* is defined as at least 3 red blood cells (RBCs) per high-power field in a centrifuged urinary sediment sample or RBCs more numerous than 10×10^6/L. *Glomerular hematuria* is characterized by the presence of dysmorphic RBCs or RBC casts (or both). *Macroscopic hematuria* due to glomerular disease is painless and often brown or a cola color rather than bright red; clots are rare. Other causes of brown urine include hemoglobinuria, myoglobinuria, and food or drug dyes (e.g., beetroot).

Renal biopsy is often required if patients have active urinary sediment (dysmorphic RBCs, RBC casts, or white blood cell [WBC] casts), proteinuria of more than 1 g/1.73 m^2 per 24 hours, or renal insufficiency and if the diagnosis cannot be determined or the prognosis adequately predicted by a less invasive diagnostic procedure. Other indications for biopsy include acute renal failure lasting longer than 3 to 4 weeks, patients with an atypical course of diabetes mellitus, and systemic diseases in which the differential diagnosis includes amyloidosis, systemic lupus erythematosus (SLE), and systemic vasculitis. Percutaneous renal biopsy is contraindicated if the patient has uncontrolled hypertension, acute pyelonephritis, perinephric abscess, or renal neoplasm or if the patient is uncooperative. Patients with bleeding disorders, including severe thrombocytopenia, should be considered for a renal biopsy through a transjugular approach together with the use of fresh frozen plasma and platelet transfusion if indicated. A solitary kidney is not an absolute contraindication to biopsy. Complications include gross hematuria (<10%), arteriovenous fistula (<1%), need for nephrectomy (0.1%), and death (0.001%). A renal biopsy is rarely indicated in patients with small, shrunken kidneys because of the increased risk of bleeding and the low probability of providing a diagnosis.

- Clinical presentations of glomerular disease: asymptomatic hematuria or proteinuria, nephrotic syndrome, nephritic syndrome, rapidly progressive glomerulonephritis, or chronic glomerulonephritis.
- Renal biopsy: to determine the diagnosis and prognosis for patients with active urinary sediment, proteinuria >1 g/1.73 m^2 per 24 hours, or unexplained renal failure.
- Other indications: acute renal failure lasting >3-4 weeks, atypical course of diabetes mellitus, and undiagnosed systemic disease.
- Contraindications to percutaneous renal biopsy: bleeding disorders, uncontrolled hypertension, acute pyelonephritis, renal neoplasm, and uncooperative patients.

Nephrotic Syndrome

Nephrotic syndrome is defined as the presence of urinary protein greater than 3.5 g/1.73 m^2 per 24 hours, hypoalbuminemia (<3.0 g/dL), peripheral edema, hypercholesterolemia, and lipiduria. Edema can be prominent. Children usually manifest matinal periorbital edema that resolves during the day as the child stands upright. Severe hyperlipidemia can result in the development of xanthelasma. Urinalysis shows waxy casts, free fat, oval fat bodies, and lipiduria ("Maltese crosses"). Complications of nephrotic syndrome include hypogammaglobulinemia (which increases infection risk, especially cellulitis and spontaneous peritonitis), vitamin D deficiency due to loss of vitamin D–binding protein, and iron deficiency anemia due to hypotransferrinemia. Thrombotic complications are common (e.g., renal vein thrombosis) and occur because of increased levels of prothrombotic factors (increased factor V, VIII, fibrinogen, and platelets and decreased antithrombin III and antiplasmin). Patients at increased risk include those with proteinuria greater than 10 g/1.73 m^2 per 24 hours and a serum albumin level less than 2 g/dL. Symptoms of renal vein thrombosis include flank pain and hematuria. In cases of bilateral renal vein thrombosis, patients may present with acute renal failure. Apart from renal vein thrombosis, in patients with nephrotic syndrome acute renal failure may develop from several mechanisms (e.g., prerenal volume depletion, sepsis, interstitial nephritis, and drugs such as angiotensin-converting enzyme inhibitors [ACEIs] and nonsteroidal anti-inflammatory drugs [NSAIDs]). Management of nephrotic syndrome includes using diuretics, controlling blood pressure (ACEIs and angiotensin receptor blockers [ARBs] are preferred), and limiting the intake of protein (0.8 g/kg per day) and sodium (<2 g/d), and controlling lipid levels (with the use of HMG-CoA reductase inhibitors). Anticoagulation should be considered for patients at increased risk, especially if the nephrotic syndrome is due to membranous nephropathy or amyloidosis.

- Nephrotic syndrome: urinary protein >3.5 g/1.73 m^2 per 24 hours.
- Other features: hypoalbuminemia, peripheral edema, hyperlipidemia, and lipiduria.

Nephritic Syndrome

Nephritic syndrome is characterized by oliguria, edema, hypertension, proteinuria (usually <3.5 g/1.73 m^2 per 24 hours), and the presence of an active urinary sediment with dysmorphic RBCs or RBC casts (or both). Because of methemoglobin formation in acidic urine, the urine has a cola or smoky appearance. The classic example is acute poststreptococcal glomerulonephritis in children.

- Nephritic syndrome: active urinary sediment (dysmorphic RBCs or RBC casts or both).
- Other features: oliguria, hypertension, edema, and proteinuria (usually <3.5 g/1.73 m^2 per 24 hours).

Glomerular Disease That Presents With Nephritic Syndrome

Poststreptococcal Glomerulonephritis

Poststreptococcal glomerulonephritis (PSGN) is an acute glomerulonephritis that develops 1 to 4 weeks after pharyngitis or skin infection with specific ("nephritogenic") strains of group A β-hemolytic streptococci. The latent period is 6 to 21 days (type 12 pharyngeal infection) or 14 to 28 days (type 49 skin infection). The typical presentation is the abrupt onset of nephritic syndrome. An active urinary sediment is present in almost all cases. Proteinuria is usually less than 3 g/24 h, but it may be in the nephrotic range in some cases. Cultures are usually negative, but titers for antistreptolysin O (ASO), antistreptokinase, antihyaluronidase, and antideoxyribonuclease (antiDNAse B) may provide evidence of recent streptococcal infection. ASO titers increase 10 to 14 days after infection and peak at 3 to 4 weeks, subsequently decreasing. Total hemolytic complement (CH50) and C3 levels are usually decreased (activation of the alternative complement pathway), but C4 levels are normal.

Light microscopy shows diffuse hypercellularity of the glomerular tufts, with mesangial and endothelial cell proliferation and infiltration of polymorphonuclear leukocytes (thus, the name *exudative*), monocytes or macrophages, and plasma cells. All glomeruli are affected in a homogeneous pattern. Early in the disease process, characteristic subepithelial "humps" can be detected with silver stain. Cellular crescents are uncommon and indicative of severe disease. Immunofluorescence shows granular deposition of IgG, C3, and occasionally IgM, which are distributed in three well-described patterns: "starry-sky," "mesangial," and "garland." With electron microscopy, small immune deposits are seen in the mesangial and subendothelial areas. Almost pathognomonic of PSGN is the presence of large "humps," which are dome-shape subepithelial deposits in the glomerular basement membrane (GBM).

The treatment of PSGN is supportive. Appropriate antibiotic therapy is indicated for persistent infection and for persons who are contacts (to prevent new cases). Sodium restriction and the use of loop diuretics reduce the risk of fluid overload and help to control hypertension. For children, the prognosis is excellent, with most patients recovering renal function within 1 to 2 months after diagnosis. ASO titers assist in confirming resolution. In a few patients, especially adults, microscopic hematuria, proteinuria, hypertension, and renal dysfunction may persist for many years. Patients presenting with a crescentic nephritis have a poorer prognosis, with approximately 50% developing ESRD. Other forms of postinfectious glomerulonephritis include bacterial endocarditis and infected ventriculoatrial shunts.

- PSGN: usually due to group A β-hemolytic streptococcal infections.
- Active urinary sediment, with proteinuria <3 g/1.73 m^2 per 24 hours.
- Total and C3 complement levels are low.
- Light microscopy: diffuse hypercellularity of the glomerular tufts, with mesangial and endothelial cell proliferation, infiltration of polymorphonuclear leukocytes, and subepithelial "humps" with silver stain.
- Immunofluorescence: granular deposition of IgG and C3 in a "starry-sky," "mesangial," or "garland" pattern.
- AntiDNAse B confirms streptococcal infection, and serial ASO titers assist in confirming resolution.

IgA Nephropathy

IgA nephropathy (IgAN), or Berger disease, is a mesangial proliferative glomerulonephritis characterized by diffuse deposition of IgA in the mesangium. It is the most common glomerulopathy worldwide, with an incidence approaching 1:100 in some countries (e.g., Japan). The typical presentation is with episodic macroscopic hematuria usually accompanying an intercurrent upper respiratory tract infection (synpharyngitic). This clinical pattern occurs most frequently in young adults in the second and third decades of life. Other patients are asymptomatic and may be identified when microscopic hematuria, with or without proteinuria, is found on routine urinalysis. Proteinuria is common, but nephrotic syndrome occurs in less than 10% of all cases. Patients with nephrotic syndrome may have minimal change disease superimposed on IgAN or other glomerulopathy. The pathogenesis has been linked to abnormal integrity of the intestinal mucosa, resulting in overexposure to ubiquitous environmental antigens. This leads to an exaggerated production of galactose-deficient (GD)-IgA1 by bone marrow–derived B cells. Undergalactosylation of the IgA1 molecules reduces their affinity to the clearance receptors on Kupffer cells in the liver and results in an increase in circulating GD-IgA1, formation of anti–GD-IgA1 autoantibodies, deposition of IgG or IgA anti–GD-IgA1 immune complexes in the mesangium, and activation of complement and cytokine cascades. Secondary causes include advanced chronic liver disease, celiac disease, dermatitis herpetiformis, and ankylosing spondylitis. With light microscopy, glomeruli may look normal or may show mesangial expansion. Immunofluorescence studies are diagnostic and demonstrate strong IgA staining within the mesangium. Electron microscopy shows electron-dense deposits in the mesangial cells that colocalize with the immune deposits.

The disease generally has a benign course, with patients maintaining a proteinuria less than 500 mg/1.73 m^2 per 24 hours and having preserved renal function. However, in 20% to 40% of patients, the disease progresses to ESRD within 10 to 25 years. Proteinuria of more than 1 g/1.73 m^2 per 24 hours, hypertension, impaired renal function at diagnosis, and glomerular or interstitial fibrosis identified in renal biopsy specimens are the most important predictors of a poor outcome. IgAN recurs in about 50% of patients after renal transplantation, but loss of the allograft from recurrent disease is uncommon. Progression to ESRD in patients at high risk has been shown to be slowed by angiotensin II converting enzyme blockade (with ACEIs or ARBs or both), administration of high doses of corticosteroids, and fish oil capsules containing omega-3 fatty acids. Mycophenolate mofetil is a new immunosuppressive agent currently being studied in clinical trials, but results so far have been disappointing. Patients with IgAN and concomitant minimal change disease respond fully to corticosteroid therapy. For patients with rapidly progressive renal failure due to crescentic IgAN, a regimen of corticosteroids and cyclophosphamide, with the addition of plasma exchange or pulse methylprednisolone, has been tried with variable results. A few familial cases of IgAN have been described.

- IgAN: the most common glomerulopathy worldwide.
- Presentation: synpharyngitic hematuria, often with RBC casts.
- Secondary causes: advanced chronic liver disease, celiac disease, dermatitis herpetiformis, and ankylosing spondylitis.
- Prognosis: generally good in patients who are normotensive, with proteinuria <1 g/1.73 m^2 per 24 hours and serum creatinine <1.5 mg/dL.
- Treatment with ACEIs or ARBs, high-dose corticosteroids, and fish oil capsules containing omega-3 fatty acids slows the progression of the disease.

Henoch-Schönlein Purpura

Henoch-Schönlein purpura is the systemic form of IgAN. Patients usually present with microscopic or gross hematuria (or both) along with RBC casts, purpura, and abdominal pain. Renal biopsy findings are similar to those of IgAN with or without vasculitis. The prognosis generally is good for children and variable for adults. In patients with normal renal function, treatment is supportive only. Patients with progressive renal failure should be considered for treatment with high-dose corticosteroids with or without cytotoxic medication.

Membranoproliferative Glomerulonephritis

Membranoproliferative glomerulonephritis (MPGN) is defined as the diffuse proliferation of the mesangium and thickening of glomerular capillary walls, as seen with light microscopy. MPGN type I affects mainly children of both sexes between the ages of 8 and 16 years. Type II MPGN is a rare disease (<1% of all renal biopsies). Secondary forms of MPGN tend to predominate in adults (>90%). The main cause of secondary MPGN is cryoglobulinemia in a patient with hepatitis C virus (HCV) infection. Other secondary causes include chronic infections, "shunt nephritis," malaria, SLE, congenital complement deficiency (C2 and C3), sickle cell disease, partial lipodystrophy (only type II), and α_1-antitrypsin deficiency. The clinical presentations of all forms of MPGN are variable and include nephrotic and nephritic features. Approximately one-third of the patients present with a combination of asymptomatic hematuria and proteinuria. Another third present with nephrotic syndrome and preserved renal function. Some patients (10%-20%) present with nephritic syndrome. Hypertension is common (50%-80% of patients). In MPGN type I and cryoglobulinemic MPGN, the levels of C3, C4, and CH50 are persistently low, reflecting activation of both complement pathways. In MPGN type II, the alternative pathway is activated, with patients having a persistently low level of C3 but a normal level of C4. A C3 nephritic factor is present in many

cases. C3 nephritic factor is an autoantibody to alternative pathway C3 convertase, resulting in persistent breakdown of C3.

In Type I MPGN, renal biopsy specimens show diffuse global thickening of capillary walls and endocapillary hypercellularity, giving the glomeruli a lobular appearance. The interposition of mesangium between the GBM and the endothelium triggers the production of neomembrane by the endothelial cells and results in glomerular capillaries developing a double contour or "tram-track" appearance, best seen with silver staining. Immunofluorescence shows the granular deposition of IgG and C3 in the mesangium and outlines the lobular contours. Electron microscopy shows immune deposits in the subendothelial space and mesangium. In type II MPGN, also known as "dense deposit disease," electron-dense deposits replace the lamina densa and produce a smooth, ribbonlike thickening. Immunofluorescence shows intense capillary wall staining (linear to bandlike) for C3.

- MPGN: about one-third of the patients present with hematuria and proteinuria; about one-third present with nephrotic syndrome and preserved renal function. Nephritic syndrome is present in 10%-20%.
- Complement values are persistently low.
- C3 nephritic factor is often present.
- Secondary causes: hepatitis B and C, chronic infections, "shunt nephritis," SLE, and sickle cell disease.
- A "tram-track," or double contour, appearance is seen with silver staining.

In children, long-term corticosteroid therapy has been helpful. The use of dipyridamole (225 mg/d) and aspirin (975 mg/d) may temporarily slow the rate of progression of type I MPGN, but results are not lasting. Treatment in adults is unknown. MPGN type I usually has a slowly progressive course, with 40% to 50% of patients reaching ESRD in 10 years. Patients with MPGN type II have a worse prognosis, and clinical remission rates are less than 5%. Predictors of poor outcome include impaired renal function at presentation, nephrotic-range proteinuria (>3 g/1.73 m^2 per 24 hours), hypertension, the number of crescents (>50%), and the degree of tubulointerstitial damage. This disorder tends to recur in transplant recipients (type I, 30%; type II, 90%).

- Prognosis: worse with hypertension, poor renal function, and proteinuria >3 g/1.73 m^2 per 24 hours.

Rapidly Progressive Glomerulonephritis—Crescentic Glomerulonephritis

Rapidly progressive glomerulonephritis (RPGN) is defined as an acute, rapidly progressive (days to weeks to months) deterioration of renal function associated with an active urinary sediment and a focal necrotizing crescentic glomerulonephritis seen on light microscopic examination of renal biopsy specimens. A pulmonary-renal syndrome is frequent, and oliguria is not uncommon. Immunofluorescence demonstrates three patterns: type I, linear IgG deposition (e.g., Goodpasture disease or anti-GBM–mediated); type II, granular immune complexes (e.g., SLE); and type III, pauci-immune (negative or weak immunofluorescence; e.g., antineutrophil cytoplasmic autoantibody [ANCA] vasculitis) (Fig. 17-1). *Goodpasture syndrome* indicates a pulmonary-renal syndrome and can be due to several

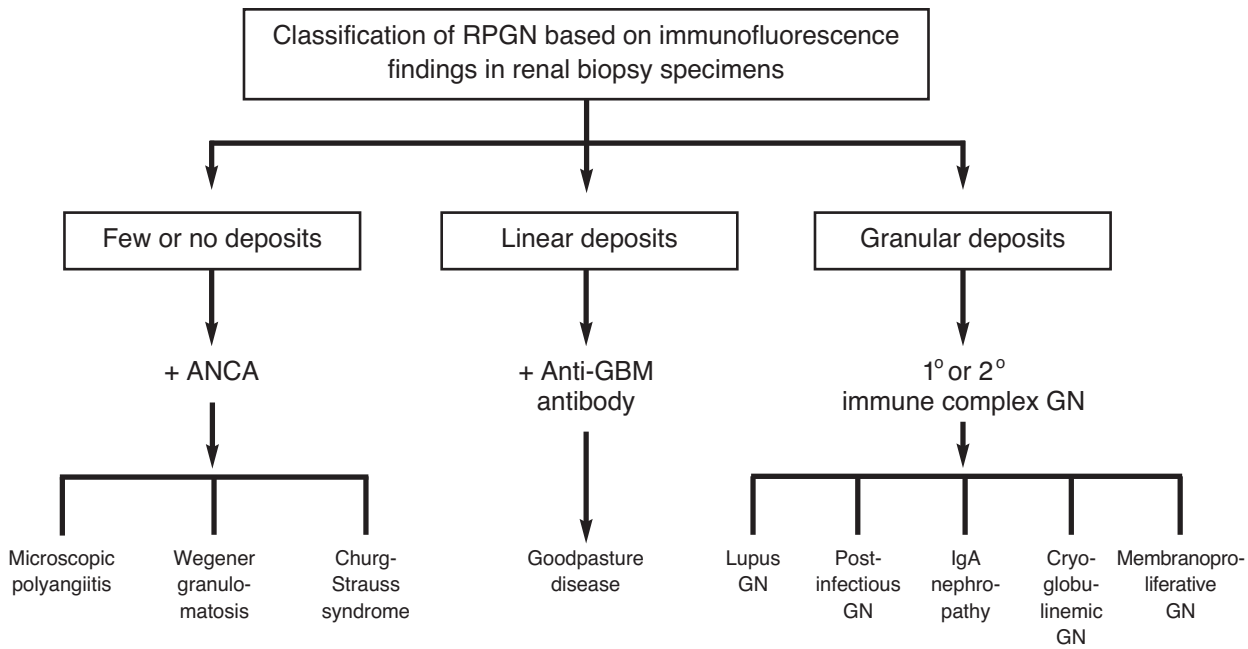

Fig. 17-1. Classification of rapidly progressive glomerulonephritis (RPGN) according to immunofluorescence microscopy findings in renal biopsy specimens. ANCA, antineutrophil cytoplasmic autoantibody; GBM, glomerular basement membrane; GN, glomerulonephritis.

conditions, including Goodpasture disease, ANCA vasculitis (microscopic polyangiitis or Wegener granulomatosis), SLE, cryoglobulinemia, and pulmonary edema.

- RPGN: acute (days to weeks to months) deterioration of renal function.
- Focal necrotizing crescentic glomerulonephritis seen in renal biopsy specimens.
- Pulmonary-renal syndrome (Goodpasture syndrome) is common and can be due to Goodpasture disease, ANCA vasculitis (microscopic polyangiitis or Wegener granulomatosis), SLE, cryoglobulinemia, pulmonary edema, and other conditions.

ANCA Vasculitides

In the Chapel Hill classification, systemic vasculitis can be classified according to the different vessels that are involved (Table 17-1). Of particular importance to nephrology are the ANCA vasculitides: microscopic polyangiitis, Wegener granulomatosis, and Churg-Strauss syndrome. This group is characterized by inflammation and necrosis of small blood vessels of the kidney and other organs that occur in association with autoantibodies against antigens present in lysosomal granules in the cytoplasm of neutrophils (ANCA). These antigens are myeloperoxidase (MPO) and proteinase-3 (PR3). On ethanol-fixed leukocytes examined with indirect immunofluorescence, anti-MPO antibodies frequently produce a perinuclear pattern (p-ANCA) and antibodies against PR3 form a cytoplasmic pattern (c-ANCA). Because nonspecific antibodies against other cytoplasmic antigens (e.g., enolase, elastase, lactoferrin, and catalase) can also give a positive ANCA pattern on immunofluorescence, confirmation of the antibody specificity by enzyme-linked immunosorbent assay (ELISA) is required. Patients with ANCA vasculitis, which is the most common cause of RPGN in patients older than 60, have a wide range of signs and symptoms (Table 17-2).

Table 17-1 **Chapel Hill Consensus on the Nomenclature of Systemic Vasculitis**

Giant cell (temporal) arteritis
Takayasu arteritis
Medium-sized vessel vasculitis
Classic polyarteritis nodosa
Kawasaki disease
Small-vessel vasculitis
Microscopic polyangiitis*
Wegener granulomatosis*
Churg-Strauss syndrome*
Henoch-Schönlein purpura
Essential cryoglobulinemic vasculitis
Cutaneous leukocytoclastic vasculitis

*Strongly associated with antineutrophil cytoplasmic autoantibody (ANCA).

Microscopic Polyangiitis

Microscopic polyangiitis is a necrotizing vasculitis with few or no immune deposits (pauci-immune) on immunofluorescence that affects small vessels (i.e., capillaries, venules, and arterioles). A necrotizing arteritis involving small and medium-size arteries can be present. Necrotizing glomerulonephritis with crescents is common, and pulmonary capillaritis often occurs. Fifty percent of patients are MPO-ANCA–positive, 40% are PR3-ANCA–positive, and a few are ANCA-negative.

Wegener Granulomatosis

Wegener granulomatosis (WG) is a granulomatous inflammation involving the respiratory tract and necrotizing vasculitis affecting small and medium-size vessels (i.e., capillaries, venules, arterioles, and arteries). In WG, as in microscopic polyangiitis, a necrotizing glomerulonephritis is common. Of the patients with WG, 75% are PR3-ANCA–positive, and 20% are MPO-ANCA–positive.

Churg-Strauss Syndrome

Churg-Strauss syndrome is characterized by peripheral blood eosinophilia, asthma or other form of atopy, an eosinophil-rich granulomatous inflammation involving the respiratory tract, and a necrotizing vasculitis affecting small and medium-size vessels. Sixty percent of the patients are MPO-ANCA–positive.

ANCA vasculitis should be treated with a combination of high-dose corticosteroids and cyclophosphamide (3-6 months). Patients with pulmonary hemorrhage or severe renal failure (serum creatinine >5.5 mg/dL or receiving dialysis) or both, should also receive plasma exchange. The prognosis in ANCA vasculitis is quite variable. According to recent reviews, 2 years after the diagnosis the mortality rate is 25% and the ESRD rate is 21%. However, with aggressive treatment up to 75% of patients may recover renal function, even if dialysis therapy was required at the start of treatment. ANCA vasculitides are associated with a high relapse rate (30%-50% within the first 5 years). Long-term treatment with low-dose corticosteroids in combination with azathioprine is beneficial in decreasing the frequency of relapses. Patients with WG who are nasal carriers for *Staphylococcus aureus* benefit from long-term treatment with trimethoprim-sulfamethoxazole. The use of serial ANCA testing as a predictor of relapses has variable degrees of success. For making a therapeutic decision, the results of this test should not be taken in isolation but

Table 17-2 **Signs and Symptoms of ANCA Vasculitis**

Cutaneous purpura, nodules, and ulcerations
Peripheral neuropathy (mononeuritis multiplex)
Abdominal pain and blood in stools
Hematuria, proteinuria, and renal failure
Hemoptysis and pulmonary infiltrates or nodules
Necrotizing (hemorrhagic) sinusitis
Myalgias and arthralgias
Muscle and pancreatic enzymes in blood

ANCA, antineutrophil cytoplasmic autoantibody.

in the context of the patient's clinical history. Several medications (propylthiouracil, hydralazine, and penicillamine) and heavy silica exposure have been associated with the induction of ANCA and necrotizing glomerulonephritis.

Polyarteritis Nodosa

Polyarateritis nodosa is characterized by necrotizing inflammation of medium-sized or small arteries without glomerulonephritis or vasculitis in arterioles, capillaries, or venules. Polyarteritis nodosa is ANCA-negative and associated with hepatitis B infection. The diagnosis is made by finding aneurysms on angiography.

- ANCA vasculitis: microscopic polyangiitis, WG, and Churg-Strauss syndrome.
- ANCA vasculitis: the most common cause of RPGN in patients older than 60 years.
- Renal biopsy: focal segmental necrotizing glomerulonephritis with crescents.
- Polyarteritis nodosa: ANCA-negative; associated with hepatitis B infection; normal glomeruli.
- "Drug-induced ANCA vasculitis": propylthiouracil, hydralazine, and penicillamine.
- Treatment: high-dose corticosteroids and cyclophosphamide.
- Plasmapheresis is also indicated for patients with ANCA vasculitis who have evidence of pulmonary hemorrhage or severe renal failure (serum creatinine >5.5 mg/dL or receiving dialysis).

Goodpasture Disease: Anti-GBM Antibody–Mediated Glomerulonephritis

Goodpasture disease is defined by a pulmonary-renal syndrome caused by circulating anti-GBM antibodies and linear staining seen along the GBM and alveolar basement membrane on immunofluorescence. The antibody is directed against the α3 chain of type IV collagen. Pulmonary hemorrhage may be absent or not clinically apparent. Other autoantibodies may coexist with anti-GBM antibodies (about 25%-30% of patients are also ANCA-positive). The treatment of Goodpasture disease is with high-dose corticosteroids (prednisone, 1 mg/kg daily up to 80 mg daily, or pulse methylprednisolone sodium succinate [Solu-Medrol], 1 g for 3 days) in combination with oral cyclophosphamide (2-3 mg/kg daily up to 200 mg daily; decrease the dose by 25% for patients older than 55 or with creatinine >5 mg/dL) and plasma exchange. The prognosis in patients with Goodpasture disease depends on the percentage of circumferential crescents of the renal biopsy specimen, the presence of oliguria, and the need for dialysis. Among patients with a serum creatinine level of 5.0 mg/dL at the start of treatment, the probability of renal survival at 5 years is more than 90%. Patients who have 100% circumferential crescents and are receiving dialysis do not recover renal function and should not be treated with the immunosuppressive regimen outlined above, except in the presence of pulmonary hemorrhage. Goodpasture disease is a "single-hit disease"—it rarely recurs. Patients with ESRD are candidates for renal transplantation after the antibody has disappeared (6-12 months).

- Goodpasture disease: pulmonary-renal syndrome, positive anti-GBM antibody, and linear staining of the GBM.

Glomerular Disease That Usually Presents as Nephrotic Syndrome

Minimal Change Nephropathy

Minimal change nephropathy (MCN) is defined by the absence of structural glomerular abnormalities, except for the fusion of epithelial cell foot processes seen on electron microscopy, in a patient with nephrotic syndrome. MCN is the most common cause of nephrotic syndrome in children. Among patients with nephrotic syndrome, MCN is the cause in 70% to 90% of children younger than 10 years (although rarely before the first year of life), in 50% of adolescents and young adults, and in less than 20% of adults with primary nephrotic syndrome.

The pathogenesis of MCN is unknown. The association with Hodgkin lymphoma suggests that MCN may be a consequence of T-lymphocyte abnormalities, with T cells producing a lymphokine that is toxic to glomerular epithelial cells. This results in fusion of foot processes and detachment of podocytes, loss of the heparin sulfate negative-charge barrier of the basement membrane, and increased glomerular permeability to protein. There is a clear association with drugs, allergy, and malignancy. Children with the disease present with an abrupt onset of nephrotic syndrome. The presence of hematuria, hypertension, or impaired renal function is unusual in children. In adults, hypertension and renal insufficiency may be present. In children, the presence of nephrotic syndrome in a patient with normal urinalysis results indicates MCN until proven otherwise. If a child does not have a response to corticosteroid therapy, renal biopsy is justified. In adults, MCN accounts for less than 20% of the cases of patients presenting with a nephrotic syndrome, and renal biopsy is required to establish the diagnosis. The most important differential diagnosis is focal segmental glomerulosclerosis (FSGS).

In some patients, MCN may have a secondary cause. The most common secondary causes of MCN are the following:

1. Viral infections—mononucleosis and human immunodeficiency virus (HIV)
2. Drugs—NSAIDs (with interstitial nephritis)
3. Tumors—Hodgkin lymphoma and leukemia
4. Allergies—food, bee sting, and poison ivy

On light microscopic and immunofluorescence examination, the glomeruli are normal. Tubules may accumulate lipid droplets from absorbed lipoproteins. Occasionally, the findings are consistent with acute tubular necrosis. Electron microscopy shows effacement of the foot processes; however, this is a nonspecific finding that is also seen in patients with heavy proteinuria due to other glomerulopathies. In children, high-dose corticosteroid therapy is the cornerstone of treatment, with more than 90% of children achieving complete remission after 4 to 6 weeks of treatment. In adolescents and adults, the response to therapy is also high (>80%), but the response is slower and some patients may require up to 16 weeks of treatment to achieve remission. Generally, therapy is continued for 4 to 8 weeks after remission. Of the patients who have a response to corticosteroid

therapy, 25% have a long-term remission. The others have at least one relapse. For patients who have frequent relapses, are steroid-dependent, or are resistant to steroids, alternative therapy includes the use of cyclophosphamide, chlorambucil, and cyclosporine. Overall, the prognosis is excellent, with patients maintaining renal function long-term. If there is no response to therapy or if progressive renal failure develops, an alternative diagnosis (such as FSGS) must be considered.

- MCN: abrupt nephrotic syndrome with normal renal function.
- It is the main cause of nephrotic syndrome in children. In adults, it accounts for <20% of cases of nephrotic syndrome.
- Secondary causes: viral, Hodgkin disease, and NSAIDs (with interstitial nephritis).
- MCN responds to corticosteroid treatment. Failure to respond to this therapy suggests an alternative diagnosis.

Focal Segmental Glomerulosclerosis

Focal segmental glomerulosclerosis (FSGS) accounts for less than 15% of cases of idiopathic nephrotic syndrome in children. In adults, it accounts for approximately 25% of nephropathies. FSGS is the most common form of idiopathic nephrotic syndrome in African Americans. It may be idiopathic or due to different causes (e.g., heroin abuse, HIV infection, sickle cell disease, obesity, vesicoureteral reflux, unilateral renal agenesis, remnant kidneys, and aging). The pathogenesis of idiopathic FSGS is unknown. In some patients, the presence of a circulating permeability factor has been demonstrated. Glomerular hypertension and hyperfiltration are thought to have a role in secondary causes of FSGS, as in patients with unilateral renal agenesis or remnant kidneys. Patients present with either asymptomatic proteinuria or full-blown nephrotic syndrome. Hypertension is found in 30% to 50% of patients, with microscopic hematuria in 25% to 75% of them. At presentation, the glomerular filtration rate is decreased in 20% to 30% of patients.

The pathologic diagnosis of FSGS is based on the identification in some glomeruli (focal) of areas of capillary obliteration, with increased mesangial matrix deposition and intracapillary hyalin deposits in parts of the glomerular tufts (segmental lesion). Interstitial fibrosis is a common finding. Immunofluorescence shows IgM and C3 deposition in the areas of glomerular scarring (nonspecific trapping). Electron microscopy demonstrates fusion of epithelial foot processes in the majority of the glomeruli, including those that appear normal on light microscopy. Four histologic variants of FSGS have been described. In the most common pattern, there is predilection for sclerosis in the perihilar regions. In the cellular/collapsing variant, hypertrophy and hyperplasia of the overlying epithelial cells result in global glomerular capillary collapse and sclerosis. The cellular/collapsing variant, which has the worst prognosis, is more common in African Americans and patients with HIV infection.

Prolonged (>4 months) high-dose corticosteroid therapy (prednisone, 1mg/kg daily) has achieved up to a 40% to 60% remission rate of nephrotic syndrome, with preservation of long-term renal function. For patients who have a response to corticosteroids, alternative therapy includes the use of cytotoxic drugs, either alone or in combination with corticosteroids, and low-dose cyclosporine. Treatment options are limited for patients who do not have a response to corticosteroids. For these patients, the best evidence is for treatment with cyclosporine, but tacrolimus and mycophenolic acid have also been used with variable success. For patients who have protein excretion of less than 3 g daily, treatment with an ACEI or angiotensin II receptor antagonist (or both) may be sufficient to reduce proteinuria and improve renal survival. For patients with secondary forms of FSGS, treatment should target the primary cause, if possible. In all patients, treatment with an ACEI or an ARB, alone or in combination, may substantially reduce proteinuria and prolong renal survival. In an increasing number of cases (both familial and sporadic, in children and adults), the disease is associated with mutations in several podocyte-associated proteins (podocin, CD2-associated protein, and α-actinin-4). Patients who are homozygous for these mutations have no response to corticosteroid treatment.

Less than 5% of patients experience a spontaneous remission of proteinuria; eventually, ESRD develops in most patients 5 to 20 years after presentation. The response to corticosteroid treatment and the degree of proteinuria are the best predictors of the long-term clinical outcome. Patients who have a non–nephrotic-range proteinuria have the best renal survival (>80% at 10 years). Patients who have the worst prognosis are those who have no response to treatment or who continue to have proteinuria of more than 10 g/1.73 m^2 per 24 hours regardless of the histologic variant; in the majority of them, ESRD develops within 3 years. Idiopathic FSGS may recur in a transplanted kidney.

- FSGS accounts for about 25% of cases of adult nephrotic syndrome.
- FSGS is the most common cause of nephrotic syndrome in African Americans.
- Patients present with hypertension, renal insufficiency, proteinuria, and hematuria.
- Secondary causes: HIV infection, heroin abuse, reflux nephropathy, and morbid obesity.
- Podocyte-related proteins are increasingly recognized as causes of FSGS.
- Prolonged high-dose corticosteroid therapy: more than 40% of patients have a response.
- The cellular/collapsing variant has the worst prognosis.

HIV-Associated Nephropathy

HIV-associated nephropathy (HIV-AN) is characterized by progressive renal insufficiency in patients with nephrotic-range proteinuria (frequently massive) but often little edema. Large echogenic kidneys are seen on ultrasonography. Renal biopsy specimens show a collapsing form of FSGS. Tubules are often dilated, forming microcysts. With electron microscopy, numerous tubuloreticular inclusions are seen within the glomerular and vascular endothelial cells. HIV-AN is much more common, and clinically more severe, in African Americans than in whites. Other types of glomerulonephritis also encountered with some frequency in HIV-infected persons include MPGN, MCN, membranous nephropathy (MN), and postinfectious glomerulonephritis. Thrombotic microangiopathy develops in some patients; it is not related to *Escherichia coli* O157:H7

and carries a high mortality. The optimal treatment for patients with HIV-AN is not clear. Suggested therapies include use of antiretroviral agents, treatment of underlying infections, and use of ACEI to reduce proteinuria.

Membranous Nephropathy

MN is the leading cause of nephrotic syndrome in white adults. It occurs in persons of all ages and races but is most often diagnosed in middle age, with the incidence peaking during the fourth and fifth decades of life. The male-female ratio is a 2:1. The pathogenic mechanisms that cause this immune complex localization and the subsequent development of proteinuria and the nephrotic syndrome are not completely understood, but in situ deposition of cationic antigens in the subepithelial space is thought to be involved. The nature of the antigen involved in the immune complex deposits of MN and its source are not known.

At presentation, proteinuria is greater than 2.0 g/1.73 m^2 per 24 hours in more than 80% of patients and more than 10 g/1.73 m^2 per 24 hours in as many as 30%. Initially, renal function is preserved in the majority of patients, and hypertension is present in 13% to 55%. A small proportion have microscopic hematuria. MN is an idiopathic (primary) or secondary disease (up to 30% of patients with biopsy-proven MN). Secondary MN is caused by autoimmune diseases (e.g., SLE and autoimmune thyroiditis), infection (e.g., hepatitis B and C), drugs (e.g., penicillamine, gold, and NSAIDs), and malignancies (e.g., colon cancer and lung cancer). MN is associated with malignancy in 7% to 15% of patients older than 60 years. Very early in the disease process, the glomeruli may appear normal in light microscopic preparations and the diagnosis can be made only with immunofluorescence or with electron microscopy to detect subepithelial deposits along the GBM. With more advanced lesions, capillary walls are thickened, and methenamine silver stain shows subepithelial projections ("spikes") along the capillary walls. The spikes represent deposition of new basement membrane material along the subepithelial deposits. Immunofluorescence microscopy shows marked granular deposition of IgG and C3 along the capillary walls.

Initial therapy for MN is generally supportive. The use of ACEIs and ARBs is recommended, but their effect in decreasing proteinuria is modest (about 40%). Therapies other than supportive care should be considered for patients who remain nephrotic after a trial of maximal angiotensin II blockade (6 months); they include a combination of corticosteroids and cytotoxic agents, and cyclosporine. Mycophenolate mofetil has been tried with success in some patients. Thrombotic complications (e.g., renal vein thrombosis causes sudden loss of renal function in 25%-50% of patients) are frequent, and anticoagulation should be considered for patients with proteinuria greater than 10 g/1.73 m^2 per 24 hours and serum albumin less than 2 g/dL. Without treatment, nearly 25% of patients have spontaneous complete remission and 50% have partial remission. In patients who have spontaneous remission, it usually occurs within 6 to 12 months after presentation. The probability of renal survival is more than 80% at 5 years and 60% at 15 years. The prognosis is worse in nephrotic patients. In 10% to 15% of patients the disease has an accelerated course, with ESRD occurring within 1 year after the diagnosis.

- MN: the primary cause of idiopathic nephrotic syndrome in white adults.
- The peak incidence occurs during the fourth and fifth decades of life.
- Renal vein thrombosis causes sudden loss of renal function in 25%-50% of patients.
- Secondary causes: infections, multisystem disease, neoplasms, and medications.
- Spontaneous complete remission occurs in 25% of patients and partial remission in 50%.

Other Glomerular Disorders

Diabetic Nephropathy

Diabetic nephropathy (DN) is the commonest cause of ESRD in the United States (>40% of patients on dialysis; 80% or more have type 2 diabetes). DN occurs in both type 1 (30%-40% of cases) and type 2 (20%-30% of cases) diabetes mellitus. In type 1 diabetes mellitus, the peak onset of nephropathy is between 10 and 15 years after the initial presentation with diabetes. Patients who do not have proteinuria after 25 years of diabetes are unlikely to develop DN. A similar natural history is likely for patients with type 2 diabetes mellitus. The main risk factors for developing DN are a positive family history of DN, hypertension, and poor glycemic control. The risk may be greater in some racial groups (e.g., Pima Indians and African Americans). The pathogenesis is secondary to increased glycosylation of proteins, with accumulation of advanced glycosylation end products that cross-link with collagen, in combination with glomerular hyperfiltration and hypertension.

DN is first manifested by the onset of microalbuminuria (defined as urinary albumin excretion of 20-200 μg/min or 30-300 mg/1.73 m^2 per 24 hours). With time, microalbuminuria evolves into overt proteinuria (>300 mg/1.73 m^2 per 24 hours) and subsequent full-blown nephrotic syndrome. The presence of microalbuminuria is the primary predictor of renal disease (in 30%-45% of patients, microalbuminuria progresses to proteinuria after 10 years), with the degree of proteinuria correlating roughly with the renal prognosis. After overt proteinuria develops, the progression toward ESRD is relentless, although rates of decline vary among patients (5-15 years). In patients with type 1 diabetes, there is a strong correlation (95%) between the development of nephropathy and other signs of diabetic microvascular compromise, such as diabetic retinopathy and DN. This correlation is weaker for patients with type 2 diabetes, and up to one-third of these patients develop nephropathy without evidence of diabetic retinopathy. Hypertension occurs in about 75% of patients with proteinuria. Other renal manifestations of diabetes include frequent urinary tract infections, which may be complicated by the development of acute pyelonephritis and perinephric abscess, and papillary necrosis. A functional obstruction caused by neurogenic bladder may also occur. Because of the accelerated rate of atherosclerosis, diabetic patients also have a high incidence of

cardiovascular disease, including renal artery stenosis. The stages of DN are listed in Table 17-3.

- DN occurs in 30%-40% of patients with type 1 diabetes mellitus and in 20%-30% of patients with type 2 diabetes mellitus.
- DN is the single most common cause of ESRD in the United States.
- Microalbuminuria is the primary predictor of renal disease.
- Other renal manifestations of diabetes are hypertension, recurrent urinary tract infections, acute pyelonephritis, perinephric abscess, papillary necrosis, and neurogenic bladder.

In the earliest stage of the disease, renal biopsy specimens show glomerular hypertrophy and thickening of the GBM. As the disease progresses, arteriolar hyalinosis and arteriosclerosis develop. This is followed by progressive mesangial expansion (diffuse diabetic glomerulosclerosis) and nodular formations (Kimmelstiel-Wilson nodules, which are pathognomonic for DN). Both the diffuse and the nodular mesangial expansions are composed of extracellular mesangial matrix and stain positive with silver and periodic acid–Schiff stain. Capsular drop lesions and fibrin cap lesions are also pathognomonic findings. Late in the disease, tubular atrophy and interstitial fibrosis occur. For patients with long-term diabetes, especially if retinopathy is present and other causes of proteinuria are excluded, renal biopsy may not be necessary. However, renal biopsy is indicated for patients with an atypical course of the disease (e.g., nephrotic-range proteinuria within the first 10 years in type 1 diabetes or if loss of renal function is rapidly progressive). Start ACEI or ARB therapy in patients who have diabetes and microalbuminuria even if they are normotensive. The progression of DN can be retarded by tight glycemic control (glycated hemoglobin <7.0%) and the use of ACEIs or ARBs (target systolic blood pressure <125 mm Hg). Patients with diabetes who develop microalbuminuria should start ACEI or ARB therapy even if they are normotensive. Patients with ESRD due to diabetes mellitus are candidates for a solitary kidney or combined kidney-pancreas transplant. Hemodialysis and continuous ambulatory peritoneal dialysis are alternatives. Pancreatic islet cell transplantation is a promising new therapy.

Table 17-3 Stages of Diabetic Nephropathy

Stage	Description
I	Hyperfiltration, glomerular filtration rate is 20%-50% above normal, microalbuminuria (30-300 mg/1.73 m^2 per 24 hours)
II	Normalization of glomerular filtration rate with early structural damage
III	Early hypertension
IV	Progression to proteinuria >500 mg/1.73 m^2 per 24 hours, hypertension, declining glomerular filtration rate (lasts 10-15 years)
V	Progression to ESRD (5-7 years); heavy proteinuria persists even to ESRD

ESRD, end-stage renal disease.

- Kimmelstiel-Wilson nodules are pathognomonic for DN.
- Aggressive glucose and blood pressure control slows progression.
- Diabetes mellitus is the most common cause of type IV renal tubular acidosis.
- Start ACEI or ARB therapy in patients who have diabetes and microalbuminuria even if they are normotensive.

Systemic Lupus Erythematosus Nephritis

Lupus nephritis (LN) is a major cause of morbidity and mortality in patients with SLE. Approximately 25% of patients with SLE have substantial renal involvement. If renal involvement occurs with SLE, it is usually early in the course of the disease, but rarely is renal involvement the sole manifestation of SLE. LN is more severe in children and in African Americans. The International Society of Nephrology/Renal Pathology Society (ISN/RPS) classification of LN recognizes six morphologic classes of renal involvement (Table 17-4). These patterns of LN are not static and may show a transition from one class to another either spontaneously or after treatment. A few patients may develop a necrotizing glomerulonephritis with crescents. Immunofluorescence shows glomerular deposition of IgG, IgM, IgA, C1q, and C4 ("full-house" pattern). As seen with electron microscopy, immune deposits are localized to the glomerular capillary subendothelium (wire-loop) and a fingerprint-like pattern of tubuloreticular inclusions is common within glomerular and vascular endothelial cells. The type of renal lesion strongly influences the

Table 17-4 Abbreviated International Society of Nephrology/Renal Pathology Society (ISN/RPS) Classification of Lupus Nephritis (2003)

Morphologic class	Renal manifestation
I. Minimal mesangial lupus nephritis	Normal urinary sediment
II. Mesangial proliferative lupus nephritis	Low-grade hematuria and/or proteinuria Normal renal function
III. Focal lupus nephritis	Active sediment; proteinuria <3 g/1.73 m^2 per 24 hours
IV. Diffuse segmental (IV-S) or global (IV-G) lupus nephritis	Nephritic and nephrotic syndromes Hypertension; progressive renal failure
V. Membranous lupus nephritis	Nephrotic syndrome
VI. Advanced sclerosing lupus nephritis	Inactive urinary sediment Chronic renal failure

Modifed from Weening JJ, D'Agati VD, Schwartz MM, Seshan SV, Alpers CE, Appel GB, et al. The classification of glomerulonephritis in systemic lupus erythematosis revisited. J Am Soc Nephrol. 2004;15:241-50. Used with permission.

management of SLE, and kidney biopsy is indicated in patients with proteinuria and active urinary sediment, regardless of whether they have decreased glomerular function, to define the morphologic class. The histopathologic features correlate with the prognosis, with classes III and IV having the worst prognosis (5-year survival is about 80%). Immunosuppressive treatment is indicated for class III or IV LN. For patients with severe LN, the combination of high-dose corticosteroid (either orally or "pulse" intravenous methylprednisolone) with intravenous cyclophosphamide has produced the most effective therapeutic results, with improvement of serologic and clinical abnormalities. Recent studies suggest that the combination of mycophenolate mofetil plus oral prednisone is as effective as cyclophosphamide plus prednisone. Membranous LN is characterized by proteinuria, weakly positive or negative antinuclear antibody, and no erythrocyte casts. Initial therapy is supportive only. Patients who remain nephrotic should be considered for immunosuppressive treatment (e.g., cyclosporine).

- Severe renal involvement occurs in 25% of patients with SLE.
- Focal or diffuse proliferative LN requires aggressive treatment with high-dose corticosteroids plus cyclophosphamide.
- Membranous LN (without proliferation) usually is not treatable with immunosuppressive agents unless nephrotic syndrome persists (>6 months).

Other manifestations of SLE include acute and chronic tubulointerstitial nephritis and glomerular capillary thrombi in patients with antiphospholipid antibodies. Drug-induced SLE rarely involves the kidney. SLE tends to flare during pregnancy, and pregnancy should be delayed until after SLE has been inactive for at least 1 year. SLE "burns out" with ESRD and generally does not recur in transplant recipients (recurrence rate, 2%-4%).

- Drug-induced SLE rarely involves the kidney.
- Pregnancy should be delayed until after SLE has been inactive.
- SLE "burns out" with ESRD and uncommonly (2%-4%) recurs in renal transplant recipients.

Monoclonal Gammopathies

Multiple Myeloma

The renal manifestation of multiple myeloma may be acute renal failure or a chronic progressive disease that may occur at any time during the course of the disease. Virtually all patients with multiple myeloma have monoclonal immunoglobulins or light chains in the serum and urine. Acute renal failure may occur as a result of intraluminal precipitation of multiple proteinaceous casts ("cast nephropathy") and the resulting acute noninflammatory interstitial nephritis (myeloma kidney). The casts are usually acellular with multiple fracture lines (broken casts), are seen mainly in the distal nephron, and are the result of aggregates of light chains and Tamm-Horsfall glycoprotein. Coaggregation of Tamm-Horsfall glycoprotein with light chains is facilitated by increased concentrations of calcium, sodium, and chloride (such as after the use of a loop diuretic) in the urine; by conditions that reduce flow rates (such as intravascular depletion and the use of NSAIDs); or by the use of radiocontrast agents. Other renal manifestations include pseudohyponatremia, low anion gap, and type 2 renal tubular acidosis with Fanconi syndrome (low levels of phosphorus, urate, and potassium; glycosuria; and aminoaciduria). Ultrasonography shows normal-size or large kidneys. Treatment of cast nephropathy includes vigorous hydration, correction of hypercalcemia, and avoidance of nephrotoxic or precipitating agents. Alkalinizing the urine to keep the pH greater than 7 may be beneficial in some patients. Plasmapheresis can quickly remove light chains from the circulation and should be considered for patients with acute renal failure or hyperviscosity syndrome. Treatment with melphalan and prednisone decreases the circulating levels of light chains and stabilizes or improves renal function in two-thirds of patients with renal failure. Recent success has been achieved with myeloablative therapy followed by bone marrow transplantation, but the mortality rate is high.

Amyloidosis

Amyloidosis is due to the systemic extracellular deposition of antiparallel, β-pleated sheet, nonbranching, 8- to 12-nm fibrils that stain positive with Congo red (green birefringence with polarized light) or thioflavin T. In primary (AL) amyloidosis, patients are typically older than 50 years, and the kidneys are affected in 50% of patients. Common renal manifestations include proteinuria, nephrotic syndrome (25% of patients), and renal failure. Immunofluorescence generally demonstrates λ light chains in the glomeruli (75% of patients). For patients with cardiac involvement, the prognosis is poor, with a median survival of less than 2 years. Treatment with prednisone and melphalan can be beneficial in some patients. In selected cases, high-dose melphalan followed by bone marrow transplantation has led to resolution of the disease. Secondary (AA) amyloidosis is most common in patients with rheumatoid arthritis, inflammatory bowel disease, chronic infection, or familial Mediterranean fever and in subcutaneous drug users (heroin). Treatment of AA amyloidosis is directed at the underlying inflammatory process. Colchicine is helpful in patients with familial Mediterranean fever.

Light Chain Deposition Disease

In light chain deposition disease (LCDD), light chain is deposited along the GBM. LCDD is strongly associated with the development of myeloma, lymphoma, and Waldenström macroglobulinemia. Renal involvement is similar to that of amyloidosis, with proteinuria, nephrotic syndrome, and renal insufficiency. Renal biopsy specimens show acellular, eosinophilic mesangial nodules that stain strongly positive with periodic acid–Schiff, often mimicking diabetes mellitus. The deposited monoclonal proteins do not form fibrils and do not bind Congo red. Immunofluorescence microscopic findings are diagnostic, showing diffuse linear Ig light chain deposition (κ in 80% of cases) along the GBM and tubular basement membranes and in the nodules. As in amyloidosis, treatment with melphalan and prednisone has led to stabilization or improved renal function in some patients. At 5 years, patient survival is 50% to 70%, with renal survival ranging from 20% to 35%. Similar to AL amyloidosis, the disease recurs in transplant recipients.

Glomerulonephritis Associated With Hepatitis Infection

Cryoglobulinemic Glomerulonephritis

Type II or mixed essential cryoglobulins (Table 17-5) are commonly found in patients with HCV infection and contain HCV RNA and anti-HCV IgG. After they precipitate in the glomeruli, they bind complement, activate a cytokine cascade, and trigger an inflammatory response. Patients with this renal disease may present with proteinuria, microscopic hematuria, nephrotic syndrome, or renal impairment. Hypertension is common and may be severe, particularly in the presence of acute nephritic syndrome. Cryoglobulinemia is usually associated with low levels of C3 and C4. The cryocrits correlate poorly with disease activity (at least 30% to 40% of the patients do not have detectable cryoglobulins). On light microscopy, renal biopsy specimens show a membranoproliferative type I pattern of injury, with massive exudation of cells, mainly monocytic, and a double-contoured appearance of the GBM. Eosinophilic thrombi are often found in the capillary lumen and consist of cryoprecipitated immunoglobulins. On electron microscopy, diffuse, dense subendothelial deposits are seen occluding the glomerular capillary; some have a peculiar microtubular or crystalline appearance due to parallel fibrils. In some cases, a vasculitis affecting small and medium-size arteries may be seen. Combination treatment with interferon alfa and ribavirin is effective in clearing the virus from the circulation and results in improvement of proteinuria and renal function. However, relapses after discontinuation of the antiviral therapy are common. Treatment with prednisone, cytotoxic agents, and plasmapheresis is indicated in patients with acute nephritis. The renal prognosis is usually good, with few patients progressing to ESRD.

Hemolytic Uremic Syndrome and Thrombocytopenic Purpura

The two forms of hemolytic uremic syndrome (HUS) are a sporadic or diarrhea-associated form (D+HUS) and a non–diarrhea-associated form (D–HUS). D+HUS is strongly linked to ingestion of meat contaminated with *E. coli* O157:H7. This bacterium produces a Shiga-like toxin that binds to a glycolipid receptor on renal endothelial cells and triggers endothelial damage. D–HUS occurs in association with the use of oral contraceptives, cyclosporine, tacrolimus, mitomycin C, bleomycin, ticlopidine, or quinine or with antiphospholipid antibody syndrome (in the context of pregnancy), underlying malignancy, or radiotherapy. A familial recurrent form of D–HUS has also been described.

Thrombocytopenic purpura (TTP) occurs as an acute form or as a chronic (relapsing) form. It also occurs in association with some systemic diseases (SLE, scleroderma, or malignancy), drugs (cocaine, quinidine, or ticlopidine), and HIV infection. TTP occurs with a deficiency of the von Willebrand factor (vWF)-cleaving protease (chronic form) or with the development of an autoantibody against vWF-cleaving protease. Patients with HUS or TTP present with a microangiopathic hemolytic anemia and thrombocytopenia. HUS more commonly causes acute renal failure, and TTP is more commonly associated with fever, neurologic signs, and purpura. Markers of hemolysis are present and include low haptoglobin levels, increased levels of lactate dehydrogenase and unconjugated bilirubin, and a high reticulocyte count. Schistocytes are present in peripheral blood smears. In D+HUS, renal biopsy specimens show mainly capillary thrombosis, whereas in D–HUS there is predominant involvement of small arteries, with intimal mucoid proliferation and arterioles with onion-skinning and thrombosis.

Therapy for HUS is supportive. Plasma infusions, plasma exchange, and anticoagulation are ineffective. However, fresh frozen plasma infusions and plasma exchange are effective treatments for TTP. The transfusion of platelets should be avoided because of the risk of accelerating the process. Children with D+HUS have a good prognosis (90% recover renal function), but older patients have an increased mortality rate and unfavorable long-term renal survival.

- D+HUS: Shiga-like toxin production by *E. coli* O157:H7.
- Presentation of patients with HUS or TTP: microangiopathic hemolytic anemia and thrombocytopenia.
- Therapy: for HUS, supportive; for TTP, fresh frozen plasma infusion and plasmapheresis.
- D+HUS: good prognosis for children.

Diseases with GBM Abnormalities: Alport Syndrome and Thin GBM Disease

Alport Syndrome

Alport syndrome is an inherited disorder of basement membranes. In more than half of the patients, the disease results from a mutation in the gene (*COL4A5*) that codes for the α5 chain of type IV

Table 17-5 **Cryoglobulins and Associated Diseases**

Cryoglobulin type	Immunoglobulin class	Associated diseases
I. Monoclonal immunoglobulins	M>G>A>BJP	Myeloma, Waldenström macroglobulinemia
II. Mixed cryoglobulins with monoclonal immunoglobulins	M/G>>G/G	Sjögren syndrome, Waldenström macroglobulinemia, lymphoma, essential cryoglobulinemia
III. Mixed polyclonal immunoglobulins	M/G	Infection, SLE, vasculitis, neoplasia, essential cryoglobulinemia

SLE, systemic lupus erythematosus.

collagen α5(IV). The syndrome is characterized by a progressive nephritis manifested by persistent or intermittent hematuria and is frequently associated with sensorineural hearing loss and ocular abnormalities. Most patients have mild proteinuria, which progresses with age; kidneys become nephrotic in approximately one-third of the patients. The disease is X-linked in at least 80% of the patients, but autosomal recessive and autosomal dominant patterns of inheritance have been described. In virtually all male patients, the syndrome progresses to ESRD, often by age 16 to 35. The disease is usually mild in heterozygous females, but some develop ESRD, usually after age 50. The rate of progression to ESRD is fairly constant among affected males within individual families, but it varies markedly from family to family. On light microscopy, the glomerular changes are nonspecific. Diagnostic features are usually seen on electron microscopy. At an early stage, thinning of the GBM may be the only visible abnormality and may suggest thin basement membrane disease. With time, the GBM thickens and the lamina densa splits into several irregular layers that may branch and rejoin, producing a characteristic "basket weave" appearance. Immunohistochemical studies of type IV collagen show the absence of α3(IV), α4(IV), and α5(IV) chains from the GBM and distal tubular basement membrane. This abnormality occurs only in patients with Alport syndrome and is diagnostic. In families with a previously defined mutation, molecular diagnosis of affected males or gene-carrying females is possible. For families in which mutations have not been defined, genetic linkage analysis can determine whether an at-risk person carries the mutant gene, provided that at least two other affected members are available for testing. No specific treatment is available for Alport syndrome. Tight control of blood pressure and moderate protein restriction are recommended to retard the progression of renal disease, but the benefit is unproven. Peritoneal dialysis, hemodialysis, and renal transplantation are used successfully. Transplant recipients have a 5% to 10% risk of Goodpasture disease developing (because of the presence of Goodpasture antigen in the transplanted kidney).

Thin GBM Disease

Thin GBM disease, or thin basement membrane nephropathy, is a relatively common condition characterized by isolated glomerular hematuria associated with the renal biopsy finding of an excessively thin GBM. The pathogenesis is unclear. In contrast to patients with Alport syndrome, immunohistochemical studies of type IV collagen in the GBM of patients with thin GBM disease do not show abnormality in the distribution on any of the six chains. The clinical presentation includes persistent hematuria first detected in childhood. In some patients, hematuria is intermittent and may not be manifested until adulthood. Macroscopic hematuria is not uncommon and may occur in association with an upper respiratory tract infection. When first detected in young adults, 60% have proteinuria less than 500 mg/1.73 m^2 per 24 hours. The glomeruli appear normal in light and immunofluorescence microscopic preparations of renal biopsy specimens. Electron microscopy shows diffuse thinning of the GBM. In adults, a GBM thickness of 250 nm is strongly suggestive of thin GBM disease. The condition is usually benign and requires no specific treatment. For the majority of patients, the prognosis is excellent, with renal function preserved for a long time. However, a small proportion of patients have progressive renal disease that leads to ESRD.

Clinical Manifestations of Tubulointerstitial Renal Disease

Acute and chronic interstitial disease preferentially involves renal tubules. Some of the patterns of renal tubular injury are 1) tubular proteinuria (<1.5-2 g/1.73 m^2 per 24 hours), 2) proximal tubule dysfunction (hypokalemia, hypouricemia, hypophosphatemia, acidosis, glycosuria, and aminoaciduria), 3) distal tubule dysfunction (hyperchloremic acidosis, hyperkalemia or hypokalemia, and salt wasting), 4) medullary concentration dysfunction, nephrogenic diabetes insipidus with decreased urine-concentrating ability, 5) urine sediment (pyuria, leukocyte casts, eosinophiluria, and hematuria), and 6) azotemia and renal insufficiency.

- Tubular proteinuria <1.5-2 g/1.73 m^2 per 24 hours.
- Proximal tubule dysfunction and distal tubule dysfunction.
- Medullary concentration dysfunction.

Acute Interstitial Nephritis

Acute interstitial nephritis (AIN) is an acute, usually reversible, inflammatory disease characterized by a mononuclear cellular infiltrate within the renal interstitium. AIN is relatively common (about 10%-15% of cases of acute renal failure) and occurs in any age group but is rare in children. AIN is most frequently associated with drugs, particularly antibiotics (such as methicillin, which interacts with anti–tubular basement membrane antibodies) and NSAIDs (which cause interstitial nephritis with nephrotic syndrome and renal insufficiency) (Table 17-6). Infections are the second most common cause. AIN also occurs in association with selected autoimmune systemic diseases and malignancies. In 10% to 20% of cases, AIN is idiopathic. Onset is sudden, with approximately 40% of patients having oliguria. In patients with drug-induced AIN, the systemic manifestations of a hypersensitivity reaction include fever (>50% of patients), maculopapular rash (40%), and arthralgias (25%). Flank pain is caused by distension of the renal capsule and occurs in approximately 50% of the patients. Renal impairment (60% of patients) varies from a mild increase in the serum level of creatinine to severe acute renal failure requiring dialysis. Tubular damage can impair the urinary concentration mechanism and result in the development of polyuria. Eosinophilia is common (50% of patients). Urinalysis demonstrates pyuria and hematuria in nearly 100% of the patients, but macroscopic hematuria is unusual. Rarely, RBC casts are seen in the urinary sediment. The presence of eosinophiluria (>1% of patients) is suggestive of AIN but is also seen in other unrelated renal diseases. The absence of eosinophiluria does not exclude the diagnosis. Proteinuria is generally mild (<1 g/1.73 m^2 per 24 hours). The predictive value of Gallium scanning is limited. Diagnosis sometimes requires renal biopsy. Therapy is primarily supportive. The likely inciting factor or factors need to be identified and eliminated. Treatment with prednisone (60 mg every other day) for 2 to 4 weeks

Table 17-6 Common Causes of Acute Interstitial Nephritis

Drugs
Antibiotics—penicillin, methicillin (anti–tubular basement membrane antibodies), ampicillin, rifampin, sulfa drugs, ciprofloxacin, pentamidine
NSAIDs—interstitial nephritis with nephrotic syndrome and renal insufficiency may have a latent period; not dose-dependent; recurs; possibly T-cell–mediated; allergic signs and symptoms are absent
Diuretics—thiazides, furosemide, bumetanide (sulfa derivatives)
Cimetidine
Allopurinol, phenytoin, phenindione
Cyclosporine
Infections
Bacteria—*Legionella*, *Brucella*, *Streptococcus*, *Staphylococcus*, *Pneumococcus*
Virus—Epstein-Barr, CMV, *Hantavirus*, HIV, hepatitis B, *Polyomavirus*
Fungus—*Candida*, *Histoplasma*
Parasites—*Plasmodium*, *Toxoplasma*, *Schistosoma*, *Leishmania*
Systemic diseases
Systemic lupus erythematosus
Sjögren syndrome
Sarcoidosis
Lymphoma, leukemic infiltration
Renal transplant rejection
Idiopathic

CMV, cytomegalovirus; HIV, human immunodeficiency virus; NSAID, nonsteroidal anti-inflammatory drug.

may hasten the recovery of renal function and may be of benefit in patients who do not regain renal function within 1 week after discontinuing use of the offending agent. Corticosteroids are not indicated in infection-related AIN. Historically, drug-induced AIN has been considered a reversible process, with renal function returning to baseline values in the majority of patients. However, recent studies have shown that impaired renal function can persist long-term in up to 40% of the patients.

- AIN: nearly 100% of patients have pyuria; >50%, fever; 60%, renal insufficiency; 50%, eosinophilia; and 25%, arthralgias.
- Methicillin (anti-tubular basement membrane antibodies).
- NSAIDs: interstitial nephritis with nephrotic syndrome and renal insufficiency.

Analgesic Chronic Interstitial Nephritis

Analgesic nephropathy is a typical example of slowly progressive chronic interstitial nephritis due to the chronic consumption of mixed analgesic preparations, frequently complicated by papillary necrosis, and resulting in bilateral renal atrophy. It is responsible for 20% of cases of chronic tubulointerstitial nephritis and accounts for approximately 3% to 10% of patients reaching ESRD. There are major regional differences in its incidence, perhaps reflecting differences in consumption behavior, availability of phenacetin-containing analgesic mixtures, and medical awareness of the condition. Most of the initial cases of analgesic nephropathy were identified in patients who consumed large amounts of phenacetin, a fact that led to the removal of phenacetin from most markets around the world. More recently, it has been recognized that acetaminophen combined with acetylsalicylic acid can cause renal damage. Also, chronic use of NSAIDs can result in the development of analgesic nephropathy. The condition is five to seven times more frequent in females than males. Besides having headaches, arthritis, muscular aches, and a history of peptic ulcer, patients usually have a history of chronic pain with the consumption of large amounts of analgesic mixtures over the years, but this can be difficult to ascertain in all patients, partly because of resistance to admit to analgesic abuse. The frequency of the diagnosis increases with age and is rare in patients younger than 30 years.

The early stages of the disease reflect abnormalities in tubular function, with impaired ability to acidify and concentrate the urine (polyuria). Hypertension occurs in 50% of patients, frequently in association with renal artery stenosis. Papillary necroses themselves usually do not cause symptoms. Renal colic and outflow obstruction can result from a sloughed papilla. Occasionally, the obstruction can be bilateral and patients may present with acute renal failure. Anemia is common and may be out of proportion to the degree of renal failure. Urinalysis shows sterile hematuria, pyuria, and mild proteinuria (<3 g/1.73 m^2 per 24 hours). Computed tomography without radiocontrast has become the standard method for making the diagnosis of analgesic nephropathy. The demonstration of a bilateral decrease in kidney size in combination with irregular ("bumpy") renal contours, especially papillary calcifications (92% positive predictive value), is considered diagnostic of analgesic nephropathy.

- Analgesic nephropathy: responsible for 20% of cases of chronic tubulointerstitial nephritis (3%-10% of patients have ESRD).
- It is five to seven times more frequent in females than males.
- Characteristics include chronic pain, headaches, arthritis and muscular aches, and history of peptic ulcer.
- Patients generally do not admit to analgesic abuse.
- Computed tomography without contrast: small kidneys bilaterally, irregular ("bumpy") renal contours, and papillary calcifications are diagnostic of analgesic nephropathy.

Potential pathogenic mechanisms include direct drug toxicity to the renal papillae, hemodynamic factors, and genetic predisposition. Metabolism of phenacetin and acetaminophen results in increased concentration of highly reactive oxygen species in the renal papillae. These reactive radicals are normally "detoxified" by glutathione. Depletion of medullary glutathione results in the binding of free reactive intermediates to lipids in the cell membranes and lipid peroxidation. Ultimately, a chain of oxidative damage results in cell death. Aspirin potentiates the toxicity of phenacetin

and acetaminophen by depleting renal glutathione. NSAIDs contribute to the renal damage by inhibiting prostaglandin synthesis, which in turn leads to a decrease in renal papillary blood flow and papillary ischemia. The amount necessary to cause analgesic nephropathy is a total intake of 3 kg of phenacetin or 1 g daily for 3 years.

There is no specific form of treatment. Chronic consumption of analgesic medications, especially analgesic mixtures, must be discontinued, and if this is not possible, the regimen needs to be switched to single analgesic preparations. Other therapeutic maneuvers are similar to those for other forms of chronic renal failure.

The prognosis depends on whether analgesic misuse is stopped. Patients with analgesic nephropathy are at an increased risk of uroepithelial tumors, particularly transitional cell carcinomas (renal pelvis, ureter, bladder, and proximal urethra). Tumors frequently occur simultaneously at different sites in the urinary tract, and close follow-up with regular urinary cytologic examination is recommended. These patients are also at an increased risk of premature atherosclerosis and coronary artery disease.

- Phenacetin and its metabolites are concentrated in the renal papillae.
- Patients with analgesic nephropathy have an increased risk of premature atherosclerosis and coronary artery disease and of uroepithelial tumors.

Other causes of papillary necrosis can be remembered with the mnemonic *POSTCARD* (pyelonephritis, obstruction, sickle cell disease or trait, tuberculosis, chronic alcoholism with cirrhosis, analgesics, renal vein thrombosis, and diabetes mellitus).

Electrolyte- and Toxin-Induced Interstitial Nephritis

Acute uric acid nephropathy is associated with the tumor lysis syndrome that develops after chemotherapy, myeloproliferative disorders, heat stroke, status epilepticus, and Lesch-Nyhan syndrome. In acute uric acid nephropathy, intraluminal crystals cause intrarenal obstruction, the serum level of uric acid is often more than 15 mg, and 24-hour urinary uric acid is more than 1,000 mg. The spot urinary uric acid value divided by the spot urinary creatinine value is often greater than 1.0. Prevention requires alkaline diuresis, allopurinol, and, sometimes, hemodialysis. This disorder generally is completely reversible. Chronic uric acid nephropathy from saturnine gout (lead from "moonshine" or paint) or chronic tophaceous gout is due to interstitial crystal formation, that is, microtophi present in the renal parenchyma. It has only limited reversibility. In renal failure, de novo gout is rare; in this setting, it should be assumed that the patient has lead nephropathy until proved otherwise.

- Acute uric acid nephropathy is associated with tumor lysis syndrome and myeloproliferative disorders.
- Serum uric acid is >15 mg, and 24-hour urinary uric acid is >1,000 mg.
- The urinary uric acid–urinary creatinine ratio is >1.
- Prevention: alkaline diuresis and allopurinol.

Initially, hypercalcemia results in mitochondrial deposits of calcium in the proximal and distal tubules as well as in the collecting duct. Later, tubular degeneration with calcium deposition and obstruction occurs. Calcium inhibits sodium transport, induces nephrogenic diabetes insipidus, and causes intrarenal vasoconstriction. It also stimulates the release of renin and catecholamines, increasing blood pressure.

Hypokalemia has been associated with vascularization of the proximal and distal tubules and, possibly, chronic interstitial fibrosis. Nephrogenic diabetes insipidus is also associated with chronic hypokalemia.

Oxalate deposition from primary hyperoxaluria causes renal and extrarenal oxalate deposition. Extrarenal sites include the eyes, heart, bones, joints, and vascular system. Secondary causes of oxalate deposition include ethylene glycol, methoxyflurane, high doses of ascorbic acid, vitamin B_6 deficiency, and enteric hyperoxaluria.

Lithium induces nephrogenic diabetes insipidus and microcystic changes in the renal tubules. Interstitial fibrosis may be present.

Heavy metals such as cadmium, pigments, glass, plastic, metal alloys, electrical equipment manufacturing, and some cigarettes induce proximal renal tubular acidosis and tubulointerstitial nephritis. Lead intoxication can cause lead nephropathy, as mentioned above. The organic salt of mercury can induce chronic tubulointerstitial nephritis and membranous nephritis or acute tubular necrosis.

Cystic Renal Disease

Autosomal Dominant Polycystic Kidney Disease

Autosomal dominant polycystic kidney disease (ADPKD) is the most common hereditary renal disease, with an incidence of 1:1,000 to 1:400. It is responsible for disease in about 10% of all patients who reach ESRD. In approximately 50% of patients, ESRD occurs by the age of 55 to 75 years. The disease is characterized by multiple, bilateral renal cysts in association with cysts in other organs such as the liver, spleen, and pancreas. Both males and females are affected. Mutations in at least two genes give rise to the disease. The *PKD1* gene is localized in the short arm of chromosome 16 and is responsible for 85% to 90% of cases of ADPKD. The *PKD2* gene maps to the long arm of chromosome 4. *PKD1* and *PKD2* encode for two distinct proteins named "polycystin 1" and "polycystin 2," respectively. The molecular structure of polycystin 1 suggests that it may function as a cell membrane receptor involved in cell-cell or cell-matrix interactions, whereas polycystin 2 has similarities to a voltage-activated calcium channel.

Manifestations of renal involvement include pain, hematuria, hypertension, and renal insufficiency. Acute flank pain may occur as a result of cyst hemorrhage, infection, or stone. Macroscopic hematuria occurs in more than 40% of patients with ADPKD and may be the presenting symptom. Cyst hemorrhage is frequent, with macroscopic hematuria or with pain and fever simulating infection of the cyst. Urinary tract infection may occur as cystitis, pyelonephritis, cyst infection, or perinephric abscess. If cyst infection is suspected, aspiration of the cyst under ultrasonographic or computed tomographic guidance may be needed to confirm the diagnosis and

to guide selection of appropriate antimicrobial therapy. Lipid-soluble antibiotics tend to penetrate the cysts well. Renal stones occur in approximately 20% of patients with ADPKD. In the majority of cases, the stones are composed of uric acid or calcium oxalate (or both). The diagnosis of renal stones can be difficult because of the distorted renal anatomy and the presence of calcifications in the cyst walls and parenchyma. Computed tomography is the procedure of choice to detect radiolucent stones and to differentiate stones from tumor or clots. The most common extrarenal manifestation of ADPKD is polycystic liver disease. Multiple cysts result in hepatomegaly. Females are affected more often than men. Other complications include cyst hemorrhage, infection, and rarely cyst rupture. Intracranial aneurysms are another important extrarenal manifestation of ADPKD. The incidence of the aneurysms varies between 5% and 22%, depending on whether the family history is negative or positive. The risk of rupture depends on the size of the aneurysm: minimal risk for aneurysms less than 5 mm in diameter but high risk for aneurysms more than 10 mm in diameter. Other associations are diverticulosis, cardiac valve myxomatous degeneration, and hypertension.

If the patient has a family history of ADPKD, the diagnosis can be established by using the following renal ultrasonographic criteria: two cysts arising unilaterally or bilaterally for persons younger than 30 years, two cysts in each kidney for those 30 to 59 years old, and at least four cysts in each kidney for those older than 60. Presymptomatic screening with ultrasonography before age 20 is not recommended because the results may not be conclusive. By age 25, cysts are usually seen with ultrasonography or computed tomography. Linkage genetic analysis can establish the diagnosis at the molecular level but requires testing other family members. It can also be used for prenatal diagnosis. Direct mutation analysis is possible in most families with *PKD2*. In patients with *PKD1*, direct mutation analysis is difficult because of the larger size of the gene and because a large part of the gene is duplicated on chromosome 16. Therapy is directed at controlling hypertension and the renal and extrarenal complications of the disease. Lower urinary tract infection or asymptomatic bacteriuria should be treated to prevent retrograde infection of the kidney. Infected cysts may require percutaneous or surgical drainage. Screening for intracranial aneurysms is not routinely indicated. Transplantation is the treatment of choice for patients who develop ESRD.

- Autosomal dominant polycystic kidney disease causes 10% of all cases of ESRD.
- By age 25, cysts are usually seen with ultrasonography or CT.
- Other cysts occur in the liver, spleen, and pancreas.
- Other associations are diverticulosis, cardiac valve myxomatous degeneration, intracranial aneurysms, and hypertension.

Medullary Sponge Kidney and Acquired Renal Cystic Disease

Medullary sponge kidney is characterized by dilated medullary and papillary collecting ducts. As a result, the renal medulla develops a "spongy" appearance on excretory urography. The disorder may be unilateral or bilateral or involve a single papilla. There is no known pattern of inheritance of this disorder. Medullary sponge kidney is clinically asymptomatic except for the development of nephrolithiasis, hematuria, and recurrent urinary tract infections.

Acquired renal cystic disease can affect up to 50% of long-term dialysis patients and may occur with hematuria and an increasing hematocrit. Although these cysts sometimes have neoplastic potential, they rarely metastasize. The disease regresses after transplantation.

Part II

Amy W. Williams, MD

Acute Renal Failure

Introduction

Acute renal failure (ARF) is characterized by a rapid decline in renal function accompanied by retention of nitrogenous waste products and electrolyte disorders. Many clinically accepted definitions are used to identify when an increase in serum creatinine should be classified as acute renal failure, including an increase in creatinine of 0.5 mg/dL in 24 hours or a doubling of creatinine in 1 to 3 days. Regardless of which criterion is used, it is important to recognize ARF early, identify the cause, and initiate treatment to avoid patient morbidity and irreversible kidney damage.

After an acute decrease in renal function has been identified by comparing baseline and present creatinine values, the next steps are to determine whether the increased creatinine level truly reflects a decrease in the glomerular filtration rate (GFR) and whether the decrease in GFR is acute or chronic. A chronically increased level of creatinine usually indicates irreversible renal impairment. Drugs such as amiloride and trimethoprim interfere with creatinine secretion in the tubules, resulting in an increased serum level of creatinine without a decrease in GFR. Other causes of increased creatinine levels independent of GFR include other drugs (cefoxitin, cimetidine, and flucytosine), ketoacidosis (acetylacetate), and rhabdomyolysis. Blood urea nitrogen (BUN), a marker for nitrogenous waste retention, can be increased despite a normal GFR in patients with gastrointestinal tract bleeding, excessive protein intake, decreased urinary flow, or tissue trauma or from use of certain drugs (glucocorticoids or tetracycline). Another indicator of ARF is a change in urine flow. Oliguria (<400 mL/d), anuria (<50 mL/d), and polyuria (>3,000 mL/d) are all clues to the cause of renal dysfunction and help guide evaluation and treatment. For example, anuria may be due to complete urinary obstruction, rapidly progressive glomerulonephritis, cortical necrosis, or bilateral renal artery occlusion. Decreased kidney size indicates a chronic, irreversible component to the overall decrease in renal function. In selected circumstances, levels of creatinine or BUN (or both) that are within the reference range may be misleading. Patients who are elderly or who have severe muscle wasting may have a markedly decreased GFR even though they have a normal creatinine level. In severe liver dysfunction or protein malnutrition, the BUN level may be normal or minimally elevated even though GFR is markedly decreased. Therefore, it is important to know the baseline values for creatinine and BUN so that a change can be identified and, in these circumstances, to be alert for a decrease in GFR despite changes in the BUN or creatinine levels that are less than expected.

Currently, ARF is broadly classified into "prerenal," "renal," and "postrenal" causes. This classification facilitates the clinical evaluation and discovery of the cause from more than 100 potential causes. The incidence of ARF in hospitalized patients is 7.2%. The mortality rate has been reported to be as high as 37.8% for hospitalized patients with sepsis and ARF and 19.4% for hospitalized patients with ARF not associated with sepsis. Thus, an understanding of the risks and potential causes of ARF, along with closely monitoring for evidence of ARF to enable early intervention, is important.

- Correlation of creatinine with GFR is less than precise because its excretion is dependent not only on GFR but also on tubular secretion.
- Causes of increased creatinine levels independent of GFR: ketoacidosis (acetylacetate), cefoxitin, cimetidine, trimethoprim, flucytosine, and rhabdomyolysis.
- Causes of an increase in BUN independent of GFR: gastrointestinal tract bleeding, tissue trauma, glucocorticoids, tetracycline.
- Anuria <50 mL/d: complete urinary obstruction, rapidly progressive glomerulonephritis, cortical necrosis, and bilateral renal artery occlusion.
- A chronically increased level of creatinine usually represents irreversible renal impairment.
- Decreased kidney size indicates a chronic, irreversible component to the overall decrease in renal function.

Prerenal Failure

Prerenal causes of ARF involve a decrease in renal blood flow that leads to a decrease in GFR. If identified and treated, prerenal failure is usually reversible. Prerenal failure accounts for more than 50% of cases of ARF in hospitalized patients. All of the following decrease renal blood flow: decreased cardiac output (as in congestive heart failure), decreased circulating volume due to hemorrhage, gastrointestinal blood losses, use of diuretics, burns and third spacing of fluid (pancreatitis, sepsis, crush injuries, or advanced cirrhosis), and renovascular disease leading to renal artery obstruction and arteriolar obstruction.

- Prerenal causes of ARF are due to a decrease in renal blood flow that leads to a decrease in GFR.
- Prerenal failure is usually reversible.

Many vasoactive drugs can cause a decrease in renal blood flow without a decrease in effective circulating volume or intravascular volume. Cyclosporine, an immunosuppressive used in transplant regimens and in treatment of immune-mediated diseases, causes renal vasoconstriction. In the setting of other renal or circulatory insults, cyclosporine can induce ARF. Nonsteroidal anti-inflammatory drugs (NSAIDs) decrease vasodilatory prostaglandin production by inhibiting cyclooxygenase. When renal blood flow is compromised, these vasodilatory prostaglandins maintain the GFR by inducing afferent arteriolar dilatation. Patients with underlying renal insufficiency, volume depletion, or advanced liver disease who take NSAIDs are at risk of ARF.

- Patients with underlying renal insufficiency, volume depletion, advanced liver disease, or CHF who take NSAIDs are at risk of ARF.

The intrarenal formation and action of angiotensin II maintains the GFR when renal perfusion is decreased. Angiotensin II increases efferent arteriolar tone, which increases the intraglomerular hydrostatic pressure, thus preserving the GFR. Medications that interfere with the action of angiotensin can induce ARF when renal blood flow is decreased. Angiotensin-converting enzyme inhibitors (ACEIs) and angiotensin receptor blockers (ARBs) increase the risk of an acute decrease in GFR in patients who have compromised intravascular volume, congestive heart failure, renal artery stenosis, or any type of chronic kidney disease. If these medications are indicated for treatment of hypertension, proteinuria, or cardiac disease, the patient's creatinine and potassium levels should be closely monitored. A slight increase in the creatinine level is expected, but use of the medication should be discontinued if there is a progressive increase in the creatinine level or evidence of ARF. If a patient taking an ACEI or ARB develops ARF due to any cause, prerenal or renal (acute tubular necrosis), use of the ACEI or ARB should be discontinued until renal function improves. Another prerenal cause of ARF is obstruction of the renal arteries or several intrarenal arteries. A rapid decline in renal function occurs with acute occlusion of the arteries supplying blood to the kidneys (thrombosis, stenosis, emboli, or vasculitis of the main renal arteries or several intrarenal arteries).

- Medications that interfere with the action of angiotensin can induce ARF when renal blood flow is decreased.
- Another prerenal cause of ARF is obstruction of the renal arteries or several intrarenal arteries.
- Rapid decline in renal function: thrombosis, stenosis, emboli, or vasculitis of the main renal arteries or several intrarenal arteries.

Prerenal Failure Due to Liver Disease

Hepatorenal syndrome is characterized by severe liver disease associated with ARF. The pathophysiologic mechanism is not completely understood, but splanchnic vasodilatation, an increase in cardiac output, a decrease in systemic resistance, and profound renovascular constriction occur. Early in the course of chronic liver disease or cirrhosis, there is a balance of intrarenal vasodilators and vasoconstrictors. As liver disease progresses, splanchnic dilatation increases, leading to severe renal vasoconstriction and ARF. This can happen with a sudden decrease in intravascular volume, as in spontaneous bacterial peritonitis, gastrointestinal tract hemorrhage, or aggressive diuresis, leading to a decrease in renal perfusion and an increase in renal vasoconstriction. Mediators proposed to have a role in the severe renal vasoconstriction include endothelin, vasoconstrictive prostaglandins, and an active renal sympathetic nervous system. Splanchnic arterial vasodilatation also induces the renin-angiotensin-aldosterone system and vasopressin, along with activation of the sympathetic nervous system, causing sodium and water retention. Patients are at increased risk of hepatorenal syndrome if they have severe liver disease associated with ascites, portal hypertension, jaundice, thrombocytopenia, hepatic encephalopathy, an increased prothrombin time, a baseline low level of urinary sodium, hyponatremia, or a mean arterial pressure less than 80 mm Hg.

The two types of hepatorenal syndrome have different prognoses and rates of progression. Type I has a much worse prognosis, with a rapid onset of ARF, and occurs with acute liver failure or chronic advanced liver disease. Type II develops over a few weeks in persons with chronic liver disease who develop diuretic resistance and gradually develop ARF. The increase in the creatinine level in type II is much less than in type I, in which the creatinine level usually doubles in less than 2 weeks. Hyponatremia, hypokalemia, and hypoalbuminemia usually accompany the syndrome.

- Hepatorenal syndrome: severe liver disease associated with ARF.
- Type I: acute doubling of creatinine level with a poor prognosis.
- Type II: gradual worsening of renal function.

Careful review for possible precipitating events is important in the diagnosis and treatment of hepatorenal syndrome. Events that decrease intravascular volume can lead to ARF in patients with chronic liver disease or acute alcohol hepatitis. Widely recognized precipitating events include gastrointestinal tract bleeding, spontaneous bacterial peritonitis, large-volume paracentesis (>5 L) without albumin infusion, systemic bacteremia, and hypovolemic shock. Overdiuresis can also lead to hepatorenal syndrome in patients with severe liver disease. Diuretics added to a treatment regimen can attenuate the already decreased renal blood flow by further decreasing intravascular volume.

When renal failure occurs in these patients, the diagnosis of hepatorenal syndrome is one of exclusion. Other causes of ARF, including volume depletion, need to be ruled out. This is often difficult when severe liver disease is associated with ascites, total body sodium, water overload, and oliguria. Urinalysis results are often suggestive of acute tubular necrosis, but urinary sediment can be benign. Urinary sodium less than 10 mEq/L, urine osmolality greater than 500 mOsm/L, and a low fractional excretion of sodium are consistent with a prerenal cause but can also be present in hepatorenal syndrome. A fluid challenge or central hemodynamic monitoring is used to determine intravascular volume status. The treatment of hepatorenal syndrome includes supportive measures until a liver transplant is available. Many other drugs have been used, with variable success, in an attempt to improve renal function: acetylcysteine, dopamine, albumin, misoprostol, and octreotide. The initial results of studies of the α_1-adrenergic agent midodrine and octreotide, a somatostatin analogue, have been promising. Several small trials have revealed that vasopressin or its analogues terlipressin reverse oliguria and ARF due to hepatorenal syndrome and improve survival. Current evidence recommends liver treatment as first-line therapy and albumin plus vasopressin or midodrine plus octreotide as preferred second-line therapy in hepatorenal syndrome. Therapy aimed at increasing circulating volumes and systemic vasoconstriction may prove to be effective in decreasing the stimuli for renovascular vasoconstriction and improving renal function until liver transplantation. Another therapy used to support patients with hepatorenal syndrome while anticipating a liver transplant is transjugular intrahepatic portal systemic shunting. This procedure has been shown to decrease the activity of the renin-angiotensin system and its effect on the

sympathetic nervous system, thus leading to an improvement in renal function.

- In patients with cirrhosis and severe liver disease who present with ARF, the intravascular volume status should be assessed to identify and treat any reversible prerenal component.
- Urinalysis results are often suggestive of acute tubular necrosis.
- The treatment of hepatorenal syndrome includes supportive measures until a liver transplant is available.

Many disease states that resemble hepatorenal syndrome need to be ruled out. Any condition that leads to a decrease in renal blood flow and is associated with liver dysfunction can resemble pseudohepatorenal syndrome (sepsis, hypotension, and congestive heart failure). Leptospirosis, acute Wilson syndrome, and immune-mediated diseases such as systemic lupus erythematosus, polyarteritis, and cryoglobulinemia can involve the liver and kidney. Ingestion of toxins or exposure to toxins (e.g., methoxyflurane) that cause both liver and kidney dysfunction also need to be considered. Any patient with end-stage liver disease is at risk of acute prerenal failure due to severe systemic vasodilatation and intrarenal vasoconstriction.

Intrinsic Acute Renal Failure

Intrinsic or structural damage to the kidney that leads to ARF can be divided into three categories: acute tubular necrosis, acute interstitial nephritis, and rapidly progressive glomerulonephritis. (Rapidly progressive glomerulonephritis is discussed in another section of this chapter). Acute tubular necrosis injury can occur from a decrease in oxygen delivery to the kidney or from nephrotoxic injury. Most likely, there is a continuum, starting with the acute reversible decline in renal function seen in prerenal failure and progressing to the irreversible ischemic renal injury due to a prolonged deficiency in oxygen delivery. Between these two extremes is an ischemic injury that is reversible if the contributing factors are readily recognized and corrected.

The incidence of acute tubular necrosis in hospitalized patients is 5%. It occurs in 50% of patients undergoing emergency abdominal aortic aneurysm repair and in 20% undergoing cardiac surgery or operations related to trauma. In severely ill patients, the cause of acute tubular necrosis is usually multifactorial, and for the recovery of the patient and kidneys, it is important that all causes are identified and corrected. The typical course of ARF due to acute tubular necrosis begins with a rapid increase in the serum level of creatinine, accompanied by a decrease in urine output. The oliguric phase lasts from 7 to 14 days if the initial insult is corrected and no further renal insult (e.g., sepsis or hypotension) occurs. If the oliguric phase lasts longer than 4 weeks, other causes of ARF should be considered, and a renal biopsy may be required for further evaluation. The oliguric phase is followed by a diuretic phase, during which urine output increases, followed by delayed improvement in serum creatinine levels and GFR. The last phase occurs over 3 to 12 months as the GFR gradually improves. If the patient is oliguric for more than 16 days, renal function most likely will not return to baseline.

- The typical course of ARF due to acute tubular necrosis begins with a rapid increase in the serum level of creatinine, accompanied by a decrease in urine output.
- The oliguric phase is followed by a diuretic phase.

Many toxins, both endogenous (hemoglobinuria, myoglobinuria, calcium, uric acid, bilirubin, and bile salt) and exogenous (antibiotics, contrast dye, cyclosporine, acyclovir, and chemotherapeutic agents) can cause tubular damage. Retained bilirubin and bile salts as well as altered abdominal hemodynamics may contribute to the increased risk of acute tubular necrosis in patients undergoing biliary tract surgery. The length of time on cardiopulmonary bypass is related directly to the incidence of acute tubular necrosis. Hemoglobinuria and decreased renal blood flow may have a role in the development of acute tubular necrosis in these patients. Heme pigments (myoglobin and hemoglobin) cause intrarenal vasoconstriction and tubular obstruction that lead to ARF (Table 17-7).

- Many toxins, both endogenous and exogenous, can cause tubular damage.
- The length of time on cardiopulmonary bypass is related directly to the incidence of acute tubular necrosis.
- Acute tubular necrosis injury can occur from a decrease in oxygen delivery to the kidney or from nephrotoxic injury.

Another cause of intrinsic ARF is acute interstitial nephritis, which can be mediated by immunologic, infectious, or allergic reactions. Patients with ARF due to acute interstitial nephritis can present with various problems. Drug-induced acute tubular necrosis can cause any combination of fever, rash, urinary eosinophilia, and peripheral eosinophilia. Some drugs, such as NSAIDs, are usually not associated with eosinophiluria. The diagnostic value of eosinophiluria is poor (positive predictive value, 50%; negative predictive value, 90%). The most common cause of acute interstitial nephritis in the hospital setting is an allergic reaction to a drug. Drugs associated with acute interstitial nephritis include β-lactam

Table 17-7 **Comparison of Heme Pigments**

	Serum color	Haptoglobin	CPK	Heme dipstick	Urine benzidine
Hemoglobin	Red	Decreased	Normal	Positive	Negative
Myoglobin	Clear	Normal	Increased	Positive	Positive

CPK, creatine phosphokinase.

antibiotics, diuretics, allopurinol, NSAIDs, cimetidine, sulfonamides, rifampin, and phenytoin.

NSAIDs and Cox-2 inhibitors can cause ARF by different mechanisms. They block the production of vasodilatory prostaglandins, causing intrarenal vasoconstriction and, when renal blood flow is compromised, reversible ARF. NSAIDs are also associated with an acute tubulointerstitial nephritis (without eosinophils), acute nephrotic syndrome, hyperkalemia, hyponatremia, and an exacerbation of hypertension.

- Patients with acute interstitial nephritis from NSAIDs usually present with proteinuria.
- The diagnostic value of eosinophiluria is poor; the positive predictive value is 50% and the negative predictive value is 90%.

Aminoglycoside renal toxicity occurs after 5 to 7 days of therapy and correlates with a cumulative dose received. Its effect on the tubules is reflected by the potassium and magnesium wasting in these patients. Despite having increased levels of creatinine, patients usually are nonoliguric. Aminoglycosides are freely filtered at the glomerulus and partially absorbed in the proximal tubule. The more amino groups on the aminoglycoside, the more toxic the agent (streptomycin is more toxic than gentamicin, which is more toxic than tobramycin). Once-daily dosing regimens have been shown to decrease the incidence of nephrotoxicity. Aminoglycoside levels should be monitored to decrease the risk of ototoxicity and nephrotoxicity.

- Aminoglycoside renal toxicity occurs after 5 to 7 days of therapy and correlates with a cumulative dose received.
- Aminoglycoside levels should be monitored to decrease the risk of ototoxicity and nephrotoxicity.

Amphotericin B is associated with distal tubule dysfunction. Findings include evidence of nephrogenic diabetes insipidus (nonoliguric) and type IV renal tubular acidosis. Toxicity occurs after a dose of 2 to 3 g. Amphotericin B in liposomes may decrease its toxicity.

- Amphotericin B is associated with distal tubule dysfunction.

Cisplatin is associated with ARF and tubular dysfunction (hypomagnesemia and hypokalemia), with a cumulative dose of 50 to 75 mg/m^2. Forced diuresis while ensuring adequate hydration can prevent renal toxicity.

- Cisplatin is associated with ARF and tubular dysfunction.

Contrast-induced ARF is due to the multiple nephrotoxic effects of the contrast dye. Renal vasoconstriction, tubular obstruction, and direct tubular toxicity all negatively affect the GFR. Patients with diabetes mellitus or severe renal dysfunction and those who receive a large dose of dye are at risk of pronounced dye toxicity. The patient's urine output decreases 24 to 48 hours after administration of the dye and increases to normal within 7 days. Clues to the diagnosis are a low fractional excretion of sodium and nephrotomograms revealing a renal outline enhanced by retained contrast dye. The following may be helpful in preventing toxicity in high-risk patients: using low ionic contrast agents with lower osmolality, limiting the dose of the agent, and spacing repeated dye loads to allow for renal recovery. The administration of drugs that either act as free radical scavengers, such as *N*-acetylcysteine, or prevent oxidant-mediated renal injury, such as sodium bicarbonate, have prevented contrast-induced injury and ARF. In recent studies, the incidence of contrast nephropathy decreased with the administration of a sodium bicarbonate solution (154 mEq/L bolus at 3 mL/kg per hour) 1 hour before administration of contrast dye, with subsequent infusion of 1 mL/kg per hour for 6 hours after the contrast dye was administered. The use of bicarbonate infusions resulted in better outcomes (less ARF) than the use of *N*-acetylcysteine or saline hydration alone.

In patients at high risk of contrast nephropathy, withholding the use of medications that alter renal blood flow or intrarenal hemodynamics may help decrease the severity of the ischemic injury potentially caused by radiocontrast dye. These medications include ARBs, ACEIs, and cyclosporine.

Cholesterol atheroembolic-induced renal failure is a cause of acute irreversible intrinsic renal failure. A history of atherosclerotic vascular disease, smoking, hyperlipidemia, hypertension, and diabetes increases the risk of ARF due to atheroemboli. It generally occurs in elderly patients, either spontaneously or after an invasive procedure. Atheroembolic disease and contrast nephropathy can occur in the same setting. Clinical findings may include livedo reticularis of the back, flank, abdomen, and extremities; emboli on funduscopic examination (Hollenhorst plaques); and evidence of microemboli of the digits and blue toe syndrome. Laboratory studies demonstrate an increased erythrocyte sedimentation rate, leukocytosis, eosinophiluria, peripheral eosinophilia, thrombocytopenia, and a low level of complement. Unlike in contrast nephropathy, recovery of renal function is rare, and if it does occur, it is gradual and incomplete. No treatment is known to reverse the microvascular occlusion and resulting inflammation. Patients often need support with renal replacement therapy.

- Cholesterol atheroembolic-induced renal failure is a cause of acute irreversible intrinsic renal failure.
- No treatment is known to reverse the microvascular occlusion and resulting inflammation.

Postrenal Failure

Urine flow can be obstructed anywhere along the urinary tract. The pathogenesis of obstructive uropathy involves early vasoconstriction, followed by vasodilatation. Crystals can cause obstruction of the collecting system, leading to ARF. In tumor lysis syndrome and other disease states in which the serum concentration of uric acid is excessive (>15-20 mg/dL), uric acid crystals can cause acute obstruction and uric acid nephropathy. Methotrexate, intravenous acyclovir, and indinavir can precipitate in the tubules and cause ARF. Prevention includes maintaining adequate hydration in the patients when these medications are administered.

- Obstruction to urine flow can occur anywhere along the urinary tract.

Ureteral obstruction can occur from stone material, necrosed papillae, blood clots, or tumor. External compression and ureteral obstruction can occur from retroperitoneal fibrosis (idiopathic or from methysergide) or genitourinary tumors. Surgical ligation, an infrequent cause of ARF, needs to be considered in patients who have had retroperitoneal or genitourinary operations. Bladder outlet obstruction due to prostatic hypertrophy or cancer is a common cause of postrenal ARF in men, and genitourinary cancers are a common cause in women. Patterns of urine flow and symptoms may help distinguish between partial and complete obstruction. Wide fluctuations in urine volume may represent partial obstruction, whereas oliguria or anuria can occur with complete obstruction. Pain is more frequent with complete obstruction because of distention of the renal capsule, collecting system, or bladder. The location of the pain is a clue to the site of obstruction. A normal anion gap (hyperchloremia) acidosis can be present in cases of urinary obstruction. The creatinine level is usually increased in bilateral or complete obstruction but can be normal or only slightly increased in partial or unilateral obstruction. Even though the creatinine level and urine output may be normal in partial obstruction, it is important to discover and correct the cause of the obstruction to avoid chronic tubular injury and irreversible renal injury.

- The pathogenesis of obstructive uropathy involves early vasoconstriction, followed by vasodilatation.
- A normal anion gap acidosis can be present in cases of urinary obstruction.

Diagnosis and Evaluation of Acute Renal Failure

Often, the differential diagnosis of the cause of ARF can be determined and narrowed considerably by obtaining a complete past medical history and a history of the present illness and by understanding the patient's risk factors for the different causes of ARF. Assessment of fluid balance is essential to distinguish between prerenal and intrinsic or postrenal causes. The presence of microinfarction and livedo reticularis suggests atheroemboli as the cause. A palpable bladder or flank tenderness is a clue that the cause is postrenal.

Laboratory studies are also critical for differentiating among causes of ARF. Findings on urinalysis can help to distinguish among prerenal, intrinsic renal, and postrenal causes. Urinary osmolality is increased early in the course of prerenal azotemia and the sediment is usually benign, with only hyaline and occasional granular casts. Acute tubular necrosis is characterized by urine that is isosmotic with the serum and urinary sediment that may contain tubular epithelial cells, granular cells, and amorphous material. Urinary eosinophils and leukocytes are seen with acute interstitial nephritis. Erythrocyte casts indicate a rapidly progressive or acute glomerulonephritis. A normal urinary sediment and a dipstick test that is positive for blood are characteristic of ARF induced by heme pigments. In postrenal failure, urinalysis findings are often unremarkable. Crystalluria may be present in patients with urolithiasis, and hematuria may be a clue to a genitourinary cancer or to an obstructing lesion or a stone.

- Laboratory studies are critical for distinguishing among the causes of ARF.
- Findings on urinalysis can help distinguish among prerenal, intrinsic renal, and postrenal causes.

Urinary chemistry tests or urinary indexes can also help distinguish among the three main categories of ARF (Table 17-8). During episodes of decreased renal blood flow (renal artery stenosis, decreased intravascular volume, congestive heart failure, or advanced cirrhosis), functional renal tubules reabsorb sodium, which helps to restore renal perfusion. Under these circumstances, urinary sodium excretion is low (<20 mEq/L) and the fractional excretion of sodium is less than 1%. Initially, in the continuum of prerenal failure, the fractional excretion of sodium is low, but as tubules are damaged by decreased oxygen delivery and acute tubular necrosis develops, the fractional excretion of sodium increases (>3%). Toxins (myoglobins, hemoglobin, and contrast media) and medications (ACEIs, ARBs, cyclosporine, and NSAIDs) that are vasoconstrictive, decreasing renal blood flow, are also associated with a low fractional excretion of sodium. Hepatorenal syndrome, early obstruction, cholesterol emboli, and acute glomerulonephritis are other causes of intrinsic renal failure that affect renal blood flow and are associated with a low fractional excretion of sodium.

It is well recognized that diuretic therapy induces natriuresis, thus causing a high fractional excretion of sodium, even in prerenal azotemia. The fractional excretion of urea is not altered by diuretics. Fractional excretion of urea that is less than 35% indicates a prerenal state.

Postrenal failure due to obstruction can be determined with ultrasonography. Of these studies, however, 2% have false-negative results because of acute obstruction or retroperitoneal fibrosis and 26% have false-positive results. A combination of ultrasonography and computed tomography without contrast medium is 100% diagnostic for obstruction and can be used to determine the cause of obstruction in 84% of cases. Ultrasonography is the test of choice to determine whether hydronephrosis is present.

- Urinary chemistry tests or urinary indexes can help distinguish among the three main categories of ARF.

Table 17-8 Comparison of Urinary Indexes in Prerenal Failure and Acute Tubular Necrosis

Urinary index	Prerenal failure	Acute tubular necrosis
Urine osmolality, mOsm/L	≥500	≤350
Ratio of urinary creatinine to plasma creatinine	≥40	≤20
Ratio of BUN to plasma creatinine	>20	<15
FeNa, %*	<1	>3

BUN, blood urea nitrogen; FeNa, fractional excretion of sodium.

*$\text{FeNa} = \dfrac{[\text{urinary Na}] \times [\text{plasma creatinine}]}{[\text{plasma Na}] \times [\text{urinary creatinine}]} \times 100.$

- Ultrasonography is the test of choice to determine whether hydronephrosis is present.
- Ultrasonography may not detect early obstruction.
- Fractional excretion of urea is reliable even in the setting of diuretic use.

Management of Acute Renal Failure

Prevention of ARF begins by determining and managing the risk factors. Avoiding intravascular volume depletion, maximizing cardiac function, and avoiding nephrotoxic medications and intravenous contrast media are all essential in preventing an acute decline in renal function. It is also important to understand which medications affect renal blood flow and possibly withholding the use of these medications or carefully monitoring for changes in renal function in acute renal injury. Medications include ACEIs, ARBs, cyclosporine, tacrolimus, Cox-2 inhibitors, and NSAIDs.

- Prevention of ARF begins by determining and managing the risk factors.

After ARF has occurred, the initial goal is to reverse any ongoing renal insults (restore intravascular volume, discontinue nephrotoxins, improve cardiac function, and relieve urinary obstruction) to prevent ongoing injury. After obstruction is relieved in patients with obstructive uropathy, polyuria occurs initially. Therapy is aimed at preventing a new prerenal component to the ARF and correcting electrolyte disturbances by replacing two-thirds of the postobstructive diuresis volume. Fluid replacement begins with 50% normal saline at 75 mL/h. Patients should be monitored for electrolyte disturbances and volume depletion. In patients with acute tubular necrosis or acute interstitial nephritis, diuretics have been used to maintain urine output and prevent hyperkalemia. It has not been proved that low-dose dopamine prevents ARF or restores renal function. If the patient becomes oliguric, despite improved hemodynamics or correction of the insult, renal replacement therapy should be considered.

- The initial goal is to reverse any ongoing renal insult.
- After the obstruction is relieved in patients with obstructive uropathy, replace two-thirds of the postobstructive diuresis volume to prevent adding a new prerenal component to the ARF.

Maintaining the nutritional requirements of patients with ARF is essential. Patients who are seriously ill are usually catabolic and require 35 to 45 kcal/kg daily and 1.5 g/kg of protein daily. Diets must be adjusted to limit potassium, sodium, magnesium, phosphorus, and fluid intake. If serum phosphorus levels increase despite dietary phosphorus restriction, phosphate binders should be added to the regimen.

- Maintaining the nutritional requirements of patients with ARF is essential.

As renal function changes, drug doses need to be adjusted and drug levels monitored. Be cautious prescribing medications that can accumulate and become toxic in patients with declining or low renal function (magnesium, aluminum-containing antacids, digoxin, renally cleared β-blockers, long-acting diltiazem preparations, and benzodiazepines). Administration of NSAIDs, Cox-2 inhibitors, contrast agents, and other agents known to be nephrotoxic should be avoided.

- As renal function changes, drug doses need to be adjusted and drug levels monitored.

Dialysis

The goals of renal replacement therapy in ARF are to maintain fluid, electrolyte, acid-base, and solute balance; to prevent further insult; to promote healing; and to permit other support measures to be used (intravenous medications and parenteral nutrition). The indications for beginning renal replacement therapy for acute conditions are similar to those for chronic conditions. An increase in BUN indicates the accumulation of uremic toxins. In acutely ill patients, a BUN concentration greater than 100 mg/dL is an indication to begin dialysis even if there are no other signs and symptoms of uremia. In patients who are not receiving adequate protein nutrition or who have little muscle mass, the absolute value of BUN can underestimate the degree of renal failure and toxin accumulation. When the estimated GFR is less than 20 mL/min and immediate renal recovery is not anticipated, dialysis should be initiated before BUN reaches 100 mg/dL. In acutely or critically ill patients, BUN greater than 60 mg/dL may be an indication to begin dialysis. Hyperkalemia, acidosis, fluid overload not responsive to diuretics, evidence of central nervous system toxicity, pericardial rub, and gastrointestinal tract bleeding believed to be due to uremia are all indications to begin dialysis immediately.

- The goals of renal replacement therapy in ARF are to maintain fluid, electrolyte, acid-base, and solute balance; to prevent further insult; to promote healing; and to permit other support measures to be used.
- Hyperkalemia, acidosis, fluid overload not responsive to diuretics, evidence of central nervous system toxicity, pericardial rub, and gastrointestinal tract bleeding believed to be due to uremia are all indications to begin dialysis immediately.

The choice of renal replacement must be customized to the needs of the patient. Severe metabolic abnormalities requiring rapid correction (hyperkalemia with electrocardiographic [ECG] changes and severe acidosis) should be treated immediately with short high-flux hemodialysis. Patients with a stable hemodynamic condition able to tolerate rapid fluid and electrolyte shifts can undergo conventional high-flux, intermittent, three-times-per-week dialysis. Severely ill catabolic patients requiring intravenous fluids for nutrition, continuous or frequent intravenous administration of medications, and intravenous fluid resuscitation are best dialyzed daily with intermittent dialysis or with continuous dialysis therapy to avoid large fluid gains and to maintain solute homeostasis. Patients with an unstable hemodynamic condition who require renal replacement therapy are best treated with a continuous dialysis modality (continuous

venovenous hemodialysis [CVVHD], continuous venovenous diafiltration [CVVDF], or continuous venovenous hemodiafiltration [CVVHDF]). These methods with continuous gentle fluid and solute removal improve hemodynamic stability by decreasing osmolar and solute concentration changes as well as limiting fluid shifts.

Management of Chronic Renal Failure and Chronic Kidney Disease

Chronic kidney disease (CKD), as defined by the National Kidney Foundation, has five stages, progressing from stage 1, when the GFR is normal or greater than 90 mL/min per 1.73 m^2, to stage 5, when the GFR is less than 15 mL/min per 1.73 m^2. As in ARF, the initial steps in evaluating any patient with an increased level of creatinine or BUN are to determine whether the value represents a true decrease in GFR, whether the damage is chronic or acute, what the cause is, and whether there is a reversible component. The reversible causes of renal insufficiency are listed in Table 17-9.

The diagnosis of CKD is established by identifying comorbid illnesses known to lead to progressive renal insufficiency and documenting evidence of progressive renal dysfunction (Table 17-10).

Patients with irreversible CKD with a GFR less than 33 mL/min per 1.73 m^2 usually have atrophic kidneys. Exceptions include patients with renal dysfunction due to amyloidosis, myeloma, diabetes mellitus, or polycystic kidney disease.

- Patients with CKD usually have small kidneys.

The goal of identifying and treating CKD is to prevent progression of the disease, to avoid the morbidity and mortality of end-stage renal disease (ESRD), and to adequately prepare patients for eventual renal replacement therapy. This requires early intervention and adequate follow-up. ESRD is defined as a GFR less than 15 mL/min per 1.73 m^2, but often patients require renal replacement therapy before the GFR is this low.

- The goal of identifying and treating CKD is to prevent progression of the disease, to avoid the morbidity and mortality of ESRD, and to adequately prepare patients for eventual renal replacement therapy.

Table 17-9 Reversible Causes of Renal Insufficiency

Obstruction

Hyperuricemia

Strict blood pressure control is essential to slow the progression of any renal disease. Blood pressure should be 130/80 mm Hg or less for those with CKD and 125/75 mm Hg or less if proteinuria is present. ACEIs and ARBs are the first-choice antihypertensive agents. They delay the progression of renal disease by lowering systemic blood pressure, by altering intrarenal hemodynamics, and by decreasing proteinuria. Diuretics are also useful in controlling blood pressure. Thiazide diuretics are useful until the GFR is less than 45 mL/min per 1.73 m^2. At that point, loop diuretics should be used. Fluid overload is often an important contributor to hypertension in persons with CKD. Electrolyte abnormalities (hyperkalemia with β-blockers, ACEIs, and ARBs) and conduction abnormalities (long-acting diltiazem and β-blockers that are renally excreted) need to be monitored.

- Strict blood pressure control is essential to slow the progression of any renal disease.
- ACEIs and ARBs are the first-choice antihypertensive agents.

Proteinuria is a marker of renal dysfunction and is also a risk factor for progression of CKD. ACEIs and ARBs are beneficial in delaying the progression of disease not only by controlling blood pressure but also by decreasing proteinuria. The goal is to decrease proteinuria by 35% to 40% and to tightly control blood pressure.

- Proteinuria is a risk factor for progression of CKD.

Dietary adjustments are important for patients with chronic renal failure (CRF). As the GFR decreases, the ability of the nephron to handle potassium and phosphorus decreases. Patients should be monitored for hyperkalemia and hyperphosphatemia. Dietary potassium and phosphorus intake should be restricted after the serum levels begin to increase. Hyperkalemia may occur with a GFR greater than 20 mL/min per 1.73 m^2 if distal tubular function is abnormal (type IV renal tubular acidosis). Hyperphosphatemia, despite patient compliance with a low-phosphorus diet, requires the addition of a phosphate binder. Restriction of dietary protein decreases uremic symptoms (decrease in acid, sodium, oxalate, and nitrogen loads and nitrogen waste products). The benefits of protein restriction must be balanced against the morbidity and mortality associated with protein malnutrition. If the patient's protein stores are normal, a protein-restricted diet is recommended. After the serum level of albumin decreases, the protein restriction should be liberalized to prevent protein malnutrition.

Table 17-10 Causes of Renal Disease

Cause	% of cases
Diabetes mellitus	42
Hypertension	26
Glomerulonephritis	11
Other/unknown	20

- Dietary adjustments are important for patients with CRF.

After the GFR decreases to less than 33 mL/min per 1.73 m^2, erythropoietin production by the renal parenchyma is not sufficient to prevent anemia. The anemia of CRF is a normochromic normocytic anemia. Treatment with erythropoietin given subcutaneously should be started for all patients who develop anemia. Also, iron should be given orally to patients without a contraindication for supplemental iron. The target hemoglobin level is 11 to 12 g/dL. All patients should have iron stores and ferritin levels monitored. Resistance to erythropoietin can be caused by iron deficiency, inflammation, malignancy, secondary hyperparathyroidism, hematologic disorders, and increasing uremia. Iron deficiency is defined as a ferritin level less than 100 ng/mL and total percent saturation of less than 20%. Anemia in patients with CKD contributes to the development of left ventricular hypertrophy and progression of underlying renal disease.

- Treatment with erythropoietin given subcutaneously should be started for all patients who develop anemia.

Patients with stage 1 or 2 CKD should be referred to a nephrologist when blood pressure targets, anemia targets, or a decrease in proteinuria cannot be achieved. All patients with CKD that is stage 3 or above should be referred to a nephrologist. In addition to helping to maximize interventions to prevent further decline in renal function and to manage and treat the complications of CKD, referral to a nephrologist allows early education concerning renal replacement therapy options. These include in-center and home hemodialysis, peritoneal dialysis, and renal transplantation.

End-Stage Renal Disease

The complications of progressive renal dysfunction and uremia involve all organ systems. Uremic symptoms and signs may occur at different levels of GFR depending on the patient's comorbid diseases and the management of the patient's condition preceding ESRD. Anemia of CRF is multifactorial; decreased erythropoietin production, hemolysis, and blood loss may all contribute to the low hemoglobin concentration. Anemia should be treated with erythropoietin and iron supplementation. Bleeding is common in CRF because of platelet dysfunction. Treatment with desmopressin is helpful in acutely reversing the bleeding tendency.

- Anemia of CRF is multifactorial.

The metabolic acidosis in early CRF is a non–anion gap acidosis due to decreased ammonium secretion. As renal dysfunction progresses and phosphates and sulfates accumulate, the acidosis becomes a high anion gap acidosis.

- The metabolic acidosis in early CRF is a non–anion gap acidosis.

Cardiovascular disease is a common cause of death in patients with ESRD and advanced renal insufficiency. In this population, hypertension is common and is associated with excess extracellular fluid volume and, in some cases, excess renin production. Hyperlipidemia and accelerated atherosclerosis contribute to the cardiovascular morbidity and mortality. As mentioned above, anemia can lead to left ventricular hypertrophy. Pericarditis may occur in two patterns. Pattern I is a hemorrhagic pericarditis that is treated with hemodialysis. Pattern II can occur in patients who are adequately dialyzed; it may be associated with hemorrhage and tamponade. A viral cause has been implicated, and corticosteroids often need to be given intrapericardially.

- Cardiovascular disease is a common cause of death of patients with ESRD.

Hyperkalemia can occur with a GFR less than 20 mL/min per 1.73 m^2 and oliguria, but distal tubular dysfunction (type 4 renal tubular acidosis or aldosterone deficiency) and medications (NSAIDs, ACEIs, ARBs, β-blockers, and potassium-sparing diuretics) that interfere with potassium handling can lead to hyperkalemia with a GFR greater than 20 mL/min per 1.73 m^2. Hyperkalemia associated with ECG changes should be treated emergently. Acute ECG changes due to hyperkalemia should be treated with an infusion of calcium to protect the myocardium, followed by an infusion of insulin to redistribute the potassium; however, with ECG changes and a low GFR, dialysis is indicated. Resins and dialysis are used to eliminate potassium. Chronic hyperkalemia can be treated with a scheduled dose of resins, a low-potassium diet, and the avoidance of medications that interfere with potassium handling.

- Hyperkalemia can occur with a GFR <20 mL/min per 1.73 m^2 and oliguria.

Through a complex feedback system, renal disease leads to phosphorus retention, hypocalcemia, acidosis, decreased 1,25-dihydroxyvitamin D production, and an increase in parathyroid hormone. Relatively early in advancing renal insufficiency (GFR, 30-40 mL/min per 1.73 m^2), the development of hyperphosphatemia and decreased levels of 1,25-dihydroxyvitamin D begin the cascade leading to secondary hyperparathyroidism and the development of osteitis fibrosa cystica. This is the classic form of bone disease in ESRD, with overactive osteoclastic and osteoblastic activity. Osteomalacia (low-turnover bone disease) due to 1,25-dihydroxyvitamin D deficiency is characterized by an increase in osteoid and diminished or absent osteoclastic and osteoblastic activity. Osteoporosis also occurs with ESRD and chronic renal insufficiency. Aluminum bone disease can occur in CRF and ESRD in patients who ingest aluminum. These patients have low levels of parathyroid hormone and 1,25-dihydroxyvitamin D. They present with a microcytic anemia and frequent bone fractures. Aluminum osteodystrophy is diagnosed with an iliac crest bone biopsy and treated with deferoxamine chelation.

- Through a complex feedback system, renal disease leads to phosphorus retention, hypocalcemia, acidosis, decreased 1,25-dihydroxyvitamin D production, and an increase in parathyroid hormone.

- Osteoporosis also occurs with ESRD and chronic renal insufficiency.
- The classic form of bone disease in ESRD is osteitis fibrosa cystica, a disease with high bone turnover and high levels of parathyroid hormone.

Treatment and prevention of renal osteodystrophy focus on the suppression of parathyroid hormone production by maintaining a normal calcium and phosphorus balance. Treatment begins with a low-phosphorus diet. If the serum level of phosphorus remains elevated, enteric phosphate binders are needed. If the serum level of calcium remains low or parathyroid hormone levels remain high (or both), 1,25-dihydroxyvitamin D supplementation is added.

- Treatment and prevention of renal osteodystrophy focus on the suppression of parathyroid hormone production by maintaining a normal calcium and phosphorus balance.

β_2-Microglobulin deposition that occurs in CRF and ESRD can lead to carpal tunnel syndrome and debilitating arthritis. Pseudogout and periarthritis due to the deposition of hydroxyapatite in joint spaces are other musculoskeletal complications of uremia. Gastrointestinal tract complications of uremia include gastritis, colitis, ileitis, peptic ulcer disease, and constipation. Anorexia is a complication that is multifactorial but leads to protein and caloric malnutrition.

- Gastrointestinal tract complications of uremia include gastritis, colitis, ileitis, peptic ulcer disease, and constipation.

The neurologic complications of uremia range from peripheral neuropathy (sensory fibers affected more than motor fibers) to cognitive impairment and eventual central nervous system irritability associated with asterixis and seizures. Without treatment (dialysis or reversal of the renal failure), eventual coma and death occur.

- Neurologic complications of uremia range from peripheral neuropathy to cognitive impairment and eventual central nervous system irritability associated with asterixis and seizures.

Dialysis

Indications for dialysis include fluid overload, acidosis, hyperkalemia, hypernatremia, and uremic signs and symptoms. The choice of dialysis (hemodialysis or peritoneal dialysis) in chronic nonemergent renal failure depends on many clinical and mechanical factors as well as on patient choice. Both types of dialysis can be done in the home. Peritoneal dialysis offers a continuous ultrafiltration and solute clearance, avoiding rapid shifts and hemodynamic instability. Hemodialysis offers more efficient clearance of solutes. Selected patients who have poor hemodialysis access, cardiomyopathy, or a scheduled transplantation may be candidates for peritoneal dialysis. The efficiency of peritoneal dialysis is low or inadequate in patients with a history of recurrent abdominal operations or diseases that lead to fibrosis of the peritoneal lining.

- Indications for dialysis include fluid overload, acidosis, hyperkalemia, hypernatremia, and uremic signs and symptoms.

Complications of Dialysis

All patients with ESRD who undergo hemodialysis in a center are at increased risk of hepatitis B and C. All of them should receive the vaccine and hepatitis B immunoglobulin.

Complications of hemodialysis include hemodialysis dysequilibrium due to brain edema and osmolar shifts with rapid dialysis and hemodynamic instability due to rapid fluctuations in potassium, calcium, and body osmoles and rapid fluid removal. These fluctuations are lessened as dialysis sessions are increased from 3 per week to 6 per week.

Infections involving central venous catheters or arteriovenous grafts can occur. Early detection and treatment with antibiotics are essential. If the catheter or graft remains contaminated, removal is required.

Complications of peritoneal dialysis include infections (peritonitis, exit site infections, and catheter tunnel infection), catheter leak, obesity, protein malnutrition, hyperlipidemia, and hyperglycemia. This form of dialysis is less efficient than high-flux hemodialysis.

Drugs removed or not removed with dialysis and drugs to be avoided if the patient receives dialysis are listed in Table 17-11.

Table 17-11 Dialysis and Overdoses

Drugs removed with dialysis
Methanol
Aspirin
Ethylene glycol
Lithium
Sodium
Mannitol
Theophylline
Drugs not removed with dialysis
Tetracycline
Benzodiazepines
Digoxin
Phenytoin (Dilantin)
Phenothiazines
Medications to avoid using in patients receiving dialysis
Tetracycline
Nitrofurantoin
Probenecid
Neomycin
Bacitracin
Methenamine
Nalidixic acid
Clofibrate
Lovastatin
Magnesium
Oral hypoglycemic agents
Antiplatelet drugs
Renally excreted β-blockers

Part III

Robert C. Albright, Jr., DO

Disorders of Water Balance

The most important principle in understanding disorders of water balance is that the serum level of sodium is the clinical index of total body water. However, it is not an index of extracellular volume or total body sodium. Total body sodium can be estimated by physical examination. The serum level of sodium is a useful clinical index for evaluating water balance, not sodium balance. Water balance is regulated by thirst, antidiuretic hormone, and the ability of the renal medulla to concentrate urine.

- The serum level of sodium is not an index of extracellular volume or total body sodium.
- Water balance is regulated by thirst, antidiuretic hormone, and the ability of the renal medulla to concentrate urine.

Hyponatremia

Hyponatremia (plasma sodium <136 mEq/L) is the most common electrolyte abnormality in hospitalized patients. Its symptoms are protean and include lethargy, cramps, decreased deep tendon reflexes, and seizures. The diagnosis and management of hyponatremia are shown in Figure 17-2.

Diagnosis

The first step in evaluating patients with hyponatremia is to measure serum osmolality. Isosmotic hyponatremia may be caused by severe hypertriglyceridemia (>1,500 mg/dL; lipemia retinalis is always present), severe hyperproteinemia (>8.0 g/dL; Waldenström macroglobulinemia or myeloma), or isotonic infusions of glucose, mannitol, or glycine. Hyperosmotic hyponatremia may be due to severe hyperglycemia (sodium decreases 1.6 mEq/L for each 100 mg/dL increase in glucose) and to hypertonic infusions of glucose, mannitol, or glycine. The use of ion-selective sodium probes in many clinical chemistry laboratories has markedly decreased the incidence of "pseudohyponatremia."

The second step is to assess the extracellular fluid volume of the hyposmotic hyponatremic patient and to determine whether that patient is hypovolemic, euvolemic, or hypervolemic.

1. Hyposmotic *hypovolemic* hyponatremia—measure urine osmolality and sodium concentration (urinary spot sodium is often <20 mEq/L; fractional excretion of sodium <1%; urine osmolality ≥600 mOsm/kg); common causes are severe volume depletion, thiazide diuretics, and adrenal insufficiency.
2. Hyposmotic *hypervolemic* hyponatremia—measure urine osmolality and sodium concentration; edematous states and renal failure are common.
3. Hyposmotic *euvolemic* hyponatremia—measure cortisol and thyroid-stimulating hormone levels, urinary sodium level, and urine osmolality. Possible diagnoses include hypothyroidism, Addison disease, reset osmostat, psychogenic polydipsia, and the syndrome of inappropriate antidiuresis (SIAD).

The term *syndrome of inappropriate antidiuresis* has recently replaced the term *syndrome of inappropriate antidiuretic hormone* because up to 20% of patients who fulfill the criteria for SIAD do not have detectable circulating levels of antidiuretic hormone. SIAD is a diagnosis of exclusion. Patients must meet the following criteria: clinical euvolemia, hypotonic plasma, urine less than maximally dilute (urine osmolality in SIAD is greater than serum osmolality or >100-150 mOsm/kg), urinary sodium matches intake, absence of hypoadrenalism and hypothyroidism, and improvement with water restriction. Important clinical clues are low serum levels of uric acid, creatinine, and blood urea nitrogen (BUN). Some of the causes of SIAD include small cell carcinoma of the lung, central nervous system disorders, and drugs such as haloperidol, fluoxetine, and chlorpropamide.

Acute hyponatremia (<48 hours) has been described in several special clinical settings. Hyponatremia may occur in up to 5% of patients after surgery and anesthesia. Plasma vasopressin concentrations are increased because of nonosmolar stimuli such as pain, nausea, and the use of narcotics. Rarely, profound hyponatremia may occur. During transurethral prostatic resection, isotonic or hypotonic fluids containing glycine can be absorbed and depress the serum level of sodium. Schizophrenic patients with severe compulsive water drinking (>14 L daily) occasionally have acute hyponatremia. Also, infusions of oxytocin and cyclophosphamide may induce acute hyponatremia.

Chronic hyponatremia may be induced by the use of thiazides, chlorpropamide, carbamazepine, and nonsteroidal anti-inflammatory drugs (NSAIDs).

- The physical examination, osmolality of plasma and urine, and urinary sodium concentration provide important information for diagnosis.
- SIAD: serum levels of uric acid, creatinine, and BUN are low.

Therapy for Hyponatremia

A general tenet of therapy for hyponatremia is that the correction should occur at the rate at which it developed.

Hypovolemic Hyponatremia

Hypovolemic hyponatremia most often reflects volume depletion. The total sodium deficit can be calculated as follows:

Sodium deficit = total body water (lean body weight in kg × 0.5) × desired serum sodium (mEq/L) – current serum sodium (mEq/L)

Euvolemic Hyponatremia

As pointed out above, hyponatremia should be reversed cautiously, at a rate similar to that at which it developed, to avoid central pontine myelinolysis. However, the rate of onset often is unknown. Therefore,

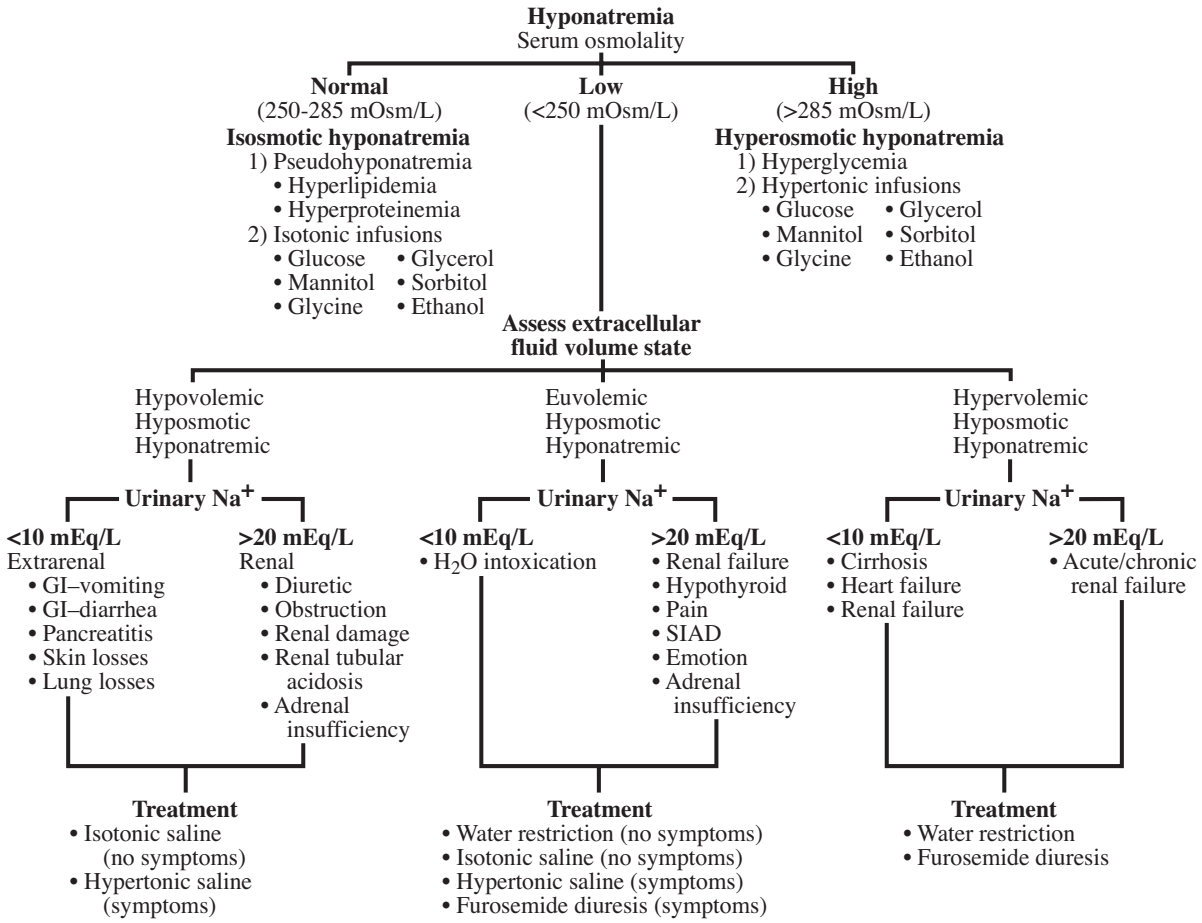

Fig. 17-2. Diagnosis and management of hyponatremia. GI, gastrointestinal; SIAD, syndrome of inappropriate antidiuresis.

therapy is directed primarily by signs and symptoms. For patients with euvolemic hyponatremia who are asymptomatic, the treatment should be water restriction only. Patients with acute euvolemic hyponatremia who have neurologic symptoms require prompt therapy designed to facilitate the excretion of free water. Options include the infusion of hypertonic saline or the simultaneous infusion of isotonic saline and a loop diuretic. The amount of hypertonic saline required to increase the serum concentration of sodium to appropriate levels can be estimated roughly by calculating free water excess. However, these calculations assume steady-state urinary concentration, which may not occur as therapy is administered. Therefore, intense monitoring is needed, including hourly measurements of serum sodium, urinary sodium, and urine osmolality. In acute hyponatremia, the rate of correction should not exceed 8 to 12 mEq/L in the first 24 hours. In chronic hyponatremia, the rate of correction can be slow—fluid restriction is least harmful. Patients with chronic SIAD may benefit from treatment with demeclocycline.

Hypervolemic Hyponatremia

Therapy for hypervolemic hyponatremia involves diuretics and correction or treatment of the underlying pathophysiologic state, which often involves liver, heart, or kidney disorders. Aquaretics, vasopressin V2-receptor antagonists that are being used in clinical trials, may eventually be used in these settings.

Hypernatremia

As in hyponatremia, the symptoms of hypernatremia (plasma sodium >145 mEq/L) are often protean, with irritability, hyperreflexia, ataxia, and seizures. Because all forms of hypernatremia are associated with hypertonicity, there is no pseudohypernatremia. Hypernatremia is categorized as *hypovolemic*, *hypervolemic*, and *euvolemic*. The diagnosis and management of hypernatremia are outlined in Figure 17-3.

Hypovolemic hypernatremia often responds to saline, followed by a hypotonic solution. Hypervolemic hypernatremia responds to diuretics; rarely, dialysis may be needed. Euvolemic patients should receive free water, either orally or intravenously, to correct the serum level of sodium, generally no faster than 0.5 mEq/h. A water deprivation test may be useful diagnostically.

The total free water deficit may be calculated as follows:

Total free water deficit = total body water (0.5 × lean body weight in kg) × [(current serum sodium in mEq/L ÷ desired serum sodium in mEq/L) − 1]

Additionally, obligate losses of free water (estimated to be 13 mL/kg daily) need to be considered in these calculations.

- Hypovolemic hypernatremia: check urinary sodium; the cause may be osmotic diuresis, excessive sweating, or diarrhea.
- Hypervolemic hypernatremia: may be caused by sodium poisoning.
- Euvolemic hypernatremia: loss of water, extrarenal (skin or lungs) or renal, diabetes insipidus (central or nephrogenic; water deprivation test).

Diabetes Insipidus

Polyuria

Polyuria is defined as urinary output of more than 3 L per day. This may represent a solute or water diuresis. The normal daily required osmolar secretion is approximately 10 mOsm/kg. Therefore, water or solute diuresis may be distinguished by measuring urine osmolality and determining the total daily solute excretion. If osmotic diuresis is excluded, polyuria is often due to primary polydipsia or diabetes insipidus.

Central Diabetes Insipidus

An absence of circulating vasopressin (partial or complete) is due to destruction of the pituitary or it is congenital (familial autosomal dominant central diabetes insipidus). This is a result of mutations in the prearginine-proarginine-vasopressin-neurophysin II gene.

Nephrogenic Diabetes Insipidus

A complete or partial resistance of the renal collecting duct cell to the actions of vasopressin may be the result of a familial X-linked disorder or, more commonly, an acquired lesion. Nephrogenic diabetes insipidus may be induced by lithium, demeclocycline, or amphotericin B (drug-induced nephrogenic diabetes insipidus). Occasionally, the concentrating defect involving lithium is not reversible. Renal diseases such as amyloidosis, sickle cell disease, light chain nephropathy, Sjögren syndrome, obstructive uropathy, and renal failure are common causes of nephrogenic diabetes insipidus.

Because of high levels of placenta-derived vasopressinase, a water diuresis may occur in pregnancy. Technically, this is not nephrogenic diabetes insipidus, though, because the women have a normal response to supplemental desmopressin, which is resistant to vasopressinase.

Hypercalcemia and hypokalemia also induce nephrogenic diabetes insipidus through multiple impaired intracellular pathways.

Patients with diabetes insipidus are symptomatic only if access to free water is restricted. This occurs primarily in very elderly, very young, or hospitalized patients or in institutional situations. Differentiating these polyuric states may be challenging. A detailed history of familial issues and use of medications is extremely important. Abrupt onset of polyuria is characteristic of acquired diabetes insipidus.

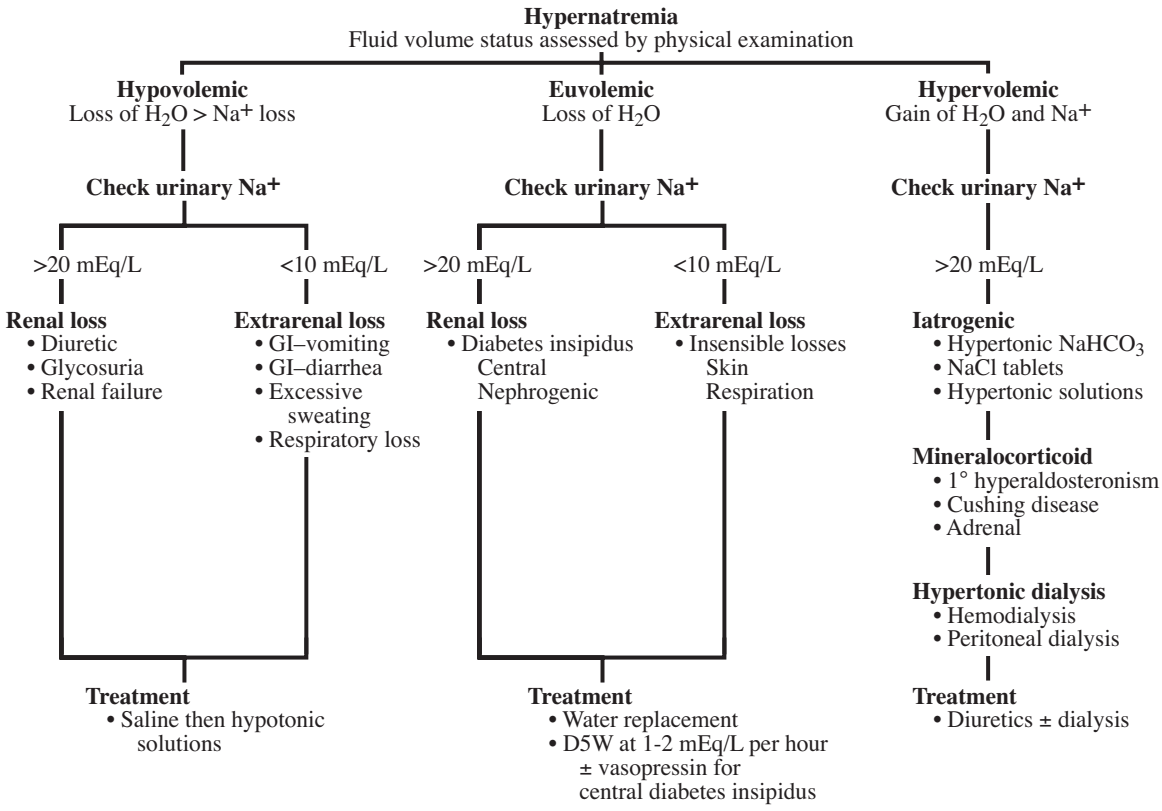

Fig. 17-3. Diagnosis and management of hypernatremia. D5W, 5% dextrose in water; GI, gastrointestinal.

A water deprivation test (or infusion of 5% saline) under closely supervised conditions often allows various polyuric states to be distinguished. The differentiation of diabetes insipidus from primary polydipsia with available laboratory tests is outlined in Table 17-12.

The serum concentration of sodium is often high-normal or increased in diabetes insipidus, whereas it is usually low-normal or low in primary polydipsia.

- Polyuria: urine output >3 L/d.
- Polyuric states are due to either water or solute diuresis.
- A closely supervised water deprivation test will differentiate most polyuric states.

Disorders of Sodium Balance

Disorders of sodium balance can be determined only by clinical examination. *Orthostatic hypotension* implies volume depletion and sodium deficiency. *Edema* implies volume excess and sodium excess.

Cerebral salt wasting has rarely been documented in situations of severe central nervous system injury. Differentiating this from SIAD may be difficult. A negative sodium balance that causes contraction of the extracellular fluid volume must be documented for cerebral salt wasting to be diagnosed. Often, the "sodium wasting" is physiologic in situations of severe central nervous system injury (such as subarachnoid hemorrhage), because high-volume therapy in the form of albumin and saline is often administered to prevent cerebral vasospasm. Hence, the apparently excessive urinary sodium levels are physiologic.

Disorders of Potassium Balance

Potassium is predominantly an intracellular cation. Total body potassium is approximately equal to 4,200 mEq, with only 60 mEq in the total volume of extracellular fluid. Gastric fluid contains 5 to 10 mEq of potassium/L and diarrheal fluid, 10 to 100 mEq/L. The intracellular balance of potassium is regulated by endogenous factors such as acidemia, sodium, adenosine triphosphatase, insulin, catecholamines, and aldosterone. The extracellular balance is regulated primarily by potassium excretion, which is regulated by urinary flow rate, aldosterone, antidiuretic hormone, and sodium delivery to the distal tubule.

Hypokalemia

Symptoms of hypokalemia include weakness, ileus, polyuria, and, sometimes, rhabdomyolysis. Hypokalemia also aggravates digoxin toxicity. A stepwise approach to the diagnosis of hypokalemia is given in Table 17-13 and outlined in Figure 17-4.

- Hypokalemia symptoms: weakness, ileus, and polyuria.

Therapy for hypokalemia involves administration of potassium chloride. If the serum level of potassium is less than 2 mEq/L, the total potassium deficit is equal to 1,000 mEq; if the serum level of potassium is between 2 and 4 mEq/L, a decrease of 0.3 mEq/L is equivalent to a 100- to 500-mEq deficit (usually treat with potassium chloride except in diabetic ketoacidosis, which is treated with potassium phosphate, and potassium citrate in severe acidosis). Do not give more than 10 mEq of potassium chloride per hour intravenously without the use of a central catheter and electrocardiographic monitoring. Dietary sodium restriction decreases the potassium-losing effects of diuretics. In patients with hypokalemia and hypomagnesemia, the magnesium levels need to be corrected.

Hyperkalemia

A stepwise approach to the diagnosis of hyperkalemia is given in Table 17-14 and outlined in Figure 17-5.

The goal of therapy for hyperkalemia is to antagonize the membrane effects and redistribute potassium. Treat, in the following order, with calcium, sodium bicarbonate, insulin, resins, and, finally, dialysis.

Table 17-12 Comparison of Diabetes Insipidus With Primary Polydipsia

Test	Normal	Complete CDI	Partial CDI	Nephrogenic DI	Primary polydipsia
Urine osmolality with H_2O deprivation,* mOsm/kg H_2O	>800	<300	300-800	<300-500	>500
Increase urine osmolality with exogenous AVP,† mOsm/kg H_2O	300	Dramatic	10% increase	0	0
Plasma AVP levels after dehydration, pg/mL	>2	Undetectable	<1.5	>5	<5

AVP, arginine vasopressin; CDI, central diabetes insipidus; DI, diabetes insipidus.
*Water restricted until patient loses 3.5% of body weight or urine osmolality does not change >10% over 2 hours.
†Aqueous AVP (5 U subcutaneously) is given, and urine osmolality is reversed in 60 minutes.

Table 17-13 Stepwise Approach to the Diagnosis of Hypokalemia

1. Exclude redistribution—β-agonists (albuterol and terbutaline for asthma and ritodrine for labor), acute alkalosis, vitamin B_{12} therapy for pernicious anemia (especially if thrombocytopenic), and barium carbonate
2. Determine whether potassium losses are renal or extrarenal—check urinary potassium level on high-sodium diet (Is potassium >20 mEq/d or <20 mEq/d?)
3. If loss is extrarenal, determine cause (laxative screen)—usually diarrhea, enemas, laxative abuse, villous adenomas, or ureterocolostomy
4. If loss is renal, determine whether hypertensive or normotensive (diuretic screen)
5. If hypertensive, check plasma renin and aldosterone levels, and check for primary aldosteronism or adrenal hyperplasia, exposure to glycyrrhizic acid in licorice or chewing tobacco, and adrenal abnormalities
6. If normotensive, check plasma HCO_3 levels and urinary chloride; the differential diagnosis includes renal tubular acidosis, vomiting, diuretic abuse, Bartter syndrome, and magnesium deficiency

For chronic therapy, use loop diuretics, sodium bicarbonate, resins, fludrocortisone, or dialysis.

Acid-Base Disorders

Clinically, it is absolutely critical that a stepwise approach to acid-base disorders be followed. The six steps listed in Table 17-15 should always be followed while interpreting an acid-base disorder.

Metabolic Acidosis

Metabolic acidosis is defined as a primary disturbance in which the retention of acid consumes endogenous alkali stores. This is reflected by a decrease in bicarbonate. The secondary response is increased ventilation, with a decrease in the partial pressure of carbon dioxide ($PaCO_2$). Metabolic acidosis can be caused by the overproduction of endogenous acid (diabetic ketoacidosis), loss of alkali stores (diarrhea or renal tubular acidosis), or failure of renal acid secretion or base resynthesis (renal failure).

- Metabolic acidosis: the primary disturbance is retention of acid or loss of bicarbonate.
- Secondary response: increased ventilation with decreased $PaCO_2$.

Some of the signs and symptoms of metabolic acidosis include fatigue, dyspnea, abdominal pain, vomiting, Kussmaul respiration, myocardial depression, hyperkalemia, leukemoid reaction, insulin resistance, and, when the pH is less than 7.1, arteriolar dilatation and hypotension.

Formulas for the predicted compensation of pure metabolic acidosis (which may take up to 24 hours) are listed in Table 17-16.

Table 17-14 Stepwise Approach to the Diagnosis of Hyperkalemia

1. Exclude pseudohyperkalemia—electrocardiogram is normal and heparinized plasma potassium is normal
   Hemolysis of clotted blood (0.3-mEq/L increase), tourniquet ischemia, or severe leukocytosis or thrombocytosis
2. Determine cause based on redistribution or excess total body potassium (see Fig. 17-5)

Metabolic acidoses are classified as either "normal anion gap" or "high anion gap." Normal anion gap acidosis (hyperchloremic metabolic acidosis) may be the result of excessive bicarbonate losses from either gastrointestinal or renal sources. These may be discriminated by calculating a urinary net charge (or urinary anion gap). The appropriate titration of acidity involves the excretion of excess hydrogen ions as ammonium ions. Electroneutrality is preserved by coupling ammonium ion to chloride, forming ammonium chloride. Hence, appropriate titration of renal acidity should result in high levels of urinary chloride. The urinary net charge (urinary anion gap) is calculated as follows:

$$\text{Urinary net charge} = [Na^+ \text{ (mEq/L)} + K^+ \text{ (mEq/L)}] - Cl^- \text{ (mEq/L)}$$

(performed on random spot sample)

Urinary net charge (urinary anion gap) should result in values that are −8 or more negative in situations of hyperchloremic metabolic acidosis with appropriate renal titration. A positive value or a value less negative than −8 suggests renal tubular disorders (renal tubular acidosis).

Also, normal anion gap metabolic acidosis may be defined in terms of the serum concentration of potassium.

Hypokalemic normal anion gap metabolic acidosis can be associated with diarrhea, ureteral diversion, or the use of carbonic anhydrase inhibitors such as acetazolamide. Type 1 renal tubular acidosis, or classic renal tubular acidosis, is also a cause. This is associated with nephrocalcinosis and osteomalacia. The causes of type 1 renal tubular acidosis include glue sniffing (toluene effect), amphotericin B, lithium, Sjögren syndrome, hypergammaglobulinemia, and sickle cell disease. Type 2 renal tubular acidosis is also a hypokalemic normal anion gap metabolic acidosis. In adults, it is often associated with other proximal tubule defects, including glycosuria, uricosuria, phosphaturia, and aminoaciduria (Fanconi syndrome). Causes of type 2 renal tubular acidosis include myeloma, cystinosis (not cystinuria), lead, tetracycline, and acetazolamide.

The causes of hyperkalemic normal anion gap metabolic acidosis include acid loads such as ammonium chloride, arginine chloride, lysine chloride, cholestyramine, total parenteral nutrition, hydrogen chloride, oral calcium chloride, obstructive uropathy, hypoaldosteronism (Addison disease), 21-hydroxylase deficiency, sulfur toxicity, and type 4 renal tubular acidosis. Type 4 renal tubular acidosis

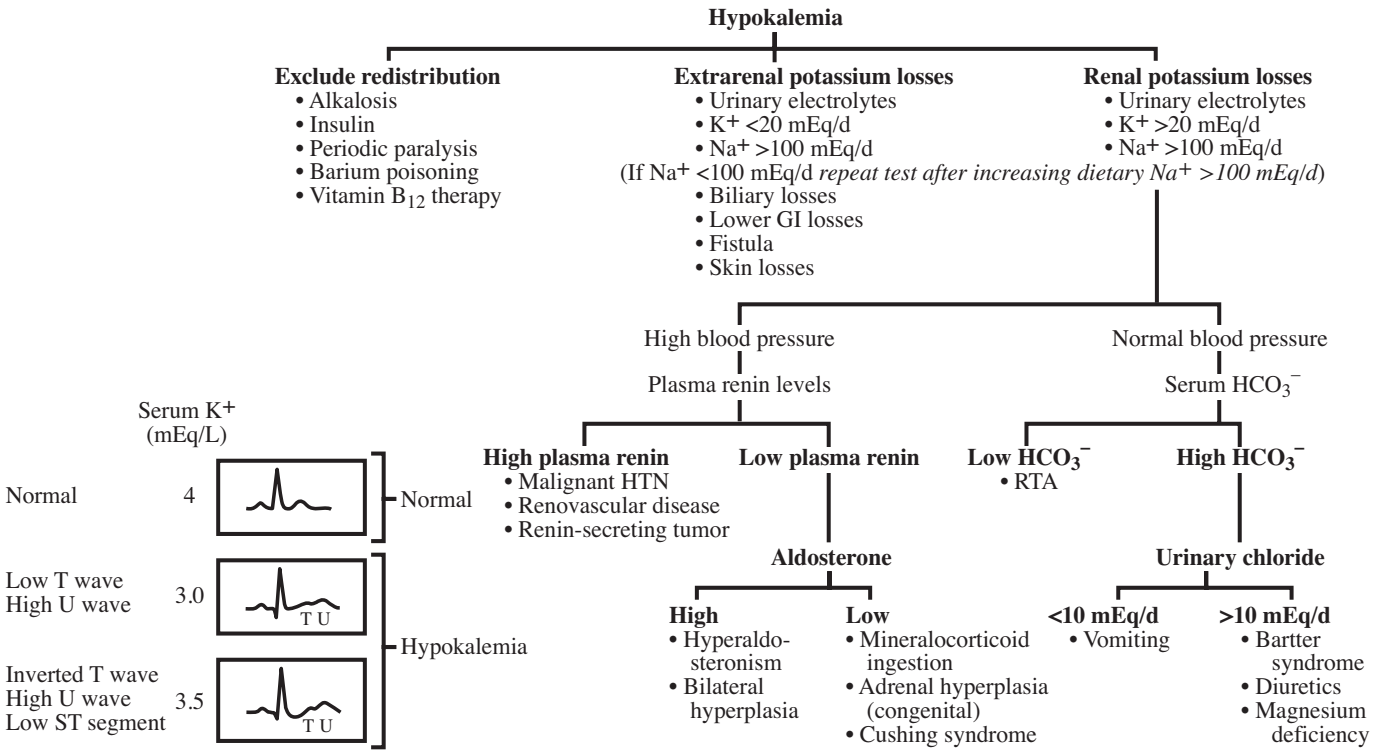

Fig. 17-4. Diagnosis of hypokalemia. GI, gastrointestinal; HTN, hypertension; RTA, renal tubular acidosis.

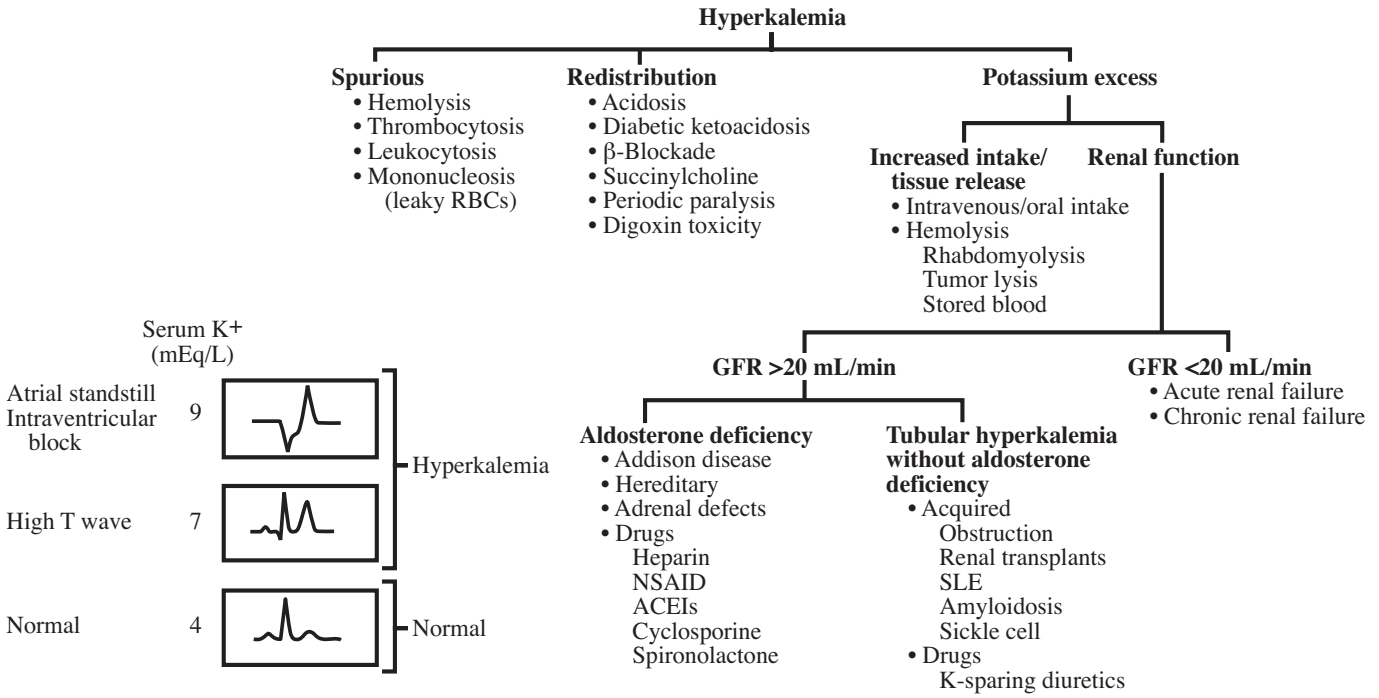

Fig. 17-5. Diagnosis of hyperkalemia. ACEI, angiotensin-converting enzyme inhibitor; GFR, glomerular filtration rate; NSAID, nonsteroidal anti-inflammatory drug; RBC, red blood cell; SLE, systemic lupus erythematosus.

Table 17-15 Six Steps for Interpreting Acid-Base Disorders

1. Note the clinical presentation
2. Always check the anion gap (hidden acidosis) and osmolar gap if possible
   - Normal anion gap Na − (HCO_3 + Cl) = 8 to 12
     - Cations = Na, gammaglobulins, Ca, Mg, K
     - Anions = Cl, HCO_3, albumin, PO_4, SO_4, organic compounds
   - High anion gap >12—MUDPILES (see text)
   - Low anion gap <8—bromism, paraproteinemia, hypercalcemia/magnesemia, lithium toxicity, severe hypernatremia, severe hypoalbuminemia
   - Osmolar gap >10 "-ols"—methan**ol**, ethan**ol**, ethylene glyc**ol**, isopropyl alcoh**ol**, mannit**ol**
3. Use the Henderson equation to check the validity of the arterial blood gas values:

$$H^+ \text{ (nEq/L)} = \frac{24 \times \text{lungs } (P_{CO_2})}{\text{kidneys } (HCO_3)}$$

pH	7.00	7.10	7.20	7.30	7.40	7.50	7.60	7.70
H^+	100	79	63	50	40	32	25	20

4. Is the pH high or low?
5. Is the primary disturbance metabolic (HCO_3) or respiratory (P_{CO_2})?
6. Is it simple or mixed?

Table 17-16 Formulas for the Predicted Compensation of Metabolic Acidosis and Alkalosis and Respiratory Acidosis and Alkalosis

Metabolic acidosis compensation
- Pa_{CO_2} = last digits of pH
- Pa_{CO_2} decreases by 1.0-1.3 mm Hg for each mEq decrease in bicarbonate
- Winter formula (favored formula):
  - $Pa_{CO_2} = (1.5 \times HCO_3^-) + 8 \pm 2$

Metabolic alkalosis compensation
- $Pa_{CO_2} = 0.9\ (HCO_3^-) + 15 \pm 5$
- $Pac_{CO_2} = (HCO_3^-) + 15$
- Pa_{CO_2} increases 6 mm Hg for each 10-mEq/L increase in HCO_3^-

Respiratory acidosis compensation
- HCO_3^- increases by 1 mEq/L for each 10–mm Hg increase in Pa_{CO_2} (acute)
- HCO_3^- increases by 3 mEq/L for each 10–mm Hg increase in Pa_{CO_2} (chronic)
- Increase* in $[H^+]$= 0.75 × increase in Pa_{CO_2} (mm Hg) from normal (acute)
- Increase* in $[H^+]$ = 0.3 × increase in Pa_{CO_2} (mm Hg) from normal (chronic)

Respiratory alkalosis compensation
- HCO_3^- decreases by 2 mEq/L for each 10–mm Hg decrease in Pa_{CO_2} (acute)
- HCO_3^- decreases by 4 mEq/L for each 10–mm Hg decrease in Pa_{CO_2} (chronic)
- Decrease† in $[H^+]$ = 0.75 × decrease in Pa_{CO_2} (mm Hg) from normal (acute)
- Decrease† in $[H^+]$ = 0.2 × decrease in Pa_{CO_2} (mm Hg) from normal (chronic)

*Delta 0.01 pH = delta 1 nEq $[H^+]$.
†pH 7.40 = 40 nEq $[H^+]$.

is associated with hyporeninemia and hypoaldosteronism, and it may be caused by diabetes mellitus, interstitial nephritis, spironolactone, amiloride, triamterene, or cyclosporine.

Patients in an intensive care unit often have normal anion gap acidosis because of "dilutional acidosis," which is due to large-volume saline resuscitation. The correction for hypoalbuminemia is necessary if the serum level of albumin is decreased. In this case, a correction factor of roughly 1.3 per gram of albumin below normal needs to be added to the anion gap calculation. Hence, in the intensive care unit or in cases of severe hypoalbuminemia, patients in whom hyperchloremic metabolic acidosis is suspected have high anion gap acidosis.

High anion gap metabolic acidosis has several causes. A common mnemonic is *MUDPILES* (**m**ethanol, **u**remia, **d**iabetic ketoacidosis, **p**araldehyde, **i**soniazid, **i**ron, **l**actic acidosis, **e**thanol, **e**thylene glycol, **s**alicylates). An anion gap should prompt calculation of an osmolar gap: measured osmolar gap – calculated osmolar gap (normally, the result is <10).

Calculated osmolar gap = [Na^+ (mEq/L) × 2] + (glucose/18 + BUN/2.8)

In chronic renal failure, the anion gap is usually less than 25. If the anion gap is greater than 25, one should think immediately of ingestion of a poison (generally a toxic alcohol: methanol, ethanol, ethylene glycol, and acetone). Isopropyl alcohol increases the osmolar gap but not the anion gap (acetone is not an anion).

- Dilutional acidosis often occurs in the intensive care unit.
- The anion gap needs to be corrected for hypoalbuminemia.
- In chronic renal failure, the anion gap usually is <25.
- An anion gap >25 suggests ingestion of a poison.

Metabolic acidosis is generally corrected by treating the underlying disorder, but the bicarbonate deficit can be determined by the following formula:

Bicarbonate deficit = 0.2 × body weight (kg) × [normal HCO_3 (i.e., 24) – measured HCO_3]

Therapy for ingestion of toxic alcohol (methanol or ethylene glycol) involves inhibiting the metabolism of the relatively nontoxic parent compound to its toxic metabolite. Alcohol dehydrogenase has a much higher affinity for ethanol than for ethylene glycol or methanol. Therefore, if ethanol or another steric inhibitor (4-methylpyrazole) is available for alcohol dehydrogenase, the ingested substance can be excreted or cleared in its native form, thereby preventing toxicity. This is the rationale for administering either ethanol or 4-methylpyrazole after the ingestion of ethylene glycol or methanol. Clinically, patients who have ingested these compounds often present with very high anion gaps with osmolar gaps (a sign that inhibition of alcohol dehydrogenase is still worthwhile) and complex acid-base disorders. After the metabolism has been blocked, it is necessary to facilitate the removal of these compounds. Although hemodialysis efficiently removes them, supplemental ethanol is required during dialysis because this will be cleared also.

Aggressive supplementation of bicarbonate is rarely warranted except for cases of severe hemodynamic instability or pH levels less than 7.10. Treatment with bicarbonate may induce hypervolemia by the obligate infusion of sodium along with the bicarbonate (1 ampule of sodium bicarbonate = 50 mEq sodium and 50 mEq bicarbonate) and ultimately requires increased minute ventilation for appropriate buffering.

Metabolic Alkalosis

Metabolic alkalosis is defined as a primary disturbance in which plasma bicarbonate is increased. This can be caused by exogenous alkali, acid loss through the gastrointestinal tract or kidney, or loss of nonbicarbonate fluid causing contraction of remaining fluid around unchanged total body bicarbonate. The kidney must also be stimulated to sustain the high level of plasma bicarbonate. This can occur by contraction of extracellular fluid volume, hypercapnia, potassium depletion, steroid excess, hypercalcemia, or hypoparathyroidism. The secondary response is decreased ventilation with an increase in $PaCO_2$. The signs and symptoms of metabolic alkalosis include weakness, muscle cramps, hyperreflexia, alveolar hypoventilation, and arrhythmias.

- Metabolic alkalosis: the primary disturbance is increased plasma bicarbonate.
- The kidney must be stimulated to sustain the high level of plasma bicarbonate.
- Secondary response: decreased ventilation with increased $PaCO_2$.

The predicted compensation for pure renal metabolic alkalosis (which will take up to 24 hours) is presented in Table 17-16. Metabolic alkalosis can then be classified in terms of the spot urinary chloride and spot urinary potassium (Fig. 17-6).

Respiratory Acidosis

The ventilatory system is responsible for maintaining $PaCO_2$ within normal levels by adjustment of minute ventilation. Minute ventilation is controlled by tidal volume and respiratory rate. Normally, minute ventilation matches the production of carbon dioxide. When

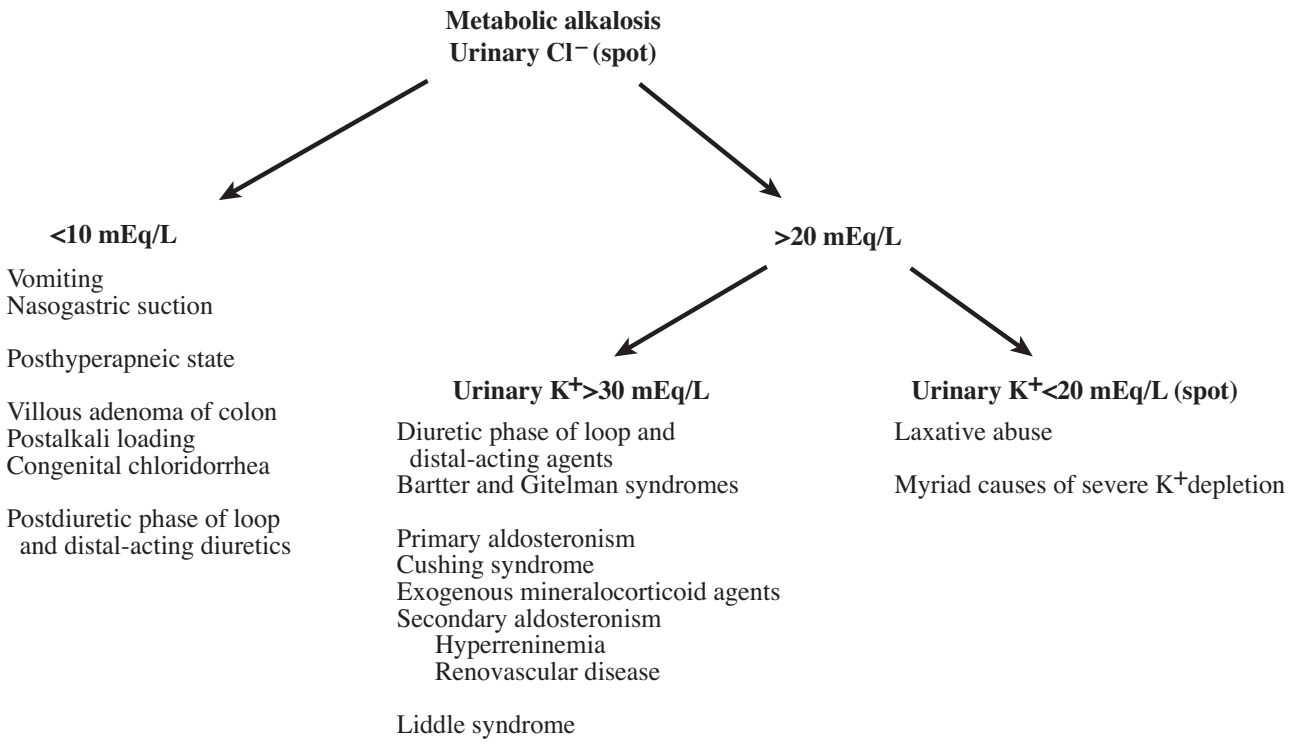

Fig. 17-6. Metabolic alkalosis classified according to spot urinary chloride and spot urinary potassium.

either carbon dioxide production exceeds the capacity of minute ventilation or respiratory physiology is deranged, carbon dioxide accumulates, causing respiratory acidosis. The kidneys compensate by retaining bicarbonate.

Pathophysiologic derangements may be divided into two basic components: 1) the respiratory pump, which generates the forces necessary for airflow, and 2) the loads opposing such forces.

- Respiratory acidosis: the primary disturbance is increased $PaCO_2$.
- Compensation: renal retention of bicarbonate.
- Disorders are caused by either a defect in the respiratory pump or an increase in the opposing load.

Abnormalities of the respiratory pump include acutely and chronically depressed central drive (medications, anatomical lesions, inflammatory or infectious conditions, and metabolic derangements such as hypothyroidism); abnormal neuromuscular transmission (medications such as succinylcholine and aminoglycosides and metabolic causes [e.g., hypokalemia]); lesions of the nervous system (Guillain-Barré syndrome, myotonic dystrophy, multiple sclerosis, and amyotrophic lateral sclerosis); and muscle dysfunction (fatigue, hypokalemia, hypophosphatemia, hyperkalemia, malnutrition, and myopathic disease such as polymyositis).

Abnormalities of opposing forces (increased load) may be divided into lung stiffness (pneumonia, pulmonary edema, and acute respiratory distress syndrome), chest wall stiffness (flail chest, severe kyphoscoliosis, hemothorax, pneumothorax, obesity, peritoneal insufflation, and peritoneal dialysis), increased ventilatory demand (pulmonary embolism, sepsis, and overfeeding with carbohydrates), and high airflow resistance (upper and lower airway obstruction, laryngospasm, aspiration, bronchospasm, edema, secretions, and chronic obstructive pulmonary disease).

Initially, evaluation of suspected respiratory acidosis requires simultaneous determination of arterial blood gas and electrolyte panel values. Immediate steps should focus on securing a patent airway and providing adequate oxygenation. Historical clues, physical examination findings, assessment of hemodynamics and gas exchange, and radiologic studies help to identify the cause.

Expected compensation for both acute and chronic respiratory acidosis is shown in Table 17-16.

Respiratory Alkalosis

Respiratory alkalosis (primary hypocapnia) results from either increased minute ventilation or decreased carbon dioxide production or both. The kidneys compensate by excreting bicarbonate over several days.

- Respiratory alkalosis: the primary disturbance is a decrease in arterial $PaCO_2$.
- Compensation: renal excretion of bicarbonate (over a period of days).

Broadly, disorders that cause primary respiratory alkalosis include hypoxemia, stimulation of ventilatory centers in the central nervous system, various drugs, pregnancy, sepsis, and liver failure (Table 17-17).

Therapy is directed at correcting the primary cause. Often, sedation or a rebreathing apparatus may be required while the primary disorder is being treated. Occasionally, it may be necessary to consider augmenting the renal excretion of bicarbonate. This can be achieved with acetazolamide (250-500 mg intravenously daily or every 12 hours). Rarely, supplemental hydrochloric acid may be needed in the form of 0.1 N hydrochloric acid. Expected metabolic compensation is indicated in Table 17-16.

- The primary causes of respiratory alkalosis include hypoxemia, stimulation of ventilatory centers in the central nervous system, pregnancy, sepsis, and liver failure.

Mixed Acid-Base Disorders

The coexistence of two primary acid-base disturbances (e.g., metabolic acidosis and metabolic alkalosis) or two disturbances separated by time (e.g., superimposed acute and chronic respiratory acidosis) or the presence of two forms of primary disorder (e.g., metabolic acidosis with high anion gap and normal anion gap concomitantly) is commonly encountered in an acute care setting. These disorders can be differentiated and classified appropriately by applying the compensation formula, as guided by the medical history and physical examination findings. A cardinal tenet is that the pH deviates from normal toward the side of the primary acid-base derangement.

Table 17-17 Disorders That Cause Primary Respiratory Alkalosis

Hypoxemia	Stimulation of chest receptors
Decreased FIO_2	Pneumonia
High altitude	Asthma
Laryngospasm	Pneumothorax
Cyanotic heart disease	ARDS
Severe circulatory failure	Pulmonary edema
Pneumonia	Pulmonary fibrosis
Pulmonary edema, embolism	Pulmonary embolism
CNS stimulation	Other
Anxiety	Mechanical ventilation (iatrogenic)
Pain	Pregnancy
Fever	Septicemia
Subarachnoid hemorrhage	Liver failure
Stroke	
Encephalitis	
Tumor	
Drugs or hormones	
Salicylates	
Xanthines	
Angiotensin II	
Catecholamines	
Progesterone	
Nicotine	

ARDS, acute respiratory distress syndrome; CNS, central nervous system; FIO_2, fraction of inspired oxygen.

Delta Gap

In the presence of a high anion gap acidosis, the coexistence of nonanion gap acidosis or metabolic alkalosis may be detected by applying the delta gap formula, which is calculated as follows:

(current anion gap – normal anion gap) + serum bicarbonate level (mEq/L) = 24.

The delta gap should be calculated in all cases of increased anion gap metabolic acidosis.

The premise of the delta gap is based on the accumulation of each excess anion above the normal anion gap accounting for the titration of 1 mEq of bicarbonate per liter. Hence, a patient with an anion gap of 20 has an excess anion gap of 8 (assuming a normal anion gap of 12). Therefore, the expected bicarbonate level measured in the patient's serum is 16 mEq/L. A bicarbonate level less than this would suggest a coexisting nonanion gap metabolic acidosis (additional loss of bicarbonate). A serum bicarbonate level that is considerably higher than 16 mEq/L suggests a preexisting metabolic alkalosis (previous excess levels of bicarbonate). Arterial blood gas values may be normal, but a high anion gap indicates a mixed metabolic alkalosis and acidosis. In metabolic alkalosis and respiratory acidosis, bicarbonate is higher than predicted for acidosis.

Common complex mixed acid-base disorders include the following: 1) salicylate intoxication (high anion gap metabolic acidosis plus respiratory alkalosis)—P_{CO_2} is lower than predicted for acidosis; 2) chronic obstructive pulmonary disease with pneumonia (acute-on-chronic respiratory acidosis); 3) hyperemesis gravidarum (metabolic alkalosis superimposed on chronic respiratory alkalosis)—bicarbonate is higher and P_{CO_2} is lower than expected; 4) sepsis with liver failure (metabolic acidosis with respiratory alkalosis); and 5) metabolic acidosis, respiratory acidosis, and metabolic alkalosis (acute ingestion of toxic alcohol, aspiration pneumonia, and chronic vomiting).

- Bicarbonate <15 mEq/L is usually caused partly by a metabolic acidosis.
- Bicarbonate >45 mEq/L is usually caused partly by a metabolic alkalosis.
- Arterial blood gas values may be normal, but a high anion gap indicates a mixed metabolic alkalosis and acidosis.
- In metabolic acidosis and respiratory alkalosis, P_{CO_2} is lower than predicted for acidosis.
- In metabolic alkalosis and respiratory acidosis, bicarbonate is higher than predicted for acidosis.
- In mixed metabolic and respiratory alkalosis, bicarbonate is higher and P_{CO_2} is lower than expected.
- Triple disorders: diabetic/alcoholic (vomiting) + (ketoacidosis/lactic acidosis) + (pneumonia).
- Calculating the delta gap allows coexisting metabolic acid-base derangements to be differentiated.

Part IV

Stephen B. Erickson, MD

Urolithiasis

Epidemiology

The prevalence of urolithiasis in the United States is about 5%. The annual incidence is about 0.1%. Of patients with untreated urolithiasis, 30% to 75% have recurrence within 10 years. Urolithiasis is strongly familial and related to diet and urine volume. Many patients have a metabolic disorder that can be demonstrated with further testing, but conservative treatment with diet and increased fluid intake eliminates the stone-forming tendency in 70% of patients. Among those for whom conservative therapy fails, medications are curative in another 25% (Fig. 17-7 and 17-8).

- Prevalence of urolithiasis in the United States is about 5%.
- It is strongly familial and related to diet and urine volume.

Risk Factors

Urine pH is important in the pathogenesis of some renal stones. Struvite and calcium phosphate stones tend to form in alkaline urine; uric acid and cystine stones form in acid urine. Some anatomical factors that predispose to urolithiasis include medullary sponge kidney, polycystic kidney disease, and chronic obstruction. Historical factors include fluid intake, dietary intake, history of urinary tract infection, drugs, family history, and other illnesses. Laboratory studies should include reviewing earlier radiographic findings; radiography of the kidneys, ureters, and bladder (KUB) and stone protocol computed tomography (CT) or excretory urography; stone analysis, serum calcium and phosphorus, urinalysis, urine culture, and 24-hour urine volume; and calcium, potassium, phosphorus, citrate, creatinine, oxalate, sodium, magnesium, uric acid, and cystine analysis with the usual diet. The characteristics of kidney stones are outlined in Table 17-18.

- Struvite and calcium phosphate stones form in alkaline urine.
- Uric acid and cystine stones form in acid urine.

Metabolic Activity and Surgical Activity

An evaluation of the disease activity to assess "surgical activity" and "metabolic activity" in patients who have urolithiasis is important for determining treatment. *Surgical activity* refers to unrelieved

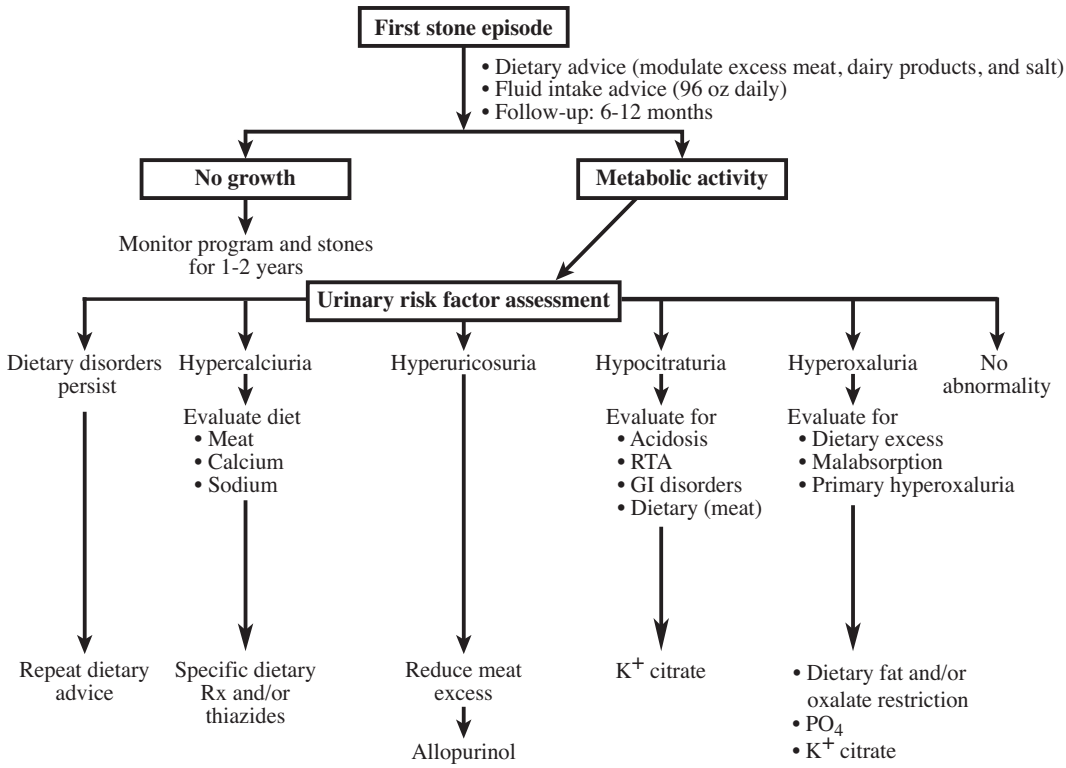

Fig. 17-7. Approach to therapy for idiopathic urolithiasis. GI, gastrointestinal; K^+, potassium; PO_4, phosphate; RTA, renal tubular acidosis; Rx, therapy. (Modified from MKSAP in the Subspecialty of Nephrology and Hypertension. Book 1 Syllabus and Questions, 1994. American College of Physicians. Used with permission.)

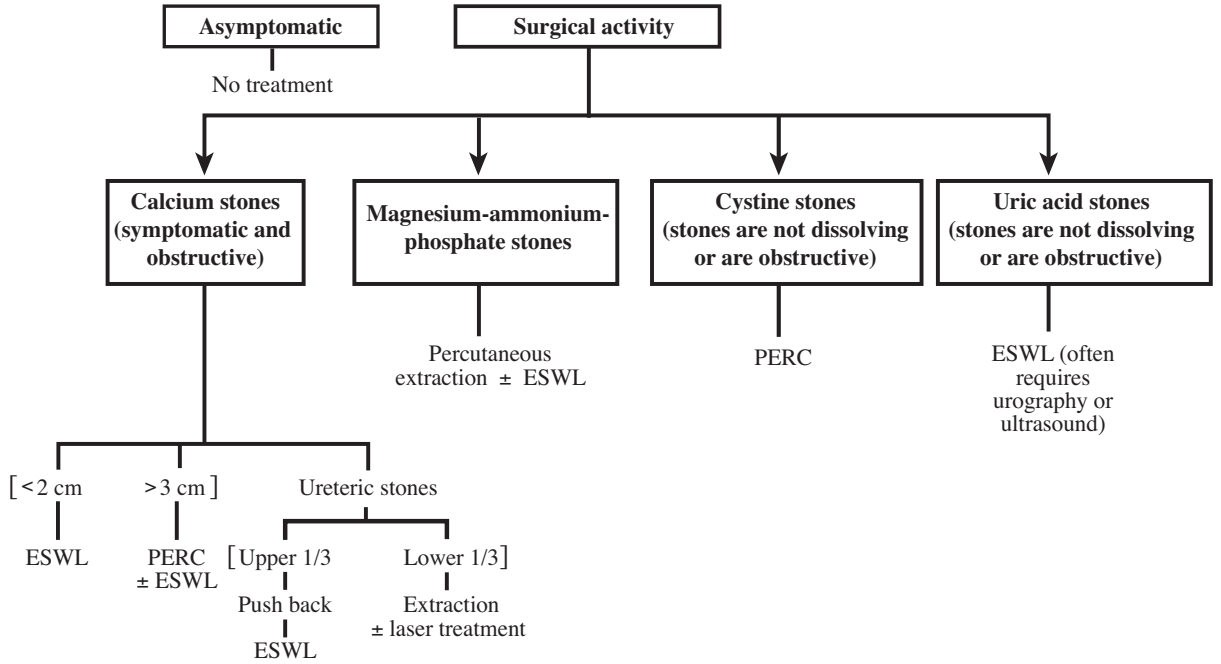

Fig. 17-8. Algorithm for surgical treatment choices based on size, location, and type of kidney stones. ESWL, extracorporeal shock-wave lithotripsy; PERC, percutaneous lithotripsy. (Modified from MKSAP in the Subspecialty of Nephrology and Hypertension. Book 1 Syllabus and Questions, 1994. American College of Physicians. Used with permission.)

hydronephrosis, unrelieved pain, or infection (stones <5 mm should pass); *metabolic activity* refers to the formation of a new stone, growth of an existing stone, or passage of stones that were not identified in the previous year (Table 17-19).

Calcium Oxalate Stones

About 70% of all kidney stones are predominantly calcium oxalate. The risk factors for calcium oxalate stones are listed in Table 17-20. Causes include idiopathic hypercalciuria, other hypercalciuric states, hyperuricosuria, hyperoxaluria, and decreased excretion of inhibitors of crystallization. Conservative treatment includes correcting dietary stresses and increasing urine volume to more than 2.5 L per day. Medications include potassium citrate for hypocitraturia, neutral phosphates for idiopathic calcium urolithiasis (but not in cases of urinary tract infection or renal insufficiency), thiazides for hypercalciuria (sodium must be restricted for urinary calcium to decrease 50%), and allopurinol for hyperuricosuria.

Primary hyperoxaluria is the most aggressive stone disease. Treatment includes fluids, pyridoxine (alters glycine metabolism, an oxalate precursor), neutral phosphates, or liver transplantation.

- Calcium oxalate stones are the most common type.
- Calcium oxalate stones have diverse causes, including various metabolic abnormalities and dietary habits.

Calcium Phosphate Stones

Stones that are predominantly calcium phosphate comprise approximately 10% of kidney stones. The formation of calcium phosphate stones indicates a relatively alkaline urine pH.

Table 17-18 Kidney Stone Characteristics

Type of stone	Color	Shape	Frequency, %	Male-female ratio	Urine pH
Calcium	White, tan, brown, black	Irregular	80	4:1	Oxalate—alkaline or acid Phosphate—relatively alkaline
Uric acid	Orange	Irregular or staghorn	10	10:1	Acid
Struvite	White, tan	Staghorn or irregular	10	1:10	Relatively alkaline
Cystine	Honey	Irregular or staghorn	1	1:1	Acid

From Year 1 Renal Systems Syllabus for Mayo Clinic College of Medicine 2003 and 2004.

Table 17-19 Metabolic Activity and Surgical Activity in Urolithiasis

Metabolic
New stones, growth of old stones, or passage of previously undetected stones in the past year
Surgical
Unrelenting pain, unrelenting obstruction, or infection-related stones

Table 17-20 Risk Factors for Calcium Oxalate Stones

Family history
Male gender
Hypercalciuria
Hyperoxaluria
Hyperuricosuria
Hypocitraturia
Low urine volume
Diet
Low fluids
High salt
High protein
High sugar

Patients who have primary hyperparathyroidism typically have predominantly calcium phosphate stones. Generally, parathyroid adenomas should be resected.

Some patients have renal tubular disorders associated with urolithiasis, including distal renal tubular acidosis (type 1). These patients often make pure calcium phosphate stones. They may also have nephrocalcinosis, a urine pH that is always greater than 5.3, and a hyperchloremic hypokalemic normal anion gap acidosis with a decreased level of urinary citrate (a stone inhibitor) and a high level of urinary calcium. The primary treatment is to correct the acidosis with alkali and to monitor urinary citrate excretion.

Other conditions associated with predominantly calcium phosphate stones are medullary sponge kidney and the use of absorbable alkalis, such as Tums, Rolaids, Alka-Seltzer, and baking soda.

- The presence of calcium phosphate stones indicates a relatively alkaline urine pH.

Uric Acid Stones

Uric acid stones account for about 10% of all cases of nephrolithiasis. Of patients with uric acid urolithiasis, 75% have normal levels of uric acid in the serum and urine. The urine is often very acidic. Of patients with primary gout, 25% form renal stones. An excess of dietary protein also can predispose to uric acid stones, as can any cause of chronic diarrhea, including colectomy and ileostomy, because of decreased urine volume and hyperacidity. Uric acid urolithiasis is treated with preventive measures such as increased intake of fluid and decreased intake of protein. Alkalizing the urine to pH 6.5 not only helps prevent uric acid urolithiasis by treating the hyperaciduria, but it may also dissolve renal stones. Although allopurinol usually is not as effective as alkalizing very acidic urine, it may be helpful in patients with hyperuricosuria and for dissolving stones.

- Of patients who form uric acid stones, 75% have persistently low urine pH.
- Renal stones form in 25% of patients with primary gout.
- Colectomy and ileostomy predispose to stones because the urine volume decreases and urine acidity increases.

Struvite Stones

Struvite stones comprise about 10% of all kidney stones. All patients who have magnesium-ammonium-phosphate stones are infected with urease-producing bacteria, which include *Proteus*, *Staphylococcus*, *Klebsiella*, *Enterobacter*, *Pseudomonas*, and, only rarely, *Escherichia coli*. The urine pH of these patients is alkaline, sometimes greater than the maximal physiologically achievable pH of approximately 8.0. Also, many of these patients have an underlying stone-forming tendency. Staghorn stones are not uncommon, and 50% occur bilaterally. Treatment includes giving antibiotics preoperatively and surgically removing all stone material, attempting to identify and treat the underlying stone-forming tendency, and giving bactericidal antibiotics for 6 to 12 months for suppression.

- All patients with magnesium-ammonium-phosphate stones are infected with urease-producing bacteria.
- Urine pH is very alkaline.
- Staghorn stones: 50% occur bilaterally.
- Treatment: surgical removal and bactericidal antibiotics for 6-12 months for suppression.

Cystine Stones

Only about 1% of patients with kidney stones have cystine stones. Cystinuria is an autosomal recessive disorder in which homozygotes develop urolithiasis. Cystine crystalluria in routine urinalysis is diagnostic, as are positive findings on the nitroprusside test. These patients have a defect in the renal and intestinal absorption of **c**ystine, **o**rnithine, **l**ysine, and **a**rginine (mnemonic: *COLA*). The stones can be dissolved with urinary alkalization, cystine chelators such as tiopronin or penicillamine, and a high intake of fluid; however, urinary alkalization must be very intense, with urine pH maintained above 7.0. Adverse effects of penicillamine therapy include blood dyscrasias, gastrointestinal tract upset, membranous glomerulopathy, and a Goodpasture-like syndrome. Patients who have cystinuria often receive pyridoxine (25 mg daily) when taking penicillamine because cystine chelators indiscriminantly bind pyridoxine.

Inhibitors of Crystallization

Multiple inhibitors of calcium crystal formation and aggregation have been discovered. For the most part, they are not routinely measured except for citrate and magnesium. Others include Tamm-Horsfall

protein, nephrocalcin, osteopontin, pyrophosphate, and glycosaminoglycans. Patients who form calcium stones and who have no metabolic abnormality may be treated successfully with potassium citrate, phosphate, or magnesium salts to prevent further stones.

Drug-Induced Stone Disease

Medications that increase the tendency for stone formation include those listed in Table 17-21.

Urolithiasis and Bowel Disease

Hyperoxaluria

Patients must have an intact colon to absorb free oxalate. Free oxalate is overabsorbed when free fatty acids complex calcium and magnesium (the usual oxalate complexers). Fatty acids and bile acids also increase colonic permeability to oxalate. Other factors that increase oxalate supersaturation include decreased water absorption, decreased bicarbonate absorption, and decreased absorption of magnesium, phosphate, and pyrophosphate (inhibitors of crystallization). Treatment of this disorder includes correcting the underlying problem, increasing dietary calcium, decreasing dietary oxalate and fat, considering use of cholestyramine to bind bile acids, and increasing urine pH and inhibitors.

- The absorption of free oxalate requires an intact colon.

Uric Acid Urolithiasis

Patients with bowel disease, especially those without a colon, may also develop uric acid urolithiasis. Ileostomy patients are frequently susceptible to these stones because of the loss of alkali and water. Treatment includes alkali, fluids, and allopurinol.

- Patients with colectomies preferentially form uric acid stones.

Transplantation

Transplantation is the treatment of choice for eligible patients who have end-stage renal disease (ESRD). More than 100,000 renal transplantations have been performed; 11,000 are performed annually (8,000 cadaveric and 3,000 living-related). More than 35,000 potential recipients are awaiting a kidney transplant, and this number increases annually. The main limitation is the small number of donor kidneys. Lifetime immunosuppression is required. Recipients range in age from younger than 1 year to older than 50 years. The recipients must not have cancer. Infections (including those of the teeth, sinuses, and bladder) need to be eradicated, and cholecystectomy for gallstones should be performed. Living donors must be older than 18 years and not have systemic or renal disease. Cadaveric donors must be older than 6 months and not have infection or malignancy (except for nonmetastasizing brain cancer).

Table 17-21 Medications Increasing the Tendency for Stone Formation

Acetazolamide (calcium phosphate stones)
Calcium carbonate
Allopurinol (xanthine or oxypurinol stones)
Triamterene
Vitamin C (oxalate)
Vitamin D, nonthiazide diuretics, steroids (hypercalciuria)
Chemotherapy (increased urate load)
Indinavir/acyclovir
Topiramate
Ephedra/guaifenesin
Sulfonamides

- Transplantation is the treatment of choice for eligible patients with ESRD.
- Lifetime immunosuppression is required.

Recurrent Allograft Renal Disease

Causes of recurrent allograft renal disease include membranoproliferative glomerulonephritis, membranous nephropathy, focal segmental glomerulosclerosis, diabetes mellitus, primary hyperoxaluria, hemolytic-uremic syndrome, and IgA nephropathy (usually not clinically important).

Immunosuppression

Immunosuppressive agents include prednisone, which blocks the production of interleukin 1 by macrophages and the production of cytokines (complications include cataracts, psychoses, peptic ulcer disease, infection, diverticulitis, and aseptic necrosis); azathioprine, which inhibits the proliferation of activated T cells (bone marrow suppression, cholestasis, and infection; never treat with allopurinol); and cyclosporine, which inhibits the activation of helper T cells and the production of interleukins 2, 3, 4, and 5 and which is hydrophobic and lipophilic, requiring bile acids for absorption (Fig. 17-9).

Cyclosporine levels are increased by ketoconazole, cimetidine, ranitidine, verapamil, diltiazem, and erythromycin. Cyclosporine levels are decreased by phenytoin, phenobarbital, ethambutol, sulfamethoxazole, ethanol, and cholestyramine.

The adverse effects of cyclosporine include gum hyperplasia, hyperkalemia, hypertension, hemolytic uremic syndrome, and thrombotic thrombocytopenic purpura.

Graft Failure (Most Commonly Chronic Rejection)

Graft failure is commonly due to chronic rejection. Acute tubular necrosis occurs after transplantation in 20% to 50% of patients. The stages of rejection are hyperacute (hours), acute (days to years), and chronic (months to years). Recurrent disease occurs in 1% of patients. Surgical complications include renal artery stenosis, ureteral obstruction or leak, and lymphocele.

The medical complications of renal transplantation are diverse and complex. Opportunistic infections are the most common cause of death, and the next most common cause is cardiovascular problems. Other complications are hyperlipidemia, malignancy (1%, including skin cancer, sarcomas, lymphomas [Epstein-Barr virus-associated], and solid tumors), polycythemia, proximal or distal renal tubular acidosis, and kidney stones (1%).

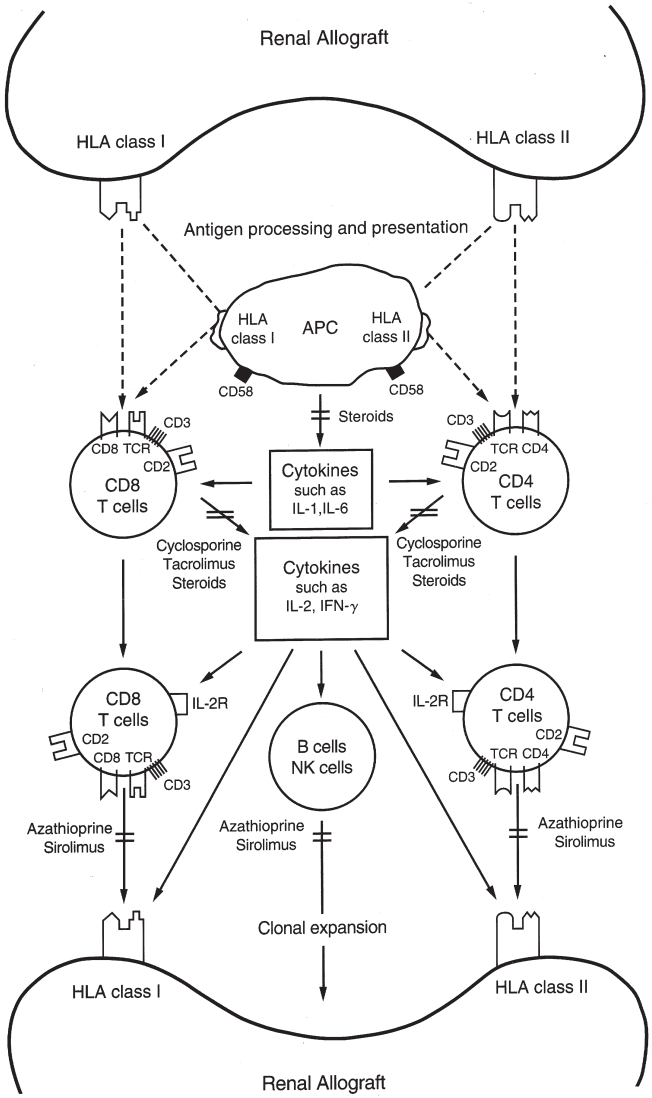

Fig. 17-9. The anti-allograft response. APC, antigen-presenting cell; HLA, human leukocyte antigen; IFN, interferon; IL, interleukin; IL-2R, IL-2 receptor; NK, natural killer; TCR, T-cell receptor. (From Suthanthiran M, Strom T. Renal transplantation. N Engl J Med. 1994;331:365-76. Used with permission.)

Pregnancy and the Kidney

Anatomical changes associated with pregnancy are renal enlargement (length may increase by 1 cm) and dilatation of the calyces, renal pelvis, and ureters. Physiologic changes include a 30% to 50% increase in glomerular filtration rate (GFR) and renal blood flow; a mean decrease in creatinine level of 0.5 mg/dL and a mean decrease in urea nitrogen of 18 mg/dL (limits: creatinine 0.8 mg/dL and urea nitrogen 26 mg/dL); intermittent glycosuria independent of plasma glucose (<1 g/d); proteinuria (but <300 mg/d, sometimes postural); aminoaciduria (<2 g/d, most but not all amino acids); increased uric acid excretion; increased total body water (6-8 L), with osmostat resetting; 50% increase in plasma volume and cardiac output; and increased ureteral peristalsis. Bacterial growth in urine is promoted by the intermittent glycosuria and aminoaciduria. Hormonal effects include increased levels of renin, angiotensin II, aldosterone, cortisol, estrogens, prostaglandins (E_2 and I_2), and progesterone; insensitivity to the pressor effects of norepinephrine and angiotensin II; and progesterone counteracting the kaliuretic effects of aldosterone.

Urinary Tract Infections

The prevalence of asymptomatic bacteriuria among pregnant women is similar to that among nonpregnant women, except that it is higher in those with diabetes mellitus and sickle cell trait. Asymptomatic urinary tract infections progress to pyelonephritis or cystitis in 40% of pregnant women. Recommendations include screening for asymptomatic bacteriuria monthly and treating asymptomatic bacteriuria (10-14 days). Symptomatic urinary tract infections frequently recur. Pyelonephritis occurs in 1% to 2% of patients. Symptomatic urinary tract infections should be treated aggressively with antibiotics (ampicillin or cephalosporins) for 6 weeks. Follow-up cultures are recommended every 2 weeks. Sulfa drugs near term and tetracyclines (because of fetal bone and tooth development and maternal liver failure) are contraindicated.

Acute Renal Failure in Pregnancy

Conditions that predispose to acute renal failure in pregnancy are sepsis, severe preeclampsia (HELLP [hemolysis, elevated liver enzymes, and low platelet count] syndrome), abruptio placentae, intrauterine fetal death, uterine hemorrhage, and presence of nephrotoxins. Cortical necrosis occurs in 10% to 30% of cases of gestational acute renal failure. Patients become anuric. Although patients may have partial recovery, they may have progression to ESRD years later. Postpartum hemolytic uremic syndrome (exclude retained placenta) may occur at 3 to 6 weeks post partum. This is characterized by acute oliguria, uremia, severe hypertension, and microangiopathic hemolytic anemia. Disseminated intravascular coagulation and Shwartzman reaction occur, as in thrombotic thrombocytopenic purpura. Therapy includes dilatation and curettage, support, perhaps antiplatelet therapy (although the evidence is not strong), and plasma infusion. Acute renal failure and acute fatty liver of pregnancy (similar to hepatorenal syndrome) are caused by tetracyclines and possibly disseminated intravascular coagulation.

Parenchymal Renal Disease in Pregnancy

The outcome of lupus erythematosus depends on the clinical status prepartum. If the disease is quiescent 6 months before birth, 90% of the women have live births. If the disease is active prepartum, 50% have exacerbation and 35% have fetal loss. If the disease is stable prepartum, 30% of the women have reversible exacerbations. Congenital heart block may occur in the newborn. Glucocorticoids and cytotoxic agents have been used without causing teratogenic effects.

Diabetes mellitus is associated with increased asymptomatic and symptomatic bacteriuria and increased preeclampsia. Proteinuria and hypertension may worsen, but renal function usually is stable.

Renal transplant recipients should postpone pregnancy for 2 years after transplantation. Increased preeclampsia, infection, and adrenal insufficiency have been reported. Pregnancy is usually

uncomplicated if the creatinine level is less than 1.5 mg/dL, blood pressure is normal, and the woman is receiving low-dose immunosuppressive therapy. Preeclampsia occurs in 25% of women, prematurity in 7%, and loss of renal function in 7%. Nonobstetrical abdominal pain indicates allograft stone or infection.

Evaluation of Kidney Function

Urinalysis

The causes of urine discoloration are listed in Table 17-22.

Dysmorphic erythrocytes (>80%) in the urinary sediment indicate upper urinary tract bleeding. The Hansel stain identifies urinary eosinophils.

Normal urine osmolality is 40 to 1,200 mOsm/kg and the pH is 4 to 7.5. A pH less than 5.5 excludes type 1 renal tubular acidosis. A pH greater than 7 suggests infection. Acid urine is indicative of a high-protein diet, acidosis, and potassium depletion. Alkaline urine is associated with a vegetarian diet, alkalosis (unless potassium-depleted), and urease-producing bacteria.

Glycosuria in the absence of hyperglycemia suggests proximal tubule dysfunction. Clearance of *p*-aminohippurate is a measure of renal blood flow. Orthoiodohippurate is used in renal scans. The clearance rates of inulin, iothalamate, diethylenetriamine pentaacetic acid (DTPA), and creatinine are measures of the GFR. The Cockgroft-Gault estimate formula for males is

$$\text{GFR} = \frac{(140 - \text{age in years}) \times (\text{lean body weight in kg})}{S_{Cr} \times 72}$$

where S_{Cr} is the serum level of creatinine. For females, the males' formula is multiplied by 0.85. Creatinine levels are increased independently of the GFR with ketoacidosis (acetoacetate), cefoxitin, cimetidine, trimethoprim, flucytosine, massive rhabdomyolysis, high intake of meat, and probenecid. Urea (blood urea nitrogen) levels are increased independently of the GFR with gastrointestinal tract bleeding, tissue trauma, glucocorticoids, and tetracyclines.

Renal Imaging

KUB plain films magnify the kidneys 30%. Normal renal size is 3.5 × the height of vertebra L2 (>11 cm). The left kidney is up to 1.5 cm longer than the right one. An enlarged kidney indicates obstruction, infiltration (amyloidosis, leukemia, or diabetes mellitus), acute glomerulonephritis, acute tubulointerstitial nephropathy, renal vein thrombosis, or polycystic kidney disease. Calcifications are associated with stone, tuberculosis, aneurysms, and necrosis of the papillary tips.

Excretory urography provides a detailed definition of the collecting system and can be used to assess renal size and contour and to detect and locate calculi. It is also used to assess renal function qualitatively. Rapid sequence excretory urography is a poor screening test for renovascular hypertension. Complications include a large osmotic load (congestive heart failure) and reactions (5%). An iodine load may occur and is a consideration if the patient has hyperthyroidism.

Ultrasonography is used to measure renal size (>9 cm) and to screen for obstruction, but the results may be negative early in the course of obstruction. Ultrasonography can be used to characterize mass lesions (angiomyolipoma and solid versus cystic) and to screen for polycystic kidney disease. Ultrasonography may be used to assess for renal vein thrombosis, that is, to assess for the presence or absence of blood flow. Ultrasonography is not a screening test for renal artery stenosis.

CT demonstrates calcification patterns. It is used to stage neoplasms and as an adjunct to determine the cause of obstruction (without contrast medium). CT is used to assess cysts, abscesses, and hematomas.

Magnetic resonance imaging may be used to identify adrenal hemorrhage and to assess a mass in patients sensitive to contrast dyes. Magnetic resonance angiography is a promising screening method for renal artery stenosis.

Arteriography and venography are used to evaluate arterial stenosis, aneurysm, fistulas, vasculitis, and mass lesions and to assess living-related donor transplants.

Gallium and indium scans are used to evaluate acute interstitial nephritis, abscess, pyelonephritis, lymphoma, and leukemia.

DTPA and hippuran renal scanning are useful in assessing a transplanted kidney, obstruction (before and after furosemide), and infarct (presence or absence of blood flow).

Table 17-22 Causes of Urine Discoloration

Color	Cause
Dark yellow, brown	Bilirubin
Brown-black	Homogentisic acid (ochronosis)
	Melanin (melanoma)
	Metronidazole
	Methyldopa/levodopa
	Phenothiazine
Red	Beets
	Rifampin
	Porphyria
	Hemoglobinuria/myoglobinuria
	Phenazopyridine hydrochloride (Pyridium)
	Urates
Blue-green	Indomethacin
	Amitriptyline
Turbid white	Pyuria
	Chylous fistula
	Crystalluria

Nephrology Pharmacy Review

Michael A. Schwarz, PharmD

Drug (trade name)	Toxic/adverse effects	Comments
Hematopoietic agent		
Epoetin alfa (Epogen, Procrit)	Hypertension, local pain, iron deficiency, clotted IV access, headache, diarrhea, edema Rare seizures, CVA Maximize iron stores before & during erythropoietin therapy	Administration, SQ or IV; usually 3 times weekly
Darbepoetin alfa (Aranesp)	Same as above	Long-acting erythropoietin; administration, SQ or IV once weekly
Iron products		
Ferric gluconate (Ferrlecit)	Hypersensitivity reaction, hypotension, flushing, cramps Increased hypotension & flushing with rapid infusion	Less incidence of anaphylaxis than with iron dextran IV infusion route only Test dose recommended but not required
Iron dextran (InFeD, Dexferrum)	Hypersensitivity reaction/anaphylaxis, bronchospasm, local pain, tissue staining, arthralgias, flushing, hypotension, rare seizures Risk decreased with dilution and slow infusion rate	Administration, IV (slowly, to avoid tissue discoloration) or IM (as a "z track") Requires test dose before administration (0.25-0.5 mL slow IV or deep IM)
Iron sucrose (Venofer)	Hypotension, leg cramps, headache, nausea/vomiting, diarrhea, low risk of hypersensitivity reaction	Administration, only by slow IV push or injection No test dose needed before administration
Oral iron products Ferrous fumarate (33% elemental) Ferrous sulfate (20% elemental) Ferrous gluconate (11.6% elemental)	GI upset, constipation, nausea/vomiting, dark stools	Best absorbed on an empty stomach Typically not adequate to replete iron stores in hemodialysis patient Iron absorption decreased with co-administration of antacids, calcium products, phosphorus binders Absorption of quinolone antibiotics decreased with coadministration of iron
Phosphorus-binding agents*		
Aluminum carbonate (Basaljel) Aluminum hydroxide (Amphojel, ALternaGEL)	Risk of aluminum accumulation/toxicity: encephalopathy, microcytic anemia, osteomalacia, seizures, dementia	Best for short-term use Does not cause hypercalcemia Aluminum absorption increased with coadministration of citrate salts (i.e., effervescent tablets), resulting in increased risk of toxicity Decreases absorption of quinolone antibiotics & oral iron
Calcium acetate (PhosLo)	Hypercalcemia, GI upset, constipation	More potent phosphorus binder than calcium carbonate Decreases absorption of quinolone antibiotics & oral iron with coadministration of calcium products Absorption of digoxin may be decreased

Nephrology Pharmacy Review (continued)

Drug (trade name)	Toxic/adverse effects	Comments
Phosphorus-binding agents* (continued)		
Calcium carbonate (Tums, Os-Cal)	Same as above	Highest elemental calcium content Decreases absorption of quinolone antibiotics & oral iron with coadministration of calcium products Absorption of digoxin may be decreased
Sevelamer HCl (Renagel)	Nausea/vomiting, diarrhea, constipation, dyspepsia, hypertension, hypotension	Does not cause hypercalcemia or aluminum toxicity May decrease LDL & total serum cholesterol levels Absorption of other medications may be decreased with coadministration of sevelamer
Lanthanum carbonate (Fosrenol)	Dyspepsia, diarrhea, nausea/vomiting; vascular dialysis graft occlusion	Very expensive; thus, not used often Long-term effects on bone & other organs unknown
Vitamin D analogues		
Calcitriol (Calcijex [IV], Rocaltrol [PO])	Hypercalcemia, hyperphosphatemia, constipation, nausea/vomiting, headache, confusion, somnolence, dry mouth, myalgia	Increases absorption of calcium & phosphorus Suppresses PTH secretion
Paricalcitol (Zemplar)	Same as above	Less absorption of calcium & phosphorus than with calcitriol
Miscellaneous		
Vitamins (Nephrocaps, Nephro-Vite)	No important ones documented	Water-soluble vitamin replacement
Quinine sulfate (several)	Hypoglycemia, pancytopenia, tinnitus, nausea/vomiting, visual disturbances, headache, photosensitivity, rare DIC	Prevention or treatment of leg cramps Absorption of quinine may be decreased with coadministration of aluminum antacids Coadministration with digoxin may lead to increased digoxin levels Coadministration with warfarin may potentiate warfarin effects

CVA, cerebrovascular accident; DIC, disseminated intravascular coagulation; GI, gastrointestinal; IM, intramuscular; IV, intravenous; LDL, low-density lipoprotein; PO, by mouth; PTH, parathyroid hormone; SQ, subcutaneous.

*All phosphorus-binding agents should be taken with food for better efficacy.

Nephrology Pharmacy Review (continued)

Drugs Associated With Acid-Base Disorders

Metabolic acidosis
- Acetaminophen OD
- Acetazolamide
- Alcohol
- Amphetamine OD
- Cocaine
- Colchicine
- Cotrimoxazole
- Ethylene glycol
- Iron OD
- Isoniazid OD
- Mafenide
- Metformin
- Methanol
- Paraldehyde
- Propofol
- Salicylate OD (late)
- Spironolactone

Metabolic alkalosis
- Bicarbonate
- Citrate salts (especially with abnormal renal function)
- Diuretics (loop and thiazides)
- Phenolphthalein (laxative abuse)

Respiratory acidosis

Part I—General Principles for Interpreting Neurologic Symptoms

Introduction

Neurologic disorders are commonly encountered in general clinical practice (about 10% of patients of primary care physicians in the United States have neurologic disorders, and about 25% of inpatients have a neurologic disorder as a primary or secondary problem). Because of the aging population, cerebrovascular disorders, dementias, and Parkinson disease are becoming more prevalent. Understanding a patient with neurologic disease depends on localizing the problem on the basis of the medical history and examination findings, considering a differential diagnosis, and correlating the clinical findings with abnormalities found on appropriate diagnostic testing.

- About 10% of patients of primary care physicians in the United States have neurologic disorders.
- About 25% of inpatients have a neurologic disorder as a primary or secondary problem.
- Primary care physicians should have a good working knowledge of common and emergency neurologic problems.

Neurologic Signs and Symptoms

General Categories

Neurologic signs and symptoms can be subdivided into four general categories:

1. Ill-defined, nonspecific, nonanatomical, and nonphysiologic regional or generalized symptoms
2. Diffuse cerebral symptoms
3. Positive focal symptoms (hyperactivity)
4. Negative focal symptoms (loss of function)

Ill-Defined Symptoms

Ill-defined symptoms include such things as ill-defined dizziness, diffuse or unusual regional pain, diffuse and unusual numbness, vague memory problems, and unusual gait. Generally, no serious underlying neurologic problem is identified, especially if the symptoms are long-standing. Many patients have a serious underlying psychopathologic disorder, but often the patient either does not recognize this or denies it. However, remember that a psychiatric diagnosis should be made on the basis of positive psychologic factors and not because the physical examination and laboratory findings are normal.

- With ill-defined symptoms, no serious underlying problem is identified in most patients.
- Many of these patients have an underlying psychopathologic condition.
- Establish a psychiatric diagnosis on the basis of positive psychologic factors, not because the physical examination and laboratory findings are normal.

Diffuse Cerebral Symptoms

Diffuse cognitive problems occur in dementia and acute confusional states. However, a common diffuse symptom is syncope or presyncope, which usually implies diffuse and not focal cerebral ischemia. Vasovagal syncope is the major culprit, especially in the young. Syncope is not a transient ischemic attack (TIA), which is a focal event. Most causes of syncope are systemic, not neurologic, problems. With primary autonomic dysfunction, other neurologic signs and symptoms usually help make the diagnosis (e.g., bladder or erectile dysfunction, peripheral neuropathy, sweating changes, parkinsonian features, and diabetes).

- Dementia and acute confusional states are due to diffuse cerebral disease.

- Syncope or presyncope implies diffuse, not focal, cerebral ischemia.
- Syncope is not a TIA.
- Systemic, not neurologic, problems usually cause syncope.

Positive Phenomena

An example of a positive sensory phenomenon is paresthesia (tingling or prickling), and an example of a positive motor phenomenon is tonic or clonic movement of muscles. Lights, flashes, sparkles, and formed images are examples of positive visual phenomena. An example of a positive language phenomenon is unusual vocalization. Positive central nervous system (CNS) phenomena usually lead to seizures or migraine accompaniments (flashing lights or squiggly lines). Positive peripheral phenomena occur with nerve damage and repair.

Negative Phenomena

Negative phenomena usually indicate damage to a specific central or peripheral area. Examples include weakness, numbness, speech difficulty, and blindness. TIAs and strokes usually produce negative phenomena; if there is more than one symptom, all the symptoms tend to appear at the same time. Migraine syndromes may have positive and negative phenomena; if there is more than one symptom, the symptoms tend to begin one after another and build up.

- TIAs and strokes produce negative phenomena.
- Migraine syndromes have positive and negative phenomena.

Localization

The neurologic history and examination findings are combined to clarify the localization of the disorder to the following four levels: supratentorial (cerebral cortex and subcortical regions, including the basal ganglia, hypothalamus, and thalamus); posterior fossa (cerebellum, brainstem, and cranial nerves); spinal cord (including extramedullary, intramedullary, cauda equina, and conus medullaris lesions); and peripheral (Table 18-1). Peripheral lesions may be localized further from proximal to distal: radiculopathy, plexopathy, peripheral neuropathy, neuromuscular junction, and muscle. Some disorders, however, are multifocal. From the signs and symptoms, the lesion is determined to be on the right or left side or bilateral. Then the temporal profile is considered: acute (seconds to hours), subacute (days to weeks), or chronic (several months to years). In addition, the course is important: progressive, static, improving, or relapsing. It is then possible to consider a differential diagnosis for the lesion and to outline the diagnostic procedures, therapeutic options, and patient education.

Table 18-1 **Localization of Neurologic Disorders**

Level
Supratentorial
Posterior fossa
Spinal cord
Peripheral
Extent
Focal
Diffuse

- The history and examination dictate localization to the level and side of the nervous system.
- The temporal profile is then used to determine a differential diagnosis.

Findings in the Elderly

Examination of healthy elderly persons may show signs that cannot be considered pathologic when present in isolation:

- Decreased acuity of the special senses: olfaction, audition, and vision
- Decrease in upward gaze, visual pursuit, and saccadic function
- Abnormal gait with reduced arm swinging, shorter steps, and slow walking speed
- Difficulty with balance, with wider base and unsteady turns
- Decreased vibratory sensation in the feet
- Decreased pupillary response to light
- Atrophy of the small muscles of the hand
- Decreased or absent ankle reflexes

In addition, in most healthy elderly people some neurodiagnostic studies may appear abnormal, including spondylitic abnormalities visible on plain cervical and lumbar radiographs and on magnetic resonance imaging (MRI) and computed tomography (CT) of the same areas, white matter changes on brain MRI, mild focal slowing on electroencephalography (EEG), and slowing of nerve conduction velocities on electrophysiologic testing.

- Age must be kept in mind when interpreting certain neurologic examination abnormalities.
- Most healthy elderly people have spondylitic abnormalities visible on plain cervical and lumbar radiographs and MRI as well as white matter changes on brain MRI.

General Principles of Neurologic Diagnostic Testing

CT and MRI

Vascular Diseases

CT is a good initial test for evaluating suspected TIA or stroke because it can quickly identify acute hemorrhage in brain parenchyma or the subarachnoid space (Table 18-2). CT (even with contrast enhancement) often gives equivocal or negative results in the first 24 to 48 hours after an ischemic cerebral infarction. In these situations, an MRI is the first neuroimaging test to show abnormalities during evolution of an ischemic cerebral infarct. With diffusion and perfusion MRI scanning, cerebral infarction or ischemia can be delineated early after the onset of symptoms, usually before CT shows any abnormality. In subacute and chronic stages of an ischemic cerebral infarction, MRI and CT provide equivalent information. Vasculitic lesions or microinfarcts, as in systemic lupus erythematosus, are often seen on MRI but missed on CT. Subacute and

Table 18-2 Comparison of Computed Tomography (CT) and Magnetic Resonance Imaging (MRI) for Neurologic Imaging

CT preferred	MRI preferred
Evaluation of suspected acute hemorrhage	Evaluation of subacute and chronic hemorrhage
Evaluation of skull fractures	Evaluation of ischemic stroke
Evaluation of meningiomas	Evaluation of posterior fossa and brainstem tumors and lesions
	Diagnosis of multiple sclerosis
	Evaluation of the spinal cord

chronic intracerebral hemorrhages are better defined by MRI, especially with gradient echo MRI, which is capable of identifying acute blood as well as old hemosiderin.

Magnetic resonance angiography (MRA) is not invasive and has replaced standard angiography for many indications. It is quite sensitive in defining the degree of stenosis in the carotid or vertebrobasilar system. However, MRA does not adequately evaluate more distal intracranial arteries, and arteriography is required for this indication. MRA is also used as a screening study for aneurysms. Arteriography is needed to examine the anatomical details of aneurysms or vascular malformations.

- For evaluating acute hemorrhage in the brain and subarachnoid space, CT is better than standard MRI.
- During evolution of an ischemic cerebral infarct, MRI is better than CT.
- For evaluating subacute and chronic stages of an ischemic cerebral infarct, CT and MRI are equivalent.

Trauma

MRI is competitive with but not comparable to CT for assessing the brain after craniocerebral trauma. Acutely after injury, CT is preferable because the examination time is shorter. Standard radiographic examination or CT is necessary to evaluate skull fractures because bone cortex is not visualized with MRI.

CT is highly dependable for demonstrating subdural hematomas, which are also visualized with MRI. Coronal MRI sections are usually best for visualizing the size, shape, location, and extent of subdural hematomas. MRI can show changes from diffuse axonal injury that are not visible on CT. This is often the pathologic substrate for mental status changes or coma after head trauma when intracerebral hemorrhage is excluded.

In adults and children with traumatic brain injury, recovery from unconsciousness is unlikely after 12 months. Recovery is rare after 3 months in adults and children with nontraumatic brain injury.

- Acutely after trauma, CT of the brain is recommended.
- Radiography or CT is needed to evaluate skull fractures.
- CT is dependable for showing subdural hematomas.
- MRI, not CT, will detect diffuse axonal injury.

Intracranial Tumors

A wide spectrum of intracranial tumors is visualized with MRI and CT. Often MRI shows more extensive involvement (of one lesion or multiple smaller lesions) than CT, especially in gliomas or metastasis. CT with contrast and MRI with gadolinium are both excellent for detecting meningiomas. MRI is far superior to CT for identifying all types of posterior fossa tumors. It is the study of choice for identifying brainstem gliomas.

- MRI is favored over CT for the evaluation of tumors because it shows more anatomical detail and allows detection of smaller lesions.
- MRI is superior to CT for identifying posterior fossa tumors and brainstem gliomas.

White Matter Lesions

MRI is superior to CT in detecting abnormalities of the white matter. MRI is far superior to CT for identifying multiple sclerosis lesions and for assessing patients who have isolated optic neuritis. MRI shows that multi-infarct dementia (with multiple white matter infarcts) may be a common cause of adult-onset dementia. However, white matter changes in the elderly must be interpreted carefully because MRI shows changes in the white matter of most normal elderly persons.

- MRI is the test of choice in multiple sclerosis.
- MRI shows changes in the white matter of most normal elderly persons.

Spinal Cord

A wide spectrum of lesions at the cervicomedullary junction and in the spinal cord can be seen clearly with MRI because direct sagittal and coronal sections can be made with this imaging method. Thus, MRI is the study of choice for assessing the cervicomedullary junction and spinal cord. Generally, MRI is better than CT for identifying intramedullary and extramedullary lesions of the spinal cord. CT can be helpful if bony detail is important (e.g., fractures and spurs).

- MRI is better than CT for assessing the cervicomedullary junction and spinal cord and intramedullary and extramedullary cord lesions.

Dementia

In assessing dementia, either CT or MRI can demonstrate potentially fixable lesions (i.e., subdural hematoma or brain tumor), but MRI shows more lesions than CT in multi-infarct dementia. MRI can assess atrophy more accurately, especially in the mesial temporal lobes. This is best viewed with a thin-slice coronal imaging technique.

Disk Disease

Protruding disks are well visualized on MRI sagittal sections, which show the relation of the disk to the spine and nerve roots. MRI is

equal to CT myelography for evaluating herniated disks at cervical and thoracic levels, but at the lumbar level, MRI is better than CT myelography. In spinal stenosis, MRI and CT are roughly equivalent and less invasive than myelography.

- MRI sagittal sections show protruding disks.
- For evaluating cervical and thoracic herniated disks, MRI is equal to CT myelography, but MRI is better at the lumbar level.

Electromyography and Nerve Conduction Studies

Electromyography (EMG) and nerve conduction studies (NCS) should be performed by experts familiar with the intricacies of the procedure and who know its value and limitations. NCS involve shocking nerves and measuring certain electrophysiologic variables (amplitude of responses, conduction velocity, and distal latencies). EMG is performed by inserting a small needle into the muscle and recording electrical activity at rest and with light muscle contraction. These tests are excellent for detecting motor unit problems and, thus, are valuable for identifying diseases of the anterior horn cell, nerve root, peripheral nerve, neuromuscular junction, and muscle. They also assess the large-fiber sensory peripheral nervous system. They give no information, however, on small-fiber function, which requires specific testing of the autonomic nerves and sweating pathways. By helping to localize and to better define further diagnostic studies, EMG and NCS are an extension of the neurologic examination.

- NCS and EMG should be performed by experts.
- NCS and EMG are valuable for identifying motor unit problems—anterior horn cell, nerve root, neuromuscular junction, and muscle—as well as large-fiber sensory problems.
- NCS and EMG do not assess small-fiber function.

Electroencephalography

EEG is used mainly to study seizure disorders, but EEG is specific in only a few forms of epilepsy, such as typical absence epilepsy. A seizure disorder, or epilepsy, is a clinical diagnosis and not an EEG diagnosis, and a normal EEG does not rule out epilepsy. EEG has many nonspecific patterns that should not be overinterpreted.

Ambulatory EEG is available for detecting frequent unusual spells. EEG telemetry with video monitoring is helpful in defining epileptic surgical candidates, nonepileptic spells (pseudoseizures), and unusual seizures. EEG is imperative in diagnosing nonconvulsive status epilepticus.

- EEG is specific in only a few forms of epilepsy, including typical absence epilepsy.
- Epilepsy is a clinical, not an EEG, diagnosis.
- A normal EEG does not rule out epilepsy.
- EEG telemetry is helpful in defining epileptic surgical candidates, nonepileptic spells, and unusual seizures.

EEG is valuable for evaluating various encephalopathies. Many drugs cause an unusual fast pattern, and most metabolic encephalopathies cause a diffuse slow or triphasic pattern. Diffuse slow patterns are seen also in diffuse cerebral disease (Alzheimer disease). Unusual high-amplitude sharp wave activity helps define Creutzfeldt-Jakob disease and subacute sclerosing panencephalitis. EEG is often valuable in diagnosing certain infectious encephalopathies (herpes simplex encephalitis).

EEG is essential for diagnosing various sleep disorders and is an *adjuvant* tool for diagnosing brain death. Recall that brain death is a clinical diagnosis. EEG may be used as a monitoring device in surgery (e.g., during carotid endarterectomy).

At 6 hours or more after a hypoxic insult, the EEG indicates the likelihood of neurologic recovery. Poor outcome is seen with "alpha" coma, burst suppression, periodic patterns, and electrocerebral silence.

- EEG is valuable in diagnosing certain infectious encephalopathies (herpes simplex encephalitis).
- EEG is an adjuvant tool for diagnosing brain death.
- Brain death is a clinical diagnosis.

Evoked Potentials

Evoked potentials indicate the intactness of various afferent pathways: visual evoked potentials, somatosensory evoked potentials, brainstem auditory evoked potentials, and motor evoked potentials. These tests have limited clinical use, mainly in multiple sclerosis and myelopathies. They are excellent monitoring devices for spinal surgery and posterior fossa surgery (monitoring spinal cord and cranial nerve function intraoperatively), and they may be useful for substantiating nonorganic disease, for example, hysterical paraplegia or hysterical blindness.

- Evoked potentials are used during intraoperative monitoring of neurologic function and also in some cases of multiple sclerosis and myelopathies.
- Evoked potentials may be useful for substantiating nonorganic disease (e.g., hysterical paraplegia or hysterical blindness).

Lumbar Puncture and Cerebrospinal Fluid Analysis

Perform lumbar puncture only after a thorough clinical evaluation and after consideration of the potential value versus the hazards of the procedure. Imaging of the brain (CT or MRI) is mandatory if there is any suspicion of a CNS process.

Indications for Lumbar Puncture

Urgent lumbar puncture is performed for suspected acute meningitis, encephalitis, or subarachnoid hemorrhage (unless preceding CT findings indicate otherwise) and for fever (even without meningeal signs) in infancy, acute confusional states, and neurologic manifestations in immunocompromised patients. Another indication for lumbar puncture is unexplained subacute dementia.

Multiple sclerosis is an indication for lumbar puncture. If the cerebrospinal fluid (CSF) cell count is greater than 50, look for another disease (e.g., sarcoidosis). Although IgG synthesis is increased in multiple sclerosis, this finding is nonspecific. The demonstration of oligoclonal bands is useful, but they also occur in other inflammatory diseases of the CNS.

Lumbar puncture is used to assess CSF pressure. High pressure occurs with pseudotumor cerebri (idiopathic intracranial hypertension) and low pressure with CSF hypovolemia from a CSF leak.

Lumbar puncture is indicated in cases of neurologic complications of infectious diseases, including acquired immunodeficiency syndrome (AIDS), Lyme disease, and any suspected acute, subacute, or chronic infection (viral, bacterial, or fungal).

Other indications for lumbar puncture are meningeal carcinomatosis, selected indications in non-Hodgkin lymphoma, certain neuropathies (Guillain-Barré syndrome, acute inflammatory demyelinating polyneuropathy, and chronic inflammatory demyelinating polyradiculopathy), and gliomatosis cerebri.

There is no difference in headache frequency after immediate mobilization or after 4 hours of bed rest following lumbar puncture. Spinal headache depends on the size of the needle used and the leakage of CSF through a dural rent or tear.

Contraindications for Lumbar Puncture

Suppuration in the skin and deeper tissues overlying the spinal canal and anticoagulation therapy or bleeding diathesis are contraindications for lumbar puncture. A minimum of 1 or 2 hours should elapse between lumbar puncture and initiation of heparin therapy. If the platelet count is less than 20×10^9/L, transfuse platelets before performing a lumbar puncture.

Increased intracranial pressure due to a focal mass lesion is a contraindication. Lumbar puncture is dangerous when papilledema is due to an intracranial mass, but it is safe (and has been used therapeutically) in pseudotumor cerebri. In complete spinal block or stenosis, lumbar puncture may aggravate the signs of spinal cord disease.

- Perform lumbar puncture only after a thorough clinical evaluation.
- Increased IgG synthesis in the CSF is a nonspecific finding.
- CSF pressure is high in pseudotumor cerebri (idiopathic intracranial hypertension).
- CSF pressure is low with CSF hypovolemia.
- Lumbar puncture is dangerous when an intracranial mass is present, with or without papilledema.
- Lumbar puncture is safe in and therapeutic for pseudotumor cerebri.
- Lumbar puncture aggravates the signs of spinal cord disease in complete spinal block.

Part II—General Principles From the Level of the Cerebral Cortex Through the Neuraxis to Muscle

Supratentorial Level: Symptoms and Clinical Correlations

The supratentorial region is large and includes all levels of the nervous system inside the skull and above the tentorium cerebelli (top of the cerebellum). Symptoms and signs related to disorders of the cerebral cortex may lead to alterations in cognition and consciousness. Unilateral neurologic symptoms involving a single neurologic symptom (such as numbness [sensory system] or weakness [motor system]) commonly localize to the cerebral cortex. Abnormalities of speech and language are localized to the dominant cerebral hemisphere (typically the left side, even in most left-handers), whereas abnormalities of the nondominant hemisphere may lead to visuospatial deficits, confusion, or neglect of the contralateral side of the body. Abnormalities in the subcortical region may lead to weakness or numbness; they typically involve more than one limb. Abnormalities in the basal ganglia may lead to movement disorders, including tremor, bradykinesia (as in Parkinson disease), and chorea (as in Huntington disease). Disorders of the thalamus, another subcortical structure, typically cause unilateral sensory abnormalities, language problems, and cognitive changes. The hypothalamus is important in many functions that affect everyday steady-state conditions, including temperature, hunger, water regulation, sleep, endocrine functions, cardiovascular functions, and regulation of the autonomic nervous system. Cortical and subcortical abnormalities may also lead to visual system deficits, usually homonymous visual field deficits.

Disorders of Consciousness

Consciousness has two dimensions: arousal and cognition. *Arousal* is a vegetative function maintained by the brainstem and medial diencephalic structures. *Cognition*—learning, memory, self-awareness, and adaptive behavior—depends on the functional integrity of the cerebral cortex and associated subcortical nuclei.

Coma or unconsciousness results from either bilateral dysfunction of the cerebral cortex or dysfunction of the reticular activating system in the upper brainstem (above the middle level of the pons). *Unconsciousness* implies global or total unawareness; *coma* implies the lack of both wakefulness and awareness.

- Coma implies the lack of both wakefulness and awareness.

Brain Death

Brain death is the absence of function of the cerebral cortex and brainstem.

Persistent Vegetative State

Persistent vegetative state is the absence of cerebral cortex function with normal brainstem function (deafferentated state). The patient has no detectable awareness but, unlike a patient in a coma, is wakeful and has sleep-wake cycles.

Locked-in Syndrome

Locked-in syndrome is normal cerebral cortex function with absence of brainstem function. The lesion usually is in the pons and causes quadriplegia and the inability to speak, swallow, and move the eyes horizontally, that is, the de-efferentated state. The patient, however, is wakeful and aware but is unable to communicate verbally because of the neurologic deficits. Often, though, these patients can communicate with eye blinks and vertical eye movements.

Stupor and Coma

For a person to stay awake, the cerebral hemispheres and reticular activating system must be intact. Patients with dysfunction of only one cerebral hemisphere have a focal neurologic deficit but are awake.

The most common, potentially reversible causes of stupor and coma are toxic, metabolic, and infectious problems that affect both cerebral hemispheres diffusely (the famed "toxic/metabolic encephalopathy"). Thus, most patients in stupor or coma have an underlying systemic problem.

- The most common reversible causes of stupor and coma are toxic, metabolic, and infectious diseases.

Patients with toxic/metabolic encephalopathies have changes in mental status and awareness before going into stupor or coma, but they typically have no focal neurologic signs. Corneal reflexes are lost early in the disease, but pupillary reflexes remain. Ocular motility tested by the doll's eye maneuver (oculocephalic reflexes) and the cold caloric response (oculovestibular reflex) are fully intact, at least early in the disease.

- Patients with systemic encephalopathies typically have no focal signs.

Patients with a large unilateral cerebral lesion may go into stupor or coma if the lesion causes shifting and pressure changes in other parts of the brain, such as the opposite hemisphere or brainstem. These patients can have focal neurologic signs. Patients with brainstem lesions that directly affect the ascending reticular activating system are in coma but, again, have focal signs. Persons who feign coma have no focal signs, no abnormal reflexes, normal caloric responses, and a normal EEG. They account for a small percentage of patients with stupor and coma.

- Large unilateral cerebral lesions that cause a shift and pressure changes in the other hemisphere or brainstem produce focal neurologic signs together with coma.
- Brainstem lesions that cause coma also produce focal signs.
- Persons who feign coma have no focal signs, no abnormal reflexes, normal caloric responses, and a normal EEG.

Minimally Conscious State

The minimally conscious state is a condition of severely altered consciousness in which minimal but definite behavioral evidence of self-awareness or environmental awareness is demonstrated. It is a disorder of limited responsiveness in which patients retain awareness, but their responses are so deficient that the evidence of their awareness may be difficult to detect. The minimally conscious state is distinguished from the vegetative state by the presence of behaviors associated with conscious awareness. The minimally conscious state may be a temporary state in a continuum from coma to vegetative state to minimally conscious state to normalcy, or, unfortunately, it may also be a permanent state. It is most important in young people with traumatic brain injury to recognize the minimally conscious state early in the course of the disease since it carries a better prognosis than the vegetative state. However, the prognosis of either of these conditions depends on the age of the patient, the duration of the condition, and the cause (traumatic brain injury in the young carries the best prognosis, whereas hypoxic/ischemic or hypoglycemic brain injury at any age carries the worst).

Acute Confusional States

Acute confusional state is malfunction of the cerebral cortex and reticular activating system. Acute confusional states are abrupt, of recent onset, and often associated with fluctuations in the state of awareness and cognition. They are manifested by confusion, inattention, disorientation, and delirium. Thus, patients may be inattentive, dazed, stuporous, restless, agitated, or excited and may have marked autonomic dysfunction and visual and tactile hallucinations. Abnormal motor manifestations are common, including paratonia, asterixis, tremor, and myoclonus. The usual etiologic factors of acute confusional states are toxic, metabolic, traumatic, infectious, organ failure of any sort, or ictal or postictal encephalopathies. Three large categories of primary causes for acute confusional states are systemic, neurologic, and psychophysiologic. Withdrawal states from alcohol, benzodiazepines, and barbiturates are also important causes of acute confusion or delirium.

- Three general causes of acute confusional states are systemic, neurologic, and psychophysiologic.

Dementia

Dementia is chronic malfunction of the cerebral cortex with normal function of the brainstem. It is a clinical state characterized by a marked loss of function in multiple cognitive domains not due to an impaired level of arousal. The presence of dementia does not necessarily imply irreversibility, a progressive course, or any specific disease. Dementia is not a disease but an entity with various causes (Table 18-3).

A small percentage of patients have reversible causes of dementia. These include medication-induced encephalopathy, depression, thyroid disease, CNS infections, vitamin deficiencies, and structural brain lesions (neoplasms, subdural hematomas, and symptomatic hydrocephalus).

- Dementia itself is not a disease; it is the potential result of many different diseases.

Alzheimer disease (AD) is the most common cause of dementia. It occurs in both young and old persons and is no longer subcategorized into "presenile" and "senile" types. Generally, patients present first with difficulties of memory, but eventually difficulties develop in several cognitive areas, including aphasia, apraxia, or agnosia. The patients also have various behavioral and psychiatric manifestations, and some may have myoclonus or akinesia. AD is not simply diffuse atrophy of the brain but a regionally specific illness that first affects hippocampal structures and acetylcholine-producing neurons.

Mild cognitive impairment (MCI) consists of memory loss that is clearly evident at bedside testing but does not interfere with everyday function. MCI represents a very early stage of dementia. In about 50% of patients, MCI progresses to AD over a 4-year period, and MCI progresses to AD in almost all patients eventually. MRI, with focus in the temporal lobes, may detect atrophy early in the mesial temporal lobe of patients with MCI at risk of AD. The apolipoprotein E (*APOE*) ε4 genotype also predicts a higher likelihood of AD.

Huntington disease
Progressive supranuclear palsy
Prion-related disorders
Creutzfeldt-Jakob disease

HIV, human immunodeficiency virus.

Additional study is needed to clarify the association of the subtypes and the power of prediction of a specific finding. Noncompetitive reversible cholinesterase inhibitors, such as donepezil (see below), may slow the progression and delay the onset of outright dementia in patients with MCI, most of whom have underlying AD pathology.

There is treatment for AD (Table 18-4). Some symptoms of AD are thought to be due to partial depletion of acetylcholine in the brain. Currently available, centrally active, noncompetitive reversible cholinesterase inhibitors, including donepezil, rivastigmine, and galantamine, may improve symptoms slightly and slow the decline of cognitive function in a small proportion of patients. Donepezil can be given once daily, whereas rivastigmine and galantamine are taken twice daily after meals. Tacrine, the first anticholinesterase agent used for the treatment of AD, may cause hepatotoxicity and is now rarely prescribed. The main side effects of these drugs are nausea, vomiting, and diarrhea. Donepezil is administered at bedtime but may cause vivid dreams, requiring that the dose be taken in the morning. Treatment with these drugs is continued until dementia reaches severe stages. The drugs should not be discontinued abruptly because the result may be abrupt cognitive deterioration. Vitamin E is also used in AD, although its efficacy in slowing the rate of progression is not clearly defined. Given the recent concern over increased mortality in patients taking vitamin E, some physicians have abandoned this treatment. A standard dose of 400 IU is probably safe.

Another mechanism for damage to neurons in AD is through excitotoxicity by glutamate. Memantine is an *N*-methyl-D-aspartate antagonist thought to reduce glutamate excitotoxicity, which has been shown to slow the progression of cognitive dysfunction in AD. The combination of memantine and donepezil can slow the disease even more in severe AD. For donepezil, the usual dosage is 5 to 10 mg daily and for memantine, 10 mg twice a day.

Another common degenerative dementia is diffuse Lewy body disease. Patients with this disease typically exhibit parkinsonism, fluctuations of cognitive function, visual hallucinations, and rapid eye movement sleep behavior disorder. Antipsychotic medications may trigger a neuroleptic malignant-type syndrome in these patients. Cholinesterase inhibitors may improve hallucinations and other symptoms. Patients with a frontotemporal dementia such as Pick disease exhibit difficulties with executive function, inappropriate behavior, and aphasia.

Normal pressure hydrocephalus (NPH) has garnered much attention lately. It is a potentially reversible cause of cognitive dysfunction. The typical triad includes dementia, a gait disorder, and urinary incontinence, although sometimes only the first two components are present. A shuffling, magnetic ("feet stuck to the floor") gait is most common. CT or MRI shows disproportionate enlargement of the ventricular system without any obstructive lesions. Removal of 30 mL of CSF, leading to improvement in the gait disorder, may predict a response to ventriculoperitoneal shunting, although through the years no clear predictive factors for shunting success have emerged. Unfortunately, shunting is not a benign procedure, and up to a third of patients eventually have complications, such as infection, hemorrhage, or failure of the shunt.

A typical diagnostic work-up for dementia may include a complete blood cell count, electrolyte survey and blood chemistry profile (including calcium, glucose, blood urea nitrogen, and creatinine), liver function tests, thyroid function tests, serum level of vitamin B_{12}, and serologic testing for syphilis. In selected patients, erythrocyte sedimentation rate, human immunodeficiency virus (HIV) testing, paraneoplastic antibody screening, chest radiography, urine collection for heavy metals, and toxicology screens should be performed. Also occasionally evaluated are antinuclear, extractable nuclear antigen, and thyroid peroxidase (TPO) antibodies. Neuroimaging should be done in all persons with dementia. MRI is

Table 18-4 Pharmacologic Therapy in Alzheimer Disease

Cholinesterase inhibitors
Donepezil, 5-10 mg daily
Rivastigmine, 6 mg twice daily
Galantamine, 12 mg twice daily
Glutamate antagonist
Memantine, 10 mg twice daily

preferred, although CT can exclude structural (and possibly reversible) causes of dementia (e.g., NPH, tumor, subdural hematoma, and strokes). MRI has the advantage of detecting atrophy in mesial temporal lobes and hippocampal structures in AD. Neuropsychometric testing may also be considered, especially in mild or questionable cases. Lumbar puncture is indicated for persons who have had recent onset of symptoms, persons younger than 55 years who have dementia, and those with immunosuppression, possible CNS infection, reactive serum syphilis serologic findings, or metastatic cancer without findings on an imaging study. EEG may be useful in evaluating for Creutzfeldt-Jakob disease. In these patients, fluid-attenuated inversion recovery (FLAIR) MRI techniques can detect abnormalities in the cerebral cortex, basal ganglia, or thalamus when the findings of a standard MRI study are negative. The presence of increased levels of 14-3-3 protein in the CSF, although a nonspecific finding, strongly supports the diagnosis of Creutzfeldt-Jakob disease.

Typical Clinical Scenarios

- AD: A 70-year-old patient has had progressive loss of recent memory over the past 2 years. Mental status testing shows poor recall and learning with calculation, information, and language errors. The results of laboratory tests are normal. MRI shows moderate cerebral atrophy but no specific lesions.
- Multi-infarct dementia: An elderly patient with known coronary artery disease and hypertension has progressive memory loss, slowed movements and responses, and difficulty walking. Deep tendon reflexes of the lower limb are brisk. The results of routine laboratory tests and CSF examination are normal. MRI shows multiple infarcts in both cerebral hemispheres.
- Creutzfeldt-Jakob disease: A 60-year-old patient has had rapidly progressive dementia and myoclonic jerks over several months. The EEG shows unusual high-amplitude sharp waves. FLAIR MRI shows increased signal intensity in the cerebral cortex and basal ganglia. The results of routine laboratory tests and CSF examination are normal, except for an increased level of 14-3-3 protein, which is highly supportive of the diagnosis.

Seizure Disorders

Seizure refers to electroclinical events, and *epilepsy* indicates a tendency for recurrent seizures. A classification of seizures is given in Table 18-5.

The proper treatment of epilepsy includes accurate diagnosis of the seizure type, identification of the cause (if possible), and management of psychosocial problems. The EEG (preferably after the patient is sleep deprived) can be important in deciding whether to treat a first unprovoked seizure. The risk of recurrent seizures is high if the initial EEG shows epileptiform activity and low if the EEG is normal.

Causes

Seizures occur at any age, but approximately 70% of all patients with epilepsy have their first seizure before age 20. Age distribution for the onset of epilepsy is bimodal, with the second most common group being the elderly population. Both the cause and the type of epilepsy are related to age at onset. However, the cause may not be found in many patients. Neonatal seizures are often due to congenital defects or prenatal injury, and head trauma is often the cause of focal seizures in young adults. Brain tumors and vascular disease are major known causes of seizures in later life. Seizures often occur during withdrawal from alcohol, barbiturates, or benzodiazepines in young and old adults. Seizures also occur with the use of drugs such as cocaine, usually in young adults. Metabolic derangements (e.g., hypoglycemia, hypocalcemia, hyponatremia, and hypernatremia) can occur at any age, as can infections (e.g., meningitis and encephalitis). Metabolic abnormalities usually cause primary generalized tonic-clonic seizures and rarely focal or multifocal seizures. CNS infections usually cause partial and secondary generalized tonic-clonic seizures.

Pseudoseizures (psychogenic, nonepileptic) are sudden changes in behavior or mentation not associated with any physiologic cause or abnormal paroxysmal discharge of electrical activity from the brain. They are often the cause of so-called intractable seizures. Effective treatment is elusive. A favorable outcome may be associated with an independent lifestyle, the absence of coexisting epilepsy, and a formal psychologic approach to therapy.

- Up to 70% of patients with epilepsy have their first seizure before age 20, although the fastest growing population with epilepsy is the elderly.
- The cause and type of epilepsy are related to age at onset.
- Head trauma is a major cause of focal seizures in young adults.

Table 18-5 Classification of Seizures

Partial (focal) seizures
Simple partial seizures
Partial simple sensory
Partial simple motor
Partial simple special sensory (unusual smells or tastes)
Speech arrest or unusual vocalizations
Complex partial seizures
Consciousness impaired at onset
Simple partial onset followed by impaired consciousness
Evolving to generalized tonic-clonic convulsions (secondary generalized tonic-clonic seizures)
Simple evolving to generalized tonic-clonic
Complex evolving to generalized tonic-clonic (including those with simple partial onset)
True auras—are actually simple partial seizures
Generalized seizures—convulsive or nonconvulsive (primary generalized seizures—generalized from onset)
Absence and atypical absence
Myoclonic
Clonic
Tonic
Tonic-clonic
Atonic
Unclassified epileptic seizures (includes some neonatal seizures)

- Brain tumors and vascular disease are major causes of seizures in older persons.
- Seizures occur with withdrawal from alcohol, barbiturates, and benzodiazepines.
- Seizures occur during the use of cocaine (young adults).
- Pseudoseizures are often the basis of so-called intractable seizures.

Anticonvulsant Therapy

Drugs used to treat seizures are listed in Table 18-6. Monotherapy is the treatment of choice. The dose of the drug may be increased as high as necessary and to as much as can be tolerated. The coadministration of antiepileptic drugs has not been shown to have more antiseizure efficacy than the administration of only one drug without concurrently increasing toxicity. In studies of a large population, one particular drug may be shown to be more efficacious and less toxic, but for a given patient, an alternate drug may be more effective or have fewer side effects. The classic antiepileptic drugs are phenobarbital, phenytoin, carbamazepine, valproic acid, benzodiazepines, and ethosuximide. Simple and complex partial seizures are most likely to be controlled with phenytoin and carbamazepine, whereas secondary generalized tonic-clonic seizures respond equally well to carbamazepine, phenytoin, or valproic acid. Phenobarbital is equally efficacious but less well tolerated because of sedative side effects. Idiopathic generalized epilepsy with absence seizures is well controlled with ethosuximide. Valproic acid controls all forms of generalized seizures. Extended-release formulations are available for carbamazepine and valproic acid, and a rectal formulation is available for diazepam.

The new anticonvulsant drugs include gabapentin, tiagabine, lamotrigine, topiramate, felbamate, zonisamide, oxcarbazepine, and levetiracetam. These agents generally have less potential for drug interactions and fewer side effects than the older drugs. They are indicated as add-on therapy for partial seizures. Felbamate, oxcarbazepine, and levetiracetam are also used as single-drug therapy for partial seizures. Felbamate, lamotrigine, and topiramate are also used as monotherapy for generalized seizures. Because the efficacy, high cost, and dosing schedule (twice daily) are similar for most of these new anticonvulsants, tolerability is frequently the major determinant in choosing a particular drug.

Anticonvulsants have both neurologic and systemic side effects. Dose-initiation side effects such as fatigue, dizziness, incoordination, and mental slowing are common in most patients and can be prevented with slow introduction of the drug. Dose-related side effects may limit the use of a particular drug in a given patient. A dose-related side effect common to most drugs is cognitive impairment. Other neurologic side effects include cerebellar ataxia (phenytoin), diplopia (carbamazepine), tremor (valproic acid), and chorea or myoclonus (phenytoin and carbamazepine). Idiosyncratic side effects are rare, unpredictable, severe, and sometimes life-threatening. Idiosyncratic and systemic side effects are listed in Table 18-7.

Many antiepileptic drugs are metabolized in the liver and are responsible for important drug interactions. Liver enzyme inducers such as carbamazepine, phenobarbital, phenytoin, primidone, oxcarbazepine, felbamate, and topiramate increase metabolism and decrease the efficacy of oral contraceptives in preventing pregnancy. Valproic acid and felbamate are enzyme inhibitors and increase the levels of other anticonvulsants. Gabapentin has the advantage of fewer drug interactions because it is eliminated primarily by renal excretion. It may be safer than other anticonvulsants in the management of seizures in patients with porphyria.

Special issues must be considered when managing epilepsy in pregnancy. Seizure control is attempted first with monotherapy, with the lowest possible dose of anticonvulsant and monitoring of drug levels. There is risk of fetal hemorrhage at delivery if the mother is taking phenytoin, phenobarbital, or carbamazepine. This risk can be minimized by administering vitamin K to the mother before delivery and to the fetus at delivery. Offspring of women with epilepsy are at increased risk of intrauterine growth retardation, minor abnormalities (digit hypoplasia and craniofacial abnormalities), major malformations (neural tube defects and cardiac malformations), microcephaly, cognitive dysfunction, and infant death. Various combinations of these findings, referred to as *fetal anticonvulsant*

Table 18-6 Guidance for Use of Antiepileptic Drugs

Criteria	Possibilities	Drug
Type of seizures	GTCSs	PHT, CBZ, VPA, lamotrigine, topiramate
	Partial seizures with or without secondary GTCSs	PHT, CBZ, VPA, PB, lamotrigine, topiramate, zonisamide, levetiracetam
	Absence seizures	Ethosuximide, VPA, lamotrigine
	Myoclonic seizure	VPA, clonazepam, lamotrigine, zonisamide
	Atonic, akinetic, or mixed	VPA, felbamate, topiramate, lamotrigine
Use of other drugs metabolized in the liver	Use drugs that do not affect metabolism of other drugs	Gabapentin, tiagabine, lamotrigine, zonisamide, levetiracetam
Avoidance of oral contraceptive pill failure	Use drugs with no or minimal effect on contraceptive metabolism	VPA, clonazepam, gabapentin, tiagabine, lamotrigine, zonisamide, levetiracetam

CBZ, carbamazepine; GTCS, generalized tonic-clonic seizure; PB, phenobarbital; PHT, phenytoin; VPA, valproic acid.

Table 18-7 Systemic Side Effects of Antiepileptic Drugs

Side effect	Drug most commonly involved
Skin rash and Stevens-Johnson syndrome	10% risk with lamotrigine, CBZ, or PHT 5% risk with other AEDs, least with VPA **Topiramate and zonisamide contraindicated for patients with allergy to sulfa drugs**
Liver failure	Highest risk with VPA and felbamate Risk increased in infants with mental retardation and receiving polytherapy, with underlying metabolic disease or poor nutritional status
Bone marrow suppression	Highest risk with felbamate and CBZ
Gum hypertrophy, hirsutism, acne, osteoporosis	Phenytoin
Weight gain, hair loss, tremor	VPA
Weight loss	Felbamate, topiramate
Headache, insomnia	Felbamate
Behavioral and cognitive disturbances	Barbiturates, benzodiazepines, topiramate
Kidney stones	Topiramate, zonisamide
Hyponatremia	CBZ or oxcarbazepine
Atrioventricular conduction defect	CBZ, PHT
Neural tube defect	VPA > CBZ, but all AEDs are potentially teratogenic

AED, antiepileptic drug; CBZ, carbamazepine; PHT, phenytoin; VPA, valproic acid.

syndrome, have been described with virtually all anticonvulsants but probably most commonly with valproic acid. Multiple drugs at high doses generally are associated with a greater frequency of anomalies. Valproic acid and, to a lesser extent, carbamazepine are selectively associated with increased risk of neural tube defects. Valproic acid has also been associated with lower IQ in children exposed in utero during the first trimester. All women with epilepsy and childbearing potential should receive folate supplementation of at least 0.4 mg daily (although dosages up to 4 mg daily have been recommended by some physicians, especially when there is a family history of newborns with neural tube defects). Prenatal screening should be offered to all women with epilepsy to detect any fetal malformation. The key is pregnancy planning. By the time a woman knows she is pregnant, any neural tube defect most likely already exists; thus, in most women with epilepsy of childbearing age, two forms of contraceptive are advocated. Before a woman attempts to get pregnant, folic acid supplementation is crucial and review of medications and optimal seizure control is vital.

- The treatment of choice is monotherapy.
- Essentially all anticonvulsant drugs have the potential to cause developmental abnormalities.
- Valproic acid (and, to a lesser extent, carbamazepine) is associated with more birth defects than the other anticonvulsants.

When to Start and When to Stop Anticonvulsant Therapy

Decisions about when to start and stop anticonvulsant therapy are difficult and there is simply no easy algorithm to rely on. The decision to begin anticonvulsant therapy after a first seizure should be individualized for each patient. The decision depends on the risk of additional seizures, the risk of seizure-related injury, the loss of employment or driving privileges, and other psychosocial factors. An important decision is whether a single generalized tonic seizure is provoked, for example, by sleep deprivation, alcohol, or concurrent illness. After the first seizure, the risk of recurrence ranges from 30% to 60%, with higher risks for patients with an abnormal EEG and a remote symptomatic cause (Table 18-8). After a second seizure, the risk of recurrence increases to 80% to 90%.

For many patients who have been seizure-free for 1 to 2 years, anticonvulsant therapy can be discontinued. The benefit of discontinuing therapy should be weighed against the possibility of seizure recurrence and its potential adverse consequences. In adults, relapse occurs in 26% to 63% of patients within 1 to 2 years after therapy is discontinued. Predictors of relapse are an abnormal EEG before or during medication withdrawal, abnormal findings on neurologic examination, frequent seizures before entering remission, or mental retardation. To lessen the chance of seizures after discontinuing therapy, withdrawal should not proceed faster than a 20% reduction in dose every 5 half-lives.

Typical Clinical Scenarios

- Absence seizures: A child has abrupt episodes of staring and unresponsiveness that last less than 10 seconds and are associated with complete recovery and no postictal abnormalities. These episodes occur several times a day, but otherwise the child appears normal. The diagnosis is absence seizure, for which ethosuximide or valproic acid is effective.
- Seizure due to an intracranial neoplasm: An elderly patient with a history of recent headaches has a generalized seizure. He has a 50-pack-year history of smoking but no previous history of a

Table 18-8 Risk Factors for Recurrence After the First Seizure

Age >60 y
No precipitating factor identified
Partial seizure
Abnormal neurologic examination
Abnormal electroencephalogram (spikes or nonspecific)
Abnormal imaging study
Other factors
Family history of seizures (in first-degree relative)
History of febrile seizures
Onset during sleep
Postictal Todd paralysis
Occupational risk

seizure disorder. Chest radiography shows a 2-cm mass in the left upper lobe of the lung. Brain metastases should be included in the differential diagnosis. Neuroimaging is indicated to establish the diagnosis.

- Drug-induced agranulocytosis: A neutropenic fever develops a month after a patient starts taking carbamazepine for a seizure disorder. The absolute neutrophil count is 1.0×10^9/L. Treatment is discontinuation of carbamazepine and use of an alternative anticonvulsant. The neutropenic fever should be managed with antibiotics.
- Interaction with oral contraceptives: A young woman with a chronic seizure disorder that has been well controlled with phenytoin for several years indicates that she has become pregnant despite taking birth control pills. The oral contraceptives have been rendered ineffective because of induction of liver enzymes by phenytoin. Lamotrigine, gabapentin, and levetiracetam do not induce liver enzymes as much and are good choices for women with a seizure disorder who take oral contraceptives.

Anticonvulsant Blood Levels

Measurement of anticonvulsant blood levels is readily available and helps attain the best control of seizures. It is extremely important to remember that therapeutic levels represent an average bell-shaped curve and that patients with well-controlled seizures are included under the bell-shaped curve. Seizures are well controlled in many patients who have anticonvulsant blood levels below or above the therapeutic range. The anticonvulsant dose should *never* be changed on the basis of blood levels alone. Remember, toxicity is a clinical, *not* a laboratory, phenomenon.

- Therapeutic levels represent an average bell-shaped curve.
- The dose of anticonvulsant should never be changed on the basis of blood levels alone.
- Toxicity is a clinical, not a laboratory, phenomenon.

If a patient with epilepsy under treatment has breakthrough seizures, several things need to be considered. These include compliance issues; excessive use of alcohol or other recreational drugs; psychologic and physiologic stress (lack of sleep or anxiety); a combination of the preceding; systemic disease of any type, organ failure of any type, or systemic infection; a new cause of seizures (neoplasm); newly prescribed medication, including other anticonvulsants (polypharmacy) and over-the-counter drugs; toxic levels of anticonvulsants (with definite clinical toxicity); pseudoseizures; progressive CNS lesion not identified previously with neuroimaging or lumbar puncture; and no cause found. If no cause is found, anticonvulsant doses must be readjusted or the drug replaced with another one.

Surgery for Epilepsy

With improved technology, the anatomical site of seizure origin can be identified more accurately. Also, technical advances have made surgical management safer. Of the 150,000 patients in whom epilepsy develops each year, 10% to 20% have "medically intractable epilepsy."

Brain surgery is an alternative therapy if treatment with antiepileptic drugs fails. However, before seizures are deemed intractable, ascertain that the correct drugs have been given in the correct amounts. Anterior temporal lobe operations and other cortical resections involve removal of the epileptic focus. These operations are performed for complex partial seizures and are 80% to 90% effective in controlling seizures in the appropriate patients. If patients with complex partial seizures have treatment failure with two anticonvulsant drugs (or possibly even one drug), they should be referred for surgical evaluation.

Corpus callosotomy (the severing of connections between the right and left cerebral hemispheres) is performed for some types of generalized epilepsy. Seizures that are medically refractory may respond to stimulation of the left vagus nerve with a permanent stimulator.

- If treatment with antiepileptic drugs fails, vagal nerve stimulation and brain surgery are alternatives.
- Anterior temporal lobe operations and other cortical resections remove the epileptic focus.
- Resection operations are performed for complex partial seizures.
- Corpus callosotomy severs the connections between the left and right sides of the brain and is performed for generalized epilepsy.

Status Epilepticus

Status epilepticus is a medical emergency and a life-threatening condition. The seizure is prolonged, lasting more than 5 to 10 minutes, or there are repetitive seizures, without recovery between seizures. The most common causes of status epilepticus include withdrawal of an anticonvulsant agent or alcohol, recreational drug toxicity, and CNS trauma or infection. Rarely, status epilepticus is the initial presenting sign of epilepsy. The management of status epilepticus is summarized in Figure 18-1.

Nonconvulsive status epilepticus may cause an acute confusional state or stupor and coma, especially in the elderly. In these cases, there is often very subtle rhythmic motor activity in the limbs or face. EEG is a critical diagnostic tool in these cases because nonconvulsive status epilepticus must be treated as quickly and vigorously as convulsive status epilepticus.

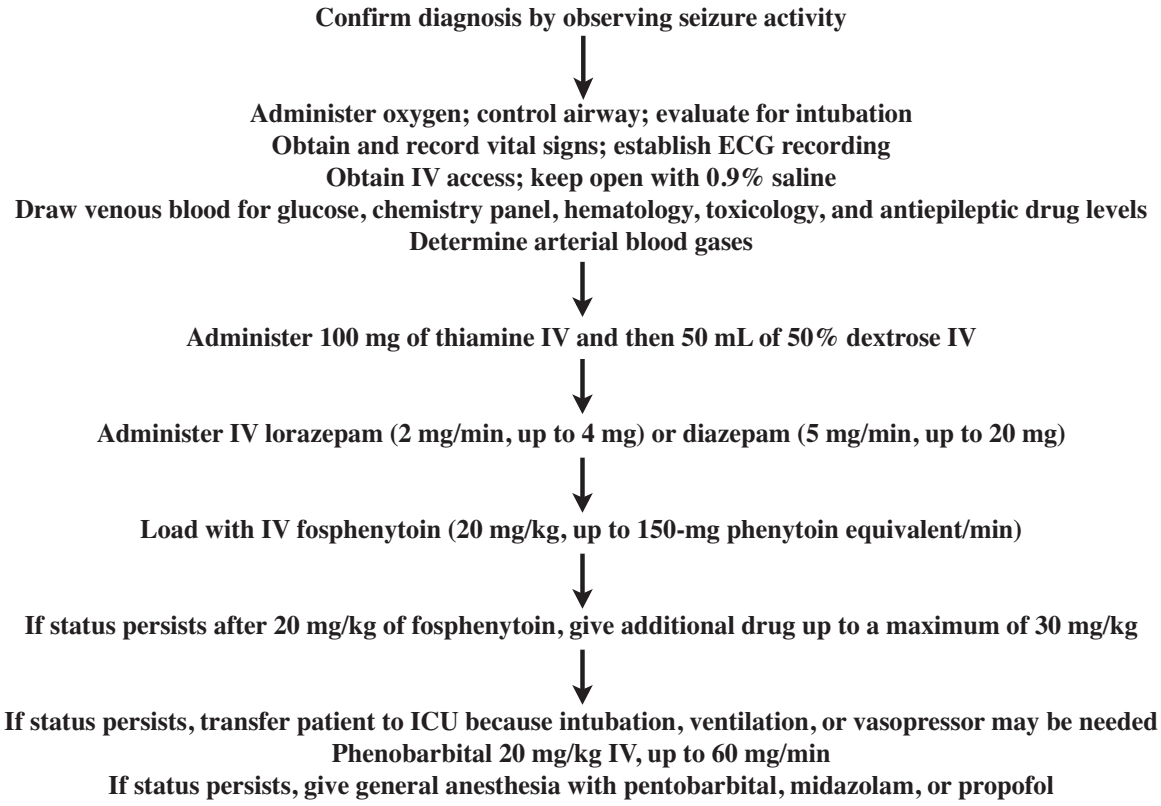

Fig. 18-1. Algorithm for the management of status epilepticus. ECG, electrocardiographic; ICU, intensive care unit; IV, intravenous.

- Status epilepticus is a life-threatening medical emergency.
- The seizure lasts >5 minutes, or there are repetitive seizures without recovery.
- Administer 50 mL of 50% dextrose with 100 mg thiamine intravenously.
- Slowly administer lorazepam intravenously.
- Antiepileptic treatment should begin with a loading dose of fosphenytoin.
- Cardiorespiratory monitoring is required if fosphenytoin or phenytoin is infused rapidly.

Headache and Facial Pain

Headache may indicate intracranial or systemic disease, a personality or situational problem, or a combination of these. Some headaches have a readily identified organic cause. Classic migraine and cluster headaches form distinctive, easily recognized clinical entities, although their pathophysiologic mechanisms are not fully understood. The major challenge is that often neither the location nor the intensity of the pain is a reliable clue to the nature of the problem. Episodic tension headache and migraine can be difficult to distinguish.

- Neither location nor intensity of headache pain is a reliable clue to the nature of the problem.

Conditions alerting physicians that a headache may have a serious cause are listed in Table 18-9. Chronic recurrent headaches are rarely, if ever, caused by eye strain, chronic sinusitis, dental problems, food allergies, high blood pressure, or temporomandibular joint syndrome. Headache without other neurologic signs or symptoms is rarely caused by a brain tumor. Serious causes of headache in which neuroimaging findings may be normal and lead to a false sense of security are listed in Table 18-10.

- "Worst headache of my life" is serious.
- Headache with abnormal neurologic findings, papilledema, obscuration of vision, or diplopia is serious.
- Most of the signs and symptoms in Table 18-9 can occur with chronic benign headache (tension-migraine headache).
- Headache without other neurologic signs or symptoms is rarely caused by a brain tumor.

Migraine and Tension Headache

Migraine is defined by multiple attacks of severe headache, often unilateral, which last several hours and are accompanied by photophobia, phonophobia, and osmophobia; nausea; a pounding quality to the headache; and an increase in the intensity with light activity. Most patients gravitate to a dark, quiet room and try to sleep. Many migraineurs experience an aura before the headache onset. The common auras are visual with flashing lights, jagged lines, or scintillating scotomas. Tension headaches can be severe but are often bilateral, squeezing or tight in quality, and lack all the other associated symptoms that occur in migraine.

Table 18-9 Conditions Indicating That a Headache May Have a Serious Cause

"Worst headache of my life"
Headache in a person not prone to headache, especially a middle-aged or elderly patient
Headache associated with abnormal neurologic findings, papilledema, obscurations of vision, or diplopia
Headache that changes with different positions or increases with exertion, coughing, or sneezing
Changes in headache patterns—character, frequency, or severity—in someone who has had chronic recurring headaches
Headache that awakens one from sound sleep
Headache associated with trauma
Headache associated with systemic symptoms, e.g., fever, malaise, or weight loss
Most of the above signs and symptoms may occur in chronic benign headache (e.g., tension-migraine)

Table 18-10 Serious Causes of Headache in Which Neuroimaging Findings May Be Normal

Cranial arteritis
Glaucoma
Trigeminal or glossopharyngeal neuralgia
Lesions around sella turcica
Warning leak of aneurysm (sentinel bleed)
Inflammation, infection, or neoplastic invasion of leptomeninges
Cervical spondylosis
Pseudotumor cerebri
Low intracranial pressure syndromes (cerebrospinal fluid leaks)

Pharmacotherapy along with psychologic and physical therapy are components of an approach to treating headache. An overview of pharmacologic treatment is shown in Tables 18-11 and 18-12.

Abortive headache medications may range from simple analgesics to anxiolytics, nonsteroidal anti-inflammatory drugs, ergots, and corticosteroids to major tranquilizers and narcotics. Dihydroergotamine mesylate (DHE 45) and sumatriptan, as well as related serotonin 1B/1D receptor agonists (the triptans: zolmitriptan, naratriptan, rizatriptan, almotriptan, eletriptan, and frovatriptan), are effective in aborting acute migraine attacks. Dihydroergotamine and sumatriptan can be administered parenterally or intranasally to patients who have severe nausea or vomiting. Sumatriptan and other vasoconstrictor drugs are contraindicated in patients with migraine associated with a focal neurologic deficit and in patients with symptomatic coronary artery disease.

Prophylactic medication should be given when the attacks occur more than 2 or 3 times a month or even less frequently if they are incapacitating, associated with focal neurologic signs, or of prolonged duration. When prophylactic medication is indicated, the following should be observed:

1. Begin with a low dose and increase it slowly
2. Perform an adequate trial of medication (1-2 months)
3. Confirm that the patient is not taking drugs that may interact with the headache agent (vasodilator, estrogens, or oral contraceptives)
4. Determine that a female patient is not pregnant and that she is using effective contraception
5. Attempt to taper and discontinue use of prophylactic medication after the headaches are well controlled
6. Avoid polypharmacy
7. Establish a strong doctor-patient partnership; emphasize that management of headache is often a team effort, with the patient having a role equal to that of the physician
8. The best medication is *no* medication

Drugs used for prophylaxis include β-blockers, calcium channel blockers, amitriptyline or nortriptyline, valproic acid, and other anticonvulsants (gabapentin or topiramate). The most widely used β-blocker is propranolol; others are atenolol, metoprolol, and timolol. Valproic acid is an excellent preventive agent, but its use may be limited because of weight gain and hair loss. Amitriptyline is particularly useful in patients with migraine and chronic-type tension headache. Verapamil is a good alternative to β-blockers in athletes and is recommended for patients with suspected vasospasm as a cause of migrainous infarction. There is excellent evidence that topiramate is effective in prevention of migraine at a dosage of 50 mg twice a day.

Naproxen and other nonsteroidal anti-inflammatory drugs produce analgesia through alternate pathways that do not appear to induce dependence. They may be useful for the following headaches: migraine, for both acute attacks and prophylaxis; menstrual migraine (especially naproxen); benign exertional migraine and sex-induced headache (especially indomethacin); cluster variants (chronic paroxysmal hemicrania, episodic paroxysmal hemicrania, and hemicrania continua); idiopathic stabbing headache, jabs-and-jolts, needle-in-the-eye, and ice-pick headaches (indomethacin is often effective); muscle contraction headaches; mixed headaches; and ergotamine-induced headache.

Cluster Headache

Cluster headache, unlike migraine, predominantly affects men. Onset usually occurs in the late 20s but may occur at any age. The main feature is periodicity. On average, the cluster period lasts 2 to 3 months and typically occurs every 1 or 2 years. Attacks occur at a frequency of 1 to 3 times daily and tend to be nocturnal in more than 50% of patients. The average period of remission is about 2 years between clusters. Cluster is not associated with an aura. The pain reaches a peak in about 10 to 15 minutes and lasts 45 to 60 minutes. It is excruciating, penetrating, usually nonthrobbing, and maximal behind the eye and in the region of the supraorbital nerve and temples. Attacks of pain typically are unilateral. The autonomic features are both sympathetic paresis and parasympathetic overreaction. They may include 1) ipsilateral lacrimation, injection of the conjunctiva, and nasal stuffiness or rhinorrhea, and 2) ptosis and miosis (ptosis may become

Gabapentin
Verapamil
Botulinum toxin type A

permanent), periorbital swelling, and bradycardia. The scalp, face, and carotid artery may be tender. In contrast to migraineurs, patients with cluster headaches tend to be hyperactive during a headache.

- Cluster headache affects mostly men, with onset in the 20s.
- Periodicity is the main feature.
- The cluster period lasts 2-3 months.
- Cluster headache is not associated with an aura.
- The pain peaks in 10-15 minutes and lasts 45-60 minutes.
- The pain typically is unilateral, excruciating, penetrating, nonthrobbing, and maximal behind the eye.
- In >50% of patients, the pain is nocturnal.
- Autonomic features are present.

Abortive therapy includes oxygen inhalation, 5 to 8 L/min for 10 minutes; sumatriptan; dihydroergotamine; ergotamine, suppositories; corticosteroids (e.g., 8 mg dexamethasone); local anesthesia (intranasal 4% lidocaine); and capsaicin in the ipsilateral nostril. Sumatriptan is the drug of choice for management of an acute attack of cluster headache. Surgical intervention may be indicated under certain circumstances for chronic cluster headache but never for episodic headache.

Prophylactic treatment is the mainstay of cluster headache treatment. Calcium channel blockers (verapamil) are widely used. The usual dose of lithium is 600 to 900 mg in divided doses. Its effectiveness is known within 1 week. Topiramate has proved useful in cluster headache treatment. Methysergide is most effective in the early course of the disease and least effective in later years. Ergotamine at bedtime is particularly beneficial for nocturnal attacks. Corticosteroids are helpful for short-term treatment, especially for patients resistant to the above drugs or to a combination of the above. The usual dose is 40 mg prednisone tapered over 3 weeks. The most effective treatment for chronic cluster headache is the combination of verapamil and lithium. Valproic acid may also be useful.

- Prophylaxis of cluster headaches is the mainstay of treatment.
- Calcium channel blockers are widely used.
- Methysergide is effective early in the disease.
- Ergotamine is effective for nocturnal attacks.
- Corticosteroids are helpful short-term.
- The combination of verapamil and lithium is best for prophylaxis of chronic cluster headache.

Typical Clinical Scenarios

- Migraine: A young patient has recurrent, episodic (once a month or so), and severe headaches. Often, the headache is unilateral and associated with nausea, vomiting, and photophobia. MRI is normal.
- Tension headache: A young patient has a 3-year history of headaches, which occur almost every month and last several days. They are bilateral and are not associated with any neurologic deficit, nausea, or vomiting.
- Cluster headache: A 27-year-old man has a 1-month history of severe, excruciating headaches that occur daily and last for approximately 1 hour. He had a similar episode 1 year ago, in which the headache lasted 3 months and then resolved completely. The pain is unilateral and worse behind the right eye. The right eye becomes red and teary during the headache.

Medication-Overuse Headache

Chronic daily headache may occur de novo, probably as a form of tension headache or, more important, it may be part of an evolution from periodic migraine or tension headache. Chronic daily headache is often accompanied by sleep disturbances, depression, anxiety, and overuse of analgesics; most patients with this disorder have a family history of headache. Episodic migraine and other episodic benign headaches can evolve into a daily refractory, intense headache. This syndrome is usually due to the overuse (>2 days a week) of ergotamine tartrate, analgesics (especially analgesics combined with

Table 18-12 Choice of Triptan According to the Attack

Pattern	Drug of choice*
Daytime attack, moderate to severe	Almotriptan (12.5 mg) Eletriptan (80 mg) Rizatriptan (10 mg)
Severe nausea or vomiting	Rizatriptan MLT (10 mg) Zolmitriptan MLT (2.5 mg) Zolmitriptan NS (5 mg)
Pain that awakens the patient	Sumatriptan SQ (6 mg) Zolmitriptan NS (5 mg)
Frequent, long-duration attacks	Frovatriptan (2.5 mg BID) Naratriptan (1-2.5 mg BID) Zolmitriptan (2.5 mg BID)

BID, twice daily; SQ, subcutaneously.
*If tolerance is a concern, choose almotriptan (12.5 mg) or naratriptan (2.5 mg).

barbiturates), narcotics, and perhaps even benzodiazepines. To control the headache, the use of these medications has to be discontinued. Two points must be stressed: the overuse of these medications causes daily headache, and the daily use of these medications prevents other useful medications from working effectively.

The treatment of daily refractory headaches can require hospitalization and withdrawal of the overused medication, with repetitive intravenous administration of dihydroergotamine together with an antiemetic drug such as metoclopramide or prochlorperazine.

β-Blockers, calcium channel blockers, and tricyclic antidepressants do not cause transformation/withdrawal syndrome. Also, patients who do not have headache but who take large amounts of analgesics for other conditions, for example, arthritis, do not develop analgesic or rebound headache. Simple withdrawal of analgesics produces marked improvement in patients with chronic daily headache. A nonprescription medication can be withdrawn abruptly. However, prescription medications (ergotamine tartrate, narcotics, and barbiturates) have to be withdrawn gradually. When narcotics or compounds containing codeine and ergotamine tartrate are withdrawn, clonidine may be helpful in repressing withdrawal symptoms. Some physicians think that even simple analgesics (e.g., aspirin and acetaminophen) taken more than 2 days a week can cause daily headache syndrome. The overuse (more than 3 days a week for 2 weeks or more) of triptan drugs is now becoming a common cause of medication-overuse syndrome.

- Chronic daily headache is often accompanied by sleep disturbances, depression, anxiety, and analgesic overuse.
- Most patients with chronic daily headache have a family history of headache.
- Migraine and other headaches can become a refractory intense headache.
- Overuse of medications causes daily headache and prevents the effective action of other drugs.
- Hospitalization and withdrawal of overused drugs are usually required.
- Nonsteroidal anti-inflammatory drugs, β-blockers, calcium channel blockers, and tricyclic antidepressants do not cause transformation/withdrawal syndrome.
- There is improvement after withdrawal of analgesics.

Temporal Arteritis

In an elderly person, temporal arteritis (also called *cranial arteritis* or *giant cell arteritis*) should be in the differential diagnosis of any new temporal headache of mild to moderate severity. About 50% of persons with this diagnosis have headache or tender temporal arteries. Common additional symptoms include low-grade fever, jaw claudication, weight loss, anorexia, and other systemic symptoms. The erythrocyte sedimentation rate or the C-reactive protein concentration (or both) is consistently increased. If vision loss has already occurred, emergent therapy with high doses of corticosteroids is needed. To prevent vision loss in those who have no visual problem, prednisone therapy should be initiated immediately after the diagnosis has been made. Temporal artery biopsy is used to confirm the diagnosis before long-term treatment with prednisone is prescribed. However, if the biopsy cannot be performed immediately, prednisone therapy may be initiated until the biopsy is performed. The erythrocyte sedimentation rate may be followed to help gauge the response to treatment. The prednisone dose can be tapered slowly after several months of therapy, although long-term treatment with prednisone may be needed.

Polymyalgia rheumatica is another rheumatologic syndrome that is sometimes associated with cranial arteritis. It affects elderly patients and is associated with aching or pain and stiffness in the neck, upper back, shoulders, upper arms, and hip girdle. Systemic symptoms include various degrees of fever, anorexia, weight loss, apathy, and depression. True muscle weakness is not present except when attributed to pain.

Trigeminal Neuralgia

Characteristically, patients with trigeminal neuralgia always have symptoms on the same side and usually in the second or third division of the trigeminal nerve. The idiopathic variety occurs in middle-aged and elderly patients and is heralded by a sharp, lancinating pain that usually can be triggered. Chewing, talking, or touching the skin or teeth often precipitates the pain of trigeminal neuralgia, and swallowing often precipitates the pain of glossopharyngeal neuralgia.

In the elderly, trigeminal neuralgia may be caused by an enlarged artery (rarely a vein) that compresses the trigeminal nerve. This can be seen on MRI or MRA. Importantly, in idiopathic trigeminal neuralgia, sensory and motor functions of the trigeminal nerve are normal. If there are signs or symptoms other than pain, evaluate for other compressive lesions, for example, neoplasm. Consider the possibility of multiple sclerosis if trigeminal neuralgia occurs in a young person. Treatment options include carbamazepine, phenytoin, baclofen, gabapentin, and clonazepam. Surgical treatment includes alcohol blocks, radiofrequency ablation of the gasserian ganglion (cranial nerve [CN] V), gamma knife radiosurgery, and an open craniotomy with microvascular decompression.

- Chewing, talking, or touching often precipitates pain in trigeminal neuralgia, as does swallowing in glossopharyngeal neuralgia.
- In idiopathic trigeminal neuralgia, there should be no other neurologic signs or symptoms when the patient is examined during an asymptomatic period.
- Consider multiple sclerosis if trigeminal neuralgia occurs in a young person.

Glossopharyngeal Neuralgia

The pain in glossopharyngeal neuralgia is similar to that in trigeminal neuralgia, but it occurs in the throat and neck and often radiates to the ear. Glossopharyngeal neuralgia may cause hypotension and syncope. It is usually idiopathic but has been reported with leptomeningeal metastasis or jugular foramen syndrome (head and neck malignancies). The treatment is the same as for trigeminal neuralgia, that is, carbamazepine and, occasionally, surgical management.

- Glossopharyngeal pain occurs in the throat and neck and radiates to the ear.

Intracranial Lesions

Leptomeningeal Lesions

Patients with inflammation, infection, or neoplastic invasion of the leptomeninges may present with similar signs and symptoms, as follows:

1. Cerebral—headache, seizures, and focal neurologic signs
2. Cranial nerve—any cranial nerve can be affected, especially CN III, IV, VI, and VII (CN VII is often affected in Lyme disease)
3. Radicular (radiculoneuropathy or radiculomyelopathy)—neck and back pain as well as radicular pain and spinal cord signs

Parasagittal Lesions

Because the cortical leg area and cortical area for control of the urinary bladder are located on the medial surface of each hemisphere, parasagittal lesions can cause spastic paraparesis with urinary problems. Meningioma is a common lesion in this location and may also cause seizures and headache.

- Parasagittal lesions may cause paraparesis with urinary problems.
- Meningioma may also cause seizures and headache.

Cortical Lesions

Cortical lesions produce focal signs. If the lesions are in the dominant hemisphere (usually the left), they cause language dysfunction, including problems of reading, writing, and speaking. Cortical lesions can also impair higher intellectual function, producing apraxia, agnosia, and neglect (denial of illness or body parts), and they often impair cortical sensation (e.g., joint position sense, traced figures, and stereognosis). A dense loss of primary sensation (e.g., pinprick and touch) occurs with thalamic lesions.

- Cortical lesions may produce aphasia, apraxia, and agnosia.
- Thalamic lesions cause loss of primary sensation (e.g., touch and pinprick).

Ventricular System

Hydrocephalus

A combination of signs and symptoms—impaired mental status, gait disturbance, and urinary problems—suggests hydrocephalus. If it is the obstructive type, signs of increased intracranial pressure may be present, including lethargy, nausea, vomiting, and headache; obscurations of vision are often associated with changes in position.

The following are types of hydrocephalus:

1. Communicating hydrocephalus
   a. Hydrocephalus ex vacuo—due to the loss of parenchyma, either gray or white matter, and not associated with the signs listed above (if the hydrocephalus is due to aging, the findings on neurologic examination are normal; if it is due to Alzheimer disease, clinical examination shows signs of dementia)
   b. Normal-pressure hydrocephalus—due to decreased reabsorption of CSF
   c. Hydrocephalus due to overproduction of CSF—rare and controversial; supposedly occurs with choroid plexus tumors
2. Obstructive (noncommunicating) hydrocephalus—due to an obstructive lesion anywhere in the ventricular system

- Normal-pressure hydrocephalus is due to decreased reabsorption of CSF and may be associated with urinary symptoms, gait disturbance, and memory dysfunction (see the "Dementia" subsection above).

Posterior Fossa Level: Symptoms and Clinical Correlations

Brainstem Lesions

Brainstem lesions can produce crossed neurologic syndromes; cranial nerve signs are ipsilateral to the lesion, but long-tract signs (i.e., corticospinal) are usually contralateral (crossed syndrome). Other symptoms associated with brainstem lesions include impairment of ocular motility; medial longitudinal fasciculus syndrome (internuclear ophthalmoplegia); rotary, horizontal, and vertical nystagmus (downbeat nystagmus is highly suggestive of a lesion at the cervicomedullary junction); ataxia; dysarthria; diplopia; vertigo; and dysphagia.

- Long-tract signs are usually contralateral to the brainstem lesion.
- Downbeat nystagmus is highly suggestive of a lesion at the cervicomedullary junction.
- Cranial nerve signs are ipsilateral to the brainstem lesion.

Cerebellar Lesions

Problems with equilibrium and coordination suggest a cerebellar lesion. Lesions of the cerebellar hemisphere usually produce ipsilateral ataxia of the arm and leg. Lesions restricted to the anterior superior vermis, as in alcoholism, usually cause ataxia of gait, that is, a wide-based gait and heel-to-shin ataxia, with relative sparing of the arms, speech, and ocular motility. Lesions of the flocculonodular lobe cause marked difficulty with equilibrium and walking but not much difficulty with finger-to-nose and heel-to-shin tests if the patient is lying down.

Vertigo and Dizziness

Accurate visual, vestibular, proprioceptive, tactile, and auditory perceptions are necessary for normal spatial orientation. These inputs are integrated in the brainstem and cerebral hemispheres. The outputs are the cortical, brainstem, and cerebellar motor systems. The impairment of any of these functions or their input, integration, or output causes a complaint of "dizziness" (a sensation of altered orientation or space). Dizziness, vertigo, and dysequilibrium are common complaints. The results of diagnostic tests are often normal. Diagnosis depends mainly on the medical history, with physical examination findings in some cases. Vestibular tests rarely provide an exact diagnosis. The types of dizziness are listed in Table 18-13.

Vertigo

Vertigo is an illusion of movement (usually that of rotation) and the feeling of vertical or horizontal rotation of either the person or the

Height vertigo

environment around the person. Most patients report this as "spinning" or "rotational" feelings. Others experience mainly a sensation of staggering. In contrast to vertigo, "dysequilibrium" is a feeling of unsteadiness or insecurity about the environment, without a rotatory sensation. Vertigo occurs when there is imbalance, especially acute, between the left and right vestibular systems. The sudden unilateral loss of vestibular function is dramatic; the patient complains of severe vertigo and nausea and vomiting and is pale and diaphoretic. With acute vertigo, the patient also has problems with equilibrium and vision, often described as "blurred vision," or diplopia. Autonomic symptoms are common—sweating, pallor, nausea, and vomiting—and occasionally can cause vasovagal syncope.

Fluctuating hearing loss and tinnitus are characteristic of Ménière disease. Abrupt complete unilateral deafness and vertigo occur with viral involvement of the labyrinth or CN VIII (or both) and with vascular occlusion of the inner ear. Patients who slowly lose vestibular function bilaterally, as with ototoxic drugs, often do not complain of vertigo but have oscillopsia with head movements and instability with walking. Even with unilateral vestibular loss, if it is a slow process (acoustic neuroma), patients usually do not complain of vertigo; they typically present with unilateral hearing loss and tinnitus. Vertigo invariably occurs in episodes. Common vestibular disorders with a genetic predisposition include migraine, Ménière disease, otosclerosis, neurofibromatosis, and spinocerebellar degeneration.

Benign positional vertigo is the most common cause of vertigo. Symptoms include brief episodes of vertigo that usually last less than 30 seconds with positional change, for example, turning over in bed, getting in or out of bed, bending over and straightening up, and extending the neck to look up. No cause is found in about half of the patients. For the other half, the most common causes are posttraumatic and postviral neurolabyrinthitis.

Typically, bouts of benign positional vertigo are intermixed with variable periods of remission. Periods of vertigo rarely last longer than 1 minute, although after a flurry of episodes, patients may complain of more prolonged nonspecific dizziness that lasts hours to days (light-headedness or a swimming sensation associated with nausea). Management includes reassurance, positional exercises (vestibular exercises), and the canalith repositioning maneuver. Drugs are not very useful, but meclizine and promethazine may help with the nausea and nonspecific dizziness. Rarely, in intractable cases, surgical treatment (section of the ampullary nerve) may be undertaken.

Vertigo of CNS origin is caused by acute cerebellar lesions (hemorrhages or infarcts) or acute brainstem lesions (especially the lateral medullary [Wallenberg] syndrome). Vertebrobasilar arterial disease is also a cause, but vertigo by itself is almost never a TIA. Other symptoms are necessary to make the diagnosis of vertebrobasilar insufficiency, such as dysarthria, dysphagia, diplopia, facial numbness, crossed syndromes, hemiparesis or alternating hemiparesis, ataxia, and visual field defects.

Presyncopal Light-Headedness

Presyncopal light-headedness is best described as the *sensation of impending faint*. It results from pancerebral ischemia. Presyncopal light-headedness is not a symptom of focal occlusive cerebrovascular disease, but it may indicate orthostatic hypotension, usually due to decreased blood volume, chronic use of antihypertensive drugs, or autonomic dysfunction. Symptoms of vasovagal attacks are induced when emotions such as fear and anxiety activate medullary vasodepressor centers. Vasodepressor episodes can also be precipitated by acute visceral pain or sudden severe attacks of vertigo. Impaired cardiac output causes presyncopal light-headedness, as does hyperventilation. Chronic anxiety with associated hyperventilation is the most common cause of persistent presyncopal light-headedness in young patients. In most subjects, only a moderate increase in respiratory rate can decrease the Pa_{CO_2} level to 25 mm Hg or less in a few minutes.

Five types of syncopal attacks especially common in the elderly are the following:

1. Orthostatic—multiple causes
2. Autonomic dysfunction due to peripheral (postganglionic) or central (preganglionic) involvement
3. Reflex—such as carotid sinus syncope or cough or micturition syncope
4. Vasovagal syncope—occurs less frequently in the elderly than in the young; however, the prognosis is worse in the elderly, with about 16% of them having major morbidity or mortality in the following 6 months compared with less than 1% of patients younger than 30 years; common

precipitating events in the elderly include emotional stress, prolonged bed rest, prolonged standing, and painful stimuli
5. Cardiac syncope

- Presyncopal light-headedness is the sensation of impending faint.
- It is not an isolated symptom of occlusive cerebrovascular disease.
- Vasovagal attacks occur less frequently in the elderly.
- In the young, a common cause of persistent presyncopal light-headedness is chronic anxiety with hyperventilation.
- The prognosis of vasovagal syncope is worse for the elderly; 16% have major morbidity or mortality within 6 months.
- In the elderly, vasovagal syncope may be precipitated by emotional stress, bed rest, prolonged standing, or pain.

Psychophysiologic Dizziness

Patients usually describe psychophysiologic dizziness as "floating," "swimming," or "giddiness." They also may report a feeling of imbalance, a rocking or falling sensation, or a spinning inside the head. The symptoms are not associated with an illusion of movement or movement of the environment or with nystagmus. Commonly associated symptoms include tension headache, heart palpitations, gastric distress, urinary frequency, backache, and a generalized feeling of weakness and fatigue. Psychophysiologic dizziness can also be associated with panic attacks.

Dysequilibrium

Patients who slowly lose vestibular function on one side, as with an acoustic neuroma, usually do not have vertigo but often describe a vague feeling of imbalance and unsteadiness on their feet. Dysequilibrium may be a presenting symptom of lesions involving motor centers of the basal ganglia and frontal lobe, for example, Parkinson disease, hydrocephalus, and multiple lacunar infarctions. The broad-based ataxic gait of cerebellar disorders is readily distinguished from milder gait disorders seen with vestibular or sensory loss or with senile gait.

- Dysequilibrium may be a presenting symptom of basal ganglia, frontal lobe, or cerebellar lesions.

Multisensory Dizziness

Multisensory dizziness is common in the elderly and especially in patients with systemic disorders such as diabetes mellitus. A typical combination includes, for example, mild peripheral neuropathy that causes diminished touch and proprioceptive input, decreased visual acuity, impaired hearing, and decreased baroreceptor function. In these patients, an added vestibular impairment, as from an ototoxic drug, can be devastating.

The resulting sensation of dizziness is usually present only when the patient walks or moves and not when supine or seated. There is a feeling of insecurity of gait and motion. The patient is usually helped by walking close to a wall, using a cane, or by holding on to another person. Drugs should not be prescribed for this disorder. Instead, the use of a cane or walker is important to improve support and to increase somatosensory signals.

- Multisensory dizziness is common in elderly diabetic patients.
- Added vestibular impairment can be devastating.
- Do not prescribe drugs for this disorder.

Spinal Level: Symptoms and Clinical Correlations

Sensory levels, signs of anterior horn cell involvement (atrophy and fasciculations), and long-tract signs in the posterior columns, corticospinal tract, and spinothalamic tract suggest a spinal cord lesion. Extramedullary cord lesions are usually heralded by radicular pain. Intramedullary cord lesions are usually painless but may have an ill-described nonlocalizable pain, sensory dissociation, and sacral sparing. Conus medullaris lesions are often indicated by "saddle anesthesia" and early involvement of the urinary bladder.

- Extramedullary lesions are heralded by radicular pain.
- Intramedullary lesions are usually painless.
- Conus medullaris lesions are indicated by saddle anesthesia and early bladder involvement.

Causes of Myelopathy

A compressive or noncompressive spinal cord lesion may cause muscle weakness, which typically occurs in the arm and leg if the lesion is at the cervical level or only in the leg if the lesion is below the lower cervical level. The upper motor neuron pattern weakness is often bilateral and prominent in lower extremity flexors (iliopsoas, hamstrings, and anterior tibialis) and upper extremity extensors (triceps and wrist extensors). Bowel and bladder difficulties and numbness are frequently noted. The findings on examination include limb weakness, spasticity, and increased muscle stretch reflexes below the level of the lesion. Extensor plantar reflexes may also be elicited. Sensory findings are often noted.

The most common noncompressive lesion is transverse myelitis, usually of unknown cause. Some patients have a history of vaccination or symptoms suggestive of viral disease that usually precede the neurologic symptoms by a few days to 1 or 2 weeks.

Compressive myelopathy is commonly due to degenerative spine or disk disease or to metastatic epidural neoplasm. The patients usually present with local vertebral column pain at the level of the spinal cord lesion. This symptom is present for weeks to months before the gross neurologic deficits occur, although occasionally bony pain may antedate other symptoms by only a few hours.

- Muscle weakness may be associated with a compressive or noncompressive spinal cord lesion.
- Transverse myelitis is the most common noncompressive lesion.

Motor Neuron Disease

Degenerative disorders that affect the motor neurons in the cerebral cortex and the anterior horn cells are called *motor neuron diseases*. The most common one is amyotrophic lateral sclerosis (ALS). This disorder is the main cause of painless weakness. Typically, patients present with asymmetric weakness that usually begins distally and is associated with cramps and fasciculations. Footdrop and hand weakness are the most common first complaints. Often the initial,

but incorrect, diagnosis is stroke, radiculopathy, carpal tunnel syndrome, or ulnar neuropathy. Some ALS patients have undergone unnecessary operations (e.g., spinal or carpal tunnel procedures) before the correct diagnosis is made. Bulbar weakness (dysarthria and dysphagia) can be the presenting problem and is always eventually present. Bowel and bladder difficulties are very uncommon, and sensory abnormalities are not noted. Findings on examination include weakness, atrophy, fasciculations, and decreased or increased muscle stretch reflexes and extensor plantar responses. The hallmark is the mixture of both upper and lower motor neuron signs. Because of the progressive weakness affecting the limbs, bulbar muscles, and diaphragm, the disease is devastating, and patients have an average life span of 3 years after the onset of symptoms.

ALS is sporadic in 80% to 90% of cases. In those that are familial, 10% of the patients harbor a mutation in the oxygen radical detoxifying enzyme superoxide dismutase (SOD-1). No drug has been found to be effective in reversing the progressive course of this disease. Some beneficial effect has been noted with riluzole, especially in patients with bulbar onset of the disease. This drug prolongs ventilator-free survival by 3 months. Treating ALS with immunosuppression, such as by use of irradiation, corticosteroids, cyclophosphamide, or intravenous immunoglobulin (IVIG), is at best futile and at worst, costly and harmful. Recent failures include gabapentin, lamotrigine, and celecoxib. Treatment of ALS focuses on rehabilitation issues, nutrition, mobility, and communication in which a multidisciplinary approach is useful.

Multifocal motor neuropathy is a syndrome of purely lower motor neuron disease that can mimic ALS. Treatment for multifocal motor neuropathy with IVIG can be very effective. It is often distal and asymmetrical, accompanied by motor conduction block on NCS and EMG, and associated with high titers of serum antibodies to GM_1 gangliosides. Kennedy disease is a pure lower motor neuron degenerative process that is X-linked and caused by an excess of CAG repeats in the androgen receptor gene. This most commonly affects elderly men and also leads to gynecomastia, diabetes, and a sensory peripheral neuropathy. Genetic testing is widely available. There is no effective treatment, although the disease is much more benign than ALS.

Radiculopathy

Nerve root lesions usually are indicated by pain that is often sharp and lancinating, follows a dermatomal or myotomal pattern, and is increased by increasing intraspinal pressure (e.g., sneezing and coughing) or by stretching of the nerve root. Paresthesias and pain occur in a dermatomal pattern. Findings are in the root distribution and include weakness, sensory impairment, and decreased muscle stretch reflexes. Radiculopathies have many causes, including compressive lesions (osteophytes, ruptured disks, and neoplasms) and noncompressive lesions (postinfectious and inflammatory radiculopathies and metabolic radiculopathies, as in diabetes). Indications for emergent neurologic and neurosurgical consultation are increasing weakness, bowel or bladder dysfunction, or intractable pain with an appropriate lesion seen on MRI. Large disk protrusions can cause minimal symptoms and are not by themselves grounds for urgent surgical intervention.

- Nerve root lesions are indicated by sharp, lancinating pain with a dermatomal or myotomal pattern.
- Pain is increased by sneezing and coughing.
- Pain often has a dermatomal pattern.
- Findings are weakness, sensory impairment, and decreased muscle stretch reflexes.
- Radiculopathies have many causes.
- Surgery is considered for increasing weakness, bowel or bladder dysfunction, or intractable pain with an appropriate lesion seen on MRI.

Degenerative Disease of the Spine

Cervical Spondylosis

MRI in combination with plain radiographs is the preferred approach for evaluating patients who have cervical spondylosis. Surgical results for the relief of symptoms of cervical radiculopathy are better when the cause is a soft disk herniation than when spondylitic radiculopathy and myelopathy are present. In fact, surgical treatment of cervical radiculopathy due to the herniation of a soft disk is so successful that most patients and doctors prefer surgical therapy to prolonged conservative treatment. Surgical treatment for cervical spondylitic myelopathy is much less successful, with fewer than two-thirds of patients having improvement, although the condition stabilizes in most. Cervical spondylitic myelopathy is a condition in which the spinal cord is damaged either directly by traumatic compression or indirectly by arterial deprivation or venous stasis as a consequence of proliferative bony changes in the cervical spine.

Lumbar Spine Disease

Bulging disks after the age of 30 years should be considered normal and are unlikely to cause nerve root compression. Bulging disks appear round and symmetrical compared with herniated disks, which appear angular and asymmetrical and extend outside the disk space. The criteria for surgical treatment of lumbar disk herniations include the presence of disk herniation on anatomical imaging; dermatome-specific reflex, sensory, or motor deficits; and failure of 6 to 8 weeks of conservative treatment.

The lateral recess syndrome is usually caused by an osteophyte on the superior articular facet and is characterized by the following: radicular pain that is unilateral or bilateral with paresthesias in the distribution of L5 or S1; the pain is provoked by standing and walking and is relieved by sitting; the results of the straight leg raising test are usually negative; and there is little or no back pain.

Lumbar stenosis is characterized by the following: most patients are older than 50 years; neurogenic intermittent claudication (pseudoclaudication) occurs; the symptoms are usually bilateral but can be asymmetrical or unilateral; the pain usually has a dull, aching quality; the whole lower extremity is generally involved; the pain is provoked while walking or standing; sitting or leaning forward provides relief; and there is often a "dead" feeling in the legs. Bicycling causes little or no pain. Decompressive operations for lumbar stenosis can be performed with low morbidity despite the advanced age of most patients. A very high initial success rate can be expected, although about 25% of patients become symptomatic again within 5 years. On

reoperation, three-fourths of the patients ultimately have a successful outcome; failures result from progression of stenosis at levels not previously decompressed or restenosis at levels previously decompressed.

Musculoskeletal low back pain (without leg pain) is treated best with a formal program of physical therapy and exercise, weight reduction, and education on postural principles.

Peripheral Level: Symptoms and Clinical Correlations

Neuropathy

Peripheral neuropathies are usually characterized by distal weakness and distal sensory changes. They are usually symmetrical, more severe in the legs than in the arms, and often accompanied by impaired or absent distal muscle stretch reflexes. Weakness related to peripheral nerve disorders is typically worse distally, occasionally with footdrop. Clumsy gait is often associated with distal numbness and paresthesias. Examination findings include distal weakness, sensory loss, atrophy, and, sometimes, fasciculations. Muscle stretch reflexes usually are decreased. If a single plexus (lumbosacral or brachial) is involved, the weakness may be isolated to a single limb. However, the findings still are consistent with a "lower motor neuron" lesion, with decreased reflexes, weakness, atrophy, and sensory loss. Neuropathy has many causes, and the pattern of the neuropathy might suggest its cause (Table 18-14). The evaluation of peripheral neuropathy is summarized in Table 18-15. An extensive search usually uncovers the cause in 70% to 80% of cases. A high percentage of the cases of "idiopathic neuropathy" referred to specialty centers are in fact hereditary neuropathies.

- The pattern of neuropathy and time course suggest the cause.
- Peripheral neuropathy: distal weakness and sensory changes more in the legs than in the arms, usually symmetrical, and with distal muscle stretch reflexes impaired or absent.
- The cause of peripheral neuropathy is usually found in 70%-80% of cases.

Mononeuropathy

Mononeuropathy is characterized by sensory and motor impairment in a single nerve. The usual cause is compression, as in compressive ulnar neuropathy at the elbow, compressive median neuropathy in the carpal tunnel, and compression of the peroneal nerve as it winds around the fibular head.

Mononeuropathy Multiplex

Mononeuropathy multiplex consists of asymmetrical involvement of several nerves either simultaneously or sequentially. It suggests such causes as trauma or compression, diabetes mellitus, vasculitis, Lyme disease, HIV neuropathy, sarcoidosis, leprosy, tumor infiltration, multifocal motor neuropathies, or hereditary neuropathy with predisposition to pressure palsies.

- Mononeuropathy multiplex: diabetes, vasculitis, leprosy, sarcoidosis, and Lyme disease.

Acute Inflammatory Polyradiculoneuropathy

A progressive neuropathy of rapid onset that affects both distal and proximal nerves suggests acute inflammatory demyelinating polyradiculoneuropathy (AIDP), or Guillain-Barré syndrome. The weakness and paresthesias ascend over several days, often accompanied by severe back pain. On examination, the reflexes are absent. There may also be respiratory muscle weakness, cranial neuropathy (particularly facial palsy, which can be bilateral), and autonomic instability. Typically, it is associated with an increased CSF protein concentration but no pleocytosis. There are characteristic NCS and EMG findings with conduction block and temporal dispersion. About 50% of patients have a mild respiratory or gastrointestinal tract infection 1 to 3 weeks before the neurologic symptoms appear. In the other patients, the syndrome may be preceded by surgery, viral exanthems, or vaccinations. Also, the syndrome may develop in patients who have autoimmune disease or a lymphoreticular malignancy. This syndrome has no particular seasonal, age, or sex predilection. Either plasma exchange or IVIG is effective in AIDP. Steroids are not effective. Attention must be paid to other complications of the disease: deep venous thrombosis, constipation, back pain, tachyarrhythmias and hypertension, peptic ulcers, decubital ulcers, and accumulation of secretions in the respiratory tract and aspiration.

- In Guillain-Barré syndrome, 50% of patients have a mild respiratory or gastrointestinal tract infection 1-3 weeks before neurologic symptoms appear.
- Surgery, viral exanthems, or vaccinations may precede Guillain-Barré syndrome.
- The diagnosis is made clinically with support from NCS, EMG, and CSF analysis.
- Treatment is with either plasma exchange or IVIG.

Typical Clinical Scenarios

- Guillain-Barré syndrome: A 35-year-old patient has a fairly acute, 1-week history of weakness in both legs that is progressively worsening. The patient does not have any constitutional symptoms, and the results of routine laboratory testing are unremarkable. The patient has some tingling sensation in both feet. Neurologic examination shows mild sensory loss over the toes and generalized loss of deep tendon reflexes. The Babinski sign is not elicited. CSF analysis shows a high concentration of protein but no increase in cell count.
- Amyotrophic lateral sclerosis ("motor neuron disease"): A 50-year-old patient has a 6-month history of slowly progressive muscle weakness. Weakness involves all four extremities. It started with a left footdrop and now also involves proximal muscles. Physical examination demonstrates muscle wasting and fasciculations. The upper limb reflexes are absent, the lower limb reflexes are brisk, and the Babinski sign is elicited. No sensory abnormalities are detected on examination.

Other causes of subacute, predominantly motor neuropathy are Lyme disease, HIV- or cytomegalovirus-related polyradiculopathy, porphyria, organophosphate poisoning, hypoglycemia, toxins (arsenic and thallium), and malignancy. Acute intermittent porphyria produces a severe,

Table 18-14 Main Clinical Features and Differential Diagnosis of Peripheral Neuropathies

Table 18-14 (continued)

Pattern of neuropathy	Common or important causes
Neuropathy with prominent autonomic involvement	Acute or subacute Guillain-Barré syndrome Subacute pandysautonomia Paraneoplastic pandysautonomia Porphyria Vincristine neuropathy Botulism Chronic Diabetes mellitus Amyloidosis Sjögren syndrome

AIDP, acute inflammatory demyelinating polyradiculopathy; CIDP, chronic inflammatory demyelinating polyradiculoneuropathy; CMV, cytomegalovirus; HIV, human immunodeficiency virus.

rapidly progressive, symmetrical polyneuropathy with or without psychosis, delirium, confusion, and convulsions. In most patients, weakness is most pronounced in the proximal muscles. Tick paralysis is a rapid, progressive ascending motor weakness caused by neurotoxin injected by the female wood tick. It occurs endemically in the southeastern and northwestern United States. After an asymptomatic period (about 1 week), symptoms develop, usually with leg weakness.

Chronic Inflammatory Neuropathies

Chronic, predominantly motor or sensorimotor neuropathies include chronic inflammatory demyelinating polyradiculoneuropathy (CIDP), paraproteinemic neuropathies (e.g., associated with POEMS, amyloidosis, or osteosclerotic myeloma), hereditary neuropathies, lead toxicity, diabetes mellitus, and amyloidosis. Most neuropathies are distal, but occasionally there is predominant proximal weakness, which suggests AIDP, CIDP, porphyria, diabetic proximal motor neuropathy (also called diabetic amyotrophy), or idiopathic brachial plexopathy (Parsonage-Turner syndrome). In sharp contrast to its lack of success in AIDP, steroid therapy works in CIDP. Plasma exchange and IVIG are also effective. The other causes of a chronic neuropathy are numerous, with diabetes and hereditary neuropathies topping the list. Hereditary neuropathies are diagnosed with a thorough family history and close examination for signs of hereditary neuropathies, such as high arched feet and hammer toes. Connective tissue diseases, vasculitis, vitamin B_{12} deficiency, copper deficiency, sarcoidosis, paraneoplastic syndromes, and medications are other potential causes.

More than 60% of neuropathies associated with monoclonal gammopathy of undetermined significance are idiopathic, but some are associated with multiple myeloma, amyloidosis, lymphoma, or leukemia. The patients usually are older than 50 years and present early with symmetrical sensorimotor radiculoneuropathy. The CSF protein concentration is usually increased; IgM is more common than IgG or IgA. Plasma exchange can be effective therapy for patients with IgG or IgA neuropathy. They have a better response than those with IgM neuropathy. Other immunosuppressive therapy such as IVIG and perhaps rituximab may also be effective.

Sensory Ataxic Neuropathy

Sensory ataxic neuropathies are characterized by severe proprioceptive sensory loss, ataxia, and areflexia. Some neuropathies are due to peripheral nerve demyelination and others to involvement of large dorsal root ganglion neurons. A predominantly sensory polyneuropathy suggests paraneoplastic disorder, Sjögren syndrome, diabetes mellitus, paraproteinemias, HIV infection, vitamin B_{12} deficiency, cisplatin toxicity, vitamin B_6 excess, or hereditary neuropathy.

Painful Neuropathy

Some peripheral neuropathies affect predominantly the small-diameter nociceptive fibers or their dorsal root ganglion neurons and are characterized by severe burning pain distally in the extremities. The examination findings are normal except for the distal loss of pain and temperature sensation. Typical causes are diabetes mellitus, vasculitis, amyloidosis, toxins, hepatitis C, cryoglobulinemia, some HIV-associated neuropathies, and alcoholism. Randomized, double-blind, placebo-controlled studies in diabetic neuropathy have shown that the following medications are helpful: amitriptyline, tramadol, gabapentin, pregabalin, and duloxetine. Others that are useful when these agents are not useful or when they lead to side effects include carbamazepine, lidocaine patch (5%), narcotics, lamotrigine, mexiletine, and venlafaxine.

Autonomic Neuropathy

Neuropathy with autonomic dysfunction (e.g., orthostatic hypotension, urinary bladder and bowel dysfunction, and impotence) suggests Guillain-Barré syndrome, acute pandysautonomia, paraneoplastic dysautonomia, porphyria, diabetes mellitus, amyloidosis, or familial neuropathy.

Acute pandysautonomia is a heterogeneous, monophasic, usually self-limiting disease that involves both the sympathetic and

parasympathetic nervous systems. It may produce orthostatic hypotension, anhydrosis, diarrhea, constipation, urinary bladder atony, and impotence. The syndrome usually evolves over a few days to a few months, with recovery generally being prolonged and partial. This may be an immunologic disorder, but it is indistinguishable from paraneoplastic autonomic neuropathy. Some of the patients may have antibodies against the ganglion-type nicotinic acetylcholine receptor. IVIG treatment limits the duration and reduces the long-term disability of patients with acute pandysautonomia.

- Motor polyneuropathy: inflammatory demyelinating polyneuropathy, hereditary neuropathy, osteosclerotic myeloma, porphyria, lead poisoning, and organophosphate toxicity.
- Sensory polyneuropathy: diabetes, paraneoplastic, Sjögren syndrome, dysproteinemias, HIV infection, vitamin B_{12} deficiency, cisplatin toxicity, vitamin B_6 excess, and hereditary neuropathy.
- Neuropathy with autonomic dysfunction: amyloidosis, diabetes, Guillain-Barré syndrome, porphyria, and familial neuropathy.

Diabetic Neuropathy

Diabetes mellitus may cause CN III neuropathy. Affected patients usually present with sudden diplopia, eye pain, impairment of the muscles supplied by CN III, and relative sparing of the pupil. With compressive CN III lesions, the pupil usually is involved early. Painful diabetic neuropathies include CN III neuropathy, acute thoracoabdominal neuropathy (truncal), acute distal sensory neuropathy, acute lumbar radiculoplexopathy, and chronic distal small-fiber neuropathy.

- Diabetes may cause CN III neuropathy.
- The pupil is involved early in compression of CN III.

Acute or subacute muscle weakness can occur in various forms of diabetic neuropathy. Weakness, atrophy, and pain affect the pelvic girdle and thigh muscles (asymmetrical or unilateral—diabetic amyotrophy). This has been termed diabetic polyradiculoplexus neuropathy and is due to a microvasculitis of the nerve. Patients with diabetes (often mild and well controlled) may have bilateral proximal and pelvic girdle weakness, wasting, weight loss, and autonomic dysfunction. Intravenous steroids may speed the recovery.

Neuromuscular Transmission Disorders

Neuromuscular transmission disorders often are missed clinically. Patients present with fluctuating weakness, with fatigable weakness in the limbs, eyelids (ptosis), tongue and palate (dysarthria and dysphagia), and extraocular muscles (diplopia). Sensation, muscle tone, and reflexes usually are normal except in Lambert-Eaton myasthenic syndrome (LEMS), in which the weakness is more constant and reflexes are diminished. Drugs may cause problems at neuromuscular junctions; for example, penicillamine can cause a syndrome that appears similar to myasthenia gravis. Three major clinical syndromes of the neuromuscular junction are myasthenia gravis, myasthenic syndrome, and botulism. Several drugs adversely affect neuromuscular transmission and may exacerbate weakness in these disorders. They include aminoglycoside antibiotics, quinine, quinidine, procainamide, propranolol, calcium channel blockers, and iodinated radiocontrast agents.

Myasthenia Gravis

Myasthenia gravis (MG) usually occurs in young women and older men and is often heralded by such cranial nerve findings as diplopia, dysarthria, dysphagia, and dyspnea. The deficits are usually fatigable, worsening with repetition or late in the day. However, muscle stretch reflexes, sensation, mentation, and sphincter function are normal. Because of remissions and exacerbations in this disease, patients can be considered "hysterical." The diagnosis of MG is based on the detection of nicotinic acetylcholine receptor antibodies and the presence of decremental responses to repetitive electrical stimulation of motor nerves. Administration of a short-acting acetylcholine esterase inhibitor (e.g., edrophonium) can immediately reverse weakness due to MG; this can be used as a diagnostic test. Acetylcholine receptor antibodies are rare in conditions other than MG (they do not occur in patients with congenital MG and in only about 50% of those with purely ocular MG). Striational antibodies are highly associated with thymoma and sometimes occur in LEMS or small cell lung carcinoma. They can occur in penicillamine recipients, bone marrow allografts, and autoimmune liver disorders. There are recent reports of antibodies to a muscle-specific kinase (MuSK) that are diagnostic for MG. These patients often have more severe weakness, often bulbar, and may be more resistant to treatments.

Treatment strategies for MG include anticholinesterase and immunomodulatory agents. Cholinesterase inhibitors, such as pyridostigmine bromide, are often given as initial therapy for MG. This therapy provides symptomatic improvement for most patients for a period of time. Thymectomy is indicated for selected patients younger than 60 years with generalized weakness and for all patients with thymoma. A CT chest scan should be performed in all patients with MG. Prednisone is the most commonly used immunomodulatory agent, but initial administration of high doses may exacerbate the weakness. Plasma exchange is an effective short-term therapy for patients with severe weakness and is particularly useful for a recent exacerbation, for preparation for surgery, or during the initiation of corticosteroid therapy. Other immunomodulatory agents include azathioprine, mycophenolate mofetil, IVIG, cyclophosphamide, and cyclosporine.

Lambert-Eaton Myasthenic Syndrome

Patients with LEMS often have proximal weakness in the legs and absent or decreased muscle stretch reflexes (sometimes reflexes are elicited after brief exercise). This syndrome usually is diagnosed in middle-aged men who often have vague complaints such as diplopia, impotence, urinary dysfunction, paresthesias, mouth dryness, and other autonomic dysfunctions (orthostatic hypotension). LEMS is due to the presence of antibodies directed against presynaptic voltage-gated P/Q-type calcium channels. It often is associated with small cell lung carcinoma. Treatment is treatment of the cancer. Pyridostigmine can be helpful, like in MG, as can steroids.

Botulism

Botulism should be suspected when more than one person has a syndrome that resembles MG or when one person has abdominal and gastrointestinal tract symptoms that precede a syndrome that resembles MG. Bulbar and respiratory weakness is common, and pupillary abnormalities are distinctive compared with findings in MG. Botulism occurs after the ingestion of improperly canned vegetables, fruit, meat, or fish contaminated by the exotoxin of *Clostridium botulinum*. There is increased concern about the potential use of this toxin as a biologic weapon. Paralysis is caused by toxin-mediated inhibition of acetylcholine release from axon terminals at the neuromuscular junction. Although an antitoxin is available, treatment is mainly supportive, especially respiratory but also psychologic, because the signs and symptoms are reversible.

- Often, lesions of the neuromuscular junction are missed clinically.
- Onset of MG: diplopia, dysarthria, dysphagia, dyspnea, and fatigability, often in young women and older men.
- LEMS: proximal weakness in the legs and decreased or absent muscle stretch reflexes.
- LEMS occurs in middle-aged men who have vague complaints of diplopia, impotence, urinary dysfunction, and dry mouth.
- LEMS is often associated with small cell lung carcinoma.
- Botulism should be suspected if more than one person has a syndrome that resembles MG.
- Ingestion of the exotoxin of *C. botulinum* causes botulism.
- In botulism, the release of acetylcholine is inhibited at the neuromuscular junction.

Organophosphate Toxicity

Organophosphate toxicity causes the characteristic combination of miosis, excessive bodily secretions, and fasciculations. A key pathophysiologic factor is decreased acetylcholinesterase activity that causes the accumulation of excessive acetylcholine at the neuromuscular junction. The onset of symptoms varies from 5 minutes to 12 hours after exposure. Treatment is with atropine.

- In organophosphate toxicity, decreased acetylcholinesterase activity causes the accumulation of excessive acetylcholine at the neuromuscular junction.
- Atropine is used to treat organophosphate toxicity.

Muscle Disease

Patients with muscle disease typically present with symmetrical proximal weakness (legs more than arms) and weakness of neck flexors and, occasionally, of cardiac muscle. Muscle stretch reflexes and sensory examination findings are usually normal. Common patient complaints are difficulty arising from a chair or raising the arms over the head. Dysphagia is uncommon. There are rare myopathies with more predominant distal involvement (myotonic dystrophy, inclusion body myositis, and distal muscular dystrophies). In myotonic dystrophy, atrophy and weakness begin distally and in the face and especially in the sternocleidomastoid muscles. An interesting feature of this dystrophy is myotonia, which is normal contraction of muscle with slow relaxation. Tests for myotonia include striking the thenar eminence with a reflex hammer and shaking the patient's hand, noting that the patient cannot let go quickly.

Muscle disease may be an acquired or progressive hereditary disease. *Myopathy* is a general term for muscle disease. If the disease is progressive and genetic, it is called *dystrophy*. However, patients

with a muscular dystrophy may not have a positive family history. A classification of myopathies is given in Table 18-16. The diagnosis of myopathy is based on the history and physical examination, increased levels of creatine kinase, and EMG and muscle biopsy results. For many adults with acquired myopathy, no underlying cause is found.

Inflammatory Myopathy

Inflammatory myopathies include polymyositis, dermatomyositis, and inclusion body myositis. With inflammatory myopathies, especially dermatomyositis, an underlying cancer may also be present. Inclusion body myositis occurs mainly in men older than 60 years; they may have asymmetrical weakness of proximal and distal muscles, with a predilection for quadriceps, biceps, and finger flexors (this pattern is highly suggestive of inclusion body myositis). Inclusion body myositis is not associated with collagen vascular diseases or neoplasms, and the creatine kinase level may be normal or slightly increased. Muscle biopsy should be used to confirm the diagnosis of an inflammatory myopathy, although it may be suggested by the history and examination findings, increased serum levels of creatine kinase, and EMG results.

Prednisone is the cornerstone for treatment of polymyositis and dermatomyositis. The most common pitfall in treating these conditions is not treating with high enough doses of prednisone for sufficient time. Dermatomyositis, unlike inclusion body myositis or polymyositis, responds to IVIG. In both polymyositis and dermatomyositis, other immunomodulatory agents, including azathioprine, methotrexate, mycophenolate mofetil, cyclosporine, cyclophosphamide, and chlorambucil, are indicated if relapse occurs during prednisone taper, if unacceptable side effects develop from prednisone, or if there is no response to prednisone or the response is slow. Plasma exchange is ineffective for polymyositis, dermatomyositis, and inclusion body myositis. Trials of immunosuppression in inclusion body myositis have been negative. A regular exercise program is important and it has been shown that physical therapy and exercise are not detrimental to patients with myopathies.

Table 18-16 Classification of Myopathies

Dystrophies
Nonprogressive or relatively nonprogressive congenital myopathies
Inflammatory myopathies
Infectious and viral—toxoplasmosis, trichinosis
Granulomatous—sarcoidosis
Idiopathic—polymyositis, dermatomyositis, IBM
With collagen vascular disease
Metabolic myopathies
Glycogenoses
Mitochondrial disorders
Endocrine
Periodic paralysis
Toxic—emetine, chloroquine, vincristine, HMG-CoA reductase inhibitors
Miscellaneous
Amyloidosis

HMG-CoA, hydroxymethylglutaryl coenzyme A; IBM, inclusion body myositis.

- *Myopathy* refers to muscle disease.
- If the disease is progressive and genetic, it is called *dystrophy*.
- Myotonic dystrophy: atrophy and weakness begin in the face and sternocleidomastoid muscles.
- Myotonia (normal contraction with slow relaxation) is a feature of myotonic dystrophy. With myotonia, the patient cannot let go quickly after a handshake.
- Acquired myopathy: no underlying cause is found in many adults.
- Patients with dermatomyositis: increased incidence of occult carcinoma.
- Causes of myopathies: collagen vascular disease, paraneoplastic changes, amyloidosis, endocrinopathy, sarcoidosis.

Acute Alcoholic Myopathy

Patients with acute alcoholic myopathy have acute pain, swelling, tenderness, and weakness of mainly proximal muscles. Gross myoglobinuria may cause renal failure.

- Gross myoglobinuria often occurs in acute alcoholic myopathy.

Toxic Myopathies

Statin drugs (HMG-CoA inhibitors) may produce an acute necrotizing myopathy characterized by myalgia, weakness, myoglobinuria, and a marked increase in creatine kinase. This toxic effect is potentiated by fibric acid–derivative drugs and cyclosporine. A more subacute to chronic myopathy can also occur with statins. Symptoms of cramps and myalgias can occur, occasionally with little or no muscle weakness or creatine kinase elevation. How soon symptoms abate after discontinuing the drug is unknown, although 3 to 6 months may be needed. It is also likely that in some patients statins unmask a presymptomatic acquired or genetic myopathy.

Electrolyte Imbalance

Severe hypokalemia (<2.5 mEq/L) and hyperkalemia (>7 mEq/L) produce muscle weakness, as do hypercalcemia, hypocalcemia, and hypophosphatemia. Familial periodic paralysis of hypokalemic-, hyperkalemic-, or normokalemic-type consists of episodes of acute paralysis that last 2 to 24 hours and can be precipitated by a carbohydrate-rich meal or strenuous exercise; cranial or respiratory muscle paralysis does not occur. The diagnosis is difficult to make and is based on the potassium levels during an attack, family history, EMG, and, occasionally, genetic testing for certain sodium and calcium channel mutations.

Endocrine Diseases

Hyperthyroidism and hypothyroidism, hyperadrenalism and hypoadrenalism, acromegaly, and primary and secondary hyperparathyroidism cause muscle weakness.

Acute Muscle Weakness

Physicians may overlook serious underlying diseases in patients whose chief or only complaint is weakness, especially if there are few or no

obvious clinical signs. A delayed or missed diagnosis can lead to life-threatening complications such as respiratory failure, irreversible spinal cord dysfunction, and acute renal failure. In some patients with neuromuscular weakness, respiratory muscles may be affected, although strength in the extremities is relatively normal. Patients with early Guillain-Barré syndrome may have distal paresthesias and increased respiratory effort and be given the diagnosis of hysterical hyperventilation.

- A missed diagnosis can lead to life-threatening complications: respiratory failure, irreversible spinal cord dysfunction, and acute renal failure.
- Early Guillain-Barré syndrome may be misdiagnosed as hysterical hyperventilation.

Acute, diffuse muscle weakness can be classified into five groups according to the anatomical location of the disorder: disease of the brain, spinal cord, peripheral nerve, neuromuscular junction, or muscle. Causes of acute muscle weakness are summarized in Table 18-17.

Table 18-17 **Important Causes of Acute Muscle Weakness**

Cerebral disease
Hemiparesis
Paraparesis—anterior cerebral artery
Spinal cord disease
Transverse myelitis
Epidural abscess
Extradural tumor
Epidural hematoma
Herniated intervertebral disk
Spinal cord tumor
Peripheral nerve disease
Guillain-Barré syndrome
Acute intermittent porphyria
Arsenic poisoning
Toxic neuropathies
Tick paralysis
Neuromuscular junction disease
Myasthenia gravis
Botulism
Organophosphate poisoning
Muscle disease
Polymyositis
Rhabdomyolysis-myoglobinuria
Acute alcoholic myopathy
Electrolyte imbalances
Endocrine disease

Part III—Disorders by Mechanism

Cerebrovascular Disease

Ischemic Cerebrovascular Disease

Pathophysiologic Mechanisms

The causes of ischemic cerebrovascular disorders, including TIA and cerebral infarction, can be classified on the basis of the site of the source for the arterial blockage (embolus from a proximal site or thrombosis in situ from distal causes) within the vascular system, starting from most proximal to distal. First, a cardiac source as the most proximal site includes both arrhythmias and structural disorders such as valve disease, dilated cardiomyopathy, recent myocardial infarction, and other cardiac structural disorders. Also, paradoxical emboli with a right-to-left shunt through a patent foramen ovale must be considered, although most patent foramen ovales are asymptomatic. Another potential proximal site of emboli is the aorta. The second site includes large-vessel disorders, with the most common cause being atherosclerosis or dissection in the carotid or vertebrobasilar system. The third site involves small-vessel occlusive disease caused by either inflammatory or noninflammatory arteriopathies (hypertension-induced disease, isolated CNS angiitis, and systemic lupus erythematosus). The fourth source is hematologic disorders, including polycythemia, sickle cell anemia, thrombocytosis, severe leukocytosis (i.e., acute leukemia), antithrombin III deficiency, protein C deficiency, protein S deficiency, hereditary resistance to activated protein C, factor V Leiden mutation, anticardiolipin antibody syndrome, lupus anticoagulant positivity, and hypercoagulable states caused by carcinoma. Illicit drug use is a common cause of stroke in young persons and results in arrhythmia, inflammatory arteriopathies, and a relative hypercoagulable state.

Pathophysiologic mechanisms of ischemic cerebrovascular disease include artery-to-artery emboli (e.g., extracranial carotid bifurcation to a branch of the middle cerebral artery), cardiac embolic stroke, and lacunar infarction (small-vessel disease). Other causes are hematologic disorders and states of altered coagulability (as mentioned above). Still other causes are nonarteriosclerotic vasculopathies (fibromuscular dysplasia, granulomatous angiitis, congophilic angiopathy, and systemic lupus erythematosus), dissection of the carotid or vertebral arteries, hemodynamic crisis with impaired distal flow, mechanical compression of arteries, steal syndromes, and AIDS. Recreational drugs are a major risk factor for stroke in young adults.

- Pathophysiologic mechanisms of ischemic cardiovascular disease include a cardiac source, large-vessel disorders, small-vessel disorders, and hematologic causes.
- In young adults, recreational drugs are a major risk factor for stroke.

Risk Factors

Risk factors for atherosclerotic occlusive disease are similar to those predisposing to coronary artery disease: hypertension, male sex, advanced age, cigarette smoking, diabetes mellitus, and hypercholesterolemia. Emboli from intracardiac mural thrombi are also an important cause of TIA and cerebral infarction. Major cardiac risk

factors include left-sided chamber enlargement or aneurysm, congestive heart failure, atrial fibrillation, transmural myocardial infarction, mitral valve disease, septic emboli, paradoxical emboli, and atrial myxoma.

Hypertension is the most powerful modifiable risk factor for stroke, but other modifiable risk factors include cigarette smoking, alcohol consumption, sedentary lifestyle, obesity, elevated cholesterol level, and, possibly, elevated homocysteine levels. Although low levels of alcohol consumption appear to have a protective effect for ischemic stroke, heavy alcohol consumption increases the risk of all types of stroke, particularly intracerebral and subarachnoid hemorrhage.

Transient Ischemic Attacks

TIAs place patients at high risk of subsequent cerebral infarctions: estimates are from 4% to 10% within 1 year to 33% within the patient's lifetime. Most TIAs are brief, usually lasting less than 10 to 15 minutes; 88% resolve within 1 hour. Patients with infarcts, hemorrhages, and mass lesions can present like patients with TIAs.

"Amaurosis fugax" is defined as temporary, partial, or complete monocular blindness and is a classic symptom of a carotid artery TIA. It can be mimicked by glaucoma, vitreous hemorrhage, retinal detachment, papilledema, migrainous aura, temporal arteritis, and even ectopic floaters.

The long-term prognosis for patients who have a TIA generally follows the rule of 3s: one-third will have cerebral infarction, one-third will have at least one more TIA, and one-third will have no more TIAs.

- Most TIAs last less than 10-15 minutes.
- Patients with infarcts, hemorrhages, and mass lesions can present with symptoms like those of a TIA.
- Amaurosis fugax is a classic symptom of a carotid artery TIA.
- The rule of 3s for patients with TIA: one-third will have cerebral infarction, one-third will have at least one more TIA, one-third will have no more TIAs.

Carotid Endarterectomy

Carotid endarterectomy markedly decreases the risk of stroke and death of *symptomatic* patients who have a 70% to 99% stenosis of the carotid artery, as seen on angiography. For a 50% to 60% stenosis, carotid endarterectomy is moderately efficacious in selected symptomatic patients. Medical treatment alone is better than carotid endarterectomy for patients with a stenosis of 49% or less. Symptoms must be those of a carotid territory TIA or minor stroke and must be of recent onset (<4 months). To have a favorable risk-benefit ratio, the perioperative complication rate must be low (4%-6%). Carotid angioplasty with stent placement may be used as an alternative to carotid endarterectomy, particularly for higher risk patients, such as those who previously had carotid endarterectomy, radiotherapy to the neck, or neck dissection; those with a stenosis high in the internal carotid artery; or those otherwise deemed at high risk for the operation. The safety and durability of the endovascular approach in comparison with those of carotid endarterectomy are not well defined.

Selected patients with an *asymptomatic* carotid stenosis of at least 60% benefit from carotid endarterectomy in terms of future risk of an ipsilateral stroke or death. In the Asymptomatic Carotid Atherosclerosis Study (ACAS), medical patients were treated with aspirin and risk-factor reduction. The risk of stroke was low for patients treated surgically and for those treated medically (5-year risk of ipsilateral stroke or death was 11% for those treated medically and 6% for those treated surgically). This amounted to approximately a 1% difference per year. No trend was noted on the basis of the various degrees of stenosis, but the number of events was small in each stenosis subdivision. Importantly, surgeons and hospitals were chosen particularly for having reported perioperative complication rates of less than 3% in asymptomatic patients.

Patients with asymptomatic carotid occlusive disease who require an operation for some other reason (e.g., coronary artery bypass graft or abdominal aortic aneurysm repair) usually can have that procedure performed without prophylactic carotid endarterectomy, because in this context the risk of stroke in asymptomatic persons is quite low. If a patient has recently had symptoms in the distribution of the stenotic carotid artery, the decision is more complicated. Generally, if a patient with an asymptomatic carotid stenosis is experiencing cardiac symptoms such as angina, coronary artery bypass graft is performed first and carotid endarterectomy may be considered later if the patient is otherwise an excellent surgical candidate.

The role of carotid angioplasty with stent placement for extracranial carotid occlusive disease has not been entirely clarified. Because the comparative risks and long-term durability of the angioplasty-with-stent procedure are unclear, many consider carotid angioplasty a reasonable alternative, especially if carotid endarterectomy poses a high risk for the patient.

Antiplatelet Agents

Aspirin, aspirin in combination with extended-release dipyridamole, clopidogrel, and ticlopidine are all effective for secondary prevention of stroke. The optimal dose of aspirin is uncertain, with ranges recommended from 30 to 1,300 mg daily. Clopidogrel is given as a single dose, 75 mg daily. A combination of low-dose aspirin and extended-release dipyridamole is well tolerated and provides another useful alternative to aspirin for prevention of stroke. The dose of ticlopidine is 250 mg twice daily. Ticlopidine is now rarely given because of the associated neutropenia (thus, a complete blood count must be monitored every 2 weeks for the first 3 months of treatment) and thrombotic thrombocytopenic purpura, which also has rarely been reported with clopidogrel.

Management of Acute Cerebral Infarction

If a patient has an important neurologic deficit caused by an acute cerebral infarction, the immediate decision in the emergency department is whether the patient is a candidate for thrombolytic therapy (tissue plasminogen activator [TPA]). The initial therapeutic approach to ischemic infarction depends greatly on the time from the onset of symptoms to the presentation for emergency medical care. If the onset of symptoms was less than 3 hours before the evaluation, emergent thrombolytic therapy should be considered. If a patient awakens from sleep with the deficit, thrombolytic therapy should not be considered unless the duration of the deficit is clearly less than 3 hours.

The CT findings are important in selecting patients for TPA. CT should not show any evidence of intracranial hemorrhage, mass effect, or midline shift. Patients who may be excluded by clinical criteria are those with rapidly improving deficit, obtunded or comatose status or presentation with seizure, history of intracranial hemorrhage or bleeding diathesis, blood pressure elevation persistently greater than 185/110 mm Hg, gastrointestinal tract hemorrhage or urinary tract hemorrhage within the previous 21 days, a large ischemic stroke within the previous 14 days or a small ischemic stroke within the previous 4 days, or mild deficit. Eligible patients should have marked weakness in at least one limb or severe aphasia. Laboratory abnormalities that may preclude treatment are heparin use within the previous 48 hours with an increased activated partial thromboplastin time, prothrombin time greater than 15 seconds, or blood glucose concentration less than 50 mg/dL or greater than 400 mg/dL.

In a treatment trial of intravenous TPA, the efficacy in improving neurologic status at 3 months was defined for TPA compared with placebo, with the agent administered within 3 hours after the onset of symptoms. Although there was a greater proportion (12% greater) of subjects with minimal or no deficit in the TPA group at 3 months after the event, there was no increase in the proportion of persons with severe deficits or disability. This is particularly important because there was an increased occurrence of symptomatic hemorrhage in the TPA group.

Intravenous TPA should be given in a 0.9-mg/kg dose (maximum, 90 mg), with 10% given as a bolus and the rest over 60 minutes.

- Intravenous TPA should be considered for patients evaluated within 3 hours after the onset of symptoms of severe cerebral infarction.
- Do not treat with TPA if CT shows hemorrhage, mass effect, or midline shift.

A mechanical device approved for use in acute ischemic stroke is the Merci Retriever. This device is used with endovascular access and has a tiny corkscrew-shaped portion designed to extract the occlusive clots from intracranial arteries, thereby minimizing ischemic damage.

Stroke Risks With Nonvalvular Atrial Fibrillation

Atrial fibrillation is associated with up to 24% of ischemic strokes and 50% of embolic strokes. The stroke rate for the entire cohort of patients with chronic atrial fibrillation is generally about 5% per year. However, patients younger than 60 with "lone atrial fibrillation" have a lower risk of stroke than other patients with atrial fibrillation and are often treated with only aspirin. Stroke risk factors with atrial fibrillation include a history of hypertension, recent congestive heart failure, previous thromboembolism (including TIAs), left ventricular dysfunction identified on two-dimensional echocardiography, and increased size of the left atrium identified on M-mode echocardiography. Patients with atrial fibrillation who have one or more risk factors generally should receive anticoagulation with warfarin (international normalized ratio [INR] 2.0-3.0) and those at low risk should receive aspirin.

For patients receiving anticoagulant therapy, the dominant risk factor for intracranial hemorrhage is the INR. Age is another risk factor for subdural hemorrhage. An INR of 2.0 to 3.0 is probably an adequate level of anticoagulation for nearly all warfarin indications except for preventing embolization from mechanical heart valves. Generally, the lowest effective intensity of anticoagulant therapy should be given.

- Atrial fibrillation is associated with 24% of ischemic strokes and 50% of embolic strokes.
- The stroke rate is about 5% per year.
- Patients with "lone atrial fibrillation" have a lower risk of stroke.

Hemorrhagic Cerebrovascular Disease

Intracerebral Hemorrhage

Hypertension commonly affects deep penetrating cerebral vessels, especially ones supplying the basal ganglia, cerebral white matter, thalamus, pons, and cerebellum. The following are common misconceptions of intracerebral hemorrhage: the onset is generally sudden and catastrophic, hypertension is invariably severe, headache is always present, reduced consciousness or coma is usually present, the CSF is always bloody, and the prognosis is poor and mortality is high. None of these features may be present, and the prognosis depends on the size and location of the hemorrhage. Amyloid angiopathy is the second most common cause of intracerebral hemorrhage in older persons and often causes recurrent lobar hemorrhages.

- With intracerebral hemorrhage, the prognosis depends on the size and site of the hemorrhage.

Surgical evacuation of intracerebral hematomas may be necessary for patients who have signs of increased intracranial pressure or for those whose condition is worsening.

Cerebellar Hemorrhage

It is important to recognize cerebellar hemorrhage because drainage may be lifesaving. The important clinical findings are vomiting and inability to walk. Long-tract signs usually are not present. Patients may have ipsilateral gaze palsy, ipsilateral CN VI palsy, or ipsilateral nuclear-type CN VII palsy (upper and lower facial weakness). They may or may not have headache, vertigo, and lethargy. Cerebellar hemorrhage may cause obstructive hydrocephalus.

- Vomiting and the inability to walk are important findings in cerebellar hemorrhage.
- Long-tract signs usually are not present.
- Cerebellar hemorrhage may cause obstructive hydrocephalus.

Subarachnoid Hemorrhage

Subarachnoid hemorrhage (SAH) accounts for about 5% of strokes, including about half of those in patients younger than 45, with a peak age range between 35 and 65 years. In up to 50% of cases, an alert patient with an aneurysm may have a small sentinel bleed with a warning headache, or the expansion of an aneurysm may cause

focal neurologic signs or symptoms, for example, an incomplete CN III palsy. The prognosis is related directly to the state of consciousness at the time of intervention. The headache is characteristically sudden in onset, and although one-third of SAHs occur during exertion, one-third occur during rest and one-third during sleep. The peak incidence of vasospasm associated with SAH occurs between days 4 and 12 after the initial hemorrhage. Other complications include 1) hemorrhagic infiltration into the brain, ventricles, and even subdural space, which requires evacuation; 2) hyponatremia associated with diabetes insipidus or the syndrome of inappropriate secretion of antidiuretic hormone; and 3) communicating hydrocephalus.

In addition to the initial hemorrhage, vasospasm and rehemorrhaging are the leading causes of morbidity and mortality of patients who have an SAH.

The outpouring of catecholamines may cause myocardial damage, with accompanying electrocardiographic abnormalities, pulmonary edema, and arrhythmias. Arrhythmias can be both supraventricular and ventricular and are most likely to occur during the initial hours or days after a moderate-to-severe SAH.

Initial treatment is supportive, often in an intensive care unit. Prevention of vasospasm is best achieved with maintaining normal or increased blood pressure and intravascular volume as well as using the calcium channel blocker nimodipine. If the SAH is from a ruptured aneurysm, early intervention (surgical clipping or endovascular coiling) is often done by an experienced team.

- About 5% of strokes are an SAH.
- In 50% of cases, an alert patient with an aneurysm may have a small sentinel bleed.
- The prognosis is related directly to the state of consciousness at the time of intervention.
- Characteristically, the headache has a sudden onset.

The differential diagnosis of subtypes of hemorrhagic cerebrovascular disease is outlined in Table 18-18.

Neoplastic Disease

The most common neurologic symptoms of patients with systemic cancer are back pain, altered mental status, and headache. However, the most common neurologic complication of systemic cancer is metastatic disease, of which cerebral metastasis is most frequent. In patients with cancer and back pain, epidural metastasis and direct vertebral metastasis are common, but no malignant cause is found in about 15% to 20% of patients. Nonstructural causes are the most common reasons for headache. Some identified causes include fever, side effects of therapy, lumbar puncture, metastasis (cerebral, leptomeningeal, or base of skull), and intracranial hemorrhage (thrombocytopenia or hemorrhage due to intracranial metastasis). The most common cause of altered mental status is toxic-metabolic encephalopathy, which is also the most common nonmetastatic manifestation of systemic cancer. Less common causes include intracranial metastatic disease (parenchymal and meningeal), paraneoplastic limbic encephalitis, intracranial hemorrhage, primary dementia, cerebral infarction, psychiatric disorder, known primary brain tumor, bacterial meningitis, and transient global amnesia.

Neoplasms that commonly cause neurologic problems are those of the lung and breast, leukemia, lymphoma, and colorectal cancer. Breast, lung, and prostate cancer are most likely to spread to bone with epidural metastasis. The most common brain metastasis is from the lung. Meningeal metastases occur in lung and breast cancer, melanoma, leukemia, and lymphoma. Colorectal cancer causes local pelvic metastasis and is the most frequent cause of neoplastic plexopathy. Head cancer and neck cancer are the most frequent sources of metastasis to the base of the skull. Melanoma produces a disproportionate number of metastases in the CNS.

Table 18-18 Differential Diagnosis of Subtypes of Hemorrhagic Cerebrovascular Disease

Hemorrhage into parenchyma
Hypertension
Amyloid angiopathy
Aneurysm
Vascular malformation
Arteriovenous malformation
Cavernous malformation
Venous malformation (rare cause of hemorrhage)
Trauma—primarily frontal and temporal
Hemorrhagic infarction
Secondary to brain tumors (primary and secondary neoplasms)
Inflammatory diseases of vasculature
Disorders of blood-forming organs (blood dyscrasia, especially leukemia and thrombocytopenic purpura)
Anticoagulant or thrombolytic therapy
Increased intracranial pressure (brainstem) (Duret hemorrhages)
Illicit drug use (cocaine or amphetamines)
Postsurgical
Fat embolism (petechial)
Hemorrhagic encephalitis (petechial)
Undetermined cause (normal blood pressure and no other recognizable disorder)
Hemorrhage into subarachnoid space (subarachnoid hemorrhage)
Trauma
Aneurysm
Saccular (“berry,” “congenital”)
Fusiform (arteriosclerotic)—rarely causes hemorrhage
Mycotic
Arteriovenous malformation
Many of the same causes listed under “Hemorrhage into parenchyma” above
Subdural and epidural hemorrhage (hematoma)
Mainly traumatic (especially during anticoagulation)
Many of the same causes listed under “Hemorrhage into parenchyma” above
Hemorrhage into pituitary (pituitary apoplexy)

Gastrointestinal tract tumors (stomach, esophagus, and pancreas) have the least number of neurologic complications.

Many neurologic problems in patients with cancer can be diagnosed on the basis of the medical history and findings on neurologic examination and require knowledge of both nonmetastatic- and noncancer-related neurologic illness. Neurologic complications of systemic cancer can be divided generally into the following categories:

- Metastatic—parenchymal, leptomeningeal, epidural, subdural, brachial and lumbosacral plexuses, and nerve infiltration; this is common
- Infectious—unusual CNS infections because of immunosuppression
- Complications of systemic metastases—hepatic encephalopathy
- Vascular complications—cerebral infarction from hypercoagulable states, nonbacterial thrombotic endocarditis, and radiation damage to carotid arteries; cerebral hemorrhage from such entities as thrombocytopenia and hemorrhagic metastases
- Toxic-metabolic encephalopathies—usually from multiple causes, hypercalcemia, syndrome of inappropriate secretion of antidiuretic hormone, medications, and systemic infections
- Complications of treatment (irradiation, chemotherapy, or surgery)—radiation necrosis of the brain, radiation myelopathy, radiation plexopathy, fibrosis of the carotid arteries, neuropathies, encephalopathies, and cerebellar ataxia
- Paraneoplastic (nonmetastatic or "remote" effect of cancer)—syndromes have been described from the cerebral cortex through the central and peripheral neuraxes to muscle; they are rare
- Miscellaneous—various systemic and neurologic illnesses having nothing to do with cancer

- Cerebral metastasis is the most common neurologic complication of systemic cancer.
- Toxic-metabolic encephalopathy is the most common nonmetastatic manifestation of cancer.
- Cancers commonly causing neurologic problems are lung, breast, and colorectal cancers, leukemia, and lymphoma.
- The most common source of brain metastasis is from lung and breast cancer, melanoma, leukemia, and lymphoma.
- The most frequent cause of tumor plexopathy is colorectal cancer.
- Melanoma produces a disproportionate number of metastases in the CNS.
- Common metastatic sites are the parenchyma of the cerebral hemispheres and cerebellum, leptomeninges, epidural and subdural spaces, brachial and lumbosacral plexuses, and nerve.

Radiosurgery (gamma knife and the linear accelerator [LINAC]-based systems) has been used to treat vascular malformations, acoustic neuromas, pituitary adenomas, and meningeal and (recently) metastatic tumors.

Primary CNS lymphoma is becoming more common in both AIDS and immunocompetent patients. Median survival has been increased with the combination of radiotherapy and chemotherapy, mainly intravenous methotrexate.

Paraneoplastic Disorders

The paraneoplastic disorders are associated with increased levels of circulating antibodies against membrane (e.g., ion channels) or cytoplasmic components of neoplastic cells. The most common underlying malignancies are small cell lung carcinoma and breast cancer. Others include ovarian or testicular carcinoma, thymoma, Hodgkin disease, and parotid tumors. Paraneoplastic autoimmunity occurs with various neurologic syndromes, including limbic encephalitis (characterized by behavioral and memory abnormalities), brainstem encephalitis, opsoclonus-myoclonus, cerebellar ataxia, myelopathy, motor neuron disease, stiff-man–like syndrome (with axial and limb rigidity), sensory ganglionopathies, LEMS, dermatomyositis, and retinopathy. These syndromes are characterized by an acute or subacute onset and increased levels of one or more antibodies. Neither the neurologic syndrome nor the antibody is pathognomonic for a particular neoplasm, and many neurologic syndromes and antibodies may coexist in the same patient.

Among patients with LEMS, anti–calcium channel antibodies are present in 80% of the patients who have primary lung cancer (small cell, squamous cell, or adenocarcinoma) and in 36% of the patients who have no evidence of cancer. Those with LEMS who have cancer other than lung cancer usually are negative for these antibodies. Antineuronal nuclear antibodies (ANNA) type I (anti-Hu) are a marker of various neurologic disorders that occur with small cell lung cancer, and the ANNA type II (anti-Ri) antibodies occur in a spectrum of neurologic disorders associated with breast cancer, including cerebellar ataxia, myelopathy, opsoclonus, and other brainstem disorders. Purkinje cell antibodies (sometimes called "anti-Yo" antibodies) are detected in women with paraneoplastic cerebellar degeneration and are associated with ovarian, fallopian tube, endometrial, surface papillary, and breast carcinomas and occasionally with lymphoma. They are not found in men with paraneoplastic cerebellar degeneration or in women with gynecologic cancer without a neurologic syndrome. In a woman who does not have clinically known or laboratory-proven cancer but is positive for these antibodies, exploratory laparotomy probably is warranted. Amphiphysin antibodies occur in patients who have rigidity, peripheral neuropathy, and other neurologic syndromes generally associated with breast cancer. Antibodies to collapsin response mediator protein-5 (CRMP-5) are associated with several cancers (especially small cell carcinoma) and can lead to many neurologic complications, most notable of which is a movement disorder (i.e., chorea) or optic neuropathy.

Movement Disorders

Tremor

Tremor is an oscillatory rhythmical movement disorder. A simple classification of tremor is rest tremor, postural tremor, and kinetic tremor (Table 18-19).

Rest tremor is observed with the arms lying in the patient's lap while he or she is sitting or with the arms at the patient's side while

Table 18-19 Differential Diagnosis of Tremor

Feature	Parkinson disease	Essential tremor
Tremor type and frequency	Rest >> postural; 3-5 Hz	Postural, kinetic; 8-12 Hz
Affected by tremor	Hands, legs, chin, jaw	Hands, head, neck, voice
Rigidity and bradykinesia	Yes	No
Family history	15%	60%
Alcohol response	Inconsistent	Consistent
Therapy	Levodopa, dopamine agonists, anticholinergics	Propranalol, primidone, gabapentin, botulinum toxin type A
Surgical treatment	Thalamic (Vim) stimulation	Subthalamic stimulation

Vim, subnucleus ventralis intermedius.

walking. Rest tremor occurs in Parkinson disease. *Postural tremor* is seen mainly with the arms outstretched, although there is often a kinetic component as well. Postural tremor is physiologic, but it is also noted pathologically in essential tremor. Drugs such as methylxanthines, β-adrenergic agonists, lithium, and amiodarone may produce postural tremor. *Kinetic tremor* is seen mainly in action, as in finger-to-nose testing. This type of tremor occurs with cerebellar disease and diseases of the cerebellar connections in the brainstem.

Essential Tremor

Essential tremor is the most common movement disorder. It is often misdiagnosed and inappropriately treated. It is a monosymptomatic condition that is manifested as rhythmic oscillations of various parts of the body. Middle-aged and older persons are most commonly affected, and there is often a genetic component. The hands are affected most, with the tremor present in the postural position and often having a kinetic component. The head and voice can be affected. Head tremor can be either horizontal ("no-no") or vertical ("yes-yes"). Head tremor almost never occurs in Parkinson disease, but parkinsonian patients may have tremor of the mouth, lips, tongue, and jaw. The legs and trunk (orthostatic tremor) are affected less frequently in essential tremor. Essential tremor is a slowly progressive condition; its pathophysiologic mechanism is not known.

The agent most effective in decreasing essential tremor is alcohol. Alcoholic drinks substantially reduce the tremor for 45 to 60 minutes. However, the rate of alcoholism among patients with essential tremor is no different from that of the general population. Propranolol (80-320 mg daily), other β-blockers, and primidone (25-250 mg at bedtime) are effective. Other drugs that have been prescribed are clonazepam, gabapentin, and topiramate. Methazolamide has also been effective in some patients, especially for head tremor. Botulinum toxin has been used recently. Stereotactic thalamotomy can be effective for patients with severe functional disability whose tremor is unresponsive to drug therapy; surgery probably is underused. Thalamic stimulation (deep brain stimulation) is effective for all types of tremor.

- Essential tremor occurs mostly in middle-aged and older persons.
- There is often a genetic component.
- The hands are affected most.
- Head tremor is almost never seen in Parkinson disease.

Parkinson Disease

Patients with Parkinson disease present with tremor (the initial symptom in 50%-70%, but 15% never have tremor), rigidity, and bradykinesia. Also, gait is unsteady—a slow, shuffling gait. Decreased blinking rate, lack of change in facial expression, small handwriting, and asymptomatic orthostatic hypotension are also common. Although dementia is more frequent among patients with Parkinson disease, it is noted in only about 25% of those in whom the disease develops after age 60. Other nonmotor manifestations of Parkinson disease are listed in Table 18-20. The detection of cerebellar findings (ataxia), corticospinal signs (increased deep tendon reflexes, spasticity, or extensor plantar response), or lower motor neuron findings (decreased reflexes, flaccidity, or fasciculations) should all suggest a disorder other than Parkinson disease as a cause for parkinsonism. Parkinson-plus syndromes are frequently the diagnoses when any of these findings are present (Table 18-21).

- Tremor does not occur in 15% of patients with Parkinson disease.
- If ataxia, increased reflexes, spasticity, extensor plantar responses, or lower motor neuron findings are present, consider Parkinson-plus syndromes.

The treatment of Parkinson disease is summarized in Table 18-22. Initial treatment options include a combination of levodopa and carbidopa (Sinemet), anticholinergic agents, amantadine, or dopaminergic agonists. Anticholinergic agents should not be given to patients older than 65 because of the high incidence of side effects, such as memory loss, delirium, urinary hesitancy, and blurred vision. When given to a patient with newly diagnosed Parkinson disease, selegiline (a monoamine oxidase type B inhibitor) may delay the initiation of levodopa therapy as well as give mild symptomatic relief. Initial dosages of a combination of levodopa and carbidopa include a 25/100 tablet three times daily on an empty stomach. Side effects include nausea, hallucinations, confusion, dyskinesias, and orthostatic hypotension. Long-term high-dose levodopa monotherapy leads to dyskinesias and motor fluctuations. Management strategies include the use of smaller and more frequent doses of levodopa, long-acting levodopa preparations, dopaminergic agonists, and inhibitors of catechol *O*-methyltransferase. A newer preparation of levodopa, apomorphine, can be administered subcutaneously for severe, hypomobile, "off" times. Unpredictable off periods may also be helped with the use of a protein restriction diet.

Dopaminergic agonists include the ergot derivatives bromocriptine and pergolide and the nonergot derivatives pramipexole and ropinirole. Although monotherapy with dopamine agonists carries

Table 18-20 Nonmotor Complications of Parkinson Disease

Complications
Sleep disorders
Autonomic involvement
Hallucinations
Depression
Cognitive impairment
Sensory symptoms
Abnormal behavior
Management
Complications tend to occur at late stages of the disease
Always consider effect of medications as possible cause
Treat only if disabling

Table 18-21 Differential Diagnosis of Parkinson-Plus Syndromes

Manifestation	Suspect
Poor response to levodopa	Any parkinson-plus syndrome (MSA and PSP may respond)
Early falls	PSP or MSA
Severe OH and urologic Sx	MSA
Cerebellar signs	MSA or spinocerebellar degeneration
Vertical gaze palsy	PSP
Asymmetric apraxia	Corticobasal degeneration
Early dementia	Dementia with Lewy bodies of Creutzfeldt-Jakob disease

MSA, multiple system atrophy; OH, orthostatic hypotension; PSP, progressive supranuclear palsy; Sx, symptoms.

a smaller risk of developing delayed motor complications than long-term levodopa therapy, these agents are less efficacious than levodopa. The use of dopaminergic agonists rather than levodopa for early treatment of Parkinson disease has been proposed. The rationale is that this will delay the potential toxic effects of dopamine metabolites in the brain. However, this point is controversial. Like levodopa, dopaminergic agonists may cause hallucinations, postural hypotension, and edema. An important side effect of all these agents is the development of unpredictable episodes of daytime sleepiness. Bromocriptine has been associated with pulmonary and retroperitoneal fibrosis. Reportedly, pergolide is associated potentially with valvular heart disease. New-generation antipsychotic drugs, such as clozapine, olanzapine, and quetiapine, can be used to manage drug-induced psychosis because they have a lower risk of exacerbating parkinsonism in these patients. Stereotactic pallidotomy and subthalamic nucleus stimulation are performed in patients with predominantly unilateral symptoms. These treatments are particularly effective for tremor and drug-induced dyskinesia.

Many patients with parkinsonism develop orthostatic hypotension, bladder dysfunction, and other autonomic manifestations. In these patients, Parkinson disease should be distinguished from multiple system atrophy. Findings suggestive of multiple system atrophy include lack of a predictable response to levodopa, the presence of cerebellar or pyramidal signs, severe orthostatic hypotension and urinary incontinence, sleep apnea, and laryngeal stridor. The management of orthostatic hypotension includes eliminating potentially offending drugs (vasodilators, diuretics, dopaminergic agonists, and clozapine), increasing sodium and water intake, performing postural maneuvers, elevating the head of the bed, and wearing support stockings. Drug treatment includes fludrocortisone (0.1-1.0 mg daily) and vasoconstrictors such as midodrine (10-40 mg daily). Pyridostigmine can also be used for orthostatic hypotension in dosages similar to those used in myasthenia gravis (30-60 mg three times a day).

Other Movement Disorders: Botulinum Toxin Therapy

Botulinum toxin, which blocks the neuromuscular junction, is effective therapy for cervical dystonia, blepharospasm, hemifacial spasm, spasmodic dysphonia, jaw-closing oromandibular dystonia, and limb dystonia, including occupational dystonias.

Inflammatory and Immune Disorders

Demyelinating Diseases

Idiopathic inflammatory demyelinating diseases of the CNS are as follows:

- Multiple sclerosis
- Isolated demyelinating syndromes—optic neuritis and transverse myelitis
- Primary progressive demyelinating diseases—chronic progressive myelopathy and progressive cerebellar syndrome
- Asymptomatic demyelinating diseases (noted on MRI or autopsy)

Multiple sclerosis is a common, disabling demyelinating CNS disorder of young adults, with an onset between 20 to 50 years of age. It affects women twice as often as men. Multiple sclerosis has a variable prognosis and an unpredictable course. Polygenetic and environmental (possibly viral) factors probably have a substantial effect on susceptibility to multiple sclerosis. The disease attacks white matter (and, later in the course, axons) of the cerebral hemispheres, brainstem, cerebellum, spinal cord, and optic nerve. Eighty percent to 85% of patients present with relapsing-remitting symptoms. In about 15% of patients, the disease is progressive from onset (primary progressive). Over time, 70% of patients with the relapsing-remitting form will develop secondary progressive multiple sclerosis. Symptoms reflect multiple white matter lesions "disseminated in space and time" and include spastic weakness of the limbs, ataxia, diplopia, sensory disturbances, loss of vision, and urinary bladder and bowel dysfunction. Other important symptoms include fatigue, subtle memory and cognitive dysfunction, and depression.

The diagnosis is based on established clinical criteria and supportive laboratory data. Abnormalities on MRI are most helpful and include multifocal lesions of various ages in the periventricular white matter, corpus callosum, brainstem, cerebellum, and spinal cord. Gadolinium-enhanced lesions are presumed to be active lesions of

Table 18-22 Treatment of Parkinson Disease

Treatment	Indications	Caveats/problems
Anticholinergic agent (e.g., trihexyphenidyl)	Tremor predominant in young patients	Anticholinergic and cognitive side effects in patients >65 years
Amantadine	Early disease; adjuvant treatment for patients with dyskinesia	Dizziness, livedo reticularis, edema
Levodopa-carbidopa Sinemet 25/100 Sinemet CR 50/200	Most efficacious treatment; give early in disease to patients with marked impairment	Nausea, vomiting, orthostatic hypotension, hallucinations, motor fluctuations with chronic treatment
Dopaminergic agonists Bromocriptine Pergolide Pramipexole Ropinirole	Motor fluctuations while taking Sinemet Some recommend use of these agonists early in course of disease	As with Sinemet (except fluctuations), pleuropulmonary reaction and retroperitoneal fibrosis with ergots; patients may fall asleep while driving
COMT inhibitors Entacapone	Prolong duration of action of levodopa in patients with "wearing-off" effect	As with levodopa; diarrhea
MAO-B inhibitors Selegiline	Delay the need to start levodopa therapy, potential (not proven) neuroprotective effect	Insomnia
Atypical antipsychotics Clozapine Olanzapine Quetiapine	Hallucinations; try to avoid extrapyramidal side effects; may improve akathisia and dyskinesia	Risk of myelosuppression and orthostatic hypotension with clozapine
Surgical treatment Pallidotomy Subthalamic nucleus stimulation	Prominent unilateral symptoms, particularly when associated with dyskinesia	Does not help axial problems/gait instability; risk of optic tract damage with pallidotomy; risk of paresis; speech or swallowing disturbances, particularly with bilateral pallidotomy

COMT, catechol *O*-methyltransferase; MAO, monoamine oxidase.

inflammatory demyelination. CSF findings include oligoclonal bands, increased IgG synthesis, and moderate lymphocytic pleocytosis (<50 mononuclear cells). Visual and somatosensory evoked potential studies are less helpful.

Predictors associated with a more favorable long-term course of multiple sclerosis include age younger than 40 at onset, female sex, optic neuritis or isolated sensory symptoms as the first clinical manifestation, and relatively infrequent attacks. Prognostic factors associated with a poor outcome include age older than 40 at onset, male sex, cerebellar or pyramidal tract findings at initial presentation, relatively frequent attacks during the first 2 years, incomplete remissions, and a chronically progressive course. However, no single clinical variable is sufficient to predict the course or outcome of this disease. Acute transverse myelopathy is usually a monophasic disorder and is rarely the first sign of multiple sclerosis. Abnormal MRI findings at presentation of a patient with a clinically isolated syndrome suggestive of multiple sclerosis (isolated involvement of the optic nerve, brainstem, or spinal cord) are a strong predictor of the eventual clinical diagnosis of multiple sclerosis in the next 5 years. Interferon beta-1b, interferon beta-1a, and glatiramer acetate decrease the relapse rate and the intensity of relapse in patients with the relapsing-remitting type of multiple sclerosis.

A study of corticosteroid therapy for optic neuritis found that oral prednisone therapy was ineffective. The recommended therapy is a 3- to 5-day course of a high dose of intravenous methylprednisolone (1.0 g daily), which may be followed by a short oral prednisone taper, although tapering is not necessary.

Several drugs are used to treat specific symptoms of multiple sclerosis. Trigeminal neuralgia, flexor spasms, and other paroxysmal symptoms respond to carbamazepine, and spasticity responds to baclofen and tizanidine. Fatigue, a disabling symptom of multiple sclerosis, occasionally responds to amantadine or modafinil.

- Typical clinical scenario for multiple sclerosis: A 35-year-old woman has a history of rapid loss of vision in the right eye, with pain on eye movement. A similar episode occurred 2 years ago and involved the same eye, and recovery was complete. She also

has noticed weakness and paresthesias of both legs in the last 6 months. CSF analysis shows increased protein levels and oligoclonal bands on electrophoresis. Multiple T2 hyperintense areas consistent with demyelination are seen on MRI.

Neurologic Infectious Diseases

Infectious diseases of the nervous system are manifested in various combinations of meningitis, encephalitis, brain abscess, granulomas, and vasculitis. The typical clinical and CSF findings and common causes of these diseases are summarized in Table 18-23. The most common causes and empirical treatment of bacterial meningitis are summarized in Table 18-24.

Lyme Disease—Multisystem Disorder

Stage I Lyme disease begins with the bite of an infected tick. Any body area may be bitten, but the thigh, groin, and axilla are common sites. Often, patients cannot recall the tick bite.

Stage II disease begins weeks to months after the initial infection and is characterized by neurologic, cardiac, and ophthalmic involvement. About 15% of the patients in the United States have neurologic involvement, usually meningoencephalitis, cranial neuritis, or radiculoneuropathy. Cranial neuropathies are common, most frequently with CN VII (bilaterally in one-third of patients). Thus, bilateral CN VII palsy in a patient from an endemic area is almost diagnostic of Lyme disease. Peripheral nervous system involvement can include the spinal roots, plexuses, and peripheral nerves.

Stage III disease marks the chronic phase and begins months to years after the initial infection. This stage is heralded by arthritic and neurologic symptoms. Any CNS symptom is possible, and there may be psychiatric symptoms and cognitive impairment. Severe fatigue is a particularly prominent feature. Rarely, a multiple sclerosis–like demyelinating illness featuring gait disturbance, urinary bladder dysfunction, spastic paraparesis, and dysarthria may develop. These symptoms may have exacerbations and remissions; MRI shows multifocal white matter lesions.

- Lyme disease is a multisystem disorder.
- Patients often do not recall the tick bite.
- In the United States, 15% of patients have neurologic involvement.
- Cranial neuropathies, especially with CN VII, are common.
- Bilateral CN VII palsy in an endemic area is almost diagnostic of Lyme disease.
- In stage III disease, severe fatigue is prominent.

The longer the duration of symptoms before diagnosis and effective antibiotic treatment, the greater the risk that serious symptoms will outlast the period of acute infection. Laboratory diagnosis can be difficult; an enzyme-linked immunosorbent assay can be undependable both in identifying new cases and in distinguishing acute from remote healed infection. Asymptomatic tick bites have a less than 1% chance of Lyme infection, and treating such patients for Lyme disease is not cost-effective. However, typical erythema migrans accompanying either a tick bite or other typical symptoms is sufficiently diagnostic to warrant treatment after exposure in an endemic area, even without abnormal serologic findings.

Neurologic Complications of AIDS

The nervous system is affected clinically in up to 40% of patients with HIV infection, and pathologic changes in the nervous system are found at autopsy in up to 90%. Neurologic features may be the presenting manifestation of the illness in 5% to 10% of patients. HIV infection is associated with various central and peripheral nervous system disorders, and multiple levels of the nervous system can be affected simultaneously. Therapy is available for many of these syndromes. The major HIV-related neurologic conditions include dementia, toxoplasmic encephalitis, CNS lymphoma, progressive multifocal leukoencephalopathy, cytomegalovirus encephalitis, cryptococcal meningitis, neurosyphilis, vacuolar myelopathy, distal symmetrical polyneuropathy, inflammatory demyelinating polyradiculoneuropathy, mononeuropathy multiplex, progressive polyradiculopathy, and myopathy.

Patients with AIDS dementia complex have an increased concentration of CSF beta$_2$-microglobulin, which may be a valuable marker for the severity of dementia and the response to treatment. Treatment with zidovudine markedly decreases the concentration of beta$_2$-microglobulin. Other treatment considerations include the following:

1. Cytomegalovirus encephalitis is treated with ganciclovir.
2. A syndrome of lumbosacral polyradiculomyelopathy in patients presenting with progressive lumbosacral radicular symptoms (weakness, areflexia, and sensory loss in the legs) is often due to cytomegalovirus and, thus, is treated with ganciclovir.
3. Cryptococcal meningitis is treated with amphotericin B (also with flucytosine or fluconazole).
4. CNS lymphoma in AIDS patients is treated the same way as CNS lymphoma in immunocompetent patients, that is, with radiotherapy and chemotherapy.
5. Acute inflammatory demyelinating polyradiculoneuropathy responds well to plasma exchange or prednisone.
6. Polymyositis is treated the same as it is in other patients, that is, with corticosteroid therapy.

Toxoplasmic encephalitis is a common opportunistic infection in AIDS patients. Treatment for this infection is with either pyrimethamine plus sulfadiazine or pyrimethamine plus clindamycin. However, CNS lymphoma and toxoplasmic encephalitis can be difficult to differentiate because they have similar clinical manifestations and CT and MRI characteristics. Therefore, patients with AIDS who present with a contrast-enhancing CNS mass lesion are treated empirically for toxoplasmic encephalitis, and they have follow-up CT or MRI scans to determine whether the lesion decreases in size. Patients whose lesions do not respond to medical treatment should have a stereotactic biopsy for diagnosis, especially for the diagnosis of lymphoma.

Current therapy for HIV and AIDS uses a "cocktail" of medications (highly active antiretroviral therapy [HAART]), some of which have their own neurologic complications. Zidovudine-induced myopathy responds to dose reduction or withdrawal of

Table 18-23 Infectious Syndromes in the Central Nervous System

Syndrome	Clinical features	CSF and other findings	Common or important causes
Aseptic meningitis	Headache, fever, neck stiffness <4 wk duration	Mild to moderate mononuclear pleocytosis, normal glucose levels	Infectious—enteroviruses, arboviruses, HSV-2 and 6, HIV, mumps, *Borrelia burgdorferi*, *Treponema pallidum*, *Mycoplasma* Noninfectious—autoimmune disease, drug-induced
Septic meningitis	Headache, fever, neck stiffness <4 wk duration	Moderate to marked polynuclear pleocytosis, low glucose levels	*Streptococcus pneumoniae*, *Neisseria meningitidis*, *Listeria monocytogenes*, *Haemophilus influenzae*
Recurrent meningitis	Multiple acute episodes <4 wk duration	Mild to moderate mixed pleocytosis, variable glucose levels	Anatomical defects (*S. pneumoniae*), HSV-2 autoimmune disease Chemical meningitis
Chronic meningitis	Chronic headache and cognitive, cranial nerve, or other focal symptoms >4 wk duration	Mild to moderate mononuclear pleocytosis, low glucose levels, meningeal enhancement and/or hydrocephalus on MRI	Infectious—*Mycobacterium tuberculosis*, fungal (e.g., *Cryptococcus neoformans*) Noninfectious—sarcoidosis, neoplastic disease, vasculitis, autoimmune disorders
Acute encephalitis	Headache, fever, altered consciousness; frequently associated with seizures and focal or multifocal neurologic deficits	Mononuclear (occasionally polynuclear) pleocytosis, normal (occasionally low) glucose levels, abnormal EEG, high T2 signal lesions on MRI	HSV-1, La Crosse encephalitis, St. Louis encephalitis, Rocky Mountain spotted fever VZV, EBV, CMV, HHV-6, and enteroviruses in immunosuppressed patients
Postinfectious encephalomyelitis	Fever, multifocal neurologic signs, altered consciousness	Multiple areas of hyperintense T2 signal consistent with multifocal demyelinating disease, lymphocytic pleocytosis	Postviral (varicella, mumps, measles, URTI), postimmunization

CMV, cytomegalovirus; CSF, cerebrospinal fluid; EBV, Epstein-Barr virus; EEG, electroencephalography; HHV, human herpesvirus; HIV, human immunodeficiency virus; HSV, herpes simplex virus; MRI, magnetic resonance imaging; URTI, upper respiratory tract infection; VZV, varicella-zoster virus.

the medication. A painful, distal, sensory peripheral neuropathy occurs in patients receiving the nucleoside analogues zalcitabine (formerly called dideoxycytidine [ddC]), didanosine (formerly called dideoxyinosine [ddI]), and stavudine (d4T). The neuropathic symptoms may worsen after removal of the offending drug, the so-called coasting phenomenon.

Neurology of Sepsis

The nervous system is commonly affected in sepsis syndrome. The neurologic conditions encountered are septic encephalopathy, critical-illness polyneuropathy or myopathy (or both), cachexia, and panfascicular muscle necrosis. Neurologic complications also occur in intensive care units for critical medical illness. These complications include metabolic encephalopathy, seizures, hypoxic-ischemic encephalopathy, and stroke.

Septic Encephalopathy

Septic encephalopathy is brain dysfunction in association with systemic infection *without* overt infection of the brain or meninges. Early encephalopathy often begins before failure of other organs and is not due to single or multiple organ failure. Endotoxin does not cross the blood-brain barrier and so probably does not directly affect adult brains. Cytokines, important components of sepsis syndrome, may contribute to encephalopathy. Gegenhalten or paratonic rigidity occurs in more than 50% of patients, and tremor, asterixis, and multifocal myoclonus occur in about 25%. Seizures and focal neurologic signs are rare.

EEG is a sensitive indicator of encephalopathy. The mildest abnormality is diffuse excessive low-voltage theta activity (4-7 Hz). The next level of severity is intermittent rhythmic delta activity (<4 Hz). As the condition worsens, delta activity becomes arrhythmic and continuous. Typical triphasic waves occur in severe cases,

Table 18-24 Causes and Management of Bacterial Meningitis by Age

Age	Major pathogens	Empirical antibiotic regimen	Pathogen	Specific therapy
3 mo to 18 y	*Neisseria meningitidis*, *Streptococcus pneumoniae*, *Haemophilus influenzae*	Ceftriaxone (or cefotaxime); add vancomycin in areas with >2% incidence of highly drug-resistant *S. pneumoniae*	*N. meningitidis* *H. influenzae*	Penicillin G or ampicillin for 7-10 d Ceftriaxone for 7-10 d
18-50 y	*S. pneumoniae*, *N. meningitidis*	Ceftriaxone (or cefotaxime), add vancomycin in areas with >2% incidence of highly drug-resistant *S. pneumoniae*	*S. pneumoniae* (MIC <0-0.1) *S. pneumoniae* (MIC >0-0.1)	Ceftriaxone (or cefotaxime) for 10-14 d Vancomycin plus ceftriaxone for 10-14 d
>50 y	*S. pneumoniae*, *Listeria monocytogenes*, gram-negative bacilli	Ampicillin plus ceftriaxone (or cefotaxime); add vancomycin if drug-resistant *S. pneumoniae* is suspected	*L. monocytogenes*	Ampicillin plus gentamicin for 14-21 d (for patients with major penicillin allergy, TMP-SMX may be substituted for ampicillin)

MIC, minimal inhibitory concentration; TMP-SMX, trimethoprim-sulfamethoxazole.

especially in hepatic failure. In these cases, MRI and CT scans of the brain may be normal.

- Brain dysfunction is associated with systemic infection.
- Encephalopathy precedes failure of other organs.
- Cytokines are an important part of sepsis syndrome.
- More than 50% of patients have paratonic rigidity.
- Tremor, asterixis, and multifocal myoclonus occur in 25% of patients.
- EEG is a sensitive indicator of encephalopathy.

Critical Illness Polyneuropathy

Critical illness polyneuropathy occurs in 70% of the patients with sepsis and multiple organ failure. There is often an unexplained difficulty in weaning from mechanical ventilation. Nerve biopsy specimens show primary axonal degeneration of motor and sensory fibers without inflammation. Some patients also have concomitant myopathy. Recovery from polyneuropathy is satisfactory if the patient survives sepsis and multiple organ failure.

- Nerve biopsy specimens show primary axonal degeneration of motor and sensory fibers without inflammation.
- Recovery from polyneuropathy is satisfactory.

Neurologic Complications of Organ Transplantation

Because almost all organ transplant recipients require some degree of chronic, lifelong immunosuppressive therapy, the major neurologic complications of organ transplantation are due to immunosuppression. These include the direct neurotoxic side effects of immunosuppressive drugs, infections, and the development of de novo malignancies. Direct neurologic side effects include the following:

Cyclosporine—Tremor is the most common side effect of cyclosporine, which also may produce various motor syndromes such as hemiparesis, paraparesis, and quadriparesis. Cyclosporine may cause encephalopathy and, less commonly, neuralgia and neuropathy; it is epileptogenic.

Corticosteroids—The side effects of corticosteroids include myopathy, steroid psychosis, withdrawal (including myalgias, arthralgias, headache, lethargy, and nausea), and spinal cord or cauda equina compression due to epidural lipomatosis.

Azathioprine—Azathioprine has no direct neurotoxic side effects.

CNS Infections

Infection of the CNS in immunosuppressed patients is relatively frequent and life-threatening. The three organisms that cause more than 80% of CNS infections are *Listeria monocytogenes*, *Cryptococcus neoformans*, and *Aspergillus fumigatus*. The greatest risk factor for CNS infection is the magnitude and duration of immunosuppression. Patients with severe and advanced CNS infections may present with little or no clinical evidence of infection. The period of the risk of infection is mainly from 1 to 6 months after transplantation. Specific infections include 1) acute meningitis, most often due to *Listeria*; 2) subacute or chronic meningitis, generally

due to *Cryptococcus*; 3) slowly progressive dementia, frequently due to progressive multifocal leukoencephalopathy (caused by the JC virus); and 4) focal brain abscess due to infection usually caused by *Aspergillus*, *Toxoplasma*, *Listeria*, or *Nocardia*.

CNS Involvement by De Novo Lymphoproliferative Diseases

There is an increase in non-Hodgkin lymphoma, especially primary CNS lymphomas. These lymphomas may be linked to infection with Epstein-Barr virus.

Other Neurologic Complications

Other complications affecting the nervous system after transplantation can be classified as follows:

Complications arising from the underlying diseases
Problems resulting from the transplantation procedure
Side effects of immunosuppression
Posttransplantation disorder peculiar to the specific type of transplant

The complications include compressive neuropathies, plexopathies, and radiculopathies; encephalopathy (especially with kidney, liver, and heart transplants); and cerebral infarctions (with bone marrow and heart transplants). Chronic graft-versus-host disease (especially with bone marrow transplants) involves the peripheral nervous system (but not the CNS), for example, polymyositis, myasthenia gravis, and peripheral neuropathy, including CIDP. A complication associated with liver transplantation is central pontine myelinolysis, which is manifested as altered mental status or coma, pseudobulbar palsy, and quadriplegia.

		Parkinson disease	
Dopamine precursor			
Levodopa-carbidopa (Sinemet, Sinemet CR)	Contraindicated: narrow-angle glaucoma, MAO inhibitors used within previous 2 wk Dyskinesias, psychiatric disturbances, nausea/vomiting, orthostatic hypotension	Decreased levodopa effect: antipsychotics, iron, pyridoxine (vitamin B_6), phenytoin, TCAs Increased levodopa effect: antacids Affected by levodopa: antihypertensives, MAO-A inhibitors	Carbidopa prevents dopa-decarboxylase activity peripherally Regular release product *without* food; CR product *with* food Wearing off & on/off phenomena require adjustments in dose and administration schedule Taper dose over 2-3 d for discontinuation
Dopamine agonist			
Pramipexole (Mirapex)	Dyskinesias, psychiatric disturbances, nausea, constipation, orthostatic hypotension, syncope, confusion, hallucinations, sedation/sleep attacks	Increased pramipexole effect: cimetidine Decreased pramipexole effect: DA antagonists*	First-line drug of choice Weekly titration to target dose Reduce pramipexole dose in renal failure Take with food to decrease nausea/vomiting
Ropinirole (Requip)	Same as for pramipexole, more syncope, fewer hallucinations	Increased ropinirole effect: ciprofloxacin, estrogen Decreased ropinirole effect: smoking, DA antagonists*	Same as pramipexole
Pergolide (Permax)	Contraindicated: frovatriptan Same as for pramipexole; in addition, pleuropulmonary reaction, retroperitoneal fibrosis, erythromelalgia, pedal edema	Decreased pergolide effect: DA antagonists*	If pleuropulmonary reaction, retroperitoneal fibrosis, or erythromelalgia occurs, must discontinue drug Take with food to decrease nausea/vomiting
Bromocriptine (Parlodel)	Same as for pergolide	Increased bromocriptine effect: clarithromycin, isometheptene Increased effect by bromocriptine: cyclosporine, tacrolimus	Same as for pergolide
Apomorphine (Apokyn)	Contraindicated: 5-HT3 antagonists (ondansetron, granisetron, etc.) Severe nausea, headache, sedation, hallucinations, dizziness, bradycardia, hypotension, painful nodules with repeated SQ administration Rarely: syncope & QT prolongation	Increased apomorphine effect: tolcapone, entacapone	Approved for acute treatment of "off" periods Give with an antiemetic Do not give IV; SQ route recommended

Neurology Pharmacy Review (continued)

Drug (trade name)	Toxic/adverse effects	Drug interactions	Comments
MAO-B inhibitor			
Selegiline (Eldepryl)	Contraindicated: methyldopa, dextromethorphan, escitalopram, paroxetine, duloxetine, isometheptene, meperidine, phenelzine, sibutramine, fluoxetine, bupropion, phenylephrine, phenylpropanolamine, pseudoephedrine, reserpine, sertraline, venlafaxine Exacerbates levodopa side effects, agitation, insomnia	Increased effect of selegiline: TCAs, oral contraceptives, tramadol, amphetamine, sumatriptan, dextromethorphan, atomoxetine, buspirone, carbamazepine, cyclobenzaprine, oxycodone	Last dose given with lunch Hypertensive crises with tyramine foods not a concern because selegiline does not inhibit MAO-A in doses <20 mg daily
Anticholinergic			
Benztropine (Cogentin) Trihexyphenidyl (Artane)	Confusion, dry mouth, blurred vision, constipation, urinary retention	Decreased effect by anticholinergics: phenothiazines	Use with caution in BPH, elderly patients, and narrow-angle glaucoma Effective in only about 25% of patients Abrupt discontinuation causes rebound and withdrawal symptoms
COMT inhibitor			
Entacapone (Comtan)	Diarrhea, nausea, anorexia, orthostatic hypotension, dyskinesias, psychiatric disturbances, orange urine, severe explosive diarrhea	Increased effect by entacapone: COMT substrates (Epi, NE, dobutamine), nonselective MAO inhibitors, probenecid, cholestyramine, ampicillin, erythromycin, rifampin	COMT inhibitors are for adjunctive therapy to levodopa only Do not administer with nonselective MAO inhibitors
Tolcapone (Tasmar)	Same as for entacapone plus acute fulminant hepatic failure Contraindicated in liver disease	Increased effect by tolcapone: levodopa	Requires written informed consent from patient Monitor LFTs q 2 wk × 1 y; then q 4 wk × 6 mo; then q 8 wk thereafter
Miscellaneous			
Amantadine (Symmetrel)	Dizziness, confusion, nausea, ankle edema, livedo reticularis, psychiatric disturbances, nausea, hypotension	Increased effect by amantadine: medications with anticholinergic properties Increased amantadine effect: triamterene, trimethoprim-sulfamethoxazole	Tolerance develops in 6-12 wk Need to taper dose for discontinuation Adjust dose in renally impaired patients

Neurology Pharmacy Review (continued)

Drug (trade name)	Toxic/adverse effects	Drug interactions	Comments
		Alzheimer disease	
Cholinesterase inhibitors†			
Donepezil (Aricept)	Nausea/vomiting, diarrhea, headache, insomnia	Possible increased donepezil effect: ketoconazole, quinidine Possible decreased donepezil effect: phenytoin, phenobarbital, carbamazepine, rifampin, dexamethasone	Fewer side effects than tacrine because works only in CNS Wait 4 wk before increasing dose
Rivastigmine (Exelon)	Nausea/vomiting, diarrhea, dizziness, headache, anorexia/weight loss	None known	Take with food Because of marked GI adverse reactions, start dose at 1.5 mg twice daily and titrate to maintenance dose If treatment is interrupted more than several days, start again with lowest daily dose
Galantamine (Reminyl)	Nausea/vomiting, diarrhea, anorexia/weight loss, sleep disturbances	Increased effect by galantamine: ketoconazole, erythromycin, cimetidine, paroxetine, fluvoxamine	Take with food Dose reduction in renal or hepatic failure
Tacrine (Cognex)	Nausea/vomiting, diarrhea, dizziness, elevated LFTs, vivid dreams, agitation, confusion, ataxia, insomnia, myalgias	Increased effect by tacrine: theophylline, succinylcholine Increased tacrine effect: cimetidine, estradiol, fluvoxamine, riluzole, levonorgestrel	Monitor LFTs every other week for weeks 4-16, then q 3 mo Discontinue if jaundice, total bilirubin >3 mg/dL, or signs/symptoms or hypersensitivity in association with ALT elevation Recommended to take on an empty stomach; if significant stomach upset, take with meals
NMDA receptor antagonist			
Memantine (Namenda)	Dose dependent: dizziness, drowsiness, insomnia, headache, akathisia, nausea	Increased memantine effect: sodium bicarbonate, carbonic anhydrase inhibitors	Can be used with a cholinesterase inhibitor Decrease dose if renal impairment Takes 14 d for initial response Wait 1 wk between dose increases

Neurology Pharmacy Review (continued)

Drug (trade name)	Toxic/adverse effects	Drug interactions	Comments
		Multiple sclerosis	
Interferon beta-1a (Avonex, Rebif)	Contraindicated: pregnancy, albumin allergy, suicidal ideation or severe depression Depression, anxiety, injection site reaction, influenza-like symptoms, photosensitivity, increased LFT & leukopenia	Increased effect by interferon beta-1a: zidovudine, live vaccines	Avonex, weekly IM dosing; Rebif, 3 times weekly SQ dosing Rebif and Avonex are not interchangeable For both interferon beta-1a and beta-1b: caution patients to immediately report depression or any thoughts of suicide, caution in preexisting seizure disorder Rebif: stop if jaundice or symptoms of liver dysfunction
Interferon beta-1b (Betaseron)	Same as for interferon beta-1a; side effects generally more severe with interferon beta-1b	Increased effect by interferon beta-1b: live vaccines	Every other day SQ dosing Injection site rotation schedule Also monitor WBCs, Plt, LFTs periodically
Glatiramer acetate (Copaxone)	Contraindicated: mannitol allergy Injection site reaction, flushing, palpitations, chest tightness, dyspnea	Not known	Daily SQ dosing at bedtime Pregnancy category B

*Common DA antagonists include phenothiazines, droperidol, metoclopramide, atypical antipsychotics.

†Antagonistic effects with anticholinergics; additive effects with cholinergics or other cholinesterase inhibitors.

5-HT3, serotonin type 3; ALT, alanine aminotransferase; BPH, benign prostatic hypertrophy; CNS, central nervous system; COMT, catechol *O*-methyltransferase; CR, continuous release; DA, dopamine; Epi, epinephrine; GI, gastrointestinal; IM, intramuscular; IV, intravenously; LFT, liver function test; MAO, monoamine oxidase; NE, norepinephrine; NMDA, *N*-methyl-D-aspartate; Plt, platelets; q, every; SQ, subcutaneous; TCA, tricyclic antidepressant; WBC, white blood cell.

Neurology Pharmacy Review (continued)

Review of Headache Drugs

Drug (trade name)	Toxic/adverse effects	Drug interactions	Comments
		Acute treatment	
Ergots			
Ergotamine tartrate (Ergostat) Ergotamine/caffeine (Cafergot, Ercaf) Dihydroergotamine (DHE 45, Migranal)	Contraindicated: pregnancy, PVD, CAD, sepsis, liver or renal disease, severe HTN N/V, CNS, rebound headache, dependence, numbness/tingling of extremities Diarrhea with DHE 45	Protease inhibitors, macrolides, NNRT inhibitors decrease ergot metabolism Triptans add to vasospastic effects, avoid use within 24 h of ergots Sibutramine: could lead to serotonin syndrome β-Blockers: unopposed ergot action may lead to peripheral ischemia Nitrates: decreased ergot metabolism, decreased antianginal effects of nitrates	Avoid prolonged administration or excessive dose because of danger of gangrene Caffeine enhances intestinal absorption of ergotamine Most effective if given early in headache course DHE 45: used IM, IV, or SC; pretreat with antiemetic
Triptans			
Sumatriptan (Imitrex) Naratriptan (Amerge) Rizatriptan (Maxalt, Maxalt-MLT) Zolmitriptan (Zomig) Almotriptan (Axert) Frovatriptan (Frova) Eletriptan (Relpax)	Contraindicated: IHD, Prinzmetal angina, uncontrolled HTN, use with or within 24 h of ergots or other serotonin agonist, use with or within 2 wk of MAO inhibitors, hemiplegic or basilar migraine CNS, chest pain, GI, photosensitivity, headache recurrence	MAO-A inhibitors (but not MAO-B inhibitors) decrease metabolism of triptans. Naratriptan is not metabolized by MAO-A & is less likely to interact with MAO inhibitors Ergots (see above) SSRIs, sibutramine: possible serotonin syndrome Propranolol increases rizatriptan by 70% and frovatriptan (in males) by 60% Almotriptan & eletriptan have important interactions with CYP3A4 inhibitors	Do not exceed recommended dose; each agent has specific requirements for daily maximum Do not give Imitrex injectable product IV Headache recurrence rate may be lower with naratriptan and frovatriptan (longer half-life)
Analgesics			
Acetaminophen (Tylenol) NSAIDs			Drugs of choice for menstrual migraine prophylaxis Ketorolac: given IV/IM for acute headache treatment
Butorphanol nasal spray (Stadol)	Somnolence, dizziness, nasal congestion; may precipitate withdrawal in the opioid-dependent		Poor tolerance is often limiting factor for routine use
Midrin (isometheptene [sympathomimetic] + dichloralphenazone [mild sedative] + acetaminophen)	Contraindicated: glaucoma, severe renal disease, HTN, organic heart disease, liver disease, MAO inhibitor therapy CNS, agranulocytosis (dichloralphenazone)	MAO inhibitors with isometheptene may cause hypertensive crisis May potentiate effects of warfarin	Maximum: 5 capsules/24 h

Neurology Pharmacy Review (continued)

Review of Headache Drugs (continued)

Drug (trade name)	Toxic/adverse effects	Drug interactions	Comments
		Acute treatment	
Analgesics			
Meperidine (Demerol)	Contraindicated: concurrent MAO inhibitor, respiratory depression CNS, dependence	MAO inhibitor: hypertensive crisis Ritonavir inhibits meperidine metabolism Sibutramine: possible serotonin syndrome	Give SC/IM for acute headache treatment Metabolized to normeperidine, which accumulates with chronic dosing and renal dysfunction to cause CNS SEs
Butalbital products (Fiorinal, Fioricet)	Contraindicated: porphyria CNS, respiratory depression, tolerance/dependence, depression	Butalbital may increase metabolism of warfarin Avoid ethanol with butalbital	Fiorinal: butalbital + caffeine + aspirin Fioricet: butalbital + caffeine + acetaminophen
Corticosteroids			
Dexamethasone (Decadron)	Contraindicated: systemic fungal infection Peptic ulceration, immunosuppression, psychosis, HPA-axis suppression, fluid retention, osteoporosis	Anticholinesterases: steroids antagonize ACHE effects Rifamycins: increased metabolism of steroids	Give IV/IM for acute headache treatment Pretreat with antiemetic Limit to 1 dose
		Prophylactic treatment*	
β-Blockers			
Propranolol (Inderal) Timolol (Blocadren) Metoprolol (Lopressor)	Contraindicated: asthma or bronchospasm, sinus bradycardia, 2nd/3rd-degree heart block Fatigue, depression, blunting of hypoglycemic/hyperthyroid reactions Abrupt withdrawal may precipitate angina or MI	Clonidine plus β-blocker: discontinue gradually and remove β-blocker first Epinephrine: initial hypertensive episode followed by bradycardia Verapamil: effects of both drugs are enhanced Ergots (see above)	Drugs of choice for migraine prophylaxis Avoid agents with ISA activity Failure of 1 agent does not preclude trial of another
Tricyclic antidepressants			
Amitriptyline (Elavil) Nortriptyline (Pamelor)	Contraindicated: avoid in acute recovery stage after MI Anticholinergic SE, cardiac abnormalities, decreased seizure threshold, CNS, photosensitivity	Clonidine: hypertensive crisis Sparfloxacin, grepafloxacin: risk of torsades de pointes MAO inhibitors: hypertensive crisis	Very toxic in overdose
Miscellaneous			
Verapamil (Calan, Isoptin)	Contraindicated: advanced heart failure, 2nd/3rd-degree AV block, LV dysfunction, sick sinus syndrome Arrhythmias, constipation	β-Blockers: increased effects of both drugs Digoxin: increased digoxin levels Use with dofetilide is contraindicated Prolongs half-life of quinidine

Review of Headache Drugs (continued)

Drug (trade name)	Toxic/adverse effects	Drug interactions	Comments
	Prophylactic treatment* (continued)		
Divalproex sodium (Depakote ER)	See table for antiepileptic agents (valproic acid derivatives)	See table for antiepileptic agents (valproic acid derivatives)	
Methysergide (Sansert)	Same as for ergots Retroperitoneal, pleuro-pulmonary, & cardiac fibrosis	Same as for ergots	Requires 3-4-wk drug holiday between each 6-mo treatment course Last-line agent because of severe SEs

ACHE, acetylcholinesterase; AV, atrioventricular; CAD, coronary artery disease; CNS, central nervous system; GI, gastrointestinal; HPA, hypothalamo-pituitary-adrenocortical; HTN, hypertension; IHD, ischemic heart disease; IM, intramuscular; ISA, intrinsic sympathomimetic activity; IV, intravenous; LV, left ventricular; MAO, monoamine oxidase; MI, myocardial infarction; NNRT, nonnucleoside reverse transcriptase; NSAID, nonsteroidal anti-inflammatory drug; N/V, nausea and vomiting; PVD, peripheral vascular disease; SC, subcutaneous; SE, side effect; SSRI, selective serotonin reuptake inhibitor.

*Prophylaxis is indicated for patients with 1) prolonged aura, 2) >2 or 3 attacks per month, in which abortive agents are ineffective or contraindicated, 3) headache requiring daily symptomatic therapy.

Neurology Pharmacy Review (continued)

Review of Antiepileptic Drugs

Drug (trade name)	Toxic/adverse effects	Drug interactions	Comments
Traditional AEDs*			
Phenytoin (Dilantin)	Contraindicated: sinus bradycardia, SA block, 2nd/3rd-degree AV block or Adams-Stokes syndrome Increased LFTs, nystagmus, gingival hyperplasia, folic acid deficiency, blood dyscrasias, hirsutism, metabolic bone disease, coarsening facial features, hyperglycemia Monitor ECG & BP during IV administration	IV administration of phenytoin during dopamine infusions may cause severe hypotension and cardiac arrest Liver enzyme inducer: causes increased metabolism of many other drugs (cyclosporine, tacrolimus, theophyllines, oral contraceptives, itraconazole, antiarrhythmics, steroids, other AEDs) Rifampin, chemotherapy agents, theophyllines, steroids decrease phenytoin levels Phenytoin interacts with tube feedings, separate phenytoin and tube feeding by 2 h Cimetidine, fluconazole, sulfas, SSRIs, felbamate, topiramate increase phenytoin concentration	IV phenytoin precipitates in solution: give IV push Maximal rate: 50 mg/min; avoid IM use Metabolism is capacity-limited & shows saturability; avoid large dose changes Highly protein bound to albumin: may choose to check free phenytoin levels in hypoalbuminemic states Avoid frequent dose changes: steady state reached in 10-14 d
Fosphenytoin (Cerebyx)	Same as for phenytoin Groin paresthesia with IV administration	As for phenytoin	Antiepileptic activity is due to phenytoin (fosphenytoin is prodrug) Dose is expressed as PE IM product must be diluted before administration IV Maximal rate of IV infusion: 150 mg PE/min Continuous monitoring of ECG, BP, & RR is essential during IV administration and for 10-20 min after end of infusion Avoid IM for treatment of status epilepticus

Neurology Pharmacy Review (continued)

Review of Antiepileptic Drugs (continued)

Drug (trade name)	Toxic/adverse effects	Drug interactions	Comments
Traditional AEDs* (continued)			
Carbamazepine (Tegretol, Tegretol-XR, Carbatrol)	Contraindicated: bone marrow suppression, with or within 14 d of MAO inhibitors Blood dyscrasias: leukopenia (10%), aplastic anemia (rare), thrombocytopenia Hyponatremia Cholestatic jaundice	Liver enzyme inducer: causes increased metabolism of other drugs (warfarin, oral contraceptives, cyclosporine, TCAs, bupropion, other AEDs) Metabolized by CYP3A4 Macrolides, azole antifungals, grapefruit, fluoxetine, cimetidine, verapamil, propoxyphene, isoniazid increase carbamazepine concentrations Valproic acid increases carbamazepine epoxide (active metabolite) by 45% Felbamate, phenobarbital, phenytoin, rifampin decrease carbamazepine concentrations	Monitor CBC/DC at baseline, monthly ×2 mo, then every 12-24 mo (discontinue if WBC <3×10^9/L or ANC <1.5×10^9/L); LFTs at baseline and periodically, serum sodium periodically Structurally related to TCAs Carbamazepine induces its own metabolism, so true steady state may not be seen for 30 d even though half-life is short
Valproic acid derivatives (Depakote, Depakote Sprinkle, Depakote ER, Depakene, Depacon)	Contraindicated: liver disease/dysfunction Pancreatitis, rare fatal hepatotoxicity (risk greatest if age <2 y), GI, platelet aggregation inhibition, alopecia, thrombocytopenia (dose related), weight gain, hyperammonemia	Liver enzyme inhibitor: causes decreased metabolism of lamotrigine, phenobarbital, phenytoin, diazepam, & ethosuximide & increased levels of carbamazepine-epoxide Use caution in patients taking other agents affecting platelet function Carbamazepine, phenytoin, phenobarbital, rifampin decrease valproic acid concentrations Felbamate, salicylates, erythromycin increase valproic acid concentrations	Do not give injectable product IM. Typical maximal infusion rate: 20 mg/min (some evidence that faster rate over 5-10 min is safe) Depakote tablets are not bioequivalent to Depakote ER tablets; do not crush any Depakote product
Phenobarbital	Contraindicated: respiratory disease when dyspnea or obstruction is present, porphyria Tolerance/dependence, hyperactivity in children, cognitive impairment, metabolic bone disease	Liver enzyme inducer: causes increased metabolism of other drugs (warfarin, metronidazole, theophyllines, oral contraceptives, steroids, β-blockers) Felbamate, valproic acid, chloramphenicol decrease metabolism of phenobarbital	Maximal infusion rate: 60 mg/min; avoid intra-articular or SC injection
Primidone (Mysoline)	As for phenobarbital	As for phenobarbital Phenytoin causes increased serum concentration of phenobarbital component	Metabolized by liver to phenylethyl-malonamide (active) and phenobarbital

Neurology Pharmacy Review (continued)

Review of Antiepileptic Drugs (continued)

Drug (trade name)	Toxic/adverse effects	Drug interactions	Comments
Traditional AEDs* (continued)			
Felbamate (Felbatol)	Contraindicated: history of blood dyscrasias, liver dysfunction Aplastic anemia, hepatotoxicity, photosensitivity	Inducers (phenytoin, carbamazepine, phenobarbital) decrease felbamate concentrations Felbamate increases phenytoin, valproic acid, phenobarbital, carbamazepine-epoxide concentrations	Monitoring: CBC/DC at baseline and every 2-4 wk LFTs and bilirubin every 1-2 wk Recommended for use *only* in severe epilepsy refractory to all other treatment
Newer AEDs†			
Lamotrigine (Lamictal)	Photosensitivity Risk of severe, potentially life-threatening rash increases if age <16 y Risk *may* increase if lamotrigine is given concurrently with valproic acid, dose exceeds recommended dose, or dose is escalated faster than recommended	Valproic acid increases lamotrigine concentrations Lamotrigine decreases valproic acid concentrations Inducers (phenytoin, carbamazepine, phenobarbital) decrease lamotrigine concentrations Lamotrigine inhibits dihydrofolate reductase; be aware if administering other inhibitors of folate metabolism	*Must* use smaller doses of lamotrigine in combination with valproic acid Discontinue lamotrigine at the first sign of rash
Tiagabine (Gabitril)	GI (give with food) Weakness	Inducers (phenytoin, carbamazepine, phenobarbital) decrease tiagabine concentration by 60% Metabolized by CYP3A	Decrease dose and/or increase interval in hepatic insufficiency
Gabapentin (Neurontin)	GI	Separate aluminum/magnesium antacids and gabapentin by 2 h	Renally eliminated, not metabolized; must be adjusted for renal insufficiency
Topiramate (Topamax, Topamax Sprinkle)	Nephrolithiasis Paresthesias	Inducers (phenytoin, carbamazepine, phenobarbital) may decrease topiramate concentrations Topiramate has additive effect with carbonic anhydrase inhibitors Topiramate decreases efficacy of estrogen component of oral contraceptives	70% of dose excreted unchanged in urine: use 1/2 normal dose in patients with renal impairment Encourage fluid intake to avoid nephrolithiasis

Neurology Pharmacy Review (continued)

Review of Antiepileptic Drugs (continued)

Drug (trade name)	Toxic/adverse effects	Drug interactions	Comments
Newer AEDs† (continued)			
Zonisamide (Zonegran)	Contraindicated: hypersensitivity to sulfa Do not use in renal failure (creatinine clearance <50 mL/min) Urolithiasis	Inducers (phenytoin, carbamazepine, phenobarbital) may decrease zonisamide concentration Concurrent drugs that induce or inhibit CYP3A4 would be expected to alter zonisamide concentrations Zonisamide is not expected to interfere with metabolism of other drugs metabolized by CYT P450	Long half-life; may take up to 2 wk to reach steady state Encourage fluid intake to avoid urolithiasis
Newest AEDs			
Oxcarbazepine (Trileptal)	Hyponatremia 25%-30% of patients with hypersensitivity to carbamazepine have hypersensitivity to oxcarbazepine	Oxcarbazepine inhibits CYP2C19, induces CYP3A4/5 Inducers (phenytoin, carbamazepine, phenobarbital) decrease 10-monohydroxy-carbazepine (active metabolite) levels Oxcarbazepine increases metabolism of oral contraceptives, felodipine	Initiate at 1/2 normal dose if creatinine clearance <30 mL/min
Levetiracetam (Keppra)	Decreased erythrocytes, hemoglobin, hematocrit Infection	Per clinical trials, levetiracetam does not appear to affect or be affected by other AEDs, but cases of increased phenytoin concentrations have been reported	2/3 of dose excreted unchanged in urine Must be adjusted for renal dysfunction

AED, antiepileptic drug; ANC, absolute neutrophil count; AV, atrioventricular; BP, blood pressure; CBC, complete blood count; CNS, central nervous system; DC, differential count; ECG, electrocardiography; GI, gastrointestinal; IM, intramuscular; IV, intravenous; LFT, liver function test; MAO, monoamine oxidase; PE, phenytoin equivalents; RR, respiratory rate; SA, sinoatrial; SC, subcutaneous; SE, side effect; SSRI, selective serotonin reuptake inhibitor; TCA, tricyclic antidepressant; WBC, white blood cell.

*For all AEDs, the most common SEs are CNS effects (drowsiness, dizziness, ataxia). With chronic administration, tolerance usually develops to these SEs. The general rule for dosing AEDs is "start low and go slow." Do not discontinue AEDs abruptly.

†Generally, the newer/newest AEDs tend to have fewer side effects than older agents, tend to have fewer drug interactions than older AEDs, and are approved as adjunctive agents with older AEDs. The value of blood level monitoring is undefined for the newer/newest AEDs.

19

Oncology

Timothy J. Moynihan, MD

Breast Cancer

Magnitude of the Problem

In the United States, more than 220,000 new cases of breast cancer are diagnosed annually. Breast cancer will develop in approximately 1 in 8 women who achieve a normal life expectancy. Breast cancer is the second most common cause of cancer death among women in the United States (lung cancer is the most common). The incidence is increasing largely due to screening.

- Breast cancer will develop in 1 in 8 American women.
- Incidence is increasing (largely due to screening).
- Breast cancer is the second most common cause of cancer death in American women.

Risk Factors

The risk factors for breast cancer are outlined in Table 19-1. Breast cancer-associated genes (*BRCA1* and *BRCA2*) occur in fewer than 5% to 10% of cases of breast cancer, but women who carry these genes may have up to a 50% to 80% chance for breast cancer developing in their lifetime. Less than 25% of women with breast cancer have known high-risk factors.

- Less than 25% of women with breast cancer have known high-risk factors.

Screening

The use of screening mammography in the age group 50 years or older has decreased breast-cancer associated mortality by 20% to 30%. The use of screening mammography in the age group 40 to 50 years is controversial. There is general consensus that women 50 years or older should be screened with annual clinical examination and mammography. For women deemed at high risk for breast cancer, screening should be instituted at an appropriate earlier age, generally taken as 5 to 10 years before the earliest diagnosis of breast cancer in the family. Currently, mammography misses about 10% of breast cancers detectable on physical examination. Thus, any palpable breast mass should be evaluated with ultrasonography. If ultrasonography shows a simple cyst, it can be either closely observed or aspirated. Biopsy should be done for a palpable lesion that shows a solid component on ultrasonography, even if the results of mammography are normal. Magnetic resonance imaging is being studied to determine whether it is helpful for screening women with dense breast tissue or a strong family history. Currently, it should be used in the study setting only, and it is not recommended for routine screening.

Table 19-1 Risk Factors for Breast Cancer

High risk: relative risk >4.0	Moderate risk: relative risk 2-4	Low risk: relative risk 1-2
Older age	Any first-degree relative with breast cancer	Menarche before age 12 y
Personal history of breast cancer	Personal history of ovarian or endometrial cancer	Menopause after age 55 y
Family history of premenopausal bilateral breast cancer or familial cancer syndrome	Age at first full-term pregnancy >30 y	Caucasian race
Breast biopsy showing proliferative disease with atypia	Nulliparous	Moderate alcohol intake
	Obesity in postmenopausal women	Long-duration (≥15 y) estrogen replacement therapy
	Upper socioeconomic class	

- Screening for breast cancer can reduce mortality.
- Women 50 years or older need annual examinations and mammography.
- There is controversy about screening normal women who are 40 to 50 years old.
- Ten percent of breast cancers found on physical examination are missed by mammography.
- Ultrasonography is recommended for a suspicious palpable lump, even if the results of mammography are negative. Biopsy should be done for lesions with a solid component on ultrasonography.
- Magnetic resonance imaging is not recommended for routine screening.

Pathology

Breast cancers are classified as ductal or lobular, corresponding to the ducts and lobules of the normal breast (Fig. 19-1). Invasive (sometimes called infiltrating) breast cancer has the potential for systemic spread, as opposed to carcinoma in situ, which does not have metastatic potential because by definition it has not invaded through the basement membrane.

Ductal carcinoma in situ is noninvasive, does not have the potential for systemic spread, and is primarily treated with local therapy only, including resection and breast irradiation. Use of selective estrogen receptor modulators (e.g., tamoxifen, raloxifene) after resection of ductal carcinoma in situ is controversial. These drugs do decrease the risk of a subsequent "breast event" (defined as either recurrent carcinoma in situ or development of an invasive breast cancer in the ipsilateral or contralateral breast) in the subsequent 10 years from 13% to 8%. However, there is no evidence of a survival advantage, and there are potential significant side effects with use of these medications.

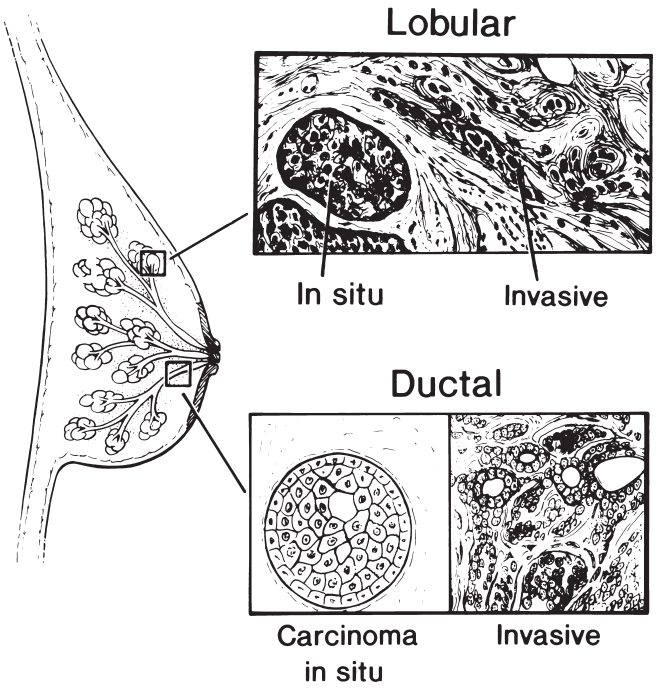

Fig. 19-1. Breast carcinomas: ductal and lobular, in situ and invasive.

Infiltrating ductal carcinoma is the most common histologic type (70% of breast cancers) of invasive breast cancer. Invasive lobular carcinoma makes up 25% of breast cancers, is more frequently multifocal and bilateral, and is less likely to be seen on mammography.

- Infiltrating ductal carcinoma is the most common histologic type of breast cancer.
- Lobular disease is more frequently multifocal and bilateral.
- Ductal carcinoma in situ is noninvasive and does not have the potential for systemic spread.
- Use of selective estrogen receptor modulators after resection of ductal carcinoma in situ is controversial.

Staging

The staging system of the American Joint Committee on Cancer is shown in Table 19-2.

Natural History and Prognostic Factors

Nodal Status

The number of involved axillary nodes remains the single best predictor of outcome (Fig. 19-2).

Tumor Size

After nodal status, tumor size is generally the most important prognostic factor (Table 19-3).

Hormone Receptor Status

In general, patients with estrogen-receptor–positive tumors have a better prognosis. However, the difference in recurrence rates at 5 years is only 8% to 10% when compared with receptor-negative disease.

Grade

Most breast cancers are high-grade. Patients with low-grade tumors have fewer recurrences and longer survival.

- The number of involved axillary nodes is the most important predictor of outcome.
- After nodal status, tumor size is the most important prognostic factor.
- Patients with receptor-positive tumors have a better prognosis.
- Patients with low-grade tumors have a better prognosis.

Treatment

Primary or Local-Regional Therapy

Primary local treatment for invasive breast cancer is either lumpectomy (also known as wide local excision or breast conservation), followed by radiation therapy, or mastectomy. Several randomized controlled clinical trials have shown therapeutic equivalence for breast conservation and mastectomy in terms of overall survival, whereas

Table 19-2 Staging of Breast Cancer

Primary tumor (T)		
	TIS	Carcinoma in situ
	T1	T = ≤2 cm
	T2	T = 2.1-5 cm
	T3	T = >5 cm
	T4	T of any size with direct extension to chest wall or skin
Regional nodes (N)		
	N0	No involved nodes
	N1	Movable ipsilateral axillary nodes
	N2	Matted or fixed nodes, or in clinically apparent ipsilateral internal mammary nodes in the absence of clinically evident axillary lymph node metastasis
	N3	Metastasis in ipsilateral infraclavicular lymph nodes
Distant metastasis (M)		
	M0	None detected
	M1	Distant metastasis present (includes ipsilateral supraclavicular nodes)
Stage grouping		
Stage I	T1 N0	
Stage IIA	T0 N1 T1 N1 T2 N0	= Operable disease
Stage IIB	T2 N1 T3 N0	
Stage IIIA	T0 N2 T1 N2 T2 N2 T3 N1,N2	= Locally advanced disease
Stage IIIB	T4, Any N	
Stage IIIC	Any T N3	= Advanced disease
Stage IV	Any T Any N M1	= Advanced or metastatic

Data from Singletary SE, Allred C, Ashley P, Bassett LW, Berry D, Bland KI, et al: Revision of the American Joint Committee on cancer staging system for breast cancer. J Clin Oncol. 2002;20:3628-36.

mastectomy has a slightly lower local recurrence rate. The outcome for women with invasive breast cancer depends on the presence of distant microscopic metastatic disease rather than on the treatment of local disease.

The most important predictor for the presence of micrometastatic disease is involvement of axillary lymph nodes. All women with invasive breast cancer need to have the status of their axillary lymph nodes determined. This can be accomplished by use of an axillary lymph node dissection or by use of a newer procedure called a sentinel lymph node biopsy. Sentinel lymph node biopsy uses a radioactive tracer or a blue dye injected into the periareolar or peritumoral bed. The surgeon then is able to identify the first draining lymph node and remove it. If this "sentinel lymph node" shows histologic signs of cancer, then the patient should undergo a complete axillary lymph node dissection. If the sentinel lymph node does not have metastatic tumor cells, then the probability of other lymph nodes being affected is less than 5%. Sentinel lymph node biopsy decreases late complications such as lymphedema. Adequate surgical training is required to perform this procedure.

- Breast conservation plus radiation is equal to mastectomy in terms of overall survival.
- Sentinel lymph node biopsy carries less risk of arm lymphedema.
- Sentinel lymph node procedure should be performed only by surgeons trained in this procedure.

Adjuvant Treatment

After primary treatment of the breast, additional systemic treatment (adjuvant) has been shown to decrease the risk of systemic recurrence and to improve overall survival. The number of involved axillary lymph nodes is the single most important predictor of outcome. Women with metastatically involved axillary lymph nodes should be offered adjuvant treatment (Table 19-4): chemotherapy or hormonal therapy or both. Women with negative lymph nodes have only a 25% chance of microscopic metastatic disease, and their risk of recurrence can be further estimated according to the data in Table 19-5. Adjuvant systemic treatment should be offered to women in the intermediate- and high-risk groups. Chemotherapy has been shown to decrease risk of recurrence and improve overall survival in both node-negative and node-positive women, but it is associated with more toxicity than hormonal therapy. Sequential therapy with chemotherapy followed by hormonal therapy does offer additive effect against cancer in women with hormonally sensitive disease. Long-term follow-up of women with breast cancer is essential because only 17% of recurrences develop during the first 5 years after initial diagnosis, and metastatic disease can develop 30 or more years later.

- Women with node-positive disease are at high risk of systemic disease and should be offered adjuvant treatment.
- Women with node-negative disease have a 25% or less chance of systemic disease.
- Adjuvant therapy decisions should be individualized based on each person's risk of recurrence.

Treatment of Advanced Disease

We currently lack curative therapy for recurrent or metastatic breast cancer. The median duration of survival for recurrent disease is 2.5 years. Survival is longer with bone or soft tissue recurrence than with visceral recurrence. Because treatment is not curative, the initial systemic treatment for patients with estrogen-receptor–positive advanced disease is usually hormonal. Chemotherapy is used once women

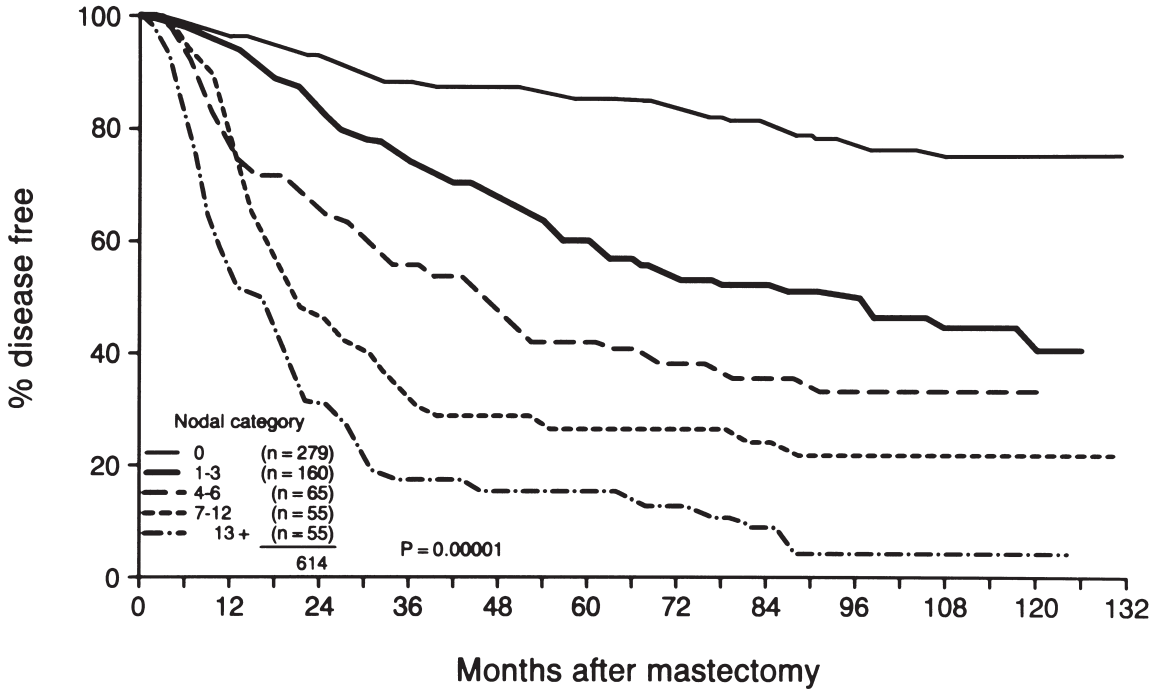

Fig. 19-2. Relation of disease-free survival to numbers of nodal metastases in more than 600 women with breast cancer treated with radical mastectomy alone in the early 1970s. (From Fisher ER, Sass R, Fisher B. Pathologic findings from the National Surgical Adjuvant Project for Breast Cancers [protocol no. 4]. X. Discriminants for tenth year treatment failure. Cancer. 1984;53:712-23. Used with permission.)

have progressed on hormonal therapy or in women with estrogen-receptor–negative breast cancer.

- There is no curative therapy for recurrent or metastatic breast cancer.
- The average survival with recurrent breast cancer is 2.5 years.

Chemotherapy

Active drugs against breast cancer include doxorubicin (Adriamycin, A), cyclophosphamide (C), methotrexate (M), 5-fluorouracil (F), paclitaxel (Taxol), docetaxel (Taxotere), capecitabine (Xeloda), vinorelbine (Navelbine), vincristine, vinblastine, mitomycin-C, etoposide, and cisplatin. Common combination regimens are CMF, CAF, and AC. The side effects of chemotherapy include reversible lowering of the blood counts and reversible hair loss. After 20 years of follow-up, there has been no increased risk of second malignancies for women who received adjuvant chemotherapy.

Hormonal Therapy

Tamoxifen is the most widely used hormonal agent in the treatment of patients with breast cancer. Tamoxifen is a nonsteroidal compound that on selected tissue acts like an antiestrogen (breast tissue) but on other tissue acts like an estrogen (bones, lipids, uterus). Its beneficial effects include 1) antitumor effects on breast cancer cells, 2) decreased risk (by 40%) of contralateral breast cancer, 3) improved bone density, and 4) favorable effects on lipid profiles. Tamoxifen also has some side effects, including 1) vaginal dryness and hot flashes, 2) thromboembolic risk (1%-2%), 3) increased risk of endometrial cancer, and 4) increased risk of cataracts.

A new class of hormonal agents, known as the aromatase inhibitors, is being used for treatment of postmenopausal women with breast cancer. These drugs include anastrozole, exemestane, and letrozole. These drugs show a slight superiority to tamoxifen for reducing the risk of recurrence of breast cancer, and they are not associated with an increased risk of thrombotic or endometrial events. The aromatase inhibitors do increase the risk of osteoporosis.

Table 19-3 Long-Term Results* in Patients With Node-Negative Breast Cancer Treated Surgically

Tumor size, cm	No. of patients	% free of recurrence	% dead of disease
<1	171	88	10
1.1-2.0	303	74	24
2.1-3.0	188	72	24
3.1-5.0	105	61	36

*Median duration of follow-up was 18 years.
Data from Rosen PP, Groshen S, Kinne DW. Survival and prognostic factors in node-negative breast cancer: results of long-term follow-up studies. Monogr Natl Cancer Inst. 1992;11:159-62.

Table 19-4 Adjuvant Therapy: Node-Positive Breast Cancer

	Estrogen-receptor status	
	Positive	Negative
Premenopausal	Chemo + Tam	Chemo
Postmenopausal	Chemo + hormones*	Chemo

Chemo, combination chemotherapy; Tam, tamoxifen.
*Hormonal therapy for postmenopausal women can be either tamoxifen or an aromatase inhibitor.

- Tamoxifen has both antiestrogen and estrogen-like activity.
- Beneficial effects of tamoxifen: antitumor effects, increased bone density, improved lipid profile, and decreased risk of contralateral breast cancer.
- Side effects of tamoxifen: hot flashes, vaginal dryness, thromboembolic risk, and increased risk of endometrial cancer.
- Aromatase inhibitors are useful only for postmenopausal women.
- Aromatase inhibitors increase the risk of osteoporosis, but they do not increase the risk of thrombosis or endometrial cancer.

Other hormonal agents include megestrol acetate, a progestational agent; fluoxymesterone, an androgen; and the estrogen receptor antagonist fulvestrant.

Premenopausal women with hormonally sensitive disease may benefit from oophorectomy (either chemical or surgical).

Other Agents

Herceptin

About 25% of breast cancers overexpress the growth factor HER2. A monoclonal antibody directed against HER2 (trastuzumab) has been shown to have activity against breast cancers that overexpress HER2. Trastuzumab (Herceptin) reduces the recurrence of HER2-positive early-stage breast cancer by half compared with chemotherapy alone. Trastuzumab is synergistic with certain chemotherapy agents. Side effects of trastuzumab can include myocardial dysfunction and should not be used in conjunction with cardiotoxic chemotherapy agents such as doxorubicin.

Zoledronic Acid and Pamidronate

The use of the bisphosphonates can reduce the need for palliative radiation, bone fixation, and pain medicine in women with lytic bone metastases.

Patterns of Recurrence

Breast cancer tends to recur in bones, liver, lungs, or brain or locally in the chest wall or residual breast. Recurrences can occur decades after initial diagnosis and must always be kept in mind in any patient with a history of breast cancer, no matter how distant.

Typical Clinical Scenarios

- A 40-year-old woman has a 3-cm mass in the right breast and two lymph nodes involved in the axilla. The biopsy result is adenocarcinoma that is hormone-receptor–negative. The diagnosis is node-positive adenocarcinoma of the right breast. Treatment is local therapy (modified radical mastectomy or lumpectomy plus radiation) followed by adjuvant chemotherapy.
- A 65-year-old patient has a history of breast carcinoma treated 10 years earlier with operation and chemotherapy. The patient presents with back pain, and bone scanning shows multiple areas of increased uptake throughout the skeleton. Biopsy shows estrogen-receptor– and progesterone-receptor–positive adenocarcinoma consistent with a breast primary lesion. There is no evidence of metastatic disease elsewhere. Initial therapy is focal radiation to painful sites, hormonal therapy, and use of bisphosphonates.

Cervical Cancer

Background

The incidence of and mortality from cervical cancer have decreased by 30% to 40% in recent decades, attributed to widespread use of Papanicolaou smear screening. Currently, 12,200 new cases of cervical cancer are diagnosed in U.S. women each year, and there are 4,100 deaths annually. In addition, more than 50,000 cases of carcinoma in situ of the cervix are diagnosed annually. Risk factors for cervical cancer include first intercourse at an early age, a greater number of sexual partners, smoking, history of sexually transmitted disease (herpesvirus or human papillomavirus lesions), and lower socioeconomic class. It is now understood that human papillomavirus is an etiologic agent for cervical carcinogenesis. Two different human papillomavirus vaccines have been shown to be effective for preventing 90% to 100% of infections with human papillomavirus.

If a cytologic smear shows dysplasia or malignant cells, colposcopy with directed biopsy should be done. The Papanicolaou smear has limited sensitivity; false-negative rates of 20% frequently are quoted. The American Cancer Society recommends that asymptomatic, low-risk women 20 years of age or older, and those younger than 20 years who are sexually active, have a Papanicolaou smear annually for 2 consecutive years and, if the results are negative, at least one every 3 years.

- Risk factors for cervical cancer include early intercourse, a greater number of sexual partners, smoking, history of sexually transmitted

Table 19-5 Adjuvant Therapy: Node-Negative Breast Cancer*

	Risk		
	Low	Intermediate	High
Tumor size, cm	<1	1-2	>2
ER or PR	+	+	–
Grade	1	1-2	2-3

ER, estrogen receptor; PR, progesterone receptor.
*Most oncologists would not treat tumors less than 1 cm.

disease, herpesvirus or human papillomavirus, and lower socioeconomic class.
- Effective human papillomavirus vaccines are now available.
- The false-negative rate of Papanicolaou smears is 20%.

Treatment

Treatment for carcinoma in situ of the cervix is usually total hysterectomy. If additional childbearing is desired, a more conservative approach, such as a therapeutic conization, is another option. Early invasive carcinoma of the cervix is usually treated with total hysterectomy. For patients with higher-stage disease, a combination of chemotherapy (cisplatin-based) and radiation therapy is recommended.

Colorectal Cancer

Background

Colorectal cancer is diagnosed in approximately 148,000 Americans each year and causes 57,000 deaths. Colorectal cancer is most common in North America and Europe. It is associated with high-fat, low-fiber diets. Population screening with fecal occult blood testing remains problematic. Although one study showed a reduction in mortality from colorectal cancer with fecal occult blood screening, any participants who had positive results went on to have colonoscopy. Another study showed that fecal occult blood tests failed to detect 70% of colorectal cancers and 80% of large (≥2 cm) polyps. Although specific screening recommendations vary, some form of screening process should be initiated by age 50 years regardless of risk. For high-risk patients, such as those with a family history of colorectal cancer or a prior colorectal cancer, structural studies of the entire large bowel, such as colonoscopy or proctoscopy plus barium enema, should be performed at appropriate intervals (such as every 1-3 years).

- Colorectal cancer is associated with high-fat, low-fiber diets.
- Although specific screening recommendations vary, some form of screening process should be initiated by age 50 years regardless of risk.
- For high-risk patients, the entire large bowel should be studied at appropriate intervals.

Risk Factors

High-risk groups include persons with 1) familial polyposis syndromes (familial adenomatous polyposis—gene recently identified on chromosome 5—and Gardner syndrome—gut polyps plus desmoid tumors, lipomas, sebaceous cysts, and other abnormalities), 2) familial cancer syndromes without polyps (hereditary nonpolyposis colorectal cancer, or Lynch, syndromes, which are marked by colon cancer with or without endometrial, breast, and other cancers), and 3) inflammatory bowel disease (incidence 12% after 25 years).

- High-risk factors for colorectal cancer are familial polyposis syndromes, including familial adenomatous polyposis and Gardner syndrome, both inherited as an autosomal dominant trait; select familial cancer syndromes without polyps; and inflammatory bowel disease.

Treatment

Surgery

Surgical resection is the preferred method of curative treatment for carcinomas of the colon or rectum. Surgical exploration and resection allows for pathologic determination of tumor depth of penetration through the bowel wall and assessment of regional lymph nodes. Prognosis is directly related to the stage of disease (Table 19-6), although rectal tumors tend to have a worse prognosis than colon carcinomas. Five-year survival rates for locoregional disease have improved in recent decades as a result of many factors, including improvements in preoperative staging, surgical technique, and adjuvant therapy.

- Surgical resection is the preferred treatment for colorectal cancer.
- Prognosis is directly related to the stage of disease.
- Five-year survival rates are improving.

Adjuvant Therapy

For colon cancers, adjuvant chemotherapy with a multidrug regimen that includes oxaliplatin, 5-fluorouracil (5-FU), and leucovorin given for 6 months is recommended for node-positive (stage III) disease. This postoperative regimen reduces the risk of recurrence of colorectal cancer. Controversy exists on standard recommendations for deeply invasive (stage II) colon carcinomas. For *rectal cancers*, a combination of chemotherapy (5-FU–based) and pelvic irradiation is standard for stage II and III disease.

- For stage III colon cancers, adjuvant chemotherapy includes oxaliplatin, 5-FU, and leucovorin.

Table 19-6 **Staging of Colorectal Cancer and Survival**

Dukes stage	AJCC stage	Depth of penetration	Nodal status	5-Year survival, %
A	I	Submucosa or muscularis	Negative	90
B	II	Through muscularis or to other organs	Negative	60-80
C	III	Any	Positive	30-60

AJCC, American Joint Committee on Cancer.

- For rectal cancer, a combination of chemotherapy (5-FU–based) and radiotherapy is the standard recommendation.

Metastatic Disease

Certain patients with metastatic colorectal cancer may be candidates for an attempt at curative resection. Of carefully selected patients with minimal metastatic disease, limited to the liver or lung, approximately 25% survive beyond 5 years without further evidence of disease recurrence after resection of metastatic lesions.

Palliative chemotherapy is the only option for the vast majority of patients with advanced metastatic colorectal cancer. The median survival for patients treated with chemotherapy is about 18 months. The combination of oxaliplatin, 5-FU, and leucovorin is the standard chemotherapy for metastatic disease. Other agents that have activity against colorectal cancer include capecitabine and irinotecan. Bevacizumab improves survival. It targets new blood vessel formation and is approved by the U.S. Food and Drug Administration for patients with metastatic colon cancer as first-line therapy in combination with any 5-FU–based chemotherapy regimen. Cetuximab, a therapy targeted against the epidermal growth factor receptor, was approved in 2004 as combination treatment with irinotecan (or alone if irinotecan is not tolerated) for metastatic colon cancer.

- Surgical resection of metastatic disease can result in long-term disease-free survival in a highly selected subset of patients.
- Palliative chemotherapy options for advanced colorectal carcinoma include oxaliplatin, 5-FU, leucovorin, capecitabine, and irinotecan.
- The biologically targeted agents bevacizumab and cetuximab are now approved for treatment of metastatic colon cancer.

Carcinoembryonic Antigen

Routine use of carcinoembryonic antigen (CEA) to monitor patients after curative resection of colon cancer is not recommended. Proponents of CEA monitoring after operation for colorectal cancer argue that early recurrences, curable surgically, can be detected. However, CEA monitoring lacks sensitivity and specificity. It is estimated that cancer cures attributable to CEA monitoring occur in less than 1% of patients monitored (JAMA. 1993;270:943-7). Routine monitoring should include history and physical examination and liver function tests, and all other studies should be based on these results.

Typical Clinical Scenarios

A 60-year-old patient has a history of altered bowel habits over 3 months. Colonoscopy shows adenocarcinoma in the descending colon. The patient undergoes left hemicolectomy. Regional lymph nodes are found to be involved. In view of the positive lymph nodes, adjuvant chemotherapy with oxaliplatin, 5-FU, and leucovorin is recommended.

A 70-year-old patient with a history of colon carcinoma resected 10 years previously presents with increasing abdominal girth and jaundice. Computed tomography shows multiple nodules in the liver. The diagnosis is metastatic colon carcinoma, and the recommended therapy consists of palliative chemotherapy with oxaliplatin, 5-FU, and leucovorin.

A 50-year-old patient has a new diagnosis of iron deficiency anemia. A mass in the ascending colon is found on a work-up for iron deficiency. The diagnosis is adenocarcinoma of the ascending colon. Resection shows no evidence of lymph node metastases. No postoperative adjuvant chemotherapy is recommended.

Lung Cancer

Magnitude of the Problem

Approximately 172,000 new cases of lung cancer are diagnosed in the United States annually, resulting in approximately 157,000 deaths. Thus, only approximately 10% of patients with lung cancer survive the disease. Lung cancer is the leading cause of cancer mortality in both American men and women.

Risk Factors

About 95% of lung cancers in men and about 80% of lung cancers in women result from cigarette smoking. Men who smoke 1 to 2 packs per day have up to a 25-fold increase in lung cancer compared with those who have never smoked. The risk of lung cancer in an ex-smoker declines with time. Passive smoking is associated with an increased risk of lung cancer. Certain occupations (smelter workers, iron workers), chemicals (arsenic, methyl ethyl ether), and exposure to radioactive agents (radon, uranium) and asbestos have been associated with increased risks for development of lung cancer.

- 95% of lung cancers in men and 80% in women result from cigarette smoking.
- Men who smoke 1 to 2 packs a day have a 25-fold increase in lung cancer compared with those who have never smoked.
- Passive smoking is associated with an increased risk of lung cancer.

Screening

Several large, randomized trials have tested the utility of chest radiography and sputum cytology in screening for lung cancer. None of these studies have shown that either sputum cytology or regular chest radiography improves survival from lung cancer. Thus, screening is not standard at the present time. However, there are recognized methodologic problems with these studies, and some believe that there is benefit to screening for this disease.

- Randomized trials have not shown a survival advantage to screening for lung cancer.

Histologic Types and Characteristics

Lung cancer is divided into small-cell and non–small-cell types. Small-cell lung cancer occurs almost exclusively in smokers. Primary small-cell tumors typically are often small but are associated with bulky mediastinal adenopathy. They may be associated with paraneoplastic syndromes, including the syndrome of inappropriate secretion of antidiuretic hormone, and various neurologic abnormalities. Non–small-cell lung cancers can be divided into squamous,

adenocarcinoma, and large-cell types. Squamous cell carcinomas may be associated with hypercalcemia due to the secretion of a parathyroid hormone-like peptide. Squamous carcinomas tend to occur centrally, whereas large-cell and adenocarcinoma types tend to be more peripheral. Adenocarcinoma is the most frequent histologic subtype in nonsmokers. Bronchoalveolar carcinoma is a low-grade non–small-cell carcinoma that frequently presents as a patchy infiltrate. It may be multifocal.

Staging

The classic *T*umor-*N*ode-*M*etastasis system is simplified in Table 19-7.

Natural History

The natural history of surgically treated lung cancer, by stage, is shown in Figure 19-3.

Treatment

Non–Small-Cell Lung Cancer

Resection is the treatment of choice for clinical stages I, II, and selected IIIA disease. The use of adjuvant chemotherapy recently was shown to improve survival by about 5% compared with operation alone. The use of adjuvant radiation does not improve survival in resected stage II and III disease, but it does decrease the likelihood of local recurrence. In patients with locally advanced unresectable non–small-cell lung cancer (NSCLC), the use of chemotherapy before radiation therapy improves the long-term survival compared with radiation alone. Although patients with metastatic disease are not cured, the use of chemotherapy has improved the overall survival by several weeks and the quality of life compared with best supportive care. These studies are hampered by lack of uniform definitions of what constitutes "best supportive care."

Active chemotherapy agents for NSCLC include etoposide, cisplatin, carboplatin, cyclophosphamide, mitomycin-C, ifosfamide, gemcitabine, irinotecan, docetaxel, and paclitaxel. Bevacizumab improves survival.

- Resection is the treatment of choice for stages I and II and selected IIIA NSCLC.
- There is some improvement in survival with adjuvant chemotherapy.
- Chemotherapy is not curative for metastatic NSCLC.
- Chemotherapy improves the overall survival by several weeks and may improve quality of life for patients with metastatic NSCLC.
- Bevacizumab improves survival in patients with lung cancer.

Small-Cell Lung Cancer

Treatment of limited-stage small-cell lung cancer consists of both chemotherapy and chest irradiation. Surgical resection has not been shown to improve survival. For patients who have a complete response to chemotherapy and chest radiation therapy, prophylactic cranial irradiation is used to decrease the frequency of recurrence in the central nervous system, but there is some controversy whether this leads to improved overall survival. Prophylactic cranial irradiation is

Table 19-7 Staging of Lung Cancer

	Non–small-cell type
Stage I	Primary tumor >2 cm from carina; node negative
Stage II	Primary tumor >2 cm from carina; hilar nodes positive
Stage IIIA	Tumor <2 cm from carina, or invading a resectable structure, or ipsilateral mediastinal nodes positive
Stage IIIB	Tumor invading an unresectable structure, supraclavicular or contralateral mediastinal nodes positive or cytologically positive pleural effusion
Stage IV	Metastatic disease
	Small-cell type
Limited	Limited to one hemithorax less supraclavicular lymph nodes. Can be encompassed within a tolerable radiation port
Extensive	All other disease (metastatic disease)

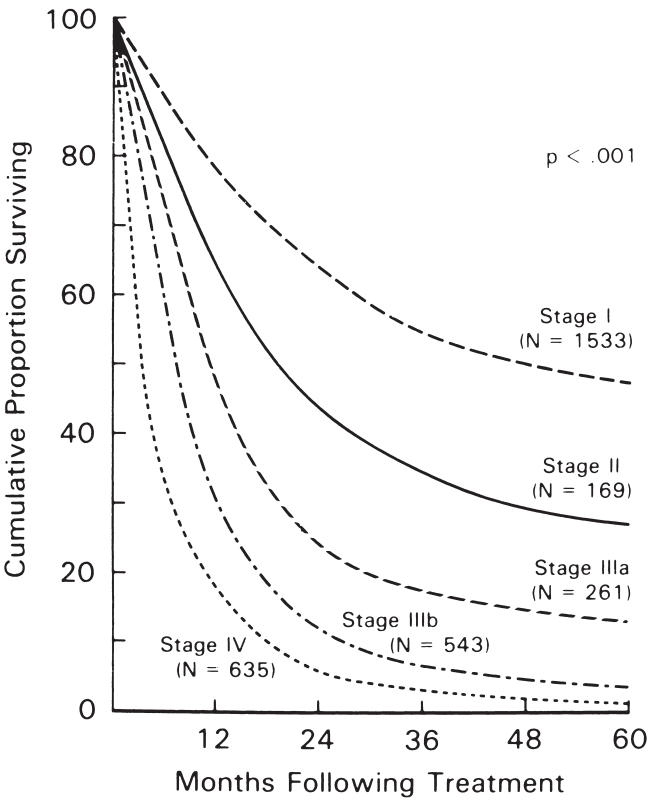

Fig. 19-3. Survival curves for patients with lung cancer by stage. (From Mountain CF. A new international staging system for lung cancer. Chest. 1986;89:225S-33S. Used with permission.)

associated with the risk of a delayed leukoencephalopathy, but this risk can be reduced by the administration of radiation in small-dose fractions without concomitant chemotherapy. For limited-stage small-cell disease, the median duration of survival is approximately 18 months; 30% to 40% of patients survive 2 years, and 10% to 20% survive 5 years.

- For small-cell lung cancer, treatment of limited-stage disease consists of both chemotherapy and chest irradiation.
- Prophylactic cranial irradiation decreases the frequency of recurrence in the central nervous system.
- Median survival is 18 months with limited-stage disease.

Chemotherapy is used for the treatment of extensive-stage (stage IV) small-cell lung cancer. Combination chemotherapy is favored over single-agent therapy. Active drugs include etoposide, cisplatin, cyclophosphamide, doxorubicin, and vincristine. High-dose chemotherapy with or without autologous bone marrow transplantation or marrow colony-stimulating factors has not been proved to be superior to standard chemotherapy. The median duration of survival is approximately 9 months; about 10% of patients survive 2 years, and 1% or less survive 5 years.

- For extensive-stage small-cell lung cancer, treatment is chemotherapy.
- The median duration of survival for patients with extensive-stage small-cell lung cancer is 9 months.

Typical Clinical Scenarios

A 60-year-old smoker presents with cough. Chest radiography and computed tomography show a 2-cm nodule in the right upper aspect of the chest without evidence of lymph node or metastatic disease. After the diagnosis of non–small-cell lung carcinoma is confirmed, therapy is surgical resection.

Another patient has findings similar to the one described above, but the biopsy result is small-cell lung carcinoma. Treatment consists of systemic chemotherapy plus radiation.

Melanoma

Background

Malignant melanoma is increasing at a rapid rate. If current trends continue, the lifetime risk for malignant melanoma to develop in an American will be 1 in 75. Fortunately, the 5-year survival rate has doubled from approximately 40% in the 1940s to approximately 80% now, a change attributed to earlier detection. Melanoma is more common among fair-skinned people; persons with a history of recurrent, blistering sunburns; persons with multiple atypical nevi; patients with freckling tendency; and certain families (first-degree relatives or persons with familial atypical mole/melanoma syndrome, formerly called the dysplastic nevus syndrome).

- The incidence of malignant melanoma is increasing rapidly.
- The 5-year survival rate has improved as a result of earlier detection.
- High-risk populations are identifiable.

Diagnosis ("ABCD") and Prognosis

Keys to the early diagnosis of malignant melanoma include the following:

A: Asymmetry, especially a changing lesion
B: Borders are irregular
C: Color is variable, especially with blues, blacks, and tans dispersed throughout the lesion
D: Diameter 6 mm or more

The Breslow microstaging method measures the thickness (i.e., depth of penetration of the tumor from the epidermis into the dermis/subcutis) of a malignant melanoma and is the best independent predictor of survival (Table 19-8).

Management

Surgical excision to achieve a 1- to 3-cm margin around the lesion remains the principal treatment for primary malignant melanoma. In the absence of palpable adenopathy, an elective lymph node dissection is not routinely performed. With clinically palpable regional nodes, a node dissection is performed for curative intent and to achieve maximal local tumor control. For patients at high risk for recurrence (deep primary tumor >4.0 mm or resected node-positive disease), recent clinical trials have had conflicting results, and therefore adjuvant therapy remains controversial.

Treatment for metastatic melanoma is primarily palliative. Surgical resection in selected patients (those with a long disease-free interval and limited disease at recurrence) can be considered. Systemic treatments commonly include immunotherapy (interleukin-2 or interferon), chemotherapy (temozolomide, dacarbazine, or nitrosoureas), or various combinations.

Typical Clinical Scenario

A 60-year-old patient presents with a mole on the right leg that has been increasing in size during the past 3 months. Resection shows malignant melanoma with a depth of invasion of 0.75 mm. Definitive therapy is reexcision to obtain a 1- to 3-cm margin around the lesion. No adjuvant therapy is recommended.

Ovarian Cancer

This disease is diagnosed annually in approximately 25,400 American women. It is the leading cause of death due to gynecologic cancer,

Table 19-8 Ten-Year Survival in Melanoma, by Depth of Tumor

Depth, mm	% alive
<0.85	96
0.85-1.69	87
1.7-3.6	66.5
>3.6	46

Data from Friedman RJ, Rigel DS, Silverman MK, Kopf AW, Vossaert KA. Malignant melanoma in the 1990s: the continued importance of early detection and the role of physician examination and self-examination of the skin. CA Cancer J Clin. 1991 July/Aug;41:201-26.

resulting in 16,210 deaths annually. There are no early warning signs; most patients present with vague gastrointestinal complaints such as bloating. Most patients (75%) present with advanced disease (i.e., stages III and IV, disease spread beyond the pelvis). The term "ovarian cancer" refers to tumors derived from the ovarian surface epithelium, not germ cell tumors.

- Ovarian cancer is the leading cause of death due to gynecologic cancer.
- There are no early warning signs.
- Most patients (75%) present with advanced disease.

Staging

Stage I is confined to the ovary, stage II is confined to the pelvis, stage III includes spread to the upper abdomen, and stage IV includes spread to distant sites.

Cancer Antigen 125

Cancer antigen 125 (CA 125) is expressed by approximately 85% of epithelial ovarian tumors and released into the circulation. However, it is detectable in only 50% of patients with stage I disease. The highest serum levels of CA 125 are found in patients with ovarian cancer, but the serum CA 125 level also may be increased in other malignancies and in pregnancy, endometriosis, and menstruation. CA 125 is clearly of value for monitoring the course of ovarian cancer.

- CA 125 is expressed by about 85% of epithelial ovarian tumors.
- The CA 125 level also may be increased in other malignancies and in pregnancy, endometriosis, and menstruation.
- CA 125 is useful for monitoring the course of ovarian cancer.

Screening

The tools evaluated thus far, namely, pelvic ultrasonography and determination of the serum CA 125 value, are inadequate for screening the general female population. Screening for this disease is difficult for several reasons. The incidence of ovarian cancer is relatively low, and there are no recognized pre-invasive lesions. Moreover, pelvic ultrasonography and CA 125 lack sufficient sensitivity and specificity. However, it seems reasonable to apply these techniques on a periodic basis to women at particularly high risk of ovarian cancer, for example, those with a strong family history of the disease (two or more affected relatives) or known carriers of *BCRA* gene mutations. The cause of epithelial ovarian cancer is unknown. A small subset of patients (<5%) has an inherited predisposition to this disease. Generally, this occurs in families with both breast and ovarian cancer.

- Population screening for ovarian cancer is not recommended.
- Pelvic ultrasonography and CA 125 testing lack sufficient sensitivity and specificity to be routinely recommended.
- A small subset of patients (<5%) has an inherited predisposition to ovarian cancer and may benefit from screening.

Treatment

The initial management of patients with epithelial ovarian cancer includes a thorough surgical staging and debulking procedure. Outcome in this disease depends on the amount of residual tumor tissue after initial operation. Patients with only microscopic residual disease fare better than those with less than optimally debulked tumors. After the surgical procedure, patients are treated with six cycles of platinum- and paclitaxel-based chemotherapy.

- Management of ovarian cancer includes thorough surgical staging and debulking followed by chemotherapy.
- The outcome depends on the amount of residual tumor tissue after initial operation.
- Subsequent chemotherapy consists of a platinum compound and paclitaxel.

Outcome

Outcome depends on the stage of disease. At 5 years, 90% of patients with stage I disease are alive and 80% of those with stage II disease are alive. Unfortunately, survival with advanced disease is poor: 15% to 20% of patients with stage III disease are alive at 5 years and only 5% of patients with stage IV disease are alive.

Typical Clinical Scenario

A 50-year-old patient presents with ascites. On evaluation, a mass is found in the right ovary. Therapy consists of surgical debulking followed by chemotherapy.

Prostate Cancer

Background

There are approximately 232,000 new cases of prostate cancer annually in the United States. It is the most common cancer in men in the United States and is the second leading cause of death from cancer in men in the United States (30,350 deaths annually). Identified risk factors for the development of prostate cancer include older age, race (African American), family history (first-degree relative), and possibly dietary fat. The American Cancer Society recommends a digital rectal examination in men 40 years or older and determination of the prostate-specific antigen (PSA) value in men 50 years or older. Use of PSA for prostate cancer screening is a controversial issue and has not been shown to reduce mortality. Screening in older men should be discontinued when they have a life expectancy of less than 10 years because of age or other comorbidities.

- Prostate cancer is the most common cancer among U.S. men and the second leading cause of death from cancer in men.
- Risk factors include older age, race (African American), family history, and a high-fat diet.

Prostate-Specific Antigen

PSA is a serine protease produced by normal and neoplastic prostatic ductal epithelium. Its concentration is proportional to the total prostatic mass. The inability to differentiate benign prostatic hyperplasia from carcinoma on the basis of the PSA level renders it inadequate as the sole screening method for prostate cancer. PSA is useful for monitoring response to therapy in cases of known prostate cancer,

particularly after radical prostatectomy, when PSA should be undetectable.

- The concentration of PSA is proportional to the total prostatic mass.
- The PSA test is inadequate as the sole screening test for prostate cancer.
- PSA is useful for monitoring response to therapy.

Prognostic factors for prostate cancer include stage of disease, grade of tumor, and pretreatment PSA level. Table 19-9 simplifies the staging of prostate cancer, including the TNM classification. Grading of tumors is performed by the pathologist with the Gleason scoring system. The surgical specimen is graded by the most predominant pattern of differentiation added to the secondary architectural pattern (e.g., 3 + 5 = 8). Gleason grades 2 through 6 are associated with a better prognosis. Recent retrospective results indicate that the pretreatment PSA value is a strong predictor of disease outcome after operation or radiotherapy.

- Prognostic factors for the outcome of prostate cancer include tumor stage, grade, and pretreatment PSA value.
- Gleason grades 2 through 6 have a better prognosis.

Management

Management of Specific Stages

Significant controversy surrounds the primary treatment of prostate cancer in nearly all stages of the disease. Because this is a disease that affects older men, comorbid conditions, age, and performance status need to be considered when directing therapy; more men will die with prostate cancer than of prostate cancer. In general, patients with T1A prostate tumors are observed without treatment. For organ-confined prostate cancer (T1B, T1C, and T2 tumors), both radiation therapy and radical prostatectomy are equally viable options. Recently, some investigators have proposed observation alone and treatment with hormonal agents at the time of progression because the rate of death from prostate cancer is low for well-differentiated early-stage disease. A large trial is currently under way in the United States to test the value of operation compared with observation for organ-confined prostate cancer.

For stage C (T3 or T4) disease (locally advanced), radiotherapy is generally used. A trial combining androgen deprivation with local radiation therapy showed improved local control and overall survival in this patient cohort. Some centers use androgen deprivation to downstage tumors before an aggressive surgical approach.

For stage D1 disease (positive pelvic nodes), the management is controversial. Divergent approaches include androgen deprivation alone, x-ray therapy with or without androgen deprivation, close observation with androgen deprivation at progression, or, infrequently, prostatectomy with androgen deprivation. For advanced (D2) disease, androgen deprivation is the treatment of choice.

Table 19-9 Staging of Prostate Cancer

Whitmore	TNM*	Criteria
A1	T1A	Incidental focus of tumor in ≤5% of resected tissue
A2	T1B	Incidental tumor in >5% of resected tissue
B0	T1C	Tumor identified by needle biopsy (performed on basis of increased PSA value)
B1	T2A	Tumor ≤1/2 of one lobe
B2	T2B	Tumor >1/2 of one lobe but not both lobes
	T2C	Tumor involvement of both lobes
C	T3 or T4	Extracapsular local disease or local invasion
D1	N1	Pelvic node involvement
D2	M1	Distant disease

PSA, prostate-specific antigen.
**Tumor-Node-Metastasis system.*

Prostatectomy

Prostatectomy is reserved for patients with localized disease. The 15-year disease-specific survival rate after prostatectomy is 85% to 90% for stage A2 or B disease. Nerve-sparing prostatectomy spares potency in 68% to 86% of patients. Risk of impotence increases with increasing age, size of tumor, extent of spread, and preoperative sexual function. Total urinary incontinence is unknown (<2% of patients), although many men will have some degree of incontinence after prostatectomy.

- Prostatectomy is the treatment of choice for localized disease.
- The 15-year survival rate is 85%-90% for stage A2 or B disease.
- Nerve-sparing operations preserve sexual function in a majority of men.

Radiation Therapy

External beam radiotherapy is considered the equivalent of prostatectomy for overall survival. It is preferred for stage C disease at most centers. Impotence can occur, but less often than with prostatectomy. Chronic radiation proctitis is not uncommon. A concern related to radiotherapy is that repeat biopsies after treatment have shown apparently viable tumor in more than 35% of patients. The clinical importance of this residual tumor is unclear, but there may be a correlation with the subsequent appearance of distant metastasis, especially with a persistent, palpable abnormality in the gland.

- External beam radiotherapy is considered the equivalent of prostatectomy for overall survival.
- Impotence is less frequent with radiotherapy than prostatectomy.

Androgen Deprivation

For advanced (D2) disease, bone is the most frequent site of metastatic disease. Hormonal therapy, although it is very effective and

produces a response in most patients, is noncurative. The average duration of response to initial hormonal maneuver is 18 months. The average duration of survival is 2 to 3 years. Once the disease progresses after the initial hormonal maneuver, it is typically less responsive to secondary hormonal therapy. Recent data have shown that prostate cancer is sensitive to chemotherapy and may improve survival in men with androgen-independent, metastatic prostate cancer (N Engl J Med. 2004;351:1502-12).

- Bone is the most frequent site of metastatic disease from the prostate.
- Hormonal therapy is effective and produces a response, but it is noncurative.
- The average duration of survival with advanced prostatic cancer is 2-3 years.

The two sources of androgens in men are the testes (testosterone, 95%) and adrenal glands (5%). Androgen deprivation can be accomplished surgically with orchiectomy or medically. Potential agents include luteinizing hormone-releasing hormone (LHRH) agonists such as leuprolide, buserelin, and goserelin. They decrease androgen levels through continuous binding of the LHRH receptor and subsequent decrease of LH and thus testosterone. They are administered as a monthly injection of a depot preparation. A 3- or 4-month depot preparation is also available. LHRH agonists, on initial binding of the LHRH receptor, transiently stimulate LH release and thus cause an initial increase in the testosterone level. This explains the transient flare of prostate cancer that can occur in men with advanced disease when therapy with an LHRH agonist is initiated. This possibility must be considered in patients with impending spinal cord compression, urinary obstruction, or extensive painful bony metastases. Use of an antiandrogen such as bicalutamide before initiation of LHRH antagonist therapy can block this flare.

- Androgen deprivation is accomplished with orchiectomy or medically.
- LHRH agonists decrease androgen levels.
- LHRH agonists initially stimulate a transient release of LH and testosterone.

Antiandrogens compete with androgens at the receptor level. These include flutamide, nilutamide, and bicalutamide. To effect total androgen blockade, an antiandrogen is added for patients who have had orchiectomy or who are receiving an LHRH agonist (these block testicular testosterone production but not adrenal androgen production). A prospective U.S. study in which a combination of an LHRH analogue with flutamide was compared with placebo suggested an advantage for the addition of flutamide. However, other studies of total blockade have failed to show an advantage. A recent clinical trial comparing orchiectomy alone with orchiectomy plus flutamide failed to show a survival advantage for total androgen blockade. The antiandrogens may also block the "flare" induced by LHRH agonists.

- The use of an antiandrogen in combination with orchiectomy or an LHRH agonist to treat advanced prostate cancer remains controversial.
- Antiandrogens block the "flare" induced by LHRH agonists.

Chemotherapy

Prostate cancer previously had been considered refractory to most chemotherapy regimens. Newer combinations that use paclitaxel and prednisone have shown not only significant responses but also improved survival in men with metastatic, hormone-refractory prostate cancer.

Bisphosphonates

The use of bisphosphonates in men with bone metastasis remains very controversial and does not improve overall survival. Bisphosphonates can be a useful adjunct for treatment of painful metastatses.

- Chemotherapy and bisphosphonates can be used for palliative effects in men with prostate cancer.

Follow-up Recommendations

After curative therapy with either definitive radiation or radical prostatectomy, PSA can be a sensitive marker for recurrence. PSA should be undetectable after successful primary therapy. After definitive local therapy, the median time between increased PSA level (biochemical recurrence) and development of symptoms from metastatic prostate cancer is 8 years, and median time to death from recurrent prostate cancer is 13 years. Thus, how closely any one patient is monitored should depend on overall health, comorbid conditions, and overall life expectancy.

Typical Clinical Scenario

A 70-year-old patient presents with back pain. The PSA value is markedly increased and the prostate is enlarged. Prostatic biopsy reveals prostatic carcinoma. Radiography and bone scanning show multiple areas of increased uptake throughout the skeleton, consistent with metastatic disease. Therapy consists of hormonal manipulation, with either orchiectomy or LHRH agonists. If LHRH agonists are chosen, the patient should receive an antiandrogen for 1 month before initiation of the LHRH agonist.

Testicular Cancer

Background

This cancer is diagnosed in 8,010 men annually. It is the most common carcinoma in males 15 to 35 years old. It is highly curable, even when metastatic. At high risk are males with cryptorchid testes (40-fold relative risk) or Klinefelter syndrome (also increased risk of breast cancer). Two broad categories are seminomas (40%) and nonseminomas. Types of nonseminomas include embryonal carcinoma, mature and immature teratoma, choriocarcinoma, yolk sac tumor, and endodermal sinus tumor. There is often an admixture of several cell types within nonseminomas. Any nonseminomatous component plus seminoma is treated as a nonseminoma.

- Testicular cancer is the most common carcinoma in males 15-35 years old.

- Testicular cancer is highly curable, even when metastatic.
- High-risk factors: cryptorchid testes, Klinefelter syndrome.
- Two categories: seminomas (40%) and nonseminomas.

Evaluation includes determination of β-human chorionic gonadotropin (hCG) and α-fetoprotein values and computed tomography of the abdomen (retroperitoneal nodes) and chest (mediastinal nodes or pulmonary nodules).

Staging

Stage I disease is confined to the testis, stage II includes infradiaphragmatic nodal metastases, and stage III is spread beyond retroperitoneal nodes. About 85% of nonseminomas are associated with an increased β-hCG or α-fetoprotein value. Approximately 10% of seminomas are associated with an increased β-hCG level. The α-fetoprotein value is never increased in pure seminoma; if it is increased, the tumor is not seminoma and should be treated as such.

- 85% of nonseminomas are associated with an increased β-hCG or α-fetoprotein value.
- 10% of seminomas are associated with an increased β-hCG value.
- The α-fetoprotein value is never increased in pure seminoma.

Management

Radical inguinal orchiectomy is the definitive procedure for both pathologic diagnosis and local control. Scrotal orchiectomy or biopsy is associated with a high incidence of local recurrence or spread to inguinal nodes. After orchiectomy, management depends on cell type (Table 19-10). Seminomas are exquisitely radiosensitive. For stage I and nonbulky stage II seminoma, infradiaphragmatic lymphatic irradiation is used. The 5-year disease-free survival rate is more than 95%. For bulky stage II disease and stage III, platinum-based chemotherapy is used. Approximately 85% of patients are cured. For stage I nonseminoma, close follow-up is often used rather than immediate retroperitoneal node dissection (a controversial issue). For stages II and III, platinum-based chemotherapy is the treatment of choice. Cure rates are more than 95% for minimal metastatic disease, 90% for moderate bulk disease, and about 50% for bulky disease (multiple pulmonary metastases, bulky abdominal masses, liver, bone, or central nervous system metastases).

- Radical inguinal orchiectomy is the definitive initial procedure for testicular cancer.

Table 19-10 Management of Testicular Cancer

	Treatment, by cell type	
Stage	Seminoma	Nonseminoma
I	XRT	? Observe
II	XRT	Chemo
III	Chemo	Chemo

Chemo, chemotherapy; XRT, x-ray therapy.

- Early-stage seminoma is treated with resection and radiation.
- Stage I nonseminoma may require no treatment after orchiectomy.
- Platinum-based chemotherapy is used for all other patients and results in high cure rates.

Extragonadal Germ Cell Tumor

This is uncommon. Patients present with increased β-hCG or α-fetoprotein values with midline mass lesions (retroperitoneum, mediastinum, or pineal gland). No gonadal primary tumor is identifiable on examination or ultrasonography. Cisplatin-based chemotherapy is frequently effective. Prognosis is not as favorable as with a testicular primary tumor.

Carcinoma of Unknown Primary Lesion

Background

Patients presenting with metastatic carcinoma with an unknown primary lesion make up 5% to 10% of general oncologic practice. The first principle of management is to establish the diagnosis with a sufficient histologic specimen. In general, open biopsy is preferable to fine-needle aspiration, because a larger specimen allows optimal histologic and immunohistochemical analysis. All patients should have a careful history and complete physical examination, including pelvic and rectal examinations. Most patients, approximately 60%, have an adenocarcinoma. In 35% of patients, poorly differentiated carcinoma will be diagnosed. Once a pathologic diagnosis is established, additional evaluation should be tailored according to the patient's risk factors (e.g., smoking, breast cancer), symptoms and signs, sites of metastasis, and the histologic diagnosis. Special consideration should be given to rule out possible curable malignancies such as germ cell tumors or lymphoma or treatable malignancies, such as breast, ovarian, or prostate cancer. Women presenting with axillary adenocarcinomas, with no clear breast primary lesion, should receive treatment for breast cancer. Women with peritoneal carcinomatosis generally have exploratory laparotomy with surgical cytoreduction, as for ovarian carcinoma. Men presenting with bone metastases, particularly osteoblastic metastases, should have a PSA test and their tumor material stained for PSA expression.

Treatment

If a potentially treatable neoplasm is ruled out, most patients with metastatic cancer of an unknown primary lesion have a very poor prognosis, with expected survival of 4 to 6 months. Some may benefit from palliative treatment (radiation or chemotherapy); many are managed best with supportive care and hospice care.

Paraneoplastic Syndromes

General

These conditions are the effects of a cancer occurring at a distance from the tumor; they are called "remote effects." They do not necessarily indicate metastatic disease. Common paraneoplastic syndromes and associated tumor types are listed in Table 19-11.

Carcinoid Syndrome

This is caused by peptide mediators secreted by carcinoid tumors that most frequently arise in the small intestine and that may have metastasized to the liver. It is less frequent with primary carcinoid tumors arising from other sites such as lung, thymus, or ovary. The most common symptoms are episodic flushing and diarrhea; bronchospasm may occur. Flushing and diarrhea may occur spontaneously or be precipitated by emotional factors or ingestion of food or alcohol. Carcinoid heart disease (right-sided valvular disease) is a potential late complication.

Lambert-Eaton Syndrome

This consists of muscle weakness (proximal) and gait disturbance. Strength is increased with exercise. It is associated with small-cell lung cancer.

Dermatomyositis

The female:male ratio is 2:1. Findings include muscle weakness (proximal), inflammatory myopathy, and increased creatine kinase values. Skin changes are variable and include heliotrope rash, periorbital edema, and Gottron papules. An underlying malignancy (lung, breast, gastrointestinal) is common in patients older than 50 years.

Chemotherapy

Basic Concepts

Currently, more than 70 cytotoxic agents are available for use in North America. Taken generally, chemotherapeutic agents impair the process of cell division. Cytotoxic chemotherapy drugs are not selective for cancer cells. These drugs have their predominant effect on cells that are more rapidly dividing, such as many forms of neoplastic cells. This selectivity for rapidly dividing cells explains the typical patterns of toxicity that occur with chemotherapy (i.e., bone marrow, gastrointestinal mucosa, and hair follicles). The general classes and mechanisms of chemotherapeutic agents are shown in Figure 19-4 and the Oncology Pharmacy Review.

Table 19-11 Classification of Paraneoplastic Syndromes

Syndrome	Mediator	Tumor type
Endocrine		
Cushing syndrome*	ACTH	Small-cell lung cancer
SIADH*	ADH	Lung, especially small cell
Hypercalcemia*	PTH-like peptide	Lung, especially squamous; breast; myeloma
Carcinoid syndrome	? Serotonin ? Substance P	Gut neuroendocrine tumors
Hypoglycemia	Insulin Insulin-like growth factors	Gut neuroendocrine tumors; other
Neuromuscular		
Cerebellar degeneration	Anti-Purkinje cell antibodies	Lung, especially small cell; ovarian; breast
Dementia	?	Lung
Peripheral neuropathy*	Autoantibodies	Lung, gastrointestinal, breast
Lambert-Eaton	Antibodies to cholinergic receptor	Small-cell lung cancer
Dermatomyositis	?	Lung, breast
Skin		
Dermatomyositis	?	Lung, breast
Acanthosis nigricans	? TGF-α	Intra-abdominal cancer, usually gastric
Hematologic		
Venous thrombosis*	Activators of clotting cascade and platelets	Various adenocarcinomas, especially pancreatic and gastric
Nonbacterial thrombotic endocarditis	Activators of clotting cascade and platelets	Various adenocarcinomas, especially pancreatic and gastric

ACTH, adrenocorticotropic hormone; ADH, antidiuretic hormone; PTH, parathyroid hormone; SIADH, syndrome of inappropriate secretion of antidiuretic hormone; TGF-α, transforming growth factor-α.

*Most common types.

Biologically Targeted Agents

Newer therapeutic agents are now available that more specifically target abnormalities intrinsic to neoplastic cells. Several biologically targeted agents recently have been approved for cancer therapy. These drugs include monoclonal antibodies such as trastuzumab, bevacizumab, rituximab, and cetuximab and tyrosine kinase inhibitors gefitinib and erlotinib. (Table 19-12). Tumor tissue can be tested to determine whether the specific target of interest is expressed. If so, these drugs can be used either alone or in combination with chemotherapy, radiation therapy, or other antitumor treatments.

Applications

Chemotherapy can be used in the following settings: 1) advanced disease with palliative intent, 2) as adjuvant therapy after definitive local treatment to reduce risk of recurrence, 3) as neoadjuvant (or preoperative) therapy, and 4) as primary therapy. Neoadjuvant therapy is used for patients who present with a locally advanced malignancy and initial tumor reduction is needed before a primary treatment (such as operation or radiation) can be applied.

Solid Tumors Sensitive to Chemotherapy

Germ cell tumors of the testis and ovary, choriocarcinomas, breast cancer, ovarian cancer, and small-cell lung cancer are sensitive to chemotherapy. In recent years, combination chemotherapy regimens also have produced impressive tumor reductions in transitional cell carcinomas of the bladder, head and neck cancer, cervical cancer, colon cancer, and prostate cancer.

Why Chemotherapy Fails to Cure Most Advanced Solid Tumors

The reasons for failure are 1) tumor cell heterogeneity, including populations of cells resistant to cytotoxic agents; 2) large numbers of noncycling or resting cells; and 3) pharmacologic sanctuaries—blood-tissue barriers and blood supply-tumor barriers.

Side Effects

The most common side effects of various chemotherapeutic agents are outlined in the Oncology Pharmacy Review.

Mechanisms of Tumor Cell Drug Resistance

Mechanisms include decreased drug uptake, increased drug efflux, decreased drug activation, increased drug inactivation, and increased production of a target enzyme.

Tumor cells may be resistant to a specific drug or they can have broad cross-resistance to structurally dissimilar drugs. This latter phenomenon is referred to as multidrug resistance. This seems to be mediated by a large plasma membrane glycoprotein, the p-glycoprotein, that functions as an energy-dependent drug-efflux pump.

- Tumor cells may be resistant to structurally dissimilar chemotherapy drugs (multidrug resistance).

Colony-Stimulating Factors

In recent years, bone marrow colony-stimulating factors have been isolated and are now available for clinical use. These naturally occurring

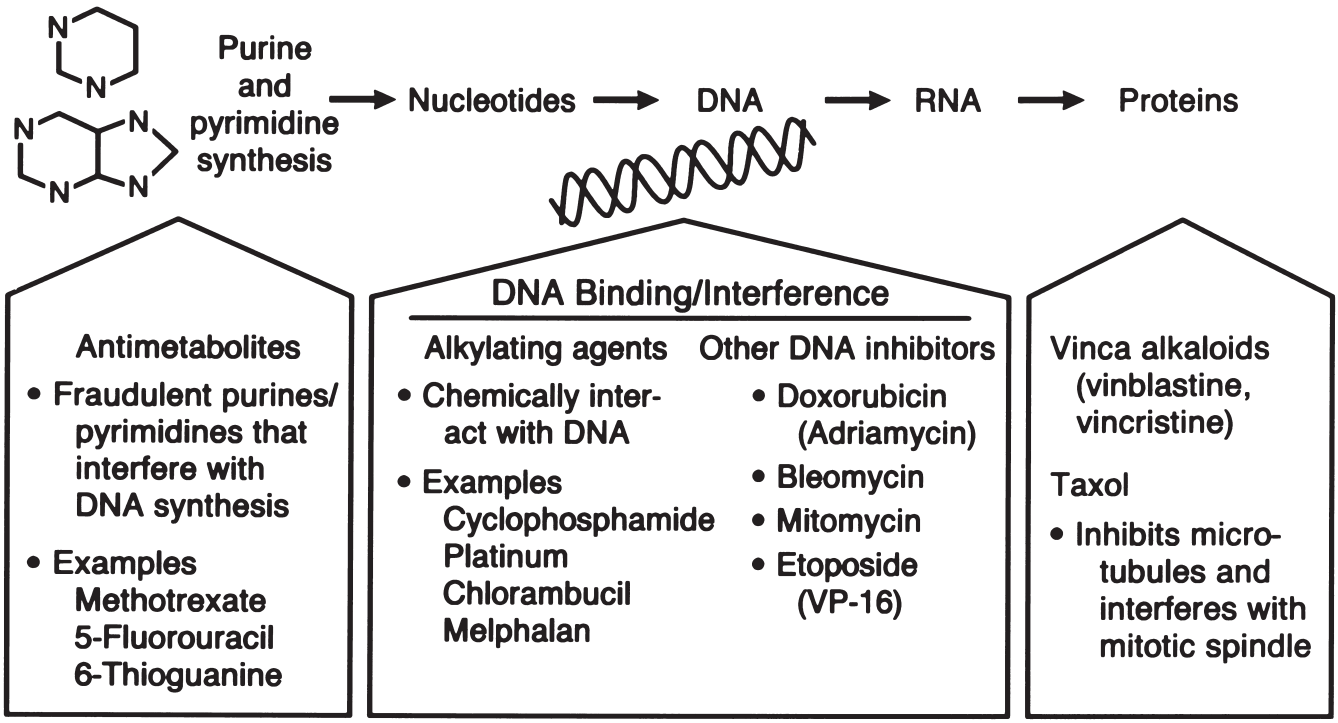

Fig. 19-4. General classes of chemotherapeutic agents.

Table 19-12 Biologically Targeted Therapies Currently Being Used for Cancer Treatment

Drug	Target	Drug class	Type of cancer active against
Trastuzumab	HER2/neu	Monoclonal antibody	Breast
Bevacizumab	Vascular endothelial growth factor receptor	Monoclonal antibody	Colon
Cetuximab	Epidermal growth factor receptor	Monoclonal antibody	Colon
Rituximab	CD20	Monoclonal antibody	CD20-positive lymphomas
Gefitinib	Epidermal growth factor receptor	Tyrosine kinase inhibitor	Non–small-cell lung
Erlotinib	Epidermal growth factor receptor	Tyrosine kinase inhibitor	Non–small-cell lung, head and neck

glycoproteins stimulate the proliferation, differentiation, and function of specific cells in the bone marrow. They may act at the level of the earliest stem cell or at later mature functional cells. They differ in their specificity.

Granulocyte colony-stimulating factor, for example, acts fairly specifically to stimulate production of mature neutrophils; granulocyte-macrophage colony-stimulating factor acts more generally, stimulating several cell lineages, including monocytes, eosinophils, and neutrophils. Both colony-stimulating factors have been used to stimulate leukocyte recovery after chemotherapy-induced myelosuppression. As a general rule, colony-stimulating factors do not affect the depth of the leukocyte nadir but shorten the duration of neutropenia. Unfortunately, no currently available colony-stimulating factor reliably protects against thrombocytopenia. To be effective, use of a colony-stimulating factor should be initiated shortly after completion of chemotherapy (1-2 days) and delivered through the expected neutrophil nadir. Sustained-release, depot preparations are now available that can be administered once a week or less frequently. Once neutropenia has developed, use of growth factors does not enhance the recovery time, and they should be used only if the expected duration of neutropenia is greater than 10 days to 2 weeks. Placebo-controlled studies examining the efficacy of G-CSF given at the start of a documented chemotherapy-induced neutropenia have failed to show clinical benefit in patients who are not at high risk. (See section below on febrile neutropenia.)

Oncologic Complications and Emergencies

Hypercalcemia

The most common underlying causes of hypercalcemia are malignancies and primary hyperparathyroidism. Patients with primary hyperparathyroidism have increased serum parathyroid hormone (PTH) values, but PTH is suppressed in cancer-associated hypercalcemia. Cancer-related hypercalcemia is often mediated by a PTH-related protein secreted by the tumor. This PTH-related protein can be detected with current assays. Tumors also can cause hypercalcemia by secreting other bone-resorbing substances or by enhancing conversion of 25-hydroxyvitamin D to 1,25-dihydroxyvitamin D. Local effects of osteolytic bone metastases are a relatively rare cause of hypercalcemia, but it can occur in prostate, breast, lung, or other cancers.

Effects on bone and kidney contribute to hypercalcemia. Accelerated bone resorption is due to activation of osteoclasts by various mediators, primarily the PTH-like peptide. The same factors that induce osteoclast-mediated bone resorption also stimulate renal tubular resorption of calcium. The hypercalcemic state interferes with renal resorption of sodium and water, leading to polyuria and eventual depletion of extracellular fluid volume. This reduces the glomerular filtration rate, further increasing the serum calcium level. Immobilization tips the balance toward bone resorption, worsening the hypercalcemia.

- PTH is suppressed in cancer-associated hypercalcemia.
- Malignancy-associated hypercalcemia is often mediated by PTH-related protein secreted by a tumor.
- Bone and kidney pathophysiologic effects lead to an increased calcium level.

Symptoms of hypercalcemia include gastrointestinal (anorexia, nausea, vomiting, constipation), renal (polyuria, polydipsia, dehydration), central nervous system (cognitive difficulties, apathy, somnolence, or even coma), and cardiovascular (hypertension, shortened QT interval, enhanced sensitivity to digitalis).

Cancers associated with hypercalcemia include lung (squamous cell), renal, myeloma, lymphoma, breast, and head and neck. Patients with breast cancer and those with myeloma are more likely to have bony involvement with their disease.

The magnitude of the hypercalcemia and the degree of symptoms are key considerations for the treatment of hypercalcemia. Generally, patients with a serum calcium value more than 14 mg/dL, mental status changes, or an inability to maintain adequate hydration should be hospitalized for immediate treatment. The serum calcium value should be adjusted if the serum albumin value is abnormal. The conversion formula is 0.8 mg/dL of serum total calcium for every 1 g of serum albumin more or less than 4 g/dL. If the serum albumin value is increased (as with dehydration), the total calcium

value should be adjusted downward; if the serum albumin value is reduced (as in chronic illness), the total calcium value should be adjusted upward.

Patients with clinically symptomatic hypercalcemia are virtually always intravascularly volume-depleted. Initial therapy therefore includes vigorous hydration with intravenously administered normal saline (200-400 mL/h). Loop diuretics are not used until *after* intravascular volume expansion has been completed. Furosemide facilitates urinary excretion of calcium by inhibiting calcium resorption in the thick ascending loop of Henle. A loop diuretic will help correct for volume overload once the patient has been rehydrated.

Bisphosphonates (pamidronate or zoledronic acid) are given intravenously (gastrointestinal absorption is poor). They bind to hydroxyapatite and inhibit osteoclasts. In addition to fluids, bisphosphonates have become the mainstay of treatment for hypercalcemia.

Gallium nitrate (200 mg/m^2 per day) is a highly effective inhibitor of bone resorption. It is administered as a continuous intravenous infusion for 5 days (unless normocalcemia is achieved earlier). Renal impairment limits its usefulness.

Mithramycin (25 µg/kg) is given intravenously over 4 hours; this treatment can be repeated if necessary. Maximal hypocalcemic effect is reached at 48 to 72 hours. It is associated with hepatic and renal side effects and thrombocytopenia.

Glucocorticoids have an antitumor effect on neoplastic lymphoid tissue and are particularly useful in hypercalcemia associated with myeloma.

Calcitonin is given subcutaneously or intramuscularly. It has a rapid onset of action; thus, it is useful in immediate life-threatening situations. Calcitonin is a relatively weak agent with short-lived effect. Allergic reactions to salmon calcitonin are unusual, but an initial skin test with 1 unit is recommended before a full dose is given.

- Volume expansion *must* precede administration of furosemide.
- Furosemide inhibits calcium resorption in the thick ascending loop of Henle.
- Bisphosphonates bind to hydroxyapatite and inhibit osteoclasts.
- Mithramycin has hepatic and renal side effects.
- Calcitonin is a relatively weak agent with a rapid, short-lived effect.

Tumor Lysis Syndrome

This syndrome occurs as a result of the overwhelming release of tumor cell contents into the bloodstream such that concentrations of certain substances become life-threatening. It most commonly occurs in cancers with large tumor burdens and high proliferation rates which are exquisitely sensitive to chemotherapy. Tumor lysis syndrome rarely occurs spontaneously before antitumor therapy begins. Examples include high-grade lymphomas, leukemia, and, much less commonly, solid tumors (small-cell lung cancer, anaplastic thyroid cancer, and germ cell tumors). The syndrome is characterized by an increased uric acid value, which leads to renal complications; acidosis; an increased potassium value, which can cause lethal cardiac arrhythmias; an increased phosphate value, which leads to acute renal failure; and a decreased calcium value, which causes muscle cramps, cardiac arrhythmias, and tetany. The syndrome can be prevented with adequate hydration, alkalinization, and administration of allopurinol before chemotherapy.

- Tumor lysis syndrome is a result of the overwhelming release of tumor cell contents into the bloodstream.
- It is most common in cancers with large tumor burdens and high proliferation rates which are exquisitely sensitive to chemotherapy.
- It is characterized by increased uric acid, increased potassium, increased phosphate, acidosis, and decreased calcium.

Febrile Neutropenia

This is defined as a temperature of 38.5°C or more on one occasion or three episodes of 38°C or more plus an absolute neutrophil count of 500 × 10^9/L or less (or a total leukocyte count of 1,000 × 10^9/L or less). The risk of neutropenia is dependent on the type and dose of chemotherapy administered. Patients usually have no infection documented, but appropriate specimens for culture should be rapidly obtained before antibiotics are given. Until recently, management generally involved hospitalization and institution of parenteral broad-spectrum antibiotics. Recent extensive clinical experience and multiple randomized clinical trials have shown the safety and efficacy of outpatient therapy for selected patients with febrile neutropenia. All patients need to be evaluated by a physician for both medical and social contraindications to outpatient treatment (Table 19-13). Patients who have no contraindication to out patient treatment should be treated with oral amoxicillin-clavulanate 875 mg twice daily and oral ciprofloxacin 500 mg every 8 hours. All patients should be reevaluated within 24 hours either by telephone or in person. Multiple randomized, placebo-controlled clinical trials have shown that the use of colony-stimulating factors at the time of febrile neutropenia is not indicated.

- Not all patients with febrile neutropenia need to be admitted to the hospital.
- Growth factors should not be used once neutropenia has developed.
- Growth factors may prevent the development of febrile neutropenia, but they are used immediately after the chemotherapy.

Spinal Cord Compression

Acute cord compression is a neurologic emergency. It results most commonly from epidural extension of vertebral body metastases. The most common tumors include lung, breast, prostate, myeloma, and kidney. Occasionally, compression can occur from neighboring nodal involvement and tumor infiltration through intervertebral foramina (lymphoma, sarcomas, lung cancer). The locations are cervical in 10% of cases, thoracic in 70%, and lumbar in 20%. Multiple noncontiguous levels are involved in 10% to 40%. The most important prognostic factor in preserving neurologic function is early diagnosis, before neurologic deficits have developed.

More than 90% of patients present with pain. Cervical pain may radiate down the arm. Thoracic pain radiates around the rib cage or abdominal wall; it may be described as a compressing band

Table 19-13 Medical and Social Contraindications to Outpatient Treatment of Febrile Neutropenia

Medical contraindications
Anticipated duration of neutropenia of >7 days (typically patients with leukemia or lymphoma)
Absolute neutrophil count <100/10^9 × L
Comorbid medical conditions
Hypertension (systolic blood pressure <90 mm Hg)
Hypoxia or tachypnea (respiratory rate >30 breaths/min)
Altered mental status
Renal insufficiency (creatinine >2.5 mg/dL)
Hyponatremia (sodium <124 mg/dL)
Bleeding
Dehydration
Poor oral intake
Social contraindications
History of noncompliance or being unreliable with prior medical therapy follow-up
Geographically remote (>30 miles from 24-hour emergency medical care)
Unable to care for self and lack of reliable caregiver
No telephone
No transportation

bilaterally around the chest or abdomen. Lumbar pain may radiate into the groin or down the leg. Pain may be aggravated by coughing, sneezing, or straight-leg raising. Focal neurologic signs depend on the level affected. Paresthesias (tingling, numbness), weakness, and altered reflexes also can be present (Table 19-14). Tenderness over the spine may help localize the level, but absence does not exclude the possibility of cord involvement. Autonomic changes of urinary or fecal retention or incontinence are very concerning and may predict development of motor function loss in the near future.

Imaging studies include bone scanning or plain radiography, which reveal vertebral metastases in approximately 85% of patients with epidural compression. Magnetic resonance imaging of the entire spine is generally recommended. Computed tomographic myelography can be used in patients who cannot undergo magnetic resonance imaging.

Table 19-14 Reflexes and Their Corresponding Roots and Muscles

Reflex	Root(s)	Muscle
Biceps	C5-6	Biceps
Triceps	C7-8	Triceps
Knee jerk	L2-4	Quadriceps
Ankle jerk	S1	Gastrocnemius

Treatment usually includes an initial bolus of 10 to 100 mg of dexamethasone intravenously, depending on the severity of block. Thereafter, dexamethasone is given (4 mg four times a day), although some physicians favor higher doses for a few days followed by a rapid taper. Radiation therapy is applied to the involved area(s). Surgical resection and stabilization may lead to an increased chance at neurologic recovery in select patients who present with weakness or paralysis or in patients who present with no prior cancer diagnosis (Table 19-15). Patients with extensive organ involvement, progressive malignancies, or poor performance status are unlikely to be able to tolerate an extensive operative procedure and should be treated more conservatively.

- Early diagnosis of spinal cord compression, before development of neurologic deficit, improves outcome.
- Surgical therapy is indicated for select patients with neurologic deficit and spinal cord compression.

Palliative Care

Cancer Pain

More than 70% of patients with cancer have significant pain during the course of their disease. Multiple studies have shown that patients with cancer-related pain are not given adequate analgesic therapy (42% of patients are not given adequate pain relief). Barriers to optimal management of cancer pain include inadequate pain assessment by health care professionals, physician reluctance and inadequate knowledge of how to prescribe opioids, and patient reluctance to take opioids. Physician reluctance to prescribe opioids stems from concern about addiction, lack of familiarity with the agents, problems with management of side effects of opioids, and legal or regulatory concerns. Psychological addiction to opioids in cancer patients is very rare, occurring in fewer than 1%.

Evaluation

Evaluation should include 1) a history regarding onset, quality, severity, and location of pain; exacerbating and relieving factors; and associated symptoms, and 2) physical examination, which should include a complete neurologic examination. Diagnostic studies are determined by the results of the history and physical examination. Administration of analgesia should not be delayed while awaiting results of diagnostic studies or other tests.

Table 19-15 Outcome of Patients With Spinal Cord Compression, by Neurologic Status

Status at presentation	% ambulatory after radiation
Ambulatory	>80
Paraparetic	<50
Paraplegic	<10

Treatment

Three-Tiered Approach

Step 1: For mild pain, administer acetaminophen or a nonsteroidal anti-inflammatory drug around the clock. Studies of nonsteroidal anti-inflammatory drugs for cancer pain have shown that these agents are 1.5 to 2 times more effective than placebo.

Step 2: When step 1 fails to provide adequate analgesia, or for moderate pain, add codeine or oxycodone.

Step 3: For severe pain or inadequate pain relief with steps 1 and 2, agents include morphine, hydromorphone, oxycodone, methadone, and fentanyl (see the Oncology Pharmacy Review).

General Principles

For most cancer pain, opioids are the main treatment approach. For mild-to-moderate pain (4 to 7 on a scale of 1 to 10), oral medications are often effective. Severe pain (> 7 on a scale of 1 to 10) should be treated with intravenous medications because they allow for much more rapid titration of dose and prompter pain relief. If an intravenous access is not available, subcutaneous administration usually works well as long as the patient is reasonably well hydrated. Intramuscular administration is strongly discouraged because it is painful and absorption of drug is very erratic. Treatment should always begin with immediate-release oral or parenteral administration until the opioid requirements and effective dose for the individual patient are determined. Once the opioid dose required to relieve the pain is known, a long-acting form should be added.

The dose of opioid used to treat pain is highly dependent on whether the patient is already receiving opioids, as many cancer patients are. Patients who are opioid-naïve should be treated with 5 to 15 mg of oral immediate-release morphine, which is equianalgesic to 2 to 5 mg given intravenously. Other opioids are equally effective when compared with morphine. Equianalgesic tables are readily available and should be used to calculate an equivalent dose. For patients already taking opioids, the total amount of opioids taken in the preceding 24 hours should be calculated. Of the 24-hour total dose, 10% to 20% should be administered in the initial dose to try to relieve the pain. Doses then will need to be adjusted to achieve adequate analgesia. Before the dose is adjusted, one must wait until the time to peak effect has passed. This is typically 1 hour for oral agents, 6 to 10 minutes for intravenous agents, and 20 to 30 minutes for subcutaneous agents. Shortly after the time to peak effect, the patient should be reevaluated. If pain has decreased substantially, the same dose may be repeated on an as-needed basis, and the duration of the effect would be expected to be 3 to 4 hours. If the pain has decreased only a small amount, then the same dose should be given. If the pain has not changed at all, the next dose should be increased 50% to 100% and the patient reevaluated shortly after the time to peak effect has passed. Use of such an algorithm allows for rapid control of pain with minimal risk of adverse events (Fig. 19-5 and 19-6).

There is no "standard dosage." The dose must be increased until analgesia is achieved. Because the source of the pain is unlikely to be eliminated quickly, scheduled, around-the-clock dosing is necessary. Once the effective dose is determined, sustained-release

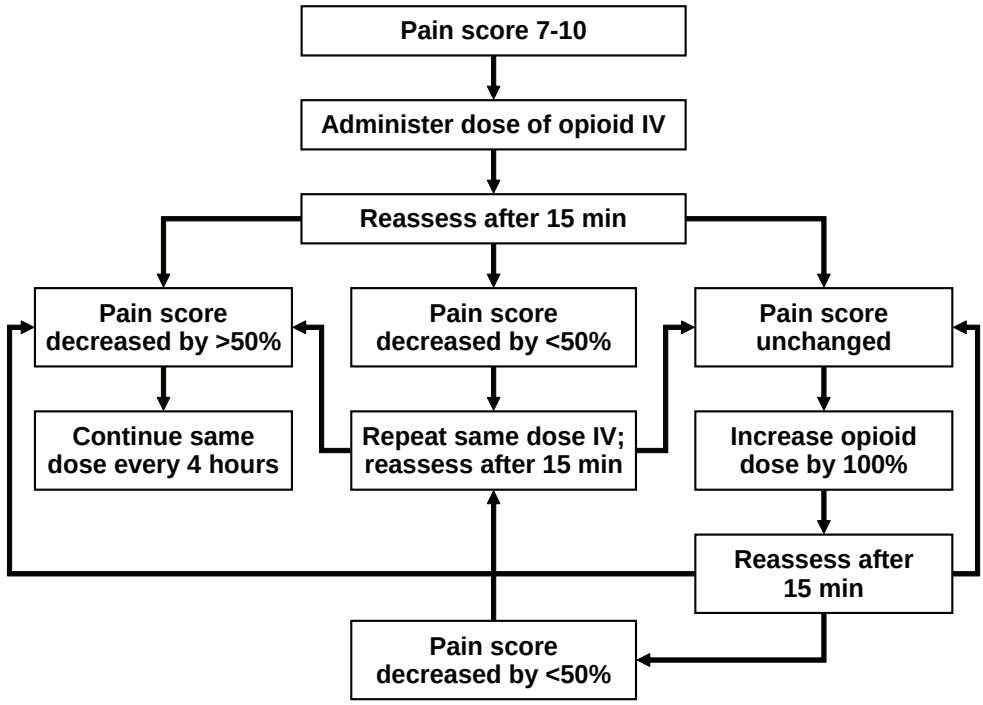

Fig. 19-5. Algorithm for treatment of severe cancer pain with intravenous opioid. Dose of opioid should be determined from patients status regarding pain and prior use of opioids. IV, intravenously.

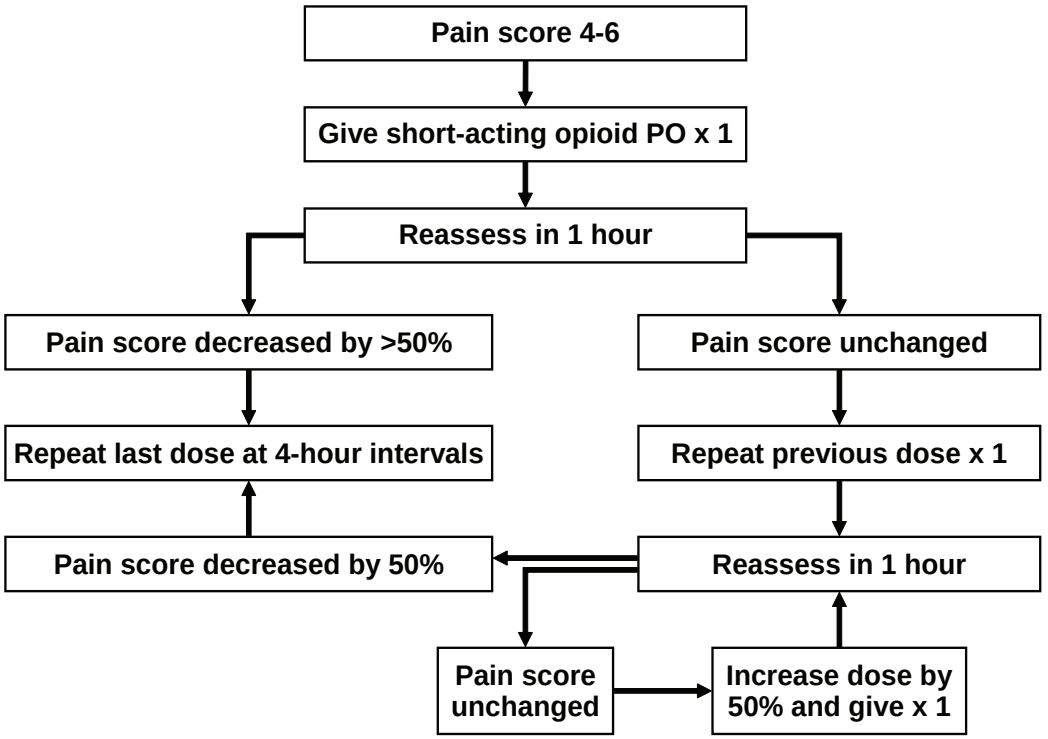

Fig. 19-6. Algorithm for treatment of mild-to-moderate cancer pain with oral opioids. PO, orally.

or continuous-infusion intravenous opioid should be given. When the algorithms are followed, the last dose given that resulted in substantial diminshment of pain should be used. This is considered the "effective" 4-hour dose, because the duration of analgesia (not to be confused with time to peak effect) would be expected to be 3 to 4 hours for both oral immediate-release and intravenous administration. All of the doses given during the titration schema should not be totaled because these doses are thought to represent a necessary "loading dose" required to saturate the opioid receptors. The effective 4-hour dose should be used to calculate the 24-hour equivalent. This amount then can be given as either a continuous infusion intravenously or as a sustained-release oral form. An immediate-release form of an opioid should continue to be made available to the patient for unexpected exacerbations of pain. This "breakthrough" dose is calculated by using 10% to 20% of the total daily dose of opioid being given. Appropriate equianalgesic conversions should be made when changing the route or drug. Patients who require 4 or more breakthrough doses in a 24-hour period should have their long-acting opioid dose adjusted. Each time the 24-hour dose is adjusted, the breakthrough dose should likewise be adjusted by using 10% to 20% of the 24-hour total.

Adverse effects of opioids include sedation, nausea, constipation, respiratory depression, and myoclonus. Tolerance to opioid-induced sedation and nausea usually develops within a few days. For opioid-induced constipation, docusate sodium and senna should be used. Respiratory depression typically follows sedation; if a patient is excessively somnolent and has a very low respiratory rate, doses should be held. No narcotic is more or less likely to result in a particular side-effect profile. However, one narcotic may produce an adverse effect in a patient whereas another will not. Thus, sequential trials of different opioids may be needed to determine the one best suited for a patient. The fentanyl patch (a transdermal formulation) delivers drug continuously over 72 hours. It is especially useful for patients with poor tolerance of orally administered opioids or those unable to take medications orally. Subcutaneous fat is required for absorption of the drug, and in patients with severe cachexia this may not be a good choice. Likewise, patients who are severely dehydrated will not have adequate skin perfusion to absorb the drug.

- Pain is common in patients with cancer and is often undertreated.
- The appropriate opioid dose for any one patient is that which relieves pain without excessive side effects.
- Acute pain exacerbations should be treated with immediate-release or parenteral opioids until the effective dose is determined.
- Once the effective opioid dose is known, scheduled, long-acting opioids should be given along with as-needed immediate-release opioids for breakthrough pain.

Other Symptoms

Patients with cancer face numerous other symptoms and challenges as they progress through the course of their illness. Dyspnea, nausea, fatigue, weight loss, depression, difficulty concentrating or thinking, and sexual dysfunction are all common. Careful attention to

symptoms and anticipation of expected symptoms can help alleviate many of these. Early referral to palliative care or hospice specialists can greatly enhance the patient's quality of life. Delineation of the patient's goals for care and development of advanced directives can allow the patient to remain in control and avoid unnecessary, painful, and, at times, harmful procedures.

- Early referral to palliative care or hospice can improve quality of life.

Acknowledgment

Lynn Hartmann, MD, and Scott Okuno, MD, are greatly acknowledged for their extensive work on this chapter in previous editions.

Oncology Pharmacy Review—Part I: General Classes of Agents

Robert C. Wolf, PharmD, Darryl C. Grendahl, RPh

A. Alkylating Agents

Drug	Toxic/adverse effects	Comments
Carboplatin	Myelosuppression (especially thrombocytopenia)	Commonly dosed with the Calvert formula
Carmustine	Myelosuppression (delayed) Renal dysfunction Pulmonary fibrosis	Crosses blood-brain barrier Pain with infusion
Cisplatin	Nephrotoxicity Peripheral neuropathy Ototoxicity Anemia	Magnesium or potassium wasting is common Dose adjustment is needed for renal insufficiency Minimize concomitant nephrotoxins
Cyclophosphamide	Myelosuppression Hemorrhagic cystitis SIADH (high dose) Cardiomyopathy (high dose)	
Dacarbazine	Myelosuppression Flu-like symptoms Photosensitivity	Pain with infusion
Ifosfamide	Myelosuppression Hemorrhagic cystitis CNS toxicity	Mesna is used to prevent hemorrhagic cystitis Lethargy, confusion, seizures
Mechlorethamine	Myelosuppression Thrombosis Thrombophlebitis Vomiting	Nitrogen mustard
Oxaliplatin	Peripheral neuropathy Hypersensitivity Myelosuppression Diarrhea	Acute, transient, cold-exacerbated dysesthesia or delayed-onset, cumulative paresthesias
Streptozocin	Nephrotoxicity	Dose adjustment is needed for renal insufficiency Vesicant
Temozolomide	Myelosuppression Lethargy Ataxia Increased LFTs	

CNS, central nervous system; LFTs, liver function test results; SIADH, syndrome of inappropriate secretion of antidiuretic hormone.

Oncology Pharmacy Review—Part I (continued)

B. Antimetabolites

Drug	Toxic/adverse effects	Comments
Capecitabine	Hand-foot syndrome Diarrhea Mucositis Fatigue	Oral prodrug of 5-fluorouracil Dose adjustment is needed for renal insufficiency Contraindicated in severe renal impairment
Fluorouracil	Diarrhea Mucositis Myelosuppression Ocular irritation Skin toxicity Myocardial ischemia	Toxicity profile is dependent on administration schedule • Bolus—myelosuppression • Continuous infusion—GI toxicity Leucovorin is concomitantly used to enhance enzyme inhibition
Gemcitabine	Myelosuppression (especially thrombocytopenia) Increased LFTs Peripheral edema Flu-like symptoms Rash Anal pruritus Hemolytic uremic syndrome	
Methotrexate	Myelosuppression Mucositis Nephrotoxicity (high dose) CNS toxicity (high dose or IT) Hepatotoxicity Pulmonary fibrosis	Leucovorin rescue for doses >100 mg/m^2 with serum level monitoring Urinary alkalinization for high dose Distributes in "third-space" fluids, leading to prolonged elimination and toxicity Drug interactions—NSAIDs, probenecid

CNS, central nervous system; GI, gastrointestinal; IT, intrathecal; LFTs, liver function test results; NSAIDs, nonsteroidal anti-inflammatory drugs.

Oncology Pharmacy Review—Part I (continued)

C. Plant Derivatives

Drug	Toxic/adverse effects	Comments
Vincristine	Neurotoxicity (peripheral, autonomic, cranial) SIADH	Dose reduction for biliary dysfunction Vesicant
Vinblastine	Myelosuppression Neuromuscular (myalgias)	Dose reduction for biliary dysfunction Vesicant
Etoposide	Myelosuppression Alopecia Mucositis (high dose) Hypotension Secondary leukemia	Renal & hepatic elimination
Paclitaxel	Myelosuppression Peripheral neuropathy Alopecia Hypersensitivity Myalgias Bradycardia	Vesicant Dose adjustment for liver dysfunction Premedicate with dexamethasone & antihistamine (H1 and H2) Drug interaction (administer before cisplatin)
Docetaxel	Myelosuppression Fluid retention Peripheral neuropathy Skin reactions Hand-foot syndrome Hypersensitivity	Dose adjustment is needed for liver dysfunction Prevent fluid retention with dexamethasone 4 mg twice daily for 5 days (begin 1 day before docetaxel)
Irinotecan	Diarrhea (acute & delayed) Myelosuppression Abdominal cramping/pain	Dose adjustment is needed for liver dysfunction Loperamide (≤24 mg/day) is used for delayed diarrhea
Topotecan	Myelosuppression Alopecia Mucositis (high dose)	Dose adjustment is needed for renal insufficiency

SIADH, syndrome of inappropriate secretion of antidiuretic hormone.

Oncology Pharmacy Review—Part I (continued)

D. Antitumor Antibiotics

Drug	Toxic/adverse effects	Comments
Bleomycin	Pulmonary fibrosis (chronic) (>400 units) Febrile reaction Hyperpigmentation Mucositis	Dose adjustment is needed for severe renal insufficiency
Doxorubicin	Myelosuppression Cardiomyopathy (chronic) (>550 mg/m^2) Mucositis Alopecia Red-orange urine Secondary leukemia	Dose reduction is needed for biliary dysfunction Dexrazoxane may be used as cardioprotectant Vesicant Venous flare reaction on injection Radiation recall
Epirubicin	Myelosuppression Cardiomyopathy Mucositis Red-orange urine	Vesicant
Mitomycin	Myelosuppression (delayed) Blue-green urine Hemolytic uremic syndrome Pulmonary toxicity	Vesicant
Mitoxantrone	Myelosuppression Blue-green urine Cardiomyopathy	Vesicant

Oncology Pharmacy Review—Part I (continued)

E. Immunotherapy

Drug	Toxic/adverse effects	Comments
Aldesleukin (IL-2)	Capillary leak syndrome (fever, fluid retention, respiratory distress, hypotension) Myelosuppression Erythema	Concurrent corticosteroids may limit efficacy
Interferon-α	Flu-like symptoms Fatigue Myelosuppression Increased LFTs	

LFTs, liver function test results.

F. Targeted Therapy

Drug	Toxic/adverse effects	Comments
Bevacizumab	Bleeding Wound healing complications	Recombinant monoclonal antibody that inhibits vascular endothelial growth factor
Cetuximab (IMC-225)	Folliculitis	Monoclonal antibody against epidermal growth factor
Gefitinib	Diarrhea Rash (acne) Interstitial lung disease Ocular irritation	Inhibits the epidermal growth factor receptor tyrosine kinase
Trastuzumab	Fever Chills or rigors Cardiac dysfunction Diarrhea	Cardiac dysfunction most common when used in combination with doxorubicin

Oncology Pharmacy Review—Part I (continued)

G. Endocrine Therapy

Drug	Toxic/adverse effects	Comments
Tamoxifen	Hot flashes Vaginal dryness Endometrial cancer Thromboembolism	Antiestrogen
Anastrozole Letrozole Exemestane	Nausea (mild) Peripheral edema Diarrhea Asthenia Hot flashes	Aromatase inhibitors
Megestrol	Fluid retention Weight gain Thromboembolism	Progestin
Leuprolide Goserelin	Decreased libido Impotence Hot flashes Tumor flare	LHRH agonists
Flutamide Bicalutamide Nilutamide	Gynecomastia Diarrhea Increased LFTs Impaired adaptation to dark (nilutamide) Pulmonary fibrosis (nilutamide)	Antiandrogens

LFTs, liver function test results; LHRH, luteinizing hormone-releasing hormone.

H. Emetogenic Potential of Select Oncology Agents

High (level 5)	Moderately high (level 4)	Moderate (level 3)	Mild (level 2)	Low (level 1)
Cisplatin	Carboplatin	Ifosfamide	Fluorouracil	Temozolomide
Carmustine	Cyclophosphamide	Gemcitabine	Methotrexate	Capecitabine
Mechlorethamine	Methotrexate*	Irinotecan	Etoposide	Vincristine
Dacarbazine	Doxorubicin	Epirubicin	Paclitaxel	Vinblastine
Streptozocin		Mitoxantrone	Docetaxel	Bleomycin
		Mitomycin	Topotecan	

*High-dose.

Oncology Pharmacy Review—Part II: Analgesics

Heidi D. Gunderson, PharmD, Robert C. Wolf, PharmD

A. Dosage Information: Common Opioid Agonists

Agonist	Dosage form	Onset, min	Duration, h	Approximate equianalgesic dose, mg	
				Parenteral	Oral
Morphine	Tablet/capsule	15-60	4-12	10	30
	Solution	15-60	4-12		
	Suppository	15-60	4-6		
	Injection	IV: <5	4-6		
Oxycodone	Tablet/capsule	15-30	4-12	NA	20
	Solution	15-30	4-6		
Fentanyl	Transdermal patch	12 h	48-72	0.1	Patch: ~17 µg/h
	Transmucosal lozenge	5-15	1-2		
	Injection	IV: <5	1-2		
Hydromorphone	Tablet	15-30	4-12	1.5	7.5
	Solution	15-30	4-6		
	Suppository	15-30	6-8		
	Injection	IV: <5	4-6		
Methadone	Tablet	30-60	4-12	1-2	3-6
	Solution	30-60	4-12		
	Injection	IV: <5	4-6		
Codeine	Tablet	30-60	4-6	120	200
	Solution	30-60	4-6		
	Injection	IV: 10-30	4-6		
Hydrocodone	Tablet/capsule	60	4-6	NA	30
	Solution	60	4-6		
Meperidine	Tablet	15-45	2-4	75	300
	Solution	15-45	2-4		
	Injection	IV: <5	2-4		

IV, intravenous; NA, not available.

Oncology Pharmacy Review—Part II (continued)

B. Dosage Information: Common Nonopioid Analgesics

Analgesic	Dosage form	Onset, min	Duration, h	Maximal dose, mg/day
Miscellaneous				
Acetaminophen	Tablet Solution Suppository	10-30	4-6	4,000
Aspirin	Tablet Suppository	30	3-6	4,000
Tramadol	Tablet	30-60	6-8	400
Nonsteroidal anti-inflammatory drugs				
Ibuprofen	Tablet Suspension	30	4-6	3,600
Naproxen	Tablet Suspension	60	6-12	1,000
Ketorolac	Tablet Injection	30 IV: 10	4-6 IV: 6	40 IV: 60-120
Cyclooxygenase-2 inhibitor				
Celecoxib	Capsule	45-60	4-8	400
Adjuvant analgesics				
Gabapentin	Tablet/capsule	1-5 days	6-8	3,600
Amitriptyline	Tablet Injection	3-14 days	12-24	200
Carbamazepine	Tablet Suspension	3-14 days	8-12	1,200

IV, intravenous.

Oncology Pharmacy Review—Part II (continued)

C. Effects and Other Considerations for Common Opioid Agonists and Nonopioid Analgesics

Drug	Toxic/adverse effects	Comments
Common opioid agonists		
Morphine	Sedation Respiratory depression	Morphine: orthostatic hypotension, use cautionsly with hemodynamic instability; pruritus not uncommon (histamine-mediated)
Oxycodone	Nausea/vomiting Pruritus	Oxycodone: available orally only; often used in combination with a nonopioid analgesic. Cumulative dose of the nonopioid analgesic generally limits the ability to increase doses
Fentanyl	Euphoria	Fentanyl: delayed onset with the transdermal patch
Hydromorphone	Constipation Delirium	Hydromorphone: relatively short-acting; use in renal failure is safe because there are no active metabolites
Methadone	Hallucinations	Methadone: longer duration of effect with chronic use; cautious dose titration
Codeine	Dry mouth	Codeine: ceiling effect
Hydrocodone	Urinary retention	Hydrocodone: available only as oral agent in combination with a nonopioid analgesic. Cumulative dose of the nonopioid analgesic generally limits the ability to increase doses
Meperidine	Physical dependence	Meperidine: neuroexcitatory active metabolites accumulate with renal insufficiency; *not* recommended for chronic pain states; drug-drug interaction with MAO inhibitors
		There are many combination products that contain both an opioid agonist and nonopioid analgesic. The cumulative dose of the nonopioid analgesic generally limits the ability to increase doses
Common nonopioid analgesics		
Miscellaneous analgesics		
Acetaminophen	Hepatic dysfunction with higher doses or chronic use Renal tubular necrosis	Higher doses inhibit warfarin metabolism, which may prolong the INR
Aspirin	GI ulceration, inhibits platelet aggregation, renal insufficiency, tinnitus	
Tramadol	Dizziness, sedation, constipation, nausea or vomiting	Higher doses increase seizure potential
Nonsteroidal anti-inflammatory drugs/cyclooxygenase-2 inhibitors		
Ibuprofen	Dyspepsia	Class: use cautiously with other nephrotoxic agents
Naproxen	GI ulceration	
Ketorolac	Salt and water retention	Ketorolac: maximal duration of use is 5 days because of risk of GI or renal side effects
Celecoxib	Renal insufficiency Inhibition of platelet aggregation	Celecoxib has fewer GI side effects and does not inhibit platelet aggregation
		Increased risk of myocardial infarction/stroke (rofecoxib and valdecoxib were withdrawn from market)

Oncology Pharmacy Review—Part II (continued)

C. Effects and Other Considerations for Common Opioid Agonists and Nonopioid Analgesics (continued)

Drug	Toxic/adverse effects	Comments
Common opioid agonists (continued)		
Adjuvant analgesics		
Gabapentin	Sedation Dizziness Fatigue	Dose reduction is necessary with renal insufficiency Initiate at bedtime and titrate to effective dose (usually divided throughout day)
Amitriptyline	Sedation, dizziness, dry mouth, confusion, constipation, blurred vision, urinary retention, orthostatic hypotension	Administer at bedtime Other tricyclic antidepressants are also effective
Carbamazepine	Dizziness, sedation, nausea or vomiting, mild leukopenia, agranulocytosis (rare)	Erythromycin, clarithromycin, and propoxyphene inhibit carbamazepine metabolism

GI, gastrointestinal; INR, international normalized ratio; MAO, monoamine oxidase.

20

Preventive Medicine

Sally J. Trippel, MD, MPH

Definitions

Preventive medicine is the practice of medicine that detects and alters or ameliorates host susceptibility in a premorbid state (e.g., immunization), risk factors for disease in a predisease state (e.g., increased cholesterol level), and disease in the presymptomatic state (e.g., in situ cervical cancer). Not all disease is preventable because not all risk factors (or all individuals at risk) are known, the cost of screening everyone is not feasible, barriers to medical access exist, interval disease occurs, characteristics of the target disease vary, and screening tests and treatments are imperfect.

Primary prevention is defined as the prevention of disease occurrence (e.g., immunization to prevent infection and blood pressure control to prevent stroke). *Secondary prevention* is defined as the detection and amelioration of disease in a presymptomatic or preclinical stage (e.g., mammography detects small foci of cancer and Pap smear detects in situ cancer). *Tertiary prevention* is defined as the prevention of future negative health effects of existing clinical disease (e.g., use of aspirin and β-blockers after myocardial infarction to prevent recurrence).

Efficacy refers to the potential or maximal benefit derived from applying a test or procedure under ideal circumstances (e.g., research studies with compliant patients and with ideal testing conditions and techniques). *Effectiveness* refers to the actual benefit derived from a test or procedure that is applied under usual—less than ideal—circumstances. Randomized trials in which results are analyzed by the *intention-to-treat* principle (i.e., all members of a group are included in the analysis whether or not they complied) give a measure of effectiveness in a population. *Cost-effectiveness* refers to the unit of cost incurred to achieve a given level of effectiveness. It is often expressed as the dollars spent per year of life saved. Often, the most cost-effective method of testing is not the most effective. For example, performing Pap smears every 5 or 10 years is more cost-effective, but performing them every year is more effective.

- Cost-effectiveness: cost incurred to achieve a given level of effectiveness.
- The most cost-effective test may not be the most effective test.

Years of potential life lost describes one measure of the relative impact of a disease on society. This term usually refers to the years lost because of death from a disease before age 65 years (or sometimes 70). For example, colon cancer kills approximately 56,000 men and women annually and breast cancer kills approximately 41,000 women. However, on average, breast cancer kills at a younger age and so results in nearly 3× as many years of potential life lost.

- Years of potential life lost: the years lost because of death from a disease before age 65 years (or sometimes 70).

Incidence (or *incidence rate*) refers to the number of new events (deaths or diagnoses) that occur in a population in a given time (e.g., 190 cancer deaths per 100,000 people in the United States annually). *Prevalence* refers to the number of cases of a condition existing at a point in time in a population. Prevalence rate is directly related to disease duration. For example, an estimated 850,000 to 950,000 people in the United States are currently infected with the human immunodeficiency virus (HIV).

Principles of Screening for Disease

The term *mass screening* is generally applied to the relatively indiscriminate testing of a population with the intent to improve the aggregate health of the population but not necessarily of every person in the population. An example is blood pressure or cholesterol testing in a public setting such as a shopping mall.

- Mass screening: indiscriminate testing of a population to improve the aggregate health of the population.

Case finding is the technical term often used for screening that is conducted in the office setting. The intent is to detect asymptomatic disease and to improve the health of the person. In testing asymptomatic persons, it is important to bear in mind the dictum "first do no harm."

- Case finding: screening conducted in the office setting to detect asymptomatic disease and to improve the health of a person.

Desirable Screening Characteristics

The following disease, test, and host characteristics are desirable for screening:

1. Disease characteristics: The diseases screened should be common, cause substantial morbidity and mortality, have a long preclinical phase (during which the disease is curable or modifiable), have an effective treatment that is available to those screened, and have an acceptable treatment (i.e., one that is not excessively painful or disfiguring).
2. Test characteristics: The tests should be inexpensive, safe, acceptable, easy to administer, technically easy to perform, and highly sensitive, and they should have a complementary, highly specific confirmatory test.
3. Host characteristics: The person should be at risk, have access to testing, be likely to comply with follow-up testing, and have adequate overall life expectancy or functional life expectancy.

Burden of Disease in the United States

Diseases that cause the most morbidity and mortality in the United States may or may not be amenable to screening or case finding. Heart disease and cancer are clearly the leading causes of death in the United States (Tables 20-1 and 20-2). The most recent year for which actual statistics exist is 2002.

Cancer Screening

Lung Cancer

Lung cancer is a highly lethal form of cancer (it kills most of the people it afflicts) and is the leading cause of cancer death for men and women. The burden of disease (2005 estimates from the American Cancer Society) is 172,570 new cases and 163,510 deaths. The peak incidence occurs in men and women aged 60 to 79 years. Risk factors include the following:

Table 20-1 Leading Causes of Death in the United States, 2002

	No. of deaths	Death rate (per 100,000 population)	% of total deaths
Heart disease	696,947	241.7	28.5
Cancer	557,271	193.2	22.8
Cerebrovascular disease	162,672	56.4	6.7
Chronic lower respiratory tract disease	124,816	43.3	5.1
Accidents (unintentional injuries)	106,742	37.0	4.4

Modified from Kochanek KD, Murphy SL, Anderson RN, Scott C. Deaths: final data for 2002. National vital statistics reports; vol 53 no 5. Hyattsville, Maryland: National Center for Health Statistics, 2004.

Table 20-2 Cancer Mortality for Women and Men, 2002 (U.S. Vital Statistics)

Age, y					
40-59		60-79		≥80	
Women					
Breast	12,115	Lung & bronchus	39,943	Lung & bronchus	16,064
Lung & bronchus	11,129	Breast	17,218	Colon & rectum	12,030
Colon & rectum	3,857	Colon & rectum	11,904	Breast	10,849
Ovary	3,285	Pancreas	7,869	Pancreas	5,436
Pancreas	1,999	Ovary	7,349	Non-Hodgkin lymphoma	4,029
Men					
Lung & bronchus	16,044	Lung & bronchus	55,996	Lung & bronchus	17,681
Colon & rectum	5,257	Colon & rectum	14,973	Prostate	15,795
Pancreas	3,195	Prostate	13,539	Colon & rectum	7,820
Liver	2,733	Pancreas	8,312	Leukemia	3,409
Esophagus	2,470	Leukemia	5,919	Urinary bladder	3,331

Modified from Jemal A, Murray T, Ward E, Samuels A, Tiwari RC, Ghafoor A, et al. Cancer statistics, 2005. CA Cancer J Clin. 2005;55:10-30. Used with permission.

1. Smoking—risk is 10× greater for smoker than for nonsmoker
2. Age—risk at 70 years is 10× greater than at 40 years
3. Sex—male-female ratio for lung cancer deaths is 1.24:1 and is related primarily to duration and intensity of smoking
4. Exposure to environmental, industrial, and occupational carcinogens—radon, asbestos, hydrocarbons, haloethers, nickel, arsenic, vinyl chloride, and ionizing radiation; risk of lung cancer increases with exposure to environmental tobacco smoke and varies with the duration and intensity of exposure

Screening tests include chest radiography and sputum cytology. Screening probably is not effective. Although the Mayo Clinic Lung Project detected more cases of cancer, mortality was not altered in approximately 12 years of follow-up study. This may have been because of "overdiagnosis" of clinically irrelevant lesions or lead-time bias. Annual chest radiography (or sputum cytology) solely to look for treatable-stage lung cancer should not be performed.

Studies are under way to evaluate newer imaging methods as well as cytologic and molecular evaluation of sputum for lung cancer screening. On the basis of these studies, low-dose spiral computed tomography (CT) of the chest appears to be better than chest radiography for detecting small lung cancers. Large population-based screening studies of low-dose spiral CT have not been completed, so currently it is uncertain whether this technology will be effective in screening for lung cancer.

Smoking is the leading preventable cause of cancer in the United States and a leading cause of heart disease and stroke. Physician advice to quit smoking and referral to smoking cessation programs are the most cost-effective preventive measures available. Smoking cessation decreases the risk of lung cancer, although the risk never returns to that of a nonsmoker.

- Lung cancer: the leading cause of cancer death for men and women.
- Risk factors for lung cancer: smoking, age, sex (male > female), environmental exposure to tobacco smoke and radon.
- Annual chest radiography or sputum cytology solely to look for treatable stage lung cancer should not be performed.
- Smoking is the leading preventable cause of cancer in the United States.

Breast Cancer

Breast cancer is the second leading cause of cancer death for women. The lifetime risk is estimated at 1 in 8 women. The burden of disease (2005 estimates from the American Cancer Society) is 211,240 new cases and 40,410 deaths. Thus, breast cancer is moderately lethal (it kills many but not most of the people it afflicts). Risk factors include the following:

1. Age—risk increases throughout life, and the risk for an 80-year-old woman is 12× that for a 30-year-old woman
2. Family history—with one first-degree relative with breast cancer, the risk increases 2× to 3×, and with two first-degree relatives, 4× to 6×
3. Socioeconomic status—if high, risk is increased 2×
4. Nulliparity or older than 30 years at first full-term pregnancy—risk is increased 2×
5. History of proliferative breast disease, history of breast cancer, or high-dose radiation exposure (before age 45)—risk is increased approximately 2×

Additional risk factors include younger age at menarche, older age at menopause, prolonged postmenopausal hormone therapy, dense tissue within the breast, moderate or high alcohol intake, and, possibly, cigarette smoking.

- Breast cancer: the second leading cause of cancer death for women.
- Lifetime risk: 1 in 8 women.
- With one first-degree relative with breast cancer, 2× to 3× risk; with two first-degree relatives, 4× to 6× risk.

Screening procedures include the following:

1. Breast self-examination—no demonstrated effectiveness
2. Clinical breast examination—sensitivity is about 50% to 70% and specificity is greater than 90%
3. Mammography—sensitivity is 75% to 95% for women 50 or older. Sensitivity is lower for women who are younger than 50, have dense breast tissue, or take hormone replacement therapy. Specificity is 95% to 99%. Positive predictive values (PPVs) are about 5% to 10%, with 20% to 50% of biopsy examinations finding cancer, depending on age (higher percentages in older women). Randomized controlled trials worldwide have examined the effectiveness of mammography. They showed an approximate 30% decrease in mortality, but only two trials showed statistical significance. Data are conflicting or inconclusive for women younger than 50 or older than 70 years.

- Breast physical examination has a sensitivity of 50%-70% and a specificity >90%.
- Mammography has a sensitivity of 75%-95% and a specificity of 95%-99%.
- Studies are inconclusive about the benefit of mammography for women younger than 50 or older than 70.

Screening Risks

Radiation is estimated to produce 80 additional radiation-induced breast cancer deaths among 1,000,000 women screened annually for 10 years, compared with more than 90,000 breast cancers expected to be detected.

- Radiation produces 80 additional cases of breast cancer among 1,000,000 women screened.

Cost-effectiveness

If 25% of women 40 to 75 years old in the United States were screened annually, 11,000,000 per year would be screened at a cost of $1.3 billion annually for physical examination and mammography. The cost of screening and the work-up would be 100× as expensive as the cost saved by reduced treatment. Cost per year of life saved ranges from about $9,000 to $12,000, with lower costs for women 50 to 69 years old and higher costs in both younger and older age groups.

- The cost of screening and work-up would be 100× as expensive as the cost saved by reduced treatment.
- The cost per year of life saved is $9,000-$12,000.

Recommendations

Current recommendations are as follows:

1. There is general agreement to recommend clinical breast examination and mammography every 1 to 2 years for women 50 to 69 years old. Otherwise, recommendations vary.
2. The American Cancer Society and several other groups recommend screening with mammography and clinical breast examination beginning at age 40. Recommendations for screening intervals differ among organizations.
3. The U.S. Preventive Services Task Force (USPSTF) recommends screening mammography alone or clinical breast examination and mammography every 1 to 2 years for women 40 or older.

Colorectal Cancer

Colorectal cancer is the second leading cause of cancer death in the United States. The burden of disease (2005 estimates from the American Cancer Society) is 104,950 new cases of colorectal cancer and 56,290 deaths due to colorectal cancer. The lifetime risk of developing this cancer is approximately 5% to 6%. Less than 2% of these cancers occur in people younger than 40, and 90% occur in those older than 50. The risk of developing colorectal cancer is approximately 2× greater than the risk of dying of it (which reflects the potential survivability of colorectal cancer and the age of the population involved, i.e., there are competing causes of death). Colorectal cancer is now the second cancer for which randomized controlled trial evidence has demonstrated decreased mortality because of screening.

- Colorectal cancer is the second leading cause of cancer death.
- Lifetime risk is 5%-6%.
- Colorectal cancers: 90% occur in patients older than 50.

Natural History

Cancer may develop de novo in the colon, but most tumors probably develop from adenomatous polyps. The risk of a polyp becoming malignant appears to be related to its histologic characteristics and size. Polyps that are histologically villous or tubulovillous increase the risk of colorectal cancer. Clinically significant polyps are ones larger than 10 mm. In addition, the presence of multiple polyps increases risk. The average time from formation to malignant transformation for a polyp is 7 to 10 years.

- The risk of a polyp becoming malignant appears to be related to its histologic characteristics and size.
- Clinically significant polyps are >10 mm.
- The time from polyp formation to malignant transformation is 7-10 years.

Risk Factors

Risk factors for colorectal cancer include the following:

1. Age—risk doubles every 7 years after age 50
2. Family history—if a first-degree relative has disease, the risk increases 2× to 3×; for multiple prior adenomatous polyps, the risk increases 2× to 4×
3. History of endometrial, ovarian, or breast cancer—risk increases 2×
4. Familial adenomatous polyposis (Gardner syndrome)—risk is approximately 100% by age 40 to 45
5. Inflammatory bowel disease (ulcerative colitis and Crohn colitis)—risk is approximately 30% with a 30- to 40-year history of disease
6. Cancer family syndrome (adenocarcinoma at various locations at an early age in multiple siblings)—risk is approximately 50%

- Risk for colorectal cancer doubles every 7 years after age 50.
- If a first-degree relative has colorectal cancer, the risk increases 2× to 3×.
- Previous adenomatous polyps—risk increases 2× to 4×.
- History of endometrial, ovarian, or breast cancer—risk increases 2×.
- Familial adenomatous polyposis (Gardner syndrome)—risk is nearly 100% by age 40-45.
- Inflammatory bowel disease—about a 30% risk with a 30- to 40-year history of chronic colitis.

Tests

The fecal occult blood test (FOBT) is 26% to 60% sensitive and does not detect polyps well. Proctoscopy is more than 90% sensitive for the area of the colon visualized; in studies, it detected about 30% of cancers. Flexible sigmoidoscopy is also more than 90% sensitive for the area of the colon visualized; in studies, it detected about 60% of cancers. With barium enema and colonoscopy, the entire colon may be visualized, with 85% to 95% sensitivity.

- FOBT is 26%-60% sensitive.
- Proctoscopy and flexible sigmoidoscopy are >90% sensitive for the area of colon visualized.
- With barium enema and colonoscopy, the entire colon may be visualized, with 85%-95% sensitivity.

Recommendations

The available randomized controlled trial data show about a 30% decrease in mortality for persons older than 50 who have an annual FOBT. There is little consensus about how to screen for colorectal cancer. Mathematical modeling suggests that annual screening with barium enema or colonoscopy might reduce mortality by 85%, but the cost would be prohibitive.

For persons with average risk, the American Cancer Society recommends starting to screen at age 50 with FOBT annually, flexible sigmoidoscopy every 5 years, or a combination of these tests. Alternative options include double-contrast barium enema every 5 years or colonoscopy every 10 years.

The USPSTF strongly recommends colorectal cancer screening for men and women 50 years or older. Screening options include

FOBT, flexible sigmoidoscopy, colonoscopy, and double-contrast barium enema. There is insufficient evidence for determining the optimal screening strategy and interval. The guidelines also recommend that persons with a family history of hereditary syndromes associated with a high risk of colon cancer should be referred for diagnosis and management.

- FOBT screening annually decreases mortality by 30% for persons older than 50.
- Annual screening with barium enema or colonoscopy might reduce mortality by 85%, but the cost would be prohibitive.

Prostate Cancer

For the purposes of screening, prostate cancer is a troublesome disease, primarily because of the great difference between the "burden" of prevalent disease and the "burden" of clinical disease. The 2005 estimates from the American Cancer Society are 232,090 new cases of prostate cancer and 30,350 deaths. Pathology studies show that a small focus of prostate cancer can be found in 30% to 40% of 60-year-old men. Prostate cancer will be diagnosed in only 8% to 9% of the men, with many cases diagnosed incidentally at transurethral resection of the prostate. Currently, 80% of diagnoses are made in men older than 65. Only 3% to 4% of men in the United States die of complications of prostate cancer.

- Prostate cancer is diagnosed in 8%-9% of U.S. men.
- Only 3%-4% of U.S. men die of prostate cancer.
- Currently, 80% of the diagnoses are made in men older than 65 years.

Natural History

Prostate cancer is a hormonally induced cancer that is generally slow growing. In most host males, it does not alter the life span or lifestyle. Growth of a tiny nidus of cancerous cells into a clinically important cancer takes 10 to 15 years. In elderly hosts, this process is usually halted by intervening causes of death. Aggressiveness and morbidity are related to size, grade, and ploidy.

- Prostate cancer is a hormonally induced cancer.
- It does not alter the life span or lifestyle of most host males.
- Growth into a clinically important cancer takes 10-15 years.

Risk Factors

Risk factors for prostate cancer include the following:

1. Age—risk increases exponentially after age 50
2. Race—in the United States, African-American men have 2× the risk of whites, and whites have 2× the risk of Asians
3. Family history—having a first-degree relative with prostate cancer increases the risk 3×, having a brother with prostate cancer before age 63 increases the risk 4×, and having a sister with breast cancer increases the risk 2×

Additional risk factors include *BRCA1* or *BRCA2* mutations, dietary factors (high intake of animal fat or low intake of vegetables), prior prostatitis, and higher serum testosterone and insulin-like growth factor 1 concentrations.

- For prostate cancer in the United States, African-American men have twice the risk of whites, who have twice the risk of Asians.

Tests

A digital rectal examination has a PPV of 6% to 33%. Transrectal ultrasonography has a PPV of about 10% to 20% (values vary depending on population and previous screening). The prostate-specific antigen (PSA) test has a PPV of 10% to 35% (values vary depending on population and prior screening). Use of PSA velocity (change in PSA over time) may improve screening accuracy, but further study is needed. Because there is much undetected disease, PPV values do not have the usual meaning.

Recommendations

No good data are available from population-based randomized controlled trials on the effect of early detection and treatment on survival. There is little agreement on recommendations for screening. Aggressive screening for prostate cancer would uncover many new cases (causing a surge in incidence) and result in many additional treatments. However, because of the natural history of the disease, screening may have minimal effect in decreasing mortality, the desired benefit. The American Cancer Society recommends that a digital rectal examination and the PSA test be offered annually to men older than 50 who have a life expectancy of at least 10 years. The USPSTF guidelines conclude that there is insufficient evidence to recommend for or against routine screening for prostate cancer with a digital rectal examination or PSA test.

- There is little agreement on recommendations for prostate cancer screening.

Some authorities have recommended against any form of screening—digital rectal examination, ultrasonography, or PSA—primarily because of concern that the effect on survival would be minimal and that the costs of detection and follow-up treatment and of deaths due to treatment (perioperative deaths) would be substantial. There is a risk that the harm outweighs the good from detection of early-stage disease. Screening, if performed, should be done in men likely to have a 10-year survival.

Cervical Cancer

The 2005 estimates from the American Cancer Society are 10,370 new cases of cervical cancer and 3,710 deaths. Cervical cancer has a bimodal risk curve divided between in situ carcinoma and invasive carcinoma. This cancer has a long preclinical phase, and progression from dysplasia to invasive cancer may take 10 to 15 years or more. A strong association exists between human papillomavirus (HPV) infection (types 16, 18, and others) and cervical cancer. Cervical cancer is largely a sexually transmitted disease.

- Cervical cancer: bimodal risk curve divided between in situ carcinoma and invasive carcinoma.
- It has a long preclinical phase.
- Cervical cancer is strongly associated with HPV infection.

Risk Factors
Risk factors for cervical cancer include the following: 1) age—the risk of invasive carcinoma increases throughout life; 2) sexual activity—early age at onset; 3) multiple sexual partners; 4) a history of sexually transmitted disease, especially HIV infection; and 5) smoking.

- Cervical cancer risk factors: early age at onset of sexual activity, multiple sexual partners, a history of sexually transmitted disease, and smoking.

Test
The Pap smear has a sensitivity of 55% to 80% and a specificity of 90% to 99%. The expertise of the cytologists and pathologists as well as the clinician's sampling technique are important for test effectiveness. The USPSTF has concluded that the evidence is insufficient to recommend for or against routine use of new technologies (liquid-based cytology, computerized rescreening, and algorithm-based screening) to screen for cervical cancer. No current guidelines recommend using HPV testing for cervical cancer screening.

- Pap smear: 55%-80% sensitivity and 90%-99% specificity.

Screening Effectiveness
No randomized controlled trial of screening has been conducted in a general population. However, evidence from case-control studies and observational studies suggests effectiveness. The estimated overall effect of screening with a Pap smear every 10 years is a 64% reduction in invasive cancer; every 5 years, an 84% reduction; every 3 years, a 91% reduction; every 2 years, a 92.5% reduction; and every year, a 93.5% reduction.

Recommendations
There is general agreement to start screening at the onset of sexual activity and every 1 to 3 years thereafter, depending on risk. The USPSTF guidelines recommend routine screening for all women who have been sexually active and who have a cervix. Screening should begin with the onset of sexual activity and should be repeated at least every 3 years. The American Cancer Society recommends that cervical cancer screening start 3 years after onset of sexual activity, but no later than age 21. Also, it recommends annual screening with a conventional Pap test, or every 2 years if liquid-based cytology is used, until age 30. The recommendation permits less frequent testing after age 30 (every 2-3 years), based on past screening results and risk factors. The recommendation suggests offering women the option to discontinue screening after age 65 to 70 if there is evidence of adequate past screening.

- General recommendation: screen at the onset of sexual activity and every 1-3 years thereafter, depending on risk.

Ovarian Cancer
Ovarian cancer is the fifth leading cause of cancer death in women. The burden of disease (2005 estimates from the American Cancer Society) is 22,220 new cases of ovarian cancer and 16,210 deaths. Ovarian cancer is the leading cause of gynecologic cancer death. Age-adjusted death rates have been increasing slowly in the past 25 years.

- Ovarian cancer is the fifth leading cause of cancer death in women.
- Age-adjusted death rates have been increasing slowly.

Risk Factors
With a history of at least one term pregnancy, the relative risk is 0.6 to 0.8. With the use of oral contraceptives for 3 to 6 months, the relative risk is 0.6; if oral contraceptives are used more than 10 years, the relative risk is 0.2. Tubal ligation may also reduce risk.

Family history as a risk is not well quantified, but it is an important factor if a first-degree relative had disease (only 4%-5% of ovarian cancers are familial). Long duration of ovulatory years (i.e., early menarche or late menopause) is a risk factor. High-fat diet and endometriosis may also increase risk.

- Only 4%-5% of ovarian cancers are familial.

Screening Tests
Bimanual examination is insensitive. Ultrasonography, either transvaginal or transabdominal, is more sensitive than bimanual examination but has a poor PPV. The cancer antigen 125 (CA 125) assay is more sensitive than bimanual examination but also has a poor PPV. Ultrasonography and the CA 125 assay have a significant false-positive rate. It is estimated that 10 to 60 abdominal operations would have to be performed for every one cancer detected, at a cost of more than $13 billion annually, to screen the 43 million women older than 45. An adequate study of efficacy, even with a highly sensitive and specific test, would require tens of thousands of participants.

- For ovarian cancer, bimanual examination is insensitive.
- Ultrasonography and the CA 125 assay are more sensitive than bimanual examination, but both have a poor PPV.
- For every one ovarian cancer detected, 10-60 abdominal operations would have to be performed.

Recommendations
USPSTF guidelines recommend against screening for ovarian cancer. The American Cancer Society recommends regular pelvic examination, including adnexal palpation, as part of cervical cancer screening.

A 1994 National Institutes of Health Consensus Conference recommended that women with presumed hereditary cancer syndrome should have a pelvic examination, a CA 125 assay, and transvaginal ultrasonography annually until childbearing is completed or until age 35, when prophylactic bilateral oophorectomy is recommended.

Table 20-3 summarizes cancer screening of proven benefit for average-risk persons. Table 20-4 summarizes cancer prevention of proven benefit.

Tuberculosis Prevention

Burden of Disease
In 1997, the worldwide prevalence of tuberculosis (TB) infection (latent or active) was estimated to be 1.86 billion cases, with an

annual incidence rate of about 8 million. Approximately 2,000,000 people worldwide die annually of TB. The U.S. incidence is approximately 15,000 cases per year, with fewer than 1,000 deaths per year. The incidence decreased from 1953 to 1985, and then TB made a resurgence because of immigration from endemic areas, HIV infection, and increased use of immunosuppressive drugs. Since 1993, the incidence has consistently decreased.

- TB: the U.S. incidence is approximately 15,000 cases and fewer than 1,000 deaths annually.

Natural History

Infection occurs through inhalation of droplets bearing *Mycobacterium tuberculosis*. After being infected, healthy persons are usually asymptomatic. However, it is believed that the tubercle bacillus remains viable in granulomata for many years. The risk of reactivation after asymptomatic infection (purified protein derivative [PPD] conversion) is 5% for the first 1 or 2 years after infection. In another 5%, disease develops later in life.

- The tubercle bacillus remains viable in granulomata for many years.
- The risk of reactivation (after PPD conversion) is 5% for the first 1-2 years after infection.
- In another 5%, disease develops later in life.

Persons at higher risk of TB infection include those with close contact with a person with active TB, foreign-born persons from areas of high prevalence, residents and employees of high-risk congregate settings (e.g., nursing homes and prisons), health care workers, medically underserved low-income populations, high-risk racial or ethnic minority populations, and persons who inject illicit drugs.

Persons at higher risk of active TB developing after infection include HIV-infected persons (7%-10% risk each year), persons recently infected with TB (5% risk for the first 1-2 years after infection), persons with certain medical conditions (e.g., diabetes mellitus and end-stage renal disease), persons who inject illicit drugs, and persons with a history of inadequately treated TB.

Table 20-3 Cancer Screening Tests With Proven Benefit*

Type of cancer	Recommendation
Cervical	Sexually active women (all ages): cervical Pap smear every 1-3 y
Breast	Normal-risk women 40 years or older: screening mammograms with or without clinical breast examination every 1-2 y
Colon	Normal-risk persons 50 years or older—1 or both of the following: 1) Fecal occult blood test 3× yearly 2) Visualization of bowel (best interval unknown)

*Secondary prevention.

- Persons infected with both *M. tuberculosis* and HIV have a 7%-10% risk each year of active TB developing.

Testing

The PPD (Mantoux) test is a 5–tuberculin-unit intradermal skin test. The area of induration (not erythema) is measured at 48 to 72 hours. All persons with a positive PPD test should have chest radiography and clinical evaluation for active TB. Targeted skin testing is recommended for high-risk groups.

In low-risk persons, consider the reaction positive if it is larger than 15 mm. A 10-mm reaction is considered positive for the following groups: recent arrivals from countries of high prevalence, persons who inject illicit drugs, residents and employees of high-risk congregate settings, mycobacteriology laboratory personnel, and persons with medical conditions that increase the risk of TB. A 5-mm reaction is considered positive for HIV-positive persons, recent contacts of a person with active TB, persons with fibrotic changes on chest radiographs consistent with old healed TB, and immunosuppressed patients.

Persons exposed in the past may be relatively anergic, but the response can be boosted by repeating the test (two-step PPD testing procedure). Previous bacille Calmette-Guérin (BCG) vaccination may produce skin reactivity, but positive reactors should be considered to have true infection and be given appropriate follow-up care. Recent measles-mumps-rubella (MMR) and oral polio vaccine (OPV) vaccination (within 6 weeks) may diminish skin reactivity, and testing should be avoided during this interval. Chest radiography and sputum are not useful screening tests for conversion but may detect active disease in high-risk persons.

- Chest radiography and sputum are not useful screening tests for TB.

Preventive Measures

Primary prevention is with BCG vaccine, an attenuated species of *Mycobacterium bovis*. The efficacy of BCG vaccine ranges from 0% to 80%. It is appropriate in high-risk areas because it is inexpensive, requires a single dose, and has a low risk (only 100 fatalities in 2 billion administrations). BCG vaccine is not indicated in areas of low prevalence because it confuses interpretation of the PPD response. Currently, BCG vaccination is not recommended for any adult in the United States. Another primary preventive measure is environmental controls, especially in a health care environment, with respiratory isolation, high-efficiency filter masks, and special venting of rooms and wards with TB cases.

Table 20-4 Cancer Prevention*

Type of cancer	Recommendation
Lung	Smoking cessation counseling
Ovarian	Oral contraceptive use

*Primary prevention.

- BCG vaccine efficacy ranges from 0%-80%.
- Its use is not indicated in low-prevalence areas.

Secondary prevention is with isoniazid treatment. Its use is indicated for recent converters (<2 years), contacts of infected persons with a PPD reaction of 5 mm or more, history of TB with inadequate treatment, positive skin test with abnormal but stable chest radiographic findings, and positive PPD test (of any duration). The dosage is 5 to 10 mg/kg daily, up to a maximum of 300 mg daily (the usual adult dose), given as a single oral dose. Treatment should continue for 9 months. Primary side effects are liver toxicity and peripheral neuropathy. Peak toxicity is in persons older than 50 years (2%-3%). Monitoring for side effects is generally through symptoms only. Baseline laboratory testing and periodic monitoring of liver transaminase (aspartate aminotransferase [AST] or alanine aminotransferase [ALT]) levels is not routinely recommended. Testing should be considered for pregnant or postpartum women, persons with liver disease or other chronic medical conditions, and those taking other medications.

Alternative treatment regimens for latent TB infection include rifampin and pyrazinamide daily for 2 months or rifampin alone for 4 months.

- Isoniazid: 5-10 mg/kg daily, up to a maximum of 300 mg daily.
- Treatment should continue for 9 months.
- Peak toxicity is in persons older than 50 (2%-3%).

Immunizations

One of the greatest successes of modern medicine for preventing disease and extending life has been immunization. Adults have continuing needs for immunization throughout life. Physicians who administer vaccines are required by law to keep permanent vaccine records (National Childhood Vaccine Act of 1986) and to report adverse events through the Vaccine Adverse Event Reporting System (VAERS). Service in the U.S. military may be considered verification of vaccination for measles, rubella, tetanus, diphtheria, and polio. Providers are now required to give patients "vaccine information pamphlets" before vaccination as a mechanism for informed consent.

Immunity may be of two types: 1) In passive immunity, preformed antibodies are provided in large quantities to prevent or diminish the effect of infection or associated toxins (e.g., tetanus immune globulin [TIG] and hepatitis B immune globulin [HBIG]). Passive immunity lasts for only several months. 2) In active immunity, an antigen is presented to the host immune system, which in turn develops antibodies (e.g., hepatitis or tetanus) or specific immune cells (e.g., BCG). Active immunity generally lasts from years to a lifetime. Active immunity may be induced by live virus vaccines (e.g., measles), killed virus vaccines (e.g., influenza), or refined antigen vaccines (e.g., pneumococcal).

Live virus vaccines are contraindicated in some persons. In general, pregnant women, people with immunodeficiency diseases, leukemia, lymphoma, generalized malignancy, or those who are immunosuppressed because of therapy with corticosteroids, alkylating drugs, antimetabolites, or radiation should *not* be given live virus vaccines. HIV-infected persons who are immunocompetent and leukemia patients who have been in remission for 3 months or more after chemotherapy generally may be vaccinated with *some* live virus vaccines. Live virus vaccines include measles, mumps, rubella, smallpox, varicella, yellow fever, and OPV.

Inactivated virus vaccines include enhanced inactivated polio (eIPV), hepatitis A, hepatitis B, influenza, and rabies. Inactivated bacterial vaccines include cholera, typhoid, meningococcal, plague, and pneumococcal.

An adult immunization schedule has been developed and endorsed by several groups (Fig. 20-1).

Specific Vaccines and Chemoprophylaxis

Diphtheria

Diphtheria is a rare disease primarily because of vaccination. However, up to 40% of adults may lack protective antibody levels.

Recommendation

Vaccinate with a combination of tetanus and diphtheria toxoids (Td) (see "Tetanus" subsection below). The diphtheria-tetanus-pertussis (DTP) preparation recommended for children should not be used for adults.

Tetanus

Approximately 50 cases of tetanus are reported each year. Most cases occur in adults who are either unvaccinated or inadequately vaccinated. Vaccination is nearly 100% effective.

Recommendation

The primary series, a three-dose series, should be completed before adulthood, usually in early childhood. The primary series consists of Td (DTP in childhood). The last childhood dose is usually a booster at age 15 years. For adults who have had a primary series, vaccinate every 10 years (e.g., mid decade is easy to remember; if the last childhood dose was at 15 years, vaccinate at ages 25, 35, 45, etc.). Clean, minor wounds during the 10-year interval require no further vaccination. However, for a contaminated wound, the patient should receive a Td booster if it has been more than 5 years since the last booster. If immune status is unknown or lacking (specifically, no primary series), both toxoid (i.e., Td) and immune globulin (i.e., TIG), 250 U intramuscularly, should be given. Td is the preferred toxoid for an emergency as well as for routine vaccination. When Td and TIG are given in an emergency setting, they should be given in separate syringes at separate locations, but they may be given at the same time.

- Tetanus vaccination: the primary series is a three-dose series.
- Adults who have had a primary series should receive a booster every 10 years.
- For a contaminated wound, the patient should receive a Td booster if it has been more than 5 years since the last booster.
- A patient with a contaminated wound and unknown or incomplete primary vaccination should receive both Td and TIG.

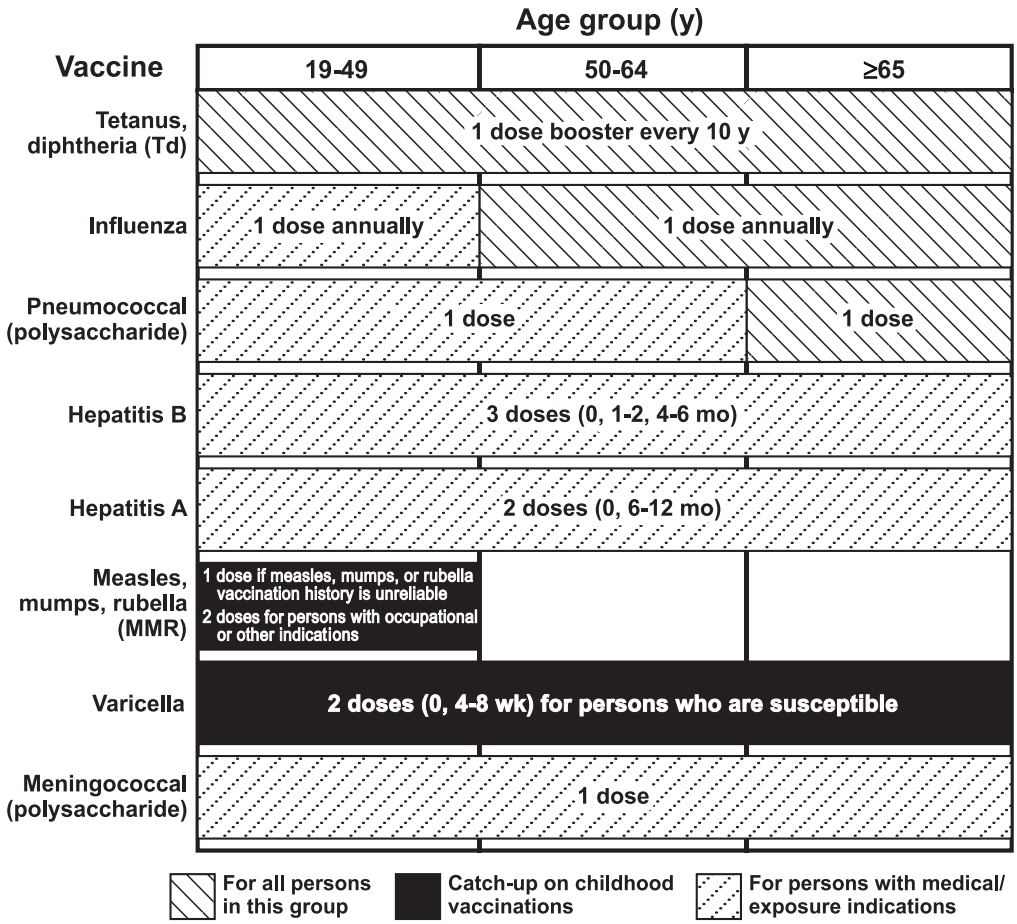

Fig. 20-1. Recommended adult immunization schedule, United States, 2004-2005, by age group. (From The Advisory Committee on Immunization Practices. Summary of Recommendations. Atlanta, Center for Disease Control and Prevention.)

Side Effects

Td may be given in pregnancy, although it is desirable to wait until the second trimester. Maternal antibodies are passed to the infant transplacentally and confer passive immunity for several months after birth.

- Maternal antibodies are passed to the infant transplacentally.

A history of neurologic reaction, urticaria, anaphylaxis, or other severe hypersensitivity reaction is a contraindication to the readministration of toxoids. Skin testing may be performed if necessary. In the emergency setting, TIG may be used when tetanus toxoid or Td is contraindicated if other than a clean minor wound is sustained. Arthus-type hypersensitivity, a severe local reaction starting 2 to 8 hours after injection, often with fever and malaise, may occur in persons who have received multiple boosters. These people have very high levels of antitoxin and do not need boosters more frequently than every 10 years, even in the emergency setting.

Measles

Vaccination decreased the number of cases of measles from 500,000 yearly (with 500 deaths) to 3,500 yearly in the mid-1980s. A disease resurgence occurred in 1989 to 1991, with a peak incidence of more than 27,000 cases in 1990. Since 1993, fewer than 500 cases have been reported in most years. Measles is no longer considered to be endemic in the United States. All cases appear to be the result of importation, with limited spread among U.S. residents. Measles is often more severe in adults. Complications include pneumonia, laryngotracheobronchitis, hepatitis, and bacterial superinfection. The risk of encephalitis with measles infection in an adult is approximately 1 in 1,000. Infection during pregnancy may result in spontaneous abortion or premature labor and low birth weight. Malformation does not appear to be as much of a problem as with rubella.

- The risk of encephalitis with measles infection in an adult is approximately 1 in 1,000.

Target

Adults born after 1956 who have no medical contraindication should be vaccinated if they have no dated documentation of at least one dose of live measles vaccine on or after their first birthday, physician-documented disease, or documented immune titer. Persons with expected exposure to measles should consider revaccination or titer

measurement because up to 10% of persons born before 1957 may not be immune. Persons at risk include travelers to endemic areas, those in school settings, and health care workers. They should have two doses of measles vaccine documented on or after their first birthday. MMR is the preferred vaccine. If they have never been vaccinated, they should receive two doses given at least 1 month apart.

Exposure Precautions

If an exposed person is unvaccinated, vaccinate within 72 hours if possible or give immune globulin (up to 6 days after exposure) if the person is not a vaccine candidate (0.25-0.5 mL/kg body weight, up to 15 mL—the dose depends on immunocompetence). Health care workers should remain away from work for 5 to 21 days after exposure if they are not immune.

Side effects include fever higher than 103°F (usually occurs on days 5 to 12) in 5% to 15% of those vaccinated and a rash in 5%. Encephalitis is rare (1 case per 1 million immunizations). No apparent increase in side effects occurs with a second vaccination. Contraindications are immune globulin or blood products given within the previous 3 to 12 months, pregnancy, gelatin or neomycin allergy, and others as noted above for live virus vaccines.

Mumps

A highly effective vaccination program decreased the number of cases of mumps from approximately 200,000 yearly to less than 1,000 yearly during the 1990s. Vaccine side effects of fever, rash, pruritus, and purpura are uncommon, and central nervous system problems and parotitis are rare. There is no increased risk with revaccination. The contraindications are the same as for measles.

Rubella

Infection with rubella in the first trimester results in congenital rubella syndrome in up to 85% of infected fetuses. The goal of vaccination is to prevent the occurrence of this disease. Vaccination is highly effective, and there is no evidence of transmission of vaccine virus to close household contacts. The target population includes all women of childbearing age, all health care workers, and travelers to endemic areas. The side effects include arthralgias in 25% and transient arthritis in 10%, usually 1 to 3 weeks after vaccination. Vaccination rarely causes chronic joint problems, certainly much less frequently than natural infection. Contraindications are immune globulin given within the previous 3 months (but not blood products, e.g., Rh_o(D) immune globulin [RhoGAM]), pregnancy or likely pregnancy within 3 months (although there are no documented cases of congenital rubella syndrome in vaccinated pregnant women), and allergy to neomycin but not to egg (because it is prepared in a diploid cell culture).

Influenza

During the 20th century, influenza pandemics occurred in 1918, 1957, and 1968, and each one resulted in a large number of deaths worldwide. Epidemics of influenza occur in the United States almost annually and are caused primarily by influenza A viruses and occasionally by influenza B viruses or both. The incidence peaks in mid to late winter—earlier in recent years. Influenza A is classified by two surface antigens: hemagglutinin (subtypes H1, H2, and H3) and neuraminidase (subtypes N1 and N2). Because of differing subtypes and antigenic drift, infection or vaccination more than 1 year previously may not give protection the following year. Influenza B is antigenically more stable but still has moderate drift. Control of both influenza A and B is with vaccination or chemoprophylaxis or both.

The vaccine is an inactivated (killed) virus vaccine (virus grown in egg culture) containing viral strains that circulated during the previous season. Each year it contains three viruses: two influenza A viruses and one influenza B virus. Vaccines may contain whole virus or split virus (subvirion). Split-virus vaccines are used in children to decrease febrile reaction. All forms may be used in adults. Ideally, vaccination should occur in October or November.

The side effects include local soreness; fever, malaise, and myalgia (which occur 6-12 hours after vaccination and may last 1-2 days); and anaphylactic reaction (probably due to egg protein). The target populations include persons 65 or older, especially those who reside in a nursing home or long-term care facility; persons with chronic pulmonary or cardiovascular disease, including asthma, chronic metabolic disease such as diabetes mellitus, renal dysfunction, or immunosuppression; health care workers; and women in the second or third trimester of pregnancy during influenza season (November-March). Consideration may be given to persons in vital roles, to those in institutional settings, and to travelers. The only contraindication is egg allergy.

A live attenuated influenza vaccine has been available for several years. The vaccine is administered intranasally by sprayer and is approved for use in healthy adults up to 49 years of age. Side effects include headache, rhinorrhea, and nasal congestion.

Chemoprophylaxis for influenza A has been available for many years, with either amantadine hydrochloride or rimantadine hydrochloride. These drugs interfere with the replication cycle of influenza A. In healthy populations, they are 70% to 90% effective if given daily throughout an epidemic. For treatment of disease, they decrease fever and other symptoms if given within 48 hours of disease onset. These agents are used to control influenza outbreaks, usually in institutions, and are given to all unvaccinated workers and residents. They may be given regardless of vaccination status to persons at high risk. Workers should continue taking the medication until 2 weeks after vaccination or indefinitely during the period of risk if the vaccine is contraindicated. The drug dosage (100-200 mg daily) varies with age.

- Amantadine and rimantadine are used for influenza A only.
- They are 70%-90% effective.
- They are used to control influenza outbreaks, usually in institutions, and are given to all unvaccinated workers and residents.

The side effects are usually minor, occurring in 5% to 10% of recipients, and may abate with continued use. Central nervous system side effects—nervousness, anxiety, insomnia, and decreased concentration—occur less frequently with rimantadine than with amantadine. Digestive system side effects include anorexia and nausea. Serious side effects are seizure and confusion, usually seen in the elderly or in those with kidney or liver disease. In these groups, the

dose should be decreased in accordance with the recommendations made in the package inserts.

Chemoprophylaxis using the neuraminidase inhibitor oseltamivir has been shown to be effective in preventing both influenza A and influenza B. When given in a dosage of 75 mg daily for up to 6 weeks during an influenza outbreak, the medication has a protective efficacy of 74%. The most common side effects of oseltamivir are nausea and vomiting.

Hepatitis A

In the United States, the rate of hepatitis A infection tends to vary from year to year. In 2001, the infection rate was 4 per 100,000 population. Clinical disease develops in more than 70% of infected older children and adults. Also, more than 10,000 infected persons are hospitalized yearly, and approximately 80 deaths are due to fulminant hepatitis. Signs and symptoms usually last less than 2 months. However, 10% to 15% of patients have prolonged or relapsing illness, which may last up to 6 months.

Spread of hepatitis A virus (HAV) occurs by the fecal-oral route, most commonly within households. Common-source outbreaks due to contaminated food and water supplies have occurred. Blood-borne transmission is uncommon but can occur through blood transfusion and contaminated blood products and from needles shared with an infected viremic person. Sexual transmission has also been reported.

Hepatitis A vaccination provides an opportunity to lower the disease incidence and ultimately to eradicate infection because humans are the only natural reservoir of the virus. A single dose of hepatitis A vaccine induces a protective antibody level within 4 weeks after vaccination. A second dose of vaccine 6 to 12 months later induces long-lasting immunity. Target groups for immunization include persons traveling to or working in countries that have high or intermediate HAV endemicity; men who have sex with men; illicit drug users; persons who have an occupational risk of infection (those who work with HAV-infected primates or with HAV in a research laboratory), chronic liver disease, or clotting-factor disorders; and some food handlers. Hepatitis A vaccination of children has been used effectively to control outbreaks in communities that have high rates of hepatitis A.

Travelers who are allergic to a vaccine component or who elect not to receive vaccine should be encouraged to get immune globulin (0.02-0.06 mL/kg provides protection for 3-5 months). Immune globulin should also be given to travelers leaving on short notice, and it can be given concomitantly with vaccine, using separate sites and syringes.

Postexposure prophylaxis with immune globulin, along with hepatitis A vaccination, is appropriate for household, sexual, and drug-using contacts of patients with hepatitis A infection.

Prevaccination serologic testing may be cost-effective for adults who were born or lived for extended periods in areas of high HAV endemicity and for men who have sex with men. Postvaccination testing is not necessary because of the high rate of vaccine response.

Hepatitis B

The lifetime risk of acquiring hepatitis B is 5% for the general population; 150,000 cases occur annually in the United States, resulting in 8,000 hospitalizations and 200 deaths. Of the patients affected, 90% are 20 years or older; 5% to 10% become carriers, and one-fourth of these develop chronic active hepatitis. Annually, 4,000 persons die of hepatitis B virus-related cirrhosis and 1,500 die of hepatitis B virus-related liver cancer.

- The lifetime risk of acquiring hepatitis B is 5% for the general population.
- Of affected patients, 5%-10% become carriers.
- Annually, 4,000 persons die of hepatitis B virus-related cirrhosis and 1,500 die of hepatitis B virus-related liver cancer.

The current vaccine is yeast recombinant, developed from the insertion of a plasmid into *Saccharomyces cerevisiae*, which produces the copies of the surface antigen. Human plasma–derived vaccine is no longer made. The target population includes adults at increased risk, that is, men who have sex with men, intravenous drug users, heterosexual persons with multiple sexual partners, and those with a history of other sexually transmitted diseases; household and sexual contacts of hepatitis B virus carriers; workers in health-related and public safety occupations involving exposure to blood or body fluids; hemodialysis patients; recipients of concentrates of clotting factors VIII and IX; morticians and their assistants; and travelers who will be living for extended periods in high-prevalence areas or who are likely to have sexual contacts or contact with blood in the endemic areas (especially in eastern Asia and sub-Saharan Africa).

Vaccination

Normally, vaccination consists of three doses, given at 0, 1, and 6 months. An alternative dosing schedule to induce immunity more rapidly (e.g., after exposure) involves 4 doses, the first three given 1 month apart and a fourth dose at 12 months. Postexposure prophylaxis consists of HBIG given in a single dose of 0.06 mL/kg or 5 mL for adults. It should be administered along with the vaccine in separate syringes at separate sites, but they may be administered at the same time. Current evidence suggests that for most vaccinees the vaccination has a duration of 7 years or more. Currently, revaccination is not routinely recommended. For persons who received the vaccine in the buttock or whose management depends on knowledge of immune status (e.g., surgeons or venipuncturists), periodic serologic testing may be valuable. Those with antibody to hepatitis B surface antigen (anti-HBsAg) titers less than 10 mIU/mL should be revaccinated. Revaccination with a single dose is usually effective.

- Currently, revaccination for hepatitis B is not routinely recommended.

The most common side effect of hepatitis B vaccination is localized soreness. Guillain-Barré syndrome (0.5 per 100,000) has been associated with human plasma–derived hepatitis B vaccine. Comparable information is not available for the recombinant vaccines. Vaccination during pregnancy is considered advisable for women who are at risk of hepatitis B infection. The risk of hepatitis B virus infection in pregnancy far outweighs the risk of vaccine-associated problems.

- Guillain-Barré syndrome (0.5 per 100,000) has been associated with human plasma–derived hepatitis B vaccine.

Pneumococcal Disease

Pneumococcal pneumonia is an important cause of death of older persons. The overall case fatality rate is 5% to 10%, but it is higher (20%-40%) among persons with underlying disease or alcoholism. The risk of bacteremia for persons 65 years or older with *Streptococcus pneumoniae* infection is 50 per 100,000. Two-thirds of persons with serious pneumococcal disease have been hospitalized in the previous 5 years, which represents a missed opportunity for vaccination.

The current adult vaccine contains purified capsular polysaccharide of 23 pneumococcal serotypes that cause approximately 90% of the bacteremic pneumococcal infections in the United States. After a single dose of vaccine, the titers persist for 5 years or more in healthy adults. Side effects of vaccination include localized erythema and pain, which occur in about 50% of all vaccinees. Other side effects, which occur in less than 1% of persons vaccinated, include fever, myalgia, and severe local reactions. Anaphylaxis occurs in 5 per 1,000,000 of those vaccinated. Revaccination within approximately 1 year is associated with increased local reactions. The target population for vaccination includes persons 65 or older, adults with chronic cardiovascular or pulmonary disease, diabetics, and persons at higher risk of pneumococcal infection because of, for example, alcoholism or cerebrospinal fluid leak. The target population also includes immunocompromised persons (e.g., those who are asplenic) and patients with Hodgkin disease, lymphoma, multiple myeloma, chronic renal failure, nephrotic syndrome, HIV infection, or organ transplant.

It is not necessary to revaccinate persons who received the original 14-valent pneumococcal vaccine. However, persons at highest risk of pneumococcal infections, especially immunocompromised persons, should be revaccinated with the 23-valent vaccine. Revaccination once after 5 years should be considered for adults with conditions associated with rapid antibody decline after initial immunization, especially those with nephrotic syndrome, renal failure, or renal transplantation. Persons 65 or older should be given a second dose of vaccine if they received an original dose more than 5 years previously and were younger than 65 at the time of primary immunization.

- The target population is persons at least 65 years old or adults with chronic disease.
- Pneumococcal vaccination should be repeated for persons 65 or older if they received their initial vaccine more than 5 years earlier and before 65 years of age.

Smallpox (Vaccinia)

The World Health Organization declared the world free of smallpox in May 1980. Smallpox vaccination subsequently was given only to laboratory personnel working directly with orthopoxviruses. During 2002 preparations began for use of smallpox vaccine for bioterrorism preparedness. Vaccination of health care workers started in 2003. The Advisory Committee on Immunization Practices of the Centers for Disease Control and Prevention has released detailed recommendations for preexposure vaccination and for use of smallpox vaccine if a smallpox emergency occurs. The live virus smallpox vaccine is highly effective in inducing immunity that lasts for up to 5 years after primary vaccination. Additional doses may confer long-term immunity, possibly for a decade or more. Side effects include fever, skin rash, eczema vaccinatum, generalized vaccinia, and postvaccinal encephalitis. Inadvertent inoculation at other sites may occur. Transmission of vaccine virus to close contacts has been documented. Contraindications include pregnancy, history or presence of eczema, HIV infection, altered immunocompetence, and known allergy to a vaccine component. Vaccinia immune globulin can be given to persons with complications of vaccination.

Polio

Polio has been eradicated from the entire Western Hemisphere. The few cases that occur in the Western Hemisphere are due to the oral vaccine virus strain. There are OPV (live virus) and eIPV (killed virus) vaccines. A primary series with either one has more than 95% effectiveness. Polio vaccination is not recommended for persons older than 18 unless they plan to travel to an endemic area and have no history of a previous primary series. For these persons, eIPV is recommended because of the lower risk of paralysis. The primary series consists of three doses of eIPV, given at 0, 1, and 6 to 12 months. If the person will be traveling in less than 4 weeks, give a single dose of eIPV. If the primary series is incomplete, complete it regardless of the interval since the last dose. If the person previously received OPV, give one dose of eIPV. For OPV, the risk of paralysis is approximately 1 in 1,000,000 after the first dose, and for susceptible household contacts, it is approximately 1 in 2,000,000.

- Polio vaccination is not recommended for persons older than 18 unless they plan to travel to an endemic area.

Rabies

Preexposure prophylactic vaccination is recommended for animal handlers, laboratory workers, persons traveling to hyperendemic areas for more than 1 month, and those with vocations or avocations with exposure to skunks, raccoons, bats, and other animals. In the United States, the reservoir of infection includes carnivorous animals, particularly skunks, raccoons, foxes, and bats. Except for woodchucks, rodents are rarely infected. Preexposure vaccination consists of three doses of rabies vaccine, given on days 0, 7, and 21 or 28. Ideally, preexposure vaccination should be completed at least 1 month before travel or potential exposure.

Following a potential or known rabies exposure (e.g., animal bite or bat contact), a person who has had preexposure vaccination needs only two doses of rabies vaccine: one immediately and another 3 days later. Appropriate postexposure treatment for unimmunized persons includes administration of rabies immune globulin (part of it infiltrated in and around the bite and the rest given intramuscularly) and five doses of rabies vaccine. The first dose of vaccine should be given as soon as possible after exposure and additional doses on days 3, 7, 14, and 28 to 35 after the first dose. Local wound care, tetanus prophylaxis, and combined postexposure treatment with rabies immune globulin and five doses of rabies vaccine are

recommended for all severe exposures. Use of postexposure treatment depends on many factors, including type of contact, animal involved, availability of the animal for observation or testing, and rabies endemicity in the area. The decision is best made with input from local public health authorities.

Varicella

Primary infection with varicella zoster virus (VZV) results in chickenpox, and recurrent infection produces herpes zoster or shingles. Factors associated with recurrent disease include aging, immunosuppression, and intrauterine exposure to VZV and varicella at a young age (<18 months).

Complications of VZV infection, which occur more commonly in older children and adults, include bacterial infection of lesions, viral or secondary bacterial pneumonia, central nervous system manifestations (aseptic meningitis and encephalitis), hospitalization, and death.

Varicella vaccination is recommended for all children between 12 and 18 months old. It is also recommended for nonimmune adolescents and adults who are at highest risk of exposure and those most likely to transmit varicella to others. These groups include health care workers, family members of immunocompromised persons, teachers of young children, women of childbearing age, military personnel, persons working in institutional settings, and international travelers.

Persons older than 13 should receive two doses of varicella vaccine 4 to 8 weeks apart. Vaccine contraindications include severe allergy to neomycin, moderate or severe illness, immunosuppression, pregnancy, and recent receipt of a blood product. Adverse events following vaccination include injection site lesions, swelling, or pain; generalized varicella-like rash; and systemic reaction with fever. There is a risk of transmission of vaccine virus from a vaccinated person, especially with vaccine-associated rash, to a susceptible contact. However, this potential risk is low, and the benefits of vaccinating susceptible health care workers are thought to outweigh this risk. Protection of high-risk individuals who cannot be vaccinated (e.g., an adult with immunodeficiency disease) involves vaccination of household and other close contacts.

Prevaccination serologic testing of adolescents and adults is probably cost-effective. Postvaccination testing is not necessary because of the high rate of seropositivity after two doses of vaccine (>99%).

Postexposure use of varicella vaccine is effective in preventing or modifying disease when given up to 3 to 5 days after exposure. Antiviral medication (acyclovir) is thought to be effective for preventing or modifying disease when started within a week of exposure.

Psychiatry

Lois E. Krahn, MD
Sheila G. Jowsey, MD

A comprehensive psychiatric evaluation is essential because many psychiatric symptoms are nonspecific. This situation is analogous to a patient presenting in general internal medicine with fever or nausea. The presence of a single symptom, for example, depressed mood, is never pathognomonic of a specific disorder. All psychiatric disorders are based on a set of inclusion and exclusion criteria outlined in the *Diagnostic and Statistical Manual of Mental Disorders* (*DSM*), which is periodically updated by the American Psychiatric Association. The fourth edition (*DSM-IV*) is currently in use. It was published in 1994 and is expected to be revised in 2006 or 2007. For patients with psychiatric symptoms, the biopsychosocial model is widely used. With this approach, the biologic, psychologic, and social factors contributing to the patient's clinical presentation are evaluated. Some psychiatric symptoms indicate severe problems, whereas others are much less important to the extent that they may not be clinically relevant. A key concept is whether the symptom interferes with a patient's functioning or causes distress. For example, a patient may have a fear of heights. If this acrophobia never causes an alteration in activity, then intervention likely is not necessary. However, if a patient hesitates to visit offices on higher floors of an office building, the distress during the visits or avoidance of these situations warrants intervention.

The common psychiatric disorders confronting general physicians in outpatient settings are anxiety disorders, mood disorders, substance abuse, somatoform (functional) disorders, and adjustment disorders. In the general hospital setting, the common psychiatric conditions are mood disorders, adjustment disorders, substance abuse, delirium, and dementia. Psychiatric disorders are difficult to identify and manage because frequently two or more specific conditions coexist. For example, comorbid alcohol or substance abuse or dependence, delirium, or dementia can complicate the presentation, course, and treatment response of major depression. Suicide, a leading cause of death in the United States, has been reported to occur in all psychiatric conditions.

- Common psychiatric disorders confronting general physicians in an outpatient setting: anxiety disorders, mood disorders, substance abuse, somatoform (functional) disorders, and adjustment disorders.
- Common psychiatric groups in a general hospital setting: mood disorders, adjustment disorders, substance abuse, delirium, and dementia.

The Suicidal Patient

Suicide is a complication of psychiatric disorders. Emergency medicine physicians are often the first to deal with patients who have suicidal ideation or who have attempted or completed suicide. The recognition of risk factors for suicide, a thorough assessment of the psychiatric and medical factors, and urgent intervention are critically important. Although the patient who overdoses with a benzodiazepine may be very serious about the intent to die, the person who overdoses with acetaminophen is more at risk of serious medical complications.

Recognition of a suicidal gesture is essential in evaluating a patient in an emergency department. Although drug overdoses are the commonest form, alcohol intoxication, single-vehicle accidents, and falls from heights may merit further investigation. Many suicidal patients see a physician the week before the attempt. Some of the risk factors to be aware of include recent psychiatric hospitalization, an older divorced or widowed man, unemployment, poor physical health, past suicide attempts, family history of suicide (especially a parent), psychosis, alcoholism, drug abuse, chronic pain syndrome, sudden life changes, loneliness, and anniversary of significant loss. Almost without exception, patients come to an emergency department with intense suicidal ideation or gestures. These patients should not be sent home alone.

- In evaluating patients in an emergency department, it is important to recognize a suicidal gesture.
- Many patients see a physician the week before they attempt suicide.
- Patients who come to an emergency department with intense suicidal ideation or gestures should not be sent home alone.

- Typical clinical scenario: A 68-year-old, lonely, divorced man has a sudden life change.

Mood Disorders

The prevalence of mood disorders in the general U.S. population is estimated to be 5% to 8%. However, in the general medical setting, the rate may be as high as 5% to 15%.

The essential feature of this group of disorders is a disturbance of mood (depressed or manic), which is in the context of related cognitive, psychomotor, vegetative (e.g., sleep and appetite), and interpersonal difficulties. Mood disorders may also be related to a general medical condition or be substance-induced. Mood fluctuation or swings are a normal occurrence. A mood disorder is diagnosed only when the frequency or intensity (or both) of these changes is extreme and accompanied by the other features. Mood disorders range in severity from mild to severe.

- Mood disorders: the essential feature is disturbance of mood in a constellation of other symptoms.
- Mood disorders are accompanied by related cognitive, psychomotor, vegetative, and interpersonal difficulties.
- Mood disorders may also be related to a general medical condition or be substance-induced.

Major Depression

Major depression is a serious psychiatric disorder that must be distinguished from an adjustment disorder and dysthymia by the severity of the mood and cognitive disturbances and potentially by the presence of major physical somatic complaints. The primary symptoms of major depression include depressed mood, diminished interest or pleasure in many activities, notable weight loss or weight gain (>5% of body weight in a month), decrease or increase in appetite, insomnia or hypersomnia, psychomotor agitation or retardation, fatigue or loss of energy, feelings of worthlessness or of excessive or inappropriate guilt, diminished ability to concentrate, recurrent thoughts of death or suicidal ideation, or a suicide attempt. These must be present for at least 2 weeks. This time frame helps in differentiating major depression from acute changes in mood seen in delirium or medical processes, for example, acute blood loss.

If delusions or hallucinations are also present, they are less prominent than in a primary psychotic disorder, and the disorder is referred to as *major depression with psychotic features*. The presence of psychotic symptoms increases the likelihood of treatment resistance. Another major depression, the melancholic type, is a severe subtype of depression. In addition to the symptoms listed above, this form is characterized by the lack of reactivity to pleasurable stimuli (does not feel better even temporarily if involved in what is usually a pleasurable activity), diurnal mood variation (depression regularly worse in the morning), and early morning awakening (at least 2 hours before the usual time of awakening).

- Major depression: symptoms include depressed mood, diminished interest or pleasure in all or almost all activities, and notable weight loss or weight gain.
- Major depression with psychotic features: presence of hallucinations or delusions, which are often subtle.
- Major depression, melancholic type: characterized by lack of reactivity to pleasurable stimuli, diurnal mood variation, and early morning awakening.
- Typical clinical scenario: A 43-year-old woman who has lost weight and has fatigue and feelings of worthlessness and excessive guilt is much less interested in many things that used to attract her. Her ability to concentrate has decreased.

Every year about 10 million Americans have a depressive episode, but about only 20% usually seek treatment. The prevalence of depression in women is twice as high as in men. The peak age at onset of depression in women is 33 to 45 years and in men, more than 55 years. Among those who seek treatment from a physician, the diagnosis is not made in as many as one-third or sometimes it is a misdiagnosis because patients often present primarily with physical or somatic complaints. As the population ages and more elderly patients seek medical care, diagnosing and treating their mood disorders become more complicated because many of these patients often have overlapping medical and neurologic problems. Patients occasionally present with the combination of a dementing process and depression. When the depressive symptoms are treated effectively in these patients, cognitive performance may also improve.

- Among persons seeking treatment for major depression, the diagnosis is not made in as many as one-third or it is a misdiagnosis.
- In elderly patients, diagnosing and treating mood disorders become more complicated because of possible comorbid psychiatric and medical conditions.
- The prevalence of depression among women is twice as high as among men.

Seasonal Affective Disorder

Seasonal affective disorder is a subtype of depression usually characterized by the onset of depression in autumn or winter. It is twice as common in women as in men and is associated with psychomotor retardation, hypersomnia, overeating (carbohydrate craving), and weight gain. To establish the diagnosis, winter episodes of depression must recur for 3 or more consecutive years. These episodes must resolve during spring or summer. Treatment has relied primarily on phototherapy, using a full-spectrum light source of 10,000 lux, which must be used for a minimum of 30 minutes a day. Antidepressant agents that selectively block serotonin reuptake are also of benefit in treating this disorder.

- Seasonal affective disorder: onset of depression in autumn or winter; it resolves in the spring.
- It is twice as common among women as among men.
- It is associated with psychomotor retardation, hypersomnia, and overeating.
- Treatment: phototherapy and antidepressant agents.
- Typical clinical scenario: A 45-year-old woman has had recurrent depression in the winter for three consecutive winters.

Because depressive disorders are heterogeneous in clinical presentation, the cause is expected to be multifactorial. There probably is no single etiologic agent. According to current theories, depression appears to be related to alterations of several neurotransmitter systems and neuropeptides, effects on presynaptic and postsynaptic receptors, neurohormonal alterations, and, in general, an alteration in the overall balance of these systems, which are interdependent on one another. Adverse life events (marital discord, bankruptcy, professional setbacks, and failure) can initiate or perpetuate a depressive episode by overwhelming a person's coping mechanisms.

Dysthymia

Dysthymia is chronic depression that is milder in severity than major depression. It may have either an early onset or a late onset, as defined by onset before or after age 21 years. It can be disabling for the person because the depressed mood is present most of the time during at least a 2-year period. Many patients have one or two associated vegetative signs, such as disturbance of sleep and appetite. Also, patients often feel inadequate, have low self-esteem, and struggle with interpersonal relationships. If onset is in late adolescence, the dysthymia may become intertwined with the person's personality, behavior, and general attitude toward life. Treatment is usually a combination of psychotherapy (cognitive or interpersonal) and pharmacotherapy. Psychopharmacotherapy may be particularly useful for patients with a family history of mood disorders or for those who have the early-onset form of dysthymia. In patients with dysthymia, superimposed major depressive episodes may develop. Also, some are prone to turn to alcohol or other substance abuse to "treat" their dysphoria.

- Dysthymia: a form of chronic depression.
- Depressed mood is present most of the time during at least a 2-year period.
- Treatment is usually a combination of psychotherapy and pharmacotherapy.
- Major depressive episodes may develop in patients with dysthymia.
- Typical clinical scenario: A 25-year-old woman has had disturbed sleep, appetite changes, low self-esteem, and issues with interpersonal relationships for 3 years.

Adjustment Disorder With Depressed Mood

Adjustment disorder with depressed mood is a reaction that develops in response to an identifiable psychosocial stressor, for example, divorce, job loss, or family or marital problems. The severity of the adjustment disorder (degree of impairment) does not always parallel the intensity of the precipitating event. The critical factor appears to be the relevance of the event or stressor to the patient and his or her ability to cope with the stress. In general, these reactions are relatively transient. Although patients generally can be managed by an empathic primary care physician, the development of extreme withdrawal, suicidal ideation, or failure to improve as the circumstances improve may prompt psychiatric referral. Treatment includes supportive psychotherapy, psychosocial interventions, and, sometimes, use of antidepressant agents.

Treatment of Depression

There are four major groups of treatment modalities for depression: psychotherapy, pharmacotherapy, electroconvulsive therapy (ECT), and circadian rhythm manipulation such as sleep deprivation or phototherapy. Generally, these therapeutic modalities are used in some combination.

Psychotherapy

There are multiple forms of psychotherapy, many of which can be used in the treatment of depression. However, the two forms that have been used extensively for treating depression are cognitive therapy and interpersonal therapy. Cognitive therapy strives to help patients have a better integration of cognition (thoughts), emotion, and behavior. This therapy is based on the premise that thoughts have a profound effect on emotions, which have an effect on behavior. For example, if a patient repeatedly thinks that he or she is failing professionally because of striving for unrealistic, perfectionist goals, then over time that person's emotions and behavior will be affected. If patients can perceive themselves in more realistic or adaptive ways, their general outlook will be expected to improve. Ultimately, they may experience an increase in a sense of worth and self-esteem. Interpersonal therapy focuses on current interpersonal functioning. It is based on the concept that depression is associated with impaired social relationships that either precipitate or perpetuate the disorder.

- Cognitive therapy: helps patients achieve a better integration of cognition (thoughts), emotion, and behavior.
- Interpersonal therapy: focuses on current interpersonal functioning.

Pharmacotherapy

The selection of medication is based on the side-effect profile of the medication and the clinical profile of the patient. Research is under way to select or avoid particular medications according to an individual patient's cytochrome P-450 polymorphisms, but this has not been incorporated into clinical practice. Initially, use a relatively low dose, and then titrate to a therapeutic dose based on clinical assessment. Blood level determinations of a drug are used less often than previously because they are meaningful only for tricyclic antidepressants. The duration of treatment is usually a minimum of 6 months, counting from the time the patient attained noticeable improvement. Often, patients may benefit from extended use of antidepressant agents, especially if they have had multiple episodes of depression. Generally, use of antidepressant agents should be tapered rather than stopped abruptly when treatment is discontinued. If the response to the first antidepressant agent is minimal, reevaluate the diagnosis, change to a different class of drug, or treat with ECT, which is still probably the most consistently effective treatment for severe depression. ECT is especially valuable if psychotic symptoms complicate the major depression.

Mania and Bipolar Disorder

The essential features of a manic episode are the presence of an abnormally euphoric, expansive, or irritable mood associated with some of

the following features: inflated self-esteem or grandiosity, decreased need for sleep, pressured speech, flight of ideas, distractibility, increase in goal-directed activity or psychomotor agitation, and excessive involvement in pleasurable activities that have a high potential for painful consequences (e.g., unrestrained buying sprees, sexual indiscretions, or inappropriate financial investments). These episodes must last a minimum of 1 week (unless the course is altered by treatment). To establish the diagnosis of bipolar disorder, the patient must have had at least one episode of mania. Most bipolar patients have had recurrent depressive episodes in addition to manic episodes, although rarely patients have mania exclusively. The prevalence of bipolar disorder is estimated to be about 1%. Bipolar disorder occurs about as frequently in women as in men, and the usual age at onset is from the teens to 30 years. A family history of bipolar or other mood disorder is more common for patients with bipolar disorder than for other mood disorders. Some patients do not experience a fully developed manic episode but have fewer symptoms. The term *hypomania* has been introduced to describe this form of bipolar disorder (type II), which generally is challenging to clinicians because its more subtle features make it more difficult to recognize.

- Mania: the essential feature is an abnormally euphoric, expansive, or irritable mood.
- The prevalence of bipolar disorder is estimated to be about 1%.
- Bipolar disorder occurs about as frequently in women as in men.
- The usual age at onset is from the teens to 30 years.
- A family history of bipolar or other mood disorder is more common for patients with bipolar disorder than for other mood disorders.
- Typical clinical scenario: For more than 1 week, a 25-year-old man has had a euphoric mood, flight of ideas, decreased need for sleep, and unrestrained buying sprees.

Treatment is aimed at mood stabilization and improved social and occupational functioning. The traditional pharmacologic treatment is lithium carbonate. In recent years, valproic acid has replaced lithium as the first-line agent for treatment of bipolar disorder. Other helpful agents include carbamazepine and newer anticonvulsants, including gabapentin. All these mood stabilizers may take up to 10 days to be effective. During this waiting period, the judicious use of antipsychotic agents or clonazepam is helpful in controlling the acute symptoms. Bipolar patients should not receive monotherapy with an antidepressant because antidepressants can trigger a hypomanic or manic episode. For bipolar patients with a depressive episode, a mood-stabilizing medication should be given simultaneously with an antidepressant to reduce the risk of triggering a hypomanic or manic episode.

- Treatment of mania and bipolar disorder is aimed at stabilizing mood and improving social and occupational functioning.
- Primary pharmacologic treatment: valproic acid, lithium carbonate, and newer anticonvulsants.

Mood Disorders Caused by a General Medical Condition

The essential feature of mood disorders caused by a general medical condition is depression or mania—including potential depressive symptoms such as energy, sleep, and appetite changes—that is attributable to the physiologic effects of the specific medical condition. The full criteria for one of these episodes regarding the number of symptoms and time course need not be met. Many medical conditions may induce mood changes, so the clinical interview needs to identify coexisting symptoms such as excessive guilt, social withdrawal, or suicidal ideation, which are more specific for a depressive disorder. Medical conditions that may cause mood symptoms include endocrinopathies (Cushing syndrome, Addison disease, hyperthyroidism, hypothyroidism, hyperparathyroidism, and hypoparathyroidism), certain malignancies (lymphomas, pancreatic carcinoma, and astrocytomas), neurologic conditions (Parkinson disease and Huntington disease), autoimmune conditions (systemic lupus erythematosus), and infections (chronic hepatitis C, encephalitis, mononucleosis, and human immunodeficiency virus [HIV] infection).

- In mood disorders due to a general medical condition, the essential feature is a disturbance of mood attributable to the physiologic effects of a specific medical condition.
- Many medical conditions may induce mood changes, so the clinical interview needs to identify coexisting symptoms such as excessive guilt, social withdrawal, or suicidal ideation, which are more specific for a depressive disorder.
- Some potential depressive symptoms such as energy, sleep, and appetite changes may be due to a medical condition in the absence of a depressive disorder.

Substance-Induced Mood Disorders

The essential feature of a substance-induced mood disorder is a disturbance of mood, either depressed or manic, that is judged to be due to the direct physiologic effects of a substance. Many substances can induce mood changes, including medications, toxins, and drugs of abuse. The mood symptoms may occur during the use of or exposure to the substance or during withdrawal from the substance. Medications that have been implicated in inducing mood disturbances include corticosteroids, interferon, reserpine, methyldopa, carbonic anhydrase inhibitors, stimulants, sedative-hypnotics, benzodiazepines, and narcotics as well as the long-term use or abuse of alcohol or hallucinogens. Recent studies have demonstrated that β-adrenergic agents are less likely to cause depressive disorders than previously thought.

- In substance-induced mood disorders, the essential feature is a disturbance of mood due to the physiologic effects of a substance.
- Many medications and drugs of abuse may induce mood changes.

Psychotic Disorders

Psychosis is a generic term used to describe altered thought and behavior in which the patient is incapable of interpreting his or her situation rationally and accurately. Psychotic symptoms can occur in various medical, neurologic, and psychiatric disorders. Many psychotic reactions seen in medical settings are associated with the use of recreational or prescription drugs (Table 21-1). Some of these drug-induced psychotic reactions are nearly indistinguishable from schizophrenia in terms of hallucinations and paranoid delusions

Table 21-1 Classes of Drugs That Can Produce Psychotic Symptoms

Stimulants
Hallucinogens
Phencyclidine (PCP)
Catecholaminergic drugs
Anticholinergic drugs
Central nervous system depressants
Glucocorticoids
Heavy metals (lead, mercury, manganese, arsenic, thallium)
Others (digitalis, disulfiram, cimetidine, bromide, tacrolimus)

(e.g., amphetamine and phencyclidine [PCP] psychoses). Many brain regions may be involved with the production of psychotic symptoms, but abnormalities in the frontal, temporal, and limbic regions are more likely than others to produce psychotic features.

- Psychosis: a generic term describing altered thought and behavior in which the patient is incapable of interpreting his or her situation rationally and accurately.
- Many psychotic reactions may be associated with the use of recreational or prescription drugs.
- Some drug-induced psychotic reactions have symptoms similar to those found in schizophrenia.

There are disorders throughout the life span that may be associated with schizophrenia-like psychoses. These include genetic abnormalities (e.g., a microdeletion of chromosome 22, the velocardiofacial syndrome), childhood neurologic disorders (autism and epilepsy), adult neurologic disorders (narcolepsy), medical and metabolic diseases (infections, inflammatory disorders, endocrinopathies, nutritional deficiencies, uremia, and hepatic encephalopathy), drug abuse, and psychologic stressors.

Schizophrenia may have multifactorial causes. It may be a neurodevelopmental disorder resulting from possible environmental or genetic factors occurring before birth. The psychotic symptoms and altered interpersonal skills typically become evident initially in the teenage years. Symptoms have been subdivided into positive (delusions and hallucinations) and negative (apathy and amotivation) symptoms. Current diagnostic criteria are divided into inclusion and exclusion criteria. Inclusion criteria include the presence of delusions and hallucinations; marked decrement in functional level in areas such as work, school, social relations, and self-care; and continuous signs of the disturbance for at least 6 months. Exclusion criteria include consistent mood disorder component and evidence of an organic factor that produces the symptoms. The five subtypes of schizophrenia are catatonic, disorganized, paranoid, undifferentiated, and residual. These subtypes are not used extensively in clinical practice because of diagnostic overlap during the course of a patient's illness.

- Schizophrenia may be a neurodevelopmental disorder resulting from possible environmental or genetic factors occurring before birth.
- The psychotic symptoms and altered interpersonal skills typically become evident initially in the teenage years.

Anxiety Disorders

This group of disorders is encountered most frequently in the outpatient setting. Anxiety symptoms may be misinterpreted as those of medical illness because many of the symptoms overlap, for example, tachycardia, diaphoresis, tremor, shortness of breath, nausea, abdominal pain, and chest pain. Autonomic arousal and anxious agitation in a medically ill patient can also be attributed quickly to stress or anxiety when the symptoms may represent pulmonary embolus or cardiac arrhythmia. Common sources of anxiety in the medical setting are related to fears of death, abandonment, loss of function, pain, dependency, and loss of control. When to treat or to seek psychiatric consultation depends on the assessment of the degree of anxiety. Is the patient able to function in his or her role without distress or avoidance?

- Anxiety symptoms may be misinterpreted as those of medical illness.
- Common sources of anxiety in the medical setting are related to fears of death, abandonment, loss of function, and pain.

Panic Disorder With or Without Agoraphobia

Panic disorder refers to recurrent, discrete episodes of extreme anxiety accompanied by various somatic symptoms such as dyspnea, unsteady feelings, palpitations, paresthesias, hyperventilation, trembling, diaphoresis, chest pain or discomfort, or abdominal distress. *Agoraphobia* refers to extreme fear of being in places or situations from which escape may be difficult or embarrassing. This may lead to avoidance of such situations as driving, travel in general, being in a crowded place, and many other situations, ultimately causing severe limitations in daily functioning for the patient. Panic disorder is more common in women (prevalence, 2%-3%) than in men (prevalence, 0.5%-1.5%). The usual age at onset is from the late teens to the early 30s. A history of childhood separation anxiety is reported in 20% to 50% of patients. The incidence is higher in first- and second-degree relatives. Most patients describe their first panic attack as spontaneous. They generally go to an emergency department after the first attack, believing they are having a heart attack or a severe medical problem.

- Panic disorder: recurrent, discrete episodes of extreme anxiety accompanied by various somatic symptoms.
- Agoraphobia: extreme fear of being in places or situations from which escape may be difficult.
- Panic disorder is more common in women than in men.
- Patients generally go to an emergency department after their first panic attack, believing they are having a heart attack or a severe medical problem.

The differential diagnosis of panic disorder includes several medical disorders, for example, endocrine disturbances (hyperthyroidism, pheochromocytoma, and hypoglycemia), gastrointestinal disturbances

(colitis and irritable bowel syndrome), cardiopulmonary disturbances (pulmonary embolism, exacerbation of chronic obstructive pulmonary disease, and acute allergic reactions), and neurologic conditions (especially conditions like seizures that are episodic or are associated with paresthesias, faintness, or dizziness).

Patients with panic attacks may also be prone to major episodes of depression. Alcohol use may temporarily reduce some of the distress of the panic attack and the interim anticipatory anxiety, but symptoms may soon rebound, potentially leading to alcohol abuse. Benzodiazepines may similarly be abused.

- Patients with panic attacks may be prone to episodes of major depression.
- Alcohol and benzodiazepines may reduce the distress of panic attacks, but symptoms may rebound, potentially leading to the abuse of these substances.

Posttraumatic Stress Disorder

Posttraumatic stress disorder can be a brief reaction that follows an extremely traumatic, overwhelming, or catastrophic experience, or it may be a chronic condition that produces severe disability. The syndrome is characterized by intrusive memories, flashbacks, nightmares, avoidance of reminders of the event, and often a restricted range of affect. It may occur in adults or children. There is increased comorbidity with substance abuse, depression, and other anxiety disorders. Patients may be more prone to impulsivity, including suicide. As for other anxiety disorders, treatment is usually a combination of behavioral, psychotherapeutic, and, if necessary, pharmacologic interventions.

- Posttraumatic stress disorder may be a brief reaction or a chronic condition that produces severe disability.
- Patients may be prone to impulsivity, including suicide.
- Typical clinical scenario: A 30-year-old man who is a military veteran has flashbacks, nightmares, and depression.

Generalized Anxiety Disorder

Generalized anxiety disorder is characterized by chronic excessive anxiety and apprehension about life circumstances accompanied by somatic symptoms of anxiety, such as trembling, restlessness, autonomic hyperactivity, and hypervigilance. Treatment is usually a mixture of behavioral, progressive muscle relaxation, psychotherapeutic, and adjunctive psychopharmacologic modalities.

Obsessive-Compulsive Disorder

Obsessive-compulsive disorder is characterized by recurrent obsessions or compulsions that are severe enough to disrupt daily life. The obsessions are distressing thoughts, ideas, or impulses experienced as unwanted. Compulsions are repetitive, intentional behaviors usually performed in response to an obsession. The obsessions cause marked anxiety or distress, and the compulsions serve to neutralize the anxiety. Prevalence rates are about 2% to 3% and are about equal in men and women. The onset of this disorder is usually in adolescence or early adulthood. Obsessive traits are often present before onset of the disorder. The predominant neurobiologic theory for the cause of obsessive-compulsive disorder involves dysfunction of brain serotonin systems. Pharmacologic treatment of this disorder is with antidepressants that are more selective for effects on the serotonin transmission system. These include clomipramine and selective serotonin reuptake inhibitors (SSRIs) (fluvoxamine, fluoxetine, paroxetine, and sertraline); occasionally, lithium augmentation is used with any of these agents. In extremely severe, debilitating cases for which other treatments have failed, neurosurgical procedures such as cingulotomy, stereotactic limbic leukotomy, or anterior capsulotomy may be of some benefit. The effectiveness of these procedures is thought to be related to disruption of the efferent pathways from the frontal cortex to the basal ganglia. Behavioral therapies and some forms of psychotherapy can also be helpful adjunctive therapies. As with the treatment of many psychiatric disorders, a combination of treatments is most often used. For obsessive-compulsive disorder, the pharmacologic treatments are generally less effective than for major depressive episodes. Also, higher doses of antidepressants may be needed for longer trial periods to see effectiveness in reducing symptoms of obsessive-compulsive disorder.

- Obsessive-compulsive disorder is characterized by recurrent obsessions (distressing thoughts) and compulsions (repetitive behaviors) that are recognized as unreasonable but irresistible.
- Treatment consists primarily of antidepressants with serotonergic activity and behavioral therapy.

Adjustment Disorder With Anxious Mood

Adjustment disorder with anxious mood is a maladaptive reaction to an identifiable environmental or psychosocial stress accompanied primarily by symptoms of anxiety that interfere with the patient's usual functioning. Treatment may include supportive counseling and help with identifying the stressor. However, in some cases, the anxiety may be so severe as to require short-term use of anxiolytic agents. However, these should be used with caution to avoid problems of long-term use and possible dependence.

- Adjustment disorder with anxious mood is characterized by a maladaptive reaction to an identifiable environmental or psychosocial stress accompanied by symptoms of anxiety.
- This disorder may require short-term use of anxiolytic agents.

Somatoform Disorders, Factitious Disorders, and Malingering

Somatoform disorders, factitious disorders, and malingering represent medical symptoms that are excessive for the degree of objective disease. These conditions differ with regard to whether the symptoms and motivations for their persistence are conscious or unconscious.

Somatoform Disorders

Somatoform disorders include somatization disorder, conversion disorder, hypochondriasis, chronic pain disorder, and body dysmorphic disorder. In all these conditions, the patient experiences physical complaints because of an effort to satisfy unconscious needs. These patients are not deliberately seeking to appear ill.

Somatization Disorder

Somatization disorder is a heterogeneous disorder that begins in early life and is characterized by recurrent multiple somatic complaints. It mostly affects women. It is often best managed by collaborative work with an empathic primary care physician and mental health professional. Regularly scheduled appointments with the primary care physician are a cost-effective strategy that lessens "doctor shopping" and frequent visits to an emergency department.

- Somatization disorder begins in early life and is characterized by recurrent multiple physical complaints.
- It mostly affects women.
- It is associated with high use of health care.

Conversion Disorder

Conversion disorder is a loss or alteration of physical functioning suggestive of a medical or neurologic disorder that cannot be explained on the basis of known physiologic mechanisms. The disorder is not limited to pain or sexual dysfunction. It is seen most often in the outpatient setting. Patients frequently respond to any of several therapeutic modalities that suggest hope of a cure. When conversion disorder becomes chronic, it carries a poorer prognosis and is difficult to treat. Treatment focuses on management of the symptoms rather than cure, much as in somatization or chronic pain disorder.

- Conversion disorder is characterized by a loss or alteration of physical functioning.
- It cannot be explained by known physiologic mechanisms.
- It is usually seen in the outpatient setting.
- Treatment focuses on managing the symptoms and encouraging the patient to resume normal functioning.

Chronic Pain Disorder

Chronic pain somatoform disorder (somatoform, chronic pain syndromes) may occur at any age but most often develops in the 30s or 40s. It is diagnosed twice as often in women as in men and is characterized by preoccupation with pain for at least 6 months. No organic lesion is found to account for the pain, or if there is a related organic lesion, the complaint of pain or resulting interference with usual life activities is in excess of what would be expected from the physical findings. A thorough assessment is essential before this diagnosis can be established. Treatment is usually multidisciplinary (primary care, psychiatry, psychology, and physiatry) and focused on helping the patient manage or live with the pain rather than continuing with the expectation of "cure." Avoidance of long-term dependence on addictive substances is an important goal.

- Chronic pain disorder: occurs at any age but usually develops in the 30s or 40s.
- It is diagnosed twice as often in women as in men.
- It is characterized by preoccupation with pain for at least 6 months.
- Treatment: usually multidisciplinary, ideally with involvement of primary care, psychiatry, psychology, and physiatry.
- Typical clinical scenario: A 33-year-old woman has been preoccupied with pain for 8 months, and this has interfered with normal function. An extensive medical evaluation has not found any organic lesion.

Hypochondriasis

Hypochondriasis is an intense preoccupation with the fear of having or the belief that one has a serious disease despite the lack of physical evidence to support the concern. It tends to be a chronic problem for the patient. The differential diagnosis includes obsessive-compulsive disorder (somatic presentation) and delusional disorder (somatic type). Patients with hypochondriasis and obsessive-compulsive disorder tend to have fleeting insight into their excessive concern for their health, unlike patients with delusional thinking. The treatment of hypochondriasis, similar to that of obsessive-compulsive disorder, depends on a combination of serotonergic antidepressants and cognitive-behavioral psychotherapy.

Factitious Disorders

Factitious disorders are characterized by the deliberate production of signs or symptoms of disease. The diagnosis of these disorders requires that the physician maintain a high degree of suspicion and look for objective data at variance with the patient's history (e.g., surgical scars that are inconsistent with past surgical history). The more common form of factitious disorder generally occurs among socially conforming young women of a higher socioeconomic class who are intelligent, educated, and frequently work in a medically related field. The possibility of a coexisting medical disorder or intercurrent illness needs to be appreciated in the diagnostic and therapeutic management of these difficult cases. Factitious disorders are often found in patients with a history of childhood emotional traumas. These patients, through their illness, may be seeking to compensate for childhood traumas and secondarily to escape from and make up for stressful life situations. The most extreme form of the disorder is Munchausen syndrome, which is characterized by the triad of simulating disease, pathologic lying, and wandering. This syndrome has been recognized primarily in men of lower socioeconomic class who have a lifelong pattern of poor social adjustment. The subtype of Munchausen disorder is not included in *DSM-IV*, which instead uses the more inclusive *factitial disorder*.

- Factitious disorder: the voluntary production of signs or symptoms of disease to assume the sick role.
- Common form: occurs among socially conforming young women of a higher socioeconomic class.
- Munchausen syndrome is the most extreme form of factitious disorder, with the characteristic triad of simulating disease, pathologic lying, and wandering.
- Factitious disorders often occur in patients with a history of childhood emotional traumas.
- Typical clinical scenario: A 32-year-old woman who is a registered nurse has recurrent fevers but no other presenting signs or symptoms, with a documented double-organism bacteremia due to self-injection.

Malingering

The essential feature of malingering is the intentional production of false or exaggerated physical or psychologic symptoms. It is motivated

by external incentives such as avoiding military service or work, obtaining financial compensation or drugs, evading criminal prosecution, or securing better living conditions. Malingering should be suspected in cases in which a medicolegal context overshadows the clinical presentation, a marked discrepancy exists between the person's claimed stress or disability and the objective findings, a lack of cooperation exists during the diagnostic evaluation and in complying with prescribed treatments, and an antisocial personality disorder is present. The person who is malingering is much less likely to present his or her symptoms in the context of emotional conflict, and the presenting symptoms are less likely to be related symbolically to an underlying emotional conflict.

- Malingering is the intentional production of false or exaggerated physical or psychologic symptoms.
- It is motivated by external incentives such as disability payments, housing, release from jail, or avoiding court appearances.

Delirium and Dementia

The primary distinguishing feature between delirium and dementia is the retention and stability of alertness in dementia.

Delirium

Delirium is characterized by a fluctuating course of an altered state of awareness and consciousness. Although the onset typically is abrupt, the symptoms of this disorder may occasionally be insidious. It may be accompanied by hallucinations (tactile, auditory, visual, or olfactory), illusions (misperceptions of sensory stimuli), delusions, emotional lability, paranoia, alterations in the sleep-wake cycle, and psychomotor slowing or hyperactivity. The symptoms can be dramatic and mimic primary psychotic disorders. Delirium is usually reversible with correction of the underlying cause. It often is related to an external toxic agent, medication side effect, metabolic abnormality, central nervous system abnormality, or withdrawal of a medication or drug. Delirium is relatively common (range, 10%-30%) in medical or surgical inpatients older than 65 years. The diagnosis is made primarily by clinical assessment and changes in the results of a patient's mental status examination. Patients may present with either agitation or withdrawal, the latter being more difficult to recognize. High-risk groups include elderly patients with medical illness (especially congestive heart failure, urinary tract infection, renal insufficiency, hyponatremia, dehydration, or stroke), postcardiotomy patients, patients with dementia, patients in drug withdrawal, patients with severe burns, and patients with acquired immunodeficiency syndrome (AIDS).

- Delirium is characterized by a fluctuating course of inattention and altered level of consciousness.
- Delirium usually is reversible with correction of the underlying cause.
- It often is related to an external toxic agent, medication side effect, metabolic abnormality, central nervous system abnormality, or withdrawal of a medication or drug.
- Delirium is relatively common in medical or surgical patients older than 65 years.

The most common cause of delirium in the elderly probably is intoxication with psychotropic drugs, especially drugs with sedative and anticholinergic side effects. The first step in management is determining whether a specific cause can be identified. Comprehensive medical investigations are frequently warranted. After the cause of the delirium has been recognized, a treatment is selected that can reverse the disease process. If the cause is unknown and the patient's behavior interferes with safety and medical care, several categories of intervention can be considered. Management aspects include monitoring vital signs, electrolytes, and fluid balance and giving neuroleptic agents such as haloperidol intravenously. Environmental supports aid orientation; these include calendars, clocks, windows, and family and other persons. Also, psychosocial support, including family or other care providers, is helpful. Severely agitated patients may require physical restraints to prevent injury to themselves or others if medications are not yet effective. Restraints should be avoided whenever possible.

- The most common cause of delirium in the elderly is intoxication with psychotropic drugs.
- Typical clinical scenario: A 70-year-old man hospitalized for renal insufficiency and hyponatremia has abrupt onset of visual hallucinations and paranoia accompanied by alternation of his sleep-wake cycle.

Dementia

Dementia is a syndrome of acquired persistent impairment of mental function involving at least three of the following five domains: memory, language, visuospatial skills, personality or mood, and cognition (including abstraction, judgment, calculations, and executive function). The most common form of cortical dementia is Alzheimer disease. The lifetime prevalence for patients reaching age 65 is estimated at 5% to 10% and for those over age 85, 15% to 20%. Dementia with Lewy bodies is a progressive neurodegenerative disorder that typically has a faster rate of decline than Alzheimer disease. Autopsy findings in this disorder include eosinophilic inclusion bodies in the cerebral cortex and brainstem. Patients have prominent visual hallucinations and extrapyramidal symptoms. Another common type of dementia is multi-infarct dementia, which represents 15% of the cases of dementia in a pure form and an additional 10% in a mixed form.

Subcortical dementia is another important subtype. Patients with this type of dementia often have other focal neurologic signs, including an associated gait disturbance. They also may have normal-pressure hydrocephalus, Huntington disease, or Parkinson disease.

Dementia may be associated with HIV infection, multiple sclerosis, amyotrophic lateral sclerosis, vitamin B_{12} deficiency, hypothyroidism, and Wilson disease. Other rare types of dementia include Pick disease and Creutzfeldt-Jakob disease.

- Cortical dementia: the common form is Alzheimer disease.
- Subcortical dementia: focal neurologic signs, including gait disturbance, other than cognitive dysfunction are often present.

Dementia is differentiated from delirium by appropriate levels of arousal, more preserved attention, and persistence of the cognitive

changes. Some forms may be reversible, as in dementia related to hypothyroidism, and some may be "treatable" without reversing the intellectual deficits, for example, preventing further ischemic injury in patients with vascular dementia. Dementia may be a chronic progressive form in which treatment is generally related to improved control of the behavioral disturbances.

Psychologic Aspects of AIDS

From the early to the terminal phases of AIDS and its sequelae, many psychiatric symptoms and complications are possible. The organic mental disorders associated with this process can be primary (i.e., directly induced by HIV infection), secondary (i.e., related to the effects of the HIV infection leading to immunodeficiency and opportunistic infections or tumors systemically or within the central nervous system), or iatrogenic (i.e., resulting from the treatment of HIV or its sequelae). The delirium of AIDS often has a multifactorial cause, similar to delirium in general, namely, electrolyte imbalance, encephalopathy from intracranial or systemic infections, hypoxemia, or medication side effects. HIV itself can cause encephalopathy. The dementia of AIDS can result from the chronic sequelae of most of the causes of delirium. However, direct cerebral infection with HIV probably causes much of the dementia. Other psychiatric symptoms are more nonspecific, such as anger, depression, mania, psychosis, and the general problems of dealing with a terminal illness. Also, all these might be complicated by undiagnosed and, thus, untreated alcohol or drug dependence, especially in the early phases of the disease. A patient who contracted HIV infection through intravenous drug abuse may need chemical dependency treatment as well as thoughtful management of pain complaints.

- AIDS has many possible psychiatric symptoms and complications.
- Organic mental disorders can be primary (due to HIV infection), secondary (due to immunodeficiency and opportunistic infections), or iatrogenic.
- Delirium in AIDS is multifactorial.
- Dementia in AIDS can result from the chronic sequelae of most of the causes of delirium.

Eating Disorders

The two common eating disorders are anorexia nervosa and bulimia. Both are markedly more prevalent among women than men. Onset is usually in the teenage or young adult years; rarely, it starts prepubertally. Eating disorders are increasingly found across all income, racial, and ethnic groups. Both disorders have a primary symptom of preoccupation with weight and distortion of body image. For example, the patient perceives herself to look less attractive than an observer would. The disorders are not mutually exclusive, and about 50% of patients with anorexia nervosa also have bulimia. Many patients with bulimia previously had at least a subclinical case of anorexia nervosa.

- The two common eating disorders are anorexia nervosa and bulimia.
- They are markedly more prevalent among women than men.
- Primary symptom: preoccupation with weight and a desire to be thinner.

Anorexia Nervosa

To meet the diagnostic criteria of anorexia nervosa, weight must be 15% below that expected for age and height. However, weight of 30% to 40% below normal is not uncommon and leads to the medical complications of starvation, such as depletion of fat, muscle wasting, bradycardia, arrhythmias, ventricular tachycardia and sudden death, constipation, abdominal pain, leukopenia, hypercortisolemia, and osteoporosis. In extreme cases, patients develop lanugo (fine hair of the body) and metabolic alterations to conserve energy. Thyroid effects include low levels of triiodothyronine (T_3), cold intolerance, and difficulty maintaining core body temperature. Reproductive effects include a pronounced decrease or cessation of the secretion of luteinizing hormone and follicle-stimulating hormone, resulting in secondary amenorrhea.

Bulimia

Patients with bulimia frequently lose control and consume large quantities of food. Many patients may have a concurrent depressive or anxiety disorder. Physical complications of the binge-purge cycle may include fluid and electrolyte abnormalities, hypochloremic-hypokalemic metabolic alkalosis, esophageal and gastric irritation and bleeding, colonic abnormalities from laxative abuse, marked erosion of dental enamel with associated decay, parotid and salivary gland hypertrophy, and amylase levels 25% to 40% higher than normal. If bulimia is untreated, it often becomes chronic. Some patients have a gradual spontaneous remission of some symptoms.

- Patients with bulimia may have a concurrent depressive or anxiety disorder.
- The binge-purge cycle causes physical complications.

Alcoholism and Substance Abuse Disorders

Alcoholism and substance abuse disorders are a major concern in all age groups and across all ethnic, socioeconomic, and racial groups. Despite national and international efforts to curb the problem and to make treatment more readily available, the condition is not diagnosed in many persons and less than 10% of persons with addiction are involved in some form of treatment, either self-help groups or professional supervision. The lifetime incidence of alcohol and drug abuse approaches 20% of the population. These disorders have devastating effects on families and other persons and contribute to social problems such as motor vehicle accidents and fatalities, domestic violence, suicide, and increased health care costs. Untreated alcoholics have been estimated to generate twice the general health care costs of nonalcoholics. Persons with addictive disorders are a heterogeneous group and may present in many different ways. Recognizing addictive disorders is critically important. The current definition of alcoholism approved by the National Council on Alcoholism and Drug Dependence may also be applicable to other drugs of abuse: alcohol abuse and dependence are primary, chronic

diseases with genetic, psychosocial, and environmental factors influencing their development and manifestations. The disease is often progressive and fatal. It is characterized by continuous or periodic impaired control over drinking, preoccupation with the drug alcohol, the use of alcohol despite adverse consequences, and distortions in thinking, most notably denial.

- Less than 10% of persons with addiction receive some form of treatment.
- Persons with addictive disorders are a heterogeneous group.
- The lifetime incidence of alcohol and drug abuse approaches 20% of the population.
- Untreated alcoholics generate twice the general health care costs of nonalcoholics.

The adverse consequences of alcohol and substance abuse disorders cross over into several domains. Physical health issues include alcohol withdrawal syndromes, liver disease, gastritis, anemia, and neurologic disorders. Psychologic functioning issues include impaired cognition and changes in mood and behavior. Interpersonal functioning issues include marital problems, child abuse, and impaired social relationships. Occupational functioning issues include academic, scholastic, or job problems. Legal, financial, and spiritual problems also occur.

Substance abuse disorders are divided by the substance involved into 10 major groups: alcohol, amphetamines, cannabis, cocaine, hallucinogens, inhalants, nicotine, opioids, PCP, and benzodiazepines, sedative-hypnotics, and anxiolytics. Some characteristics are specific to each of these groups, but what may be unexpected is that they probably have more similarities than differences when it comes to diagnosing a problem of abuse or dependence (or both). These drugs are grouped according to their perceived effects in Table 21-2. The descriptive titles of the groups give an idea of the physiologic and psychologic activity of the drug when taken. Within the group of central nervous system depressants ("downers"), there is considerable potential for crossover addictions (barbiturates and alcohol).

- Within the group of central nervous system depressants, there is considerable potential for crossover addictions.

Alcoholism

Medical data from physical examination and laboratory tests can be helpful. However, most of the pertinent findings are not apparent until after several years (often up to 5 years) of notable alcohol use and, thus, do not reflect the earliest stages of the disease. Two of the earlier detectable signs are increases in serum γ-glutamyltransferase level and mean corpuscular volume. In both men and women, the combination of increased γ-glutamyltransferase level and mean corpuscular volume can identify up to 90% of alcoholics. Carbohydrate-deficient transferrin is the most sensitive screening test. Other abnormal laboratory findings include increased levels of alkaline phosphatase, bilirubin, uric acid, and triglycerides. However, because of the number of false-negative results, it is not practical to rely on laboratory data alone to establish the diagnosis of alcoholism. The CAGE questions (related to attempts to **c**ut down on alcohol use, other persons expressing **a**nnoyance, experiencing **g**uilt, and **e**arly-morning drinking) have excellent sensitivity and specificity. Alcohol withdrawal can range from mild to quite severe, with the occurrence of withdrawal seizures or delirium tremens (or both). The medical complications of alcoholism can affect nearly every organ system, but the liver, gastrointestinal tract, pancreas, and central nervous system are particularly susceptible to the effects of alcohol.

- Increased γ-glutamyltransferase level and mean corpuscular volume can identify up to 90% of alcoholics.
- It is not practical to rely on laboratory data alone to diagnose alcoholism.
- Medical complications of alcoholism can affect nearly every organ system.

Benzodiazepines, Sedative-Hypnotics, and Anxiolytics

Benzodiazepines, sedative-hypnotics, and anxiolytics are widely prescribed in many areas of medicine, so abuse and dependence are often iatrogenic. However, five characteristics may help distinguish medical use from nonmedical use:

1. Intent—What is the purpose of the use?
2. Effect—What is the effect on the user's life?
3. Control—Is the use controlled by the user only or does a physician share in the control?
4. Legality—Is the use of the drug legal or illegal? Medical drug use is legal.
5. Pattern—In what settings is the drug used?

These same characteristics may also be used to distinguish between the medical and nonmedical use of opioids. Withdrawal from use of benzodiazepines and barbiturates, in particular, may be serious because of the increased risk of withdrawal seizures.

- Withdrawal of the use of benzodiazepines and barbiturates, in particular, can be serious because of the increased risk of withdrawal seizures.

Psychopharmacology

The use of a pharmacologic treatment of a psychiatric disorder or the use of psychoactive medications in other disorders is a decision that generally is made after considering multiple factors in the case. Medication alone is rarely the sole treatment for a psychiatric disorder but rather a component of a comprehensive treatment plan.

Table 21-2 Drugs Grouped According to Their Perceived Effects

Uppers	Downers	Multiple effects
Cocaine	Alcohol	Cannabis
Amphetamines	Opioids	Hallucinogens
Caffeine	Benzodiazepines	Inhalants
Nicotine	Sedative-hypnotics	Phencyclidine (PCP)
	Barbiturates	

Because psychoactive medications are used in various circumstances for many different indications, the major groups of these medications—antidepressants, antipsychotics, antimanic agents, anxiolytics, and sedative drugs—are discussed below in general terms rather than for treatment of specific disorders. The choice of a medication usually is based on its side-effect profile and the clinical profile of the patient. There are many effective drugs in each of the major groups, but they differ in terms of pharmacokinetics, side effects, and available routes of administration.

- Medication alone is rarely the sole treatment for a psychiatric disorder.
- The choice of a medication generally is based on its side-effect profile and the clinical profile of the patient.

Antidepressants

In the United States, more than 30 antidepressants are available to treat depression, and several others have been approved by the U.S. Food and Drug Administration exclusively for certain indications, such as obsessive-compulsive disorder (clomipramine and fluvoxamine) and attention-deficit/hyperactivity disorder (atomoxetine). First-generation antidepressants include tricyclic agents and monoamine oxidase inhibitors. Newer generation antidepressants are not easily grouped by their chemical structure or function; they are instead a diverse group of compounds. Currently, the most widely used of this group of agents are SSRIs.

Although older generation antidepressants were effective in treating depression, they were associated with important side effects that limited their use in certain groups of patients, especially those with other medical problems. In particular, tricyclic agents are associated with orthostatic hypotension, anticholinergic side effects, and cardiac conduction defects. Monoamine oxidase inhibitors are effective antidepressants but require special dietary restrictions and attention to interactions with other medications. Because the newer generation antidepressants have fewer potential side effects and drug interactions than older agents, they are prescribed more widely, but they are not optimal for all patients.

Types of antidepressants with examples include the following:

1. Tricyclics—tertiary amines (including amitriptyline, doxepin, imipramine, and trimipramine) and secondary amines (including desipramine, nortriptyline, and protriptyline)
2. Monoamine oxidase inhibitors—pargyline, phenelzine, and tranylcypromine
3. SSRIs—citalopram, fluoxetine, fluvoxamine, paroxetine, and sertraline
4. Norepinephrine reuptake inhibitors—atomoxetine
5. Newer generation antidepressants—bupropion, nefazodone, trazodone, and venlafaxine
6. Isolated enantiomer of an SSRI—escitaolpram (*S*-enantiomer [single isomer] of citalopram)

The mechanism of action of virtually all antidepressants is their effect, to varying degrees, on the noradrenergic and serotonergic systems of the central nervous system. Various antidepressant agents block the reuptake of norepinephrine or serotonin (or both), thus increasing the amount of these neurotransmitters at the synapse. Bupropion, an example of an antidepressant with insignificant serotonergic action, instead works through dopaminergic and not adrenergic systems. The ability of this agent to increase levels of dopamine in the synaptic cleft likely underlies its unique efficacy in nicotine dependence.

Monoamine oxidase inhibitors block the catabolism of several biogenic amines (norepinephrine, serotonin, tyramine, phenylephrine, and dopamine), thereby increasing the amount of these neurotransmitters available for synaptic release.

- Antidepressants affect the noradenergic and serotonergic systems of the central nervous system.
- Bupropion acts on dopamine and norepinephrine neurotransmission and not serotonin.
- Monoamine oxidase inhibitors block the catabolism of several biogenic amines.

Antidepressants have been approved primarily for use in the treatment of depression. However, they are useful in several other disorders, including panic disorder, obsessive-compulsive disorder, generalized anxiety disorder, social anxiety disorder, posttraumatic stress disorder, enuresis, bulimia, and attention-deficit/hyperactivity disorder. Noradrenergic antidepressants such as tricyclic agents and venlafaxine can be beneficial for the treatment of chronic pain and migraines. Theoretically, SSRIs have potential for these conditions as well but as yet have not been tested extensively.

Because antidepressants are widely used, familiarity with the basic facts of their use, side effects, and drug interactions may be helpful. The choice of which antidepressant to use is often made on the basis of the side-effect profile of the drug and the clinical presentation of the patient. The side effects of the major groups of antidepressant agents are listed in Table 21-3. A complete trial of antidepressant medication consists of 6 weeks of therapeutic doses

Table 21-3 Side Effects of the Major Groups of Antidepressants

Orthostatic hypotension—The cardiovascular side effect that most commonly results in serious morbidity, especially in the elderly
Anticholinergic effects—Dry mouth, blurred vision, urinary retention; beware of these side effects in patients with prostatic hypertrophy and narrow-angle glaucoma. Drugs with more anticholinergic side effects also seem to be the more sedating, e.g., tertiary amine tricyclics
Cardiac conduction effects—Most of the tricyclics prolong PR and QRS intervals. Thus, these drugs need to be used with caution in patients with preexisting heart block, such as second-degree heart block or markedly prolonged QRS and QT intervals. The tricyclics are potent antiarrhythmic agents because of their quinidine-like effect. Newer generation antidepressants have considerably fewer cardiac interactions
Sedation—Tertiary amine tricyclics and trazodone
Potential stimulation—Secondary amine tricyclics, bupropion, fluoxetine, sertraline, and paroxetine

before considering refractoriness. If improvement has occurred with the initial trial of the medication but the patient's condition has not returned to baseline, it may be worthwhile augmenting therapy with lithium carbonate before changing the medication to another class of antidepressant. After clinical improvement has been noted, the medication may need to be maintained for an extended period. Another option is to switch to an antidepressant with a different mechanism of action that interacts with different neurochemical pathways.

Monoamine Oxidase Inhibitors

Monoamine oxidase inhibitors are now seldom used because of concerns about drug-drug and drug-food interactions. The mechanism of action is to inhibit irreversibly the enzyme monoamine oxidase A or B, which degrades catecholamines, serotonin, and the neurotransmitter amino acid precursor tyramine. Most clinical concerns about the use of monoamine oxidase inhibitors are related to reactions from the ingestion of tyramine, which is not metabolized because of the inhibition of intestinal monoamine oxidase. Tyramine may act as a false transmitter and displace norepinephrine from synaptic vesicles. Patients should be instructed in a tyramine-restricted diet, especially to avoid aged cheeses, smoked meats, pickled herring, beer, red wine, yeast extracts, fava beans, and overripe bananas and avocados. Certain general anesthetics and drugs with sympathomimetic activity should be avoided; patients should beware especially of over-the-counter cough and cold preparations, decongestants, and appetite suppressants. Meperidine (Demerol) is absolutely contraindicated because of its potentially lethal interaction with monoamine oxidase inhibitors.

- Clinical concerns about monoamine oxidase inhibitors: reactions due to ingestion of tyramine, which is not metabolized.
- Tyramine is a false neurotransmitter that displaces norepinephrine from synaptic vesicles.
- Meperidine (Demerol) is absolutely contraindicated because of its potentially lethal interaction with monoamine oxidase inhibitors.

Treatment of hypertensive reactions relies on administering drugs with α-adrenergic blocking properties, such as intravenous administration of phentolamine.

Antipsychotic Agents

Clinically, "atypical" antipsychotic agents are now used widely and are replacing "standard antipsychotics" such as chlorpromazine and haloperidol. The currently available newer generation antipsychotics include aripiprazole, clozapine, olanzapine, quetiapine, risperidone, and ziprasidone.

The choice of medication is based on the patient's clinical situation, side-effect profile of the chosen agent, history of previous response, and issues related to compliance. The prevailing theory about the mechanism of action of these agents is that they cause blockade of postsynaptic dopamine receptors. This is related to both the antipsychotic activity and the other side effects, depending on which dopamine pathways in the brain are affected and which type of dopamine receptor is preferentially affected. If the nigrostriatal dopaminergic system (involved with motor activity) is affected, extrapyramidal symptoms may result. Blockade of the dopamine pathways in the pituitary and hypothalamus causes increased release of prolactin and changes in appetite and temperature regulation. The effects of these drugs on the limbic system, midbrain tegmentum, septal nuclei, and mesocortical dopaminergic projections are thought to be responsible for their antipsychotic action. Atypical antipsychotic medications combine dopaminergic and serotonergic antagonism, which appears to minimize extrapyramidal side effects.

- The theory about the mechanism of action of antipsychotic agents is that they cause blockade of postsynaptic dopamine receptors.
- The antipsychotic effects of these agents are due to their actions on the limbic system, midbrain tegmentum, septal nuclei, and mesocortical dopaminergic projections.

Side Effects: Extrapyramidal Reactions

Atypical antipsychotic agents have a lower rate of extrapyramidal side effects. Yet, because these events are still reported occasionally, it is important to recognize these possible complications of therapy. Acute dystonic reactions occur within hours or days after treatment is initiated with antipsychotic drugs. These reactions are characterized by uncontrollable tightening of the face and neck muscles with spasms. The effect on the eyes may cause an oculogyric crisis, and the effect on the laryngeal muscles may cause respiratory or ventilatory difficulties. Treatment is usually with intravenous or intramuscular administration of an anticholinergic agent, followed by the use of an oral anticholinergic agent for a few days.

- Acute dystonic reactions occur within hours or days after treatment is initiated with antipsychotic drugs.
- Reactions include uncontrollable tightening of the face and neck muscles with spasms.
- Treatment: intravenous or intramuscular administration of an anticholinergic agent.

Parkinsonian syndrome has a more gradual onset and can be treated with oral anticholinergic agents or decreased doses of the antipsychotic agent (or both). *Akathisia* is an unpleasant feeling of restlessness and the inability to sit still. It often occurs within days after treatment is initiated with an antipsychotic agent. Akathisia is sometimes mistaken for exacerbation of the psychosis. Treatment, if possible, is to decrease the dose of the antipsychotic agent or to try using a β-adrenergic blocking agent such as propranolol, if not contraindicated.

Tardive dyskinesia has an incidence of 3% to 5% annually and consists of involuntary movements of the face, trunk, or extremities. The most consistent risk factors for its development are long-term use (>6 months) of typical antipsychotics and older age. Prevention is the most important aspect of management because no reliable treatment is available. It is best if treatment with the antipsychotic agent can be discontinued because the dyskinesia is sometimes reversible, although the involuntary movements may increase temporarily.

- Tardive dyskinesia is involuntary movements of the face, trunk, or extremities.

- Prevention is the most important aspect of management.

Neuroleptic malignant syndrome is a potentially life-threatening disorder that may occur after the use of any antipsychotic agent, although it is more common with rapid increases in the dosage of high-potency antipsychotic agents. Its clinical presentation is characterized by severe rigidity, fever, leukocytosis, tachycardia, tachypnea, diaphoresis, blood pressure fluctuations, and marked increase in creatine kinase levels because of muscle breakdown. Treatment consists of discontinuing the use of the antipsychotic agent and providing life-support measures (ventilation and cooling). Pharmacologic interventions may include the use of one or both of the following: dantrolene sodium, which is a direct-acting muscle relaxant, or bromocriptine, which is a centrally acting dopamine agonist. Often, one of the most effective treatments is ECT, which likely increases presynaptic dopamine release markedly; this reverses the extreme degree of dopamine receptor blockade present in neuroleptic malignant syndrome.

- Neuroleptic malignant syndrome is potentially life-threatening.
- It may occur after the use of any antipsychotic agent.
- Characteristics include severe rigidity, fever, leukocytosis, tachycardia, tachypnea, diaphoresis, blood pressure fluctuations, and marked increase in creatine kinase levels (from muscle breakdown).

Side effects of antipsychotic agents other than extrapyramidal effects are listed in Table 21-4.

Newer ("Atypical") Antipsychotic Agents

The atypical antipsychotic agents are different from their predecessors in terms of potential mechanisms of action and side-effect profiles. They are less likely to cause bothersome extrapyramidal side effects, and their potential for causing tardive dyskinesia may be less. The evidence for the latter will take time to establish because the onset of the symptoms is delayed and the drugs have not been widely used long enough to determine the risk of tardive dyskinesia. Neuroleptic malignant syndrome has been reported to occur with clozapine and risperidone. Clozapine has a 1% to 2% risk of producing agranulocytosis, which is reversible if use of the medication is withdrawn immediately. Because of this serious potential side effect, a specific requirement is that blood cell counts be made regularly (weekly for the first 6-18 months and then every 2 weeks). As with their predecessors, increased levels of prolactin are associated with risperidone and notable weight gain may occur with olanzapine. These newer generation antipsychotic agents are also considerably more expensive than their predecessors. Currently, they are not available in parenteral form, which makes them less versatile in the case of psychiatric emergencies.

Antianxiety Medications

Antianxiety medications are used most appropriately to treat time-limited anxiety or insomnia related to an identifiable stress or change in sleep cycle. After long-term use (>2-3 months), the use of benzodiazepines and related substances should be tapered rather than discontinued abruptly to avoid any of the three "discontinuation syndromes," which include relapse, rebound, and withdrawal.

Relapse is the return of the original anxiety symptoms, often after weeks to months. *Rebound* is the intensification of the original symptoms which usually lasts several days and appears within hours to days after abrupt cessation of drug use. *Withdrawal* may be mild to severe and includes autonomic and central nervous system symptoms that are different from the original presenting symptoms of the disorder.

Benzodiazepines are well absorbed orally but have unpredictable availability with intramuscular use, except for lorazepam. There is great variability in the pharmacokinetics of benzodiazepines. Several of these drugs have metabolites with a long half-life. Therefore, much smaller doses need to be used in the elderly, in patients with cognitive dysfunction, and in children. All these patient groups are prone to paradoxical reactions (anxiety, irritability, aggression, agitation, and insomnia), especially patients with known brain damage.

- Benzodiazepines have great variability in their half-life, which directly determines the duration of action and side effects.

Buspirone is a non-benzodiazepine anxiolytic drug whose mechanism of action is well understood. However, the drug has effects on many neurotransmitter systems, especially the serotonergic and dopaminergic systems. Cross-tolerance does not exist between benzodiazepines and buspirone. It generally takes 2 to 3 weeks for the drug to become effective. Patient compliance can be an issue because of the long latency to effectiveness and the need for divided doses daily.

- Buspirone is a non-benzodiazepine anxiolytic drug.
- It takes 2 to 3 weeks for the drug to become effective.

Lithium

For many years, lithium carbonate was the drug of choice for treating bipolar disorders. It may also be effective in patients with recurrent unipolar depression and as an adjunct for maintenance of remission of depression after ECT. Acute manic symptoms usually respond to treatment with lithium within 7 to 10 days; during this time, the adjunctive use of antipsychotic agents and benzodiazepines

Table 21-4 Side Effects of Antipsychotic Agents Aside From Extrapyramidal Effects

Anticholinergic
Orthostatic hypotension—related to α-adrenergic receptor blockade
Hyperprolactinemia—gynecomastia possible in men and women, galactorrhea (rare), amenorrhea, weight gain, breast tenderness, decreased libido
Sexual dysfunction
Dermatologic—pigmentary changes in the skin, photosensitivity
Decreased seizure threshold

may be helpful. Lithium is well absorbed from the gastrointestinal tract, with peak levels in 1 to 2 hours. Its half-life is about 24 hours. Levels are generally checked 10 to 12 hours after the latest dose. Relatively common side effects include resting tremor, diarrhea, polyuria, polydipsia, thirst, and nausea, which is often improved by taking the medication on a full stomach. Lithium is contraindicated in the first trimester of pregnancy because of its potential for causing defects in the developing cardiac system. Renal effects generally can be reversed with discontinuation of lithium therapy. The most noticeable renal effect is the vasopressin-resistant effect leading to impaired concentrating ability and nephrogenic diabetes insipidus with polyuria and polydipsia. Most patients who take lithium develop some degree of polyuria, but not all develop the more severe manifestations of nephrogenic diabetes insipidus. Renal function should be followed in all patients receiving maintenance lithium therapy. However, whether lithium has severe nephrotoxic effects is a matter of controversy. A hematologic side effect is benign leukocytosis. Hypothyroidism may occur in as many as 20% of patients taking lithium because of the direct inhibitory effects on thyroid hormone production or increased antithyroid antibodies.

- Lithium carbonate: the common side effects are hand tremor, diarrhea, polyuria, polydipsia, thirst, and nausea.
- Renal effects generally can be reversed with discontinuation of lithium therapy.
- The most noticeable renal effect is impaired concentrating ability.
- Hypothyroidism occurs in as many as 20% of patients taking lithium.

Because the range between the therapeutic and toxic levels of lithium in the plasma is narrow, patients and physicians should be familiar with conditions that may increase or decrease lithium levels and with the signs and symptoms of lithium toxicity so it can be recognized and treated promptly (Tables 21-5 and 21-6).

Other Mood Stabilizers

The anticonvulsant valproic acid is effective in the treatment of acute manic episodes and for prophylactic maintenance therapy for bipolar disorders. Because of fewer side effects and a wider therapeutic index (reducing potential toxicity), valproic acid is now the most commonly prescribed mood stabilizer. The mechanism of action for its mood-stabilizing effects is not clear. The side effect of most concern with valproic acid is hepatotoxicity, which has occurred mostly in children receiving treatment with multiple anticonvulsants. Carbamazepine has also been used in this context, and because its chemical structure is similar to that of tricyclic antidepressants, it has a quinidine-like effect. Other anticonvulsants such as gabapentin and lamotrigine are also being investigated as mood-stabilizing agents.

- Valproic acid is effective for the treatment of acute mania and maintenance therapy of bipolar disorders.

Electroconvulsive Therapy

ECT is the most effective treatment for severely depressed patients, especially those with psychotic features. It is also helpful in treating catatonia and mania and may be used in children and adults. Also, ECT can be administered safely to pregnant women, provided fetal monitoring is available. It may be effective in patients with overlapping depression and Parkinson disease or dementia. ECT induces rapid changes in several transmitter-receptor systems simultaneously, particularly acetylcholine, norepinephrine, dopamine, and serotonin. ECT is administered with the patient under barbiturate anesthesia, with succinylcholine or a similar muscle relaxant to minimize peripheral manifestations of the seizure. An anticholinergic agent such as atropine is generally given to decrease secretions and to prevent bradycardia caused by central stimulation of the vagus nerve. A usual course of treatment is 6 to 12 sessions given over 2 to 4 weeks. Therapy is often initiated with unilateral, nondominant electrode placement to minimize memory loss. If satisfactory results cannot be obtained with this method, bilateral electrode placement is used.

- ECT is the most effective treatment for severely depressed patients, especially those with psychotic features.
- It is also helpful in treating catatonia and mania.
- ECT can be administered to pregnant women.
- It may be helpful in cases of overlapping depression and Parkinson disease or dementia.
- Mechanism of action—ECT induces rapid changes in several transmitter-receptor systems simultaneously, particularly acetylcholine, norepinephrine, dopamine, and serotonin.

Table 21-5 **Conditions That Increase or Decrease Lithium Levels in the Plasma**

Increase levels	Decrease levels
Dehydration	Increased caffeine consumption
Overheating and increased perspiration with exercise and/or hot weather	Theophylline
Nonsteroidal anti-inflammatory drugs	
Thiazide diuretics	
Angiotensin-converting enzyme inhibitors	
Certain antibiotics—tetracycline, spectinomycin, and metronidazole	

ECT no longer has any absolute contraindications, although it has several relative contraindications. Previously, the only absolute contraindication was the presence of an intracranial space-occupying lesion and increased intracranial pressure. Serious complications or mortality is generally reported as less than 1 per 10,000, which makes this therapy one of the safest interventions that uses general anesthesia. Morbidity and mortality usually are due to cardiovascular complications, such as arrhythmia, myocardial infarction, or hypotension. The major risks are those associated with the brief general anesthesia. Medical evaluations performed before ECT is administered should pay particular attention to cardiovascular function, pulmonary function, electrolyte balance, neurologic disorder (epilepsy), and the patient's previous experiences with anesthesia.

- ECT no longer has any absolute contraindications.
- It has several relative contraindications.
- Morbidity and mortality are usually due to cardiovascular complications.

Table 21-6 **Signs and Symptoms of Lithium Toxicity**

Mild-to-moderate toxicity (plasma level, 1.5-2.0 mEq/L)	Moderate-to-severe toxicity (plasma level, 2.0-2.5 mEq/L)	Severe toxicity (plasma level >2.5 mEq/L)
Vomiting	Persistent nausea and vomiting	Generalized seizures
Abdominal pain	Anorexia	Oliguria and renal failure
Dry mouth	Blurred vision	Death
Ataxia	Muscle fasciculations	
Slurred speech	Hyperactive deep tendon reflexes	
Nystagmus	Delirium	
Muscle weakness	Convulsions	
	Electroencephalographic changes	
	Stupor and coma	
	Circulatory system failure	
	Decreased blood pressure	
	Cardiac arrhythmias	
	Conduction abnormalities

Psychiatry Pharmacy Review

Julie L. Cunningham, PharmD, BCPP

Review of Antipsychotic Agents

Drug	Toxic/adverse effects	Drug interactions/comments
Typical agents Chlorpromazine Fluphenazine Mesoridazine Perphenazine Thioridazine Trifluoperazine Haloperidol Loxapine Molindone Thiothixene	EPS—dystonia, pseudoparkinsonism, akathisia, TD, NMS Anticholinergic effects, sedation, orthostatic hypotension, galactorrhea, amenorrhea, gynecomastia, weight gain, sexual dysfunction, photosensitivity, risk of seizures Pigmentary retinopathy—thioridazine	Thioridazine—contraindicated in patients with QTc interval >450 msec & coadministration of other drugs that cause QTc prolongation Drug interactions: Additive sedative effects with CNS depressants Decreased concentrations in the presence of carbamazepine, barbiturates, cigarette smoking Increased concentrations in the presence of quinidine, fluoxetine, & paroxetine Antihypertensive agents may produce additive hypotensive effects Haloperidol and fluphenazine—available as depot, long-acting injections
Atypical agents Aripiprazole (Abilify) Clozapine (Clozaril) Olanzapine (Zyprexa) Quetiapine (Seroquel) Risperidone (Risperdal) Ziprasidone (Geodon)	Increased risk of DM & hyperglycemia Increased incidence of mortality in dementia patients treated for behavioral disorders EPS & prolactin elevation risk highest with risperidone (dose-related) Anticholinergic effects greatest with clozapine & olanzapine Orthostatic hypotension risks greatest with clozapine, risperidone, & quetiapine Sedative risks greatest with clozapine, olanzapine, & quetiapine Weight gain greatest with clozapine & olanzapine Hypertriglyceridemia with clozapine & olanzapine Increased risk of seizures with clozapine (dose-related) Mandatory WBC monitoring with clozapine (risk of agranulocytosis)	Decreased risk of EPS, TD, and prolactin effects than with typical agents Drug interactions—all have lower levels when used concurrently with carbamazepine; additive orthostatic hypotension with trazodone Aripiprazole, risperidone—increased levels with use of paroxetine, fluoxetine, duloxetine Clozapine—increased risk of agranulocytosis with captopril, carbamazepine, sulfonamides Clozapine/olanzapine—increased levels with cimetidine, erythromycin, fluoroquinolones, fluoxetine, fluvoxamine; decreased levels with cigarette smoking Quetiapine—increased levels with ketoconazole & nefazodone; decreased levels with phenytoin Ziprasidone—contraindicated for patients with QTc prolongation or with other agents that prolong the QTc interval Risperidone—available as a depot, long-acting injectable Aripiprazole—unique mechanism with both dopamine antagonist and agonist activity

CNS, central nervous system; DM, diabetes mellitus; EPS, extrapyramidal symptoms; NMS, neuroleptic malignant syndrome; TD, tardive dyskinesia; WBC, white blood cells.

Psychiatry Pharmacy Review (continued)

Review of Antidepressants*†

Drug	Toxic/adverse effects	Comments
NDRI Bupropion (Wellbutrin)	Can cause agitation, insomnia, psychosis, confusion, weight loss	Contraindicated in patients with seizure or history of anorexia, bulimia, or MAOIs Low incidence of sexual dysfunction and minimal drug interactions Also available as SR & XL formulations
MAOI Phenelzine (Nardil) Tranylcypromine (Parnate)	Associated with weight gain, orthostatic hypotension, sexual dysfunction Hypertensive crisis may occur with tyramine-containing foods	Limited use because of drug/food interactions Contraindicated with use of other antidepressants, alcohol, meperidine, or general anesthesia
Mirtazapine (Remeron)	Low risk of sexual dysfunction May cause weight gain & increase serum cholesterol & triglycerides Rare incidence of agranulocytosis Can lower seizure threshold	Avoid use with MAOIs, clozapine, or carbamazepine Unique mechanism of action—may be beneficial for resistant cases Lower doses more sedating than higher doses
Nefazodone	Low risk of sexual dysfunction Some sedative, orthostatic hypotensive, & anticholinergic effects Liver failure	May improve symptoms of anxiety & insomnia Contraindicated with triazolam, alprazolam, MAOIs, & cisapride because nefazodone inhibits their metabolism
SSRIs Citalopram (Celexa) Escitalopram (Lexapro) Fluoxetine (Prozac) Paroxetine (Paxil) Sertraline (Zoloft)	Common: insomnia, GI upset, HA, sexual dysfunction, & tremors Rare: extrapyramidal symptoms & hyponatremia/SIADH May impair platelet aggregation & increase risk of bleeding	No significant anticholinergic effects, minimal weight gain, & relatively safe in overdose Avoid with use of MAOIs, tramadol, & migraine agents (may precipitate serotonin syndrome) Fluoxetine—long half-life & active metabolites; available in a weekly formulation Paroxetine—also available in a CR formulation
Tricyclic antidepressants Tertiary amines Amitriptyline (Elavil) Imipramine (Tofranil) Doxepin (Sinequan) Secondary amines Nortriptyline (Pamelor) Desipramine (Norpramin)	Potentially fatal in overdose Increased risk of seizures & conduction abnormalities Common anticholinergic effects, weight gain, sedation, sexual dysfunction, & orthostatic hypotension	Secondary amine agents generally have milder side effects Blood levels are useful for monitoring Contraindicated with use of MAOIs & in patients with recent myocardial infarction SSRIs may inhibit metabolism and cause toxicity
SNRIs Duloxetine (Cymbalta) Venlafaxine (Effexor)	Can cause insomnia, GI upset, HA, sexual dysfunction, sustained increase in blood pressure Minimal weight gain	No significant anticholinergic effects Avoid with use of MAOIs May be beneficial for resistant cases because of dual mechanism of action (venlafaxine at doses >200 mg/d)
Mood stabilizer Lithium (Lithobid, Eskalith)	Hand tremor, nausea, polyuria, polydipsia, diarrhea, weight gain, & hypothyroidism	Adjust for renal function Monitor trough levels Contraindicated in severe CV or renal disease, dehydration, sodium depletion Use cautiously with drugs that affect sodium—diuretics, NSAIDs, ACEIs (lithium toxicity) Caffeine use may decrease lithium levels

ACEI, angiotensin-converting enzyme inhibitor; CR, continuous release; CV, cardiovascular; GI, gastrointestinal; HA, headache; MAOI, monoamine oxidase inhibitor; NDRI, norepinephrine-dopamine reuptake inhibitor; NSAID, nonsteroidal anti-inflammatory drug; SIADH, syndrome of inappropriate antidiuretic hormone; SNRI, serotonin-norepinephrine reuptake inhibitor; SR, sustained release; SSRI, selective serotonin reuptake inhibitor; XL, extended release.

*Avoid abrupt discontinuation of use, which may cause withdrawal effects.

†All antidepressants have the potential to cause switch to mania in bipolar patients.

Psychiatry Pharmacy Review (continued)

Review of Anxiolytics

Drug	Toxic/adverse effects	Drug interactions	Comments
Benzodiazepines Alprazolam (Xanax) Chlordiazepoxide (Librium) Clonazepam (Klonopin) Clorazepate (Tranxene) Diazepam (Valium) Estazolam (ProSom) Flurazepam (Dalmane) Lorazepam (Ativan) Midazolam (Versed) Oxazepam (Serax) Quazepam (Doral) Temazepam (Restoril) Triazolam (Halcion)	CNS effects—drowsiness, fatigue, light-headedness, confusion, impairments in memory & attention, headaches Tachycardia, palpitations Nausea, diarrhea Blurred vision	Additive CNS effects with other CNS agents, including alcohol CYP3A4 inhibitors may increase concentration of many BZDs (erythromycin, clarithromycin, ketoconazole, itraconazole, diltiazem, verapamil, grapefruit) CYP3A4 inducers may decrease concentration of many BZDs (carbamazepine, rifampin)	DEA schedule IV substances Elderly may be more susceptible to adverse effects Doses should be adjusted in hepatic and renal failure Adolescents and patients with MR may have a paradoxical disinhibition effect Avoid abrupt discontinuation (withdrawal effects)
Buspirone (BuSpar)	Dizziness, nervousness, headaches, excitement, anger/hostility, confusion, nausea, diarrhea	Risk of serotonin syndrome with SSRIs and serotonin agents Contraindicated with MAOIs CYP3A4 inhibitors may increase concentration of buspirone (see above) CYP3A4 inducers may decrease concentration of buspirone (see above)	Not controlled by DEA Give with food for increased tolerability Adjust dose in hepatic/renal failure

BZD, benzodiazepine; CNS, central nervous system; DEA, Drug Enforcement Administration; MAOI, monoamine oxidase inhibitor; MR, mental retardation; SSRI, selective serotonin reuptake inhibitor.

Symptoms and Signs

Cough

Cough is an explosive expiration that clears and protects the airways. It is one of the most common presenting complaints encountered in an outpatient practice. A cough is under both voluntary and involuntary control. The latter is the cough reflex, which has five components: cough receptors, afferent nerves, cough center (medulla), efferent nerves, and effector organs. The afferent limb of the cough reflex includes the sensory branches of the trigeminal, glossopharyngeal, and vagus nerves. Inflammatory, mechanical, chemical, or thermal stimulation of the receptors and sensory pathways can trigger cough. The efferent limb includes the recurrent laryngeal and spinal nerves that innervate the expiratory and laryngotracheobronchial musculature. Lesions in the nose, ears, pharynx, larynx, bronchi, lungs, pleura, or abdominal viscera can cause cough.

- Cough is one of the most common symptoms in an outpatient practice.
- Lesions in the nose, ears, pharynx, larynx, bronchi, lungs, pleura, or abdominal viscera can cause cough.

Chronic cough is cough that lasts 3 weeks or more without an obvious cause such as cigarette smoking. The most common causes of chronic cough are postinfectious (viral, *Mycoplasma*, *Chlamydia pneumoniae* TWAR, or *Bordetella pertussis*), postnasal drip, asthma, gastroesophageal reflux, and chronic obstructive pulmonary disease (COPD). Connective tissue diseases such as giant cell arteritis, rheumatoid bronchiolitis, and Sjögren syndrome may also present with cough. Cough can be the presenting manifestation or the only manifestation of asthma. Cough is a complication in up to 10% of patients who take angiotensin-converting enzyme inhibitors (ACEIs). Angiotensin-converting enzyme receptor blockers (ARBs) are much less likely to produce cough. About one-half of the patients with persistent cough may have more than one cause for the cough. Initial diagnostic testing may include computed tomography (CT) of the sinuses and ear-nose-throat consultation, sputum analysis, methacholine inhalation challenge, 24-hour esophageal pH monitoring, or esophagography. If no chest radiographic (CXR) abnormalities are detected, bronchoscopy has a low (4%) diagnostic yield. In cough syncope, a hard cough produces increased intrathoracic pressure, which decreases cardiac output and cerebral perfusion. Other complications include rib fracture and pneumothorax.

- Postnasal drip, asthma, gastroesophageal reflux, COPD, and recent infection account for 80%-90% of cases of chronic cough.
- Cough can be the presenting manifestation or the only manifestation of asthma.
- ACEIs cause cough in 10% of patients.
- Up to 50% of patients may have more than one cause of chronic cough.
- Bronchoscopy: low diagnostic yield if CXR is normal.
- Complications of cough: cough syncope, rib fracture, pneumothorax.

Sputum

Purulent sputum is found in bronchiectasis and lung abscess. The sputum is frothy pink in pulmonary edema. Expectoration of bronchial casts, mucous plugs, or thin strings occurs in asthma, bronchopulmonary aspergillosis, and mucoid impaction syndrome. Plastic bronchitis is the formation of thick bronchial casts in asthma, bronchopulmonary aspergillosis, and other conditions. Bronchorrhea (expectoration of thin serous fluid >100 mL daily) occurs in 20% of patients with diffuse alveolar cell carcinoma. Sputum analysis may

identify eosinophils, Charcot-Leyden crystals, and Curschmann spirals, which are seen with asthma. The most important cause of broncholithiasis is histoplasmosis.

- Bronchorrhea is uncommon in diffuse alveolar cell carcinoma.
- The most common cause of broncholithiasis: histoplasmosis.
- Sputum analysis may identify eosinophils, Charcot-Leyden crystals, and Curschmann spirals in patients with asthma.

Hemoptysis

Hemoptysis is the expectoration of blood or blood-streaked sputum that originates below the level of the larynx. *Pseudohemoptysis* is expectoration of blood previously aspirated into the airways from the gastrointestinal tract, nose, or supraglottic areas. History, examination, and CXR findings are important in the diagnosis of hemoptysis. Bronchial arterial bleeding occurs in chronic bronchitis, bronchiectasis, malignancies, and broncholithiasis and with the presence of foreign bodies. Pulmonary arterial bleeding occurs in pulmonary arteriovenous malformations, fungus ball, tumors, vasculitis, pulmonary hypertension, and lung abscess. Pulmonary capillary bleeding occurs in mitral stenosis, left ventricular failure, pulmonary infarction, vasculitis, Goodpasture syndrome, and idiopathic pulmonary hemosiderosis. A common cause of streaky hemoptysis is acute exacerbation of chronic bronchitis. Airway-vessel fistula (e.g., tracheoinnominate) can cause massive hemoptysis (>200 mL/24 h). The cause of death in massive hemoptysis is asphyxiation, not exsanguination.

- History, examination, and CXR findings are important in the diagnosis of hemoptysis.
- Common cause of streaky hemoptysis: acute exacerbation of chronic bronchitis.
- The cause of death in massive hemoptysis is asphyxiation, not exsanguination.

Dyspnea

Dyspnea is the subjective awareness of breathlessness. It usually is the result of increased work of breathing. Other mechanisms include abnormal activation of respiratory centers, voluntary hyperventilation, and Cheyne-Stokes respiration. Dyspnea may be due to cardiopulmonary disease or to disorders of the skeletal (e.g., kyphoscoliosis), endocrine, metabolic, neurologic, or hematologic systems. Other causes are physiologic dyspnea of pregnancy, drugs, psychogenic, deconditioning, and obesity. The grades of severity are based on the New York Heart Association classification: grade 0, no dyspnea except with strenuous exercise; grade 1, slight dyspnea on hurrying on a level surface or walking up a hill; grade 2, dyspnea while walking on a level surface and being unable to keep up with peers and having to stop to catch breath; grade 3, dyspnea on walking 100 yards or after a few minutes and the need to stop for breath; grade 4, dyspnea on dressing or undressing or minimal exertion; and grade 5, dyspnea at rest. Recent studies have suggested that an increased serum level of brain natriuretic peptide (>100 pg/mL) differentiates dyspnea due to congestive heart failure from that due to pulmonary dysfunction.

- Disease in any organ can cause dyspnea, but the most common cause is cardiopulmonary dysfunction.
- The grades of dyspnea are defined according to the New York Heart Association classification.

A medical history, physical examination, CXR, electrocardiography (ECG), complete blood count, and pulmonary function tests (PFTs) are required for most patients. Arterial blood gases and cardiopulmonary physiologic testing may also be required. *Tachypnea* is breathing more than 20 breaths/min, and *bradypnea* is fewer than 10 breaths/min. *Orthopnea* is dyspnea in the supine posture, as in congestive heart failure, bilateral diaphragmatic paralysis, severe COPD, asthma, sleep apnea, or severe gastroesophageal reflux disease. *Trepopnea* is dyspnea in the lateral decubitus position, as occurs with tumors of the main bronchi, unilateral pleural effusion, or after pneumonectomy. *Platypnea* is dyspnea in the upright posture and is due to an increased right-to-left shunt in lung bases; it is seen in liver disease, severe lung fibrosis, or after pneumonectomy. *Paroxysmal nocturnal dyspnea* is nocturnal episodes of dyspnea, resulting in frequent waking up (associated with pulmonary edema and asthma).

Chest Pain

Pulmonary causes of chest pain are often difficult to distinguish from cardiac and other causes. Tightness of the chest and dyspnea are also described as "chest pain" by patients. Pleuritic pain is encountered in pleuritis, pleuropericarditis, pericarditis, pneumothorax, pleural effusion, mediastinitis, pulmonary embolism, pulmonary infarction, esophageal disease, aortic dissection, and chest wall trauma. Subdiaphragmatic diseases that produce chest pain include pancreatitis, cholecystitis, and colonic distention.

Cyanosis

Cyanosis, the bluish discoloration of the skin and mucous membranes that appears when the capillary content of reduced hemoglobin is greater than 5 g/dL, may be difficult to detect clinically. The causes of central cyanosis are severe hypoxia (arterial oxygen tension [PaO_2] is usually <55 mm Hg), anatomical right-to-left shunt, mild hypoxia with polycythemia ("red cyanosis"), shock, and abnormal hemoglobin level. Methemoglobinemia and sulfhemoglobinemia cause cyanosis in the setting of normal PaO_2. Certain systemic diseases, such as argyria (silver deposition) can cause blue-gray discoloration of the nails which is not cyanosis. Cherry-red flush (not cyanosis) is caused by carboxyhemoglobinemia. Anemia does not cause cyanosis. Peripheral cyanosis results from decreased peripheral perfusion with increased oxygen extraction.

- Cyanosis occurs when reduced hemoglobin is >5 g/dL.
- Central cyanosis should be distinguished from peripheral cyanosis.
- Polycythemia vera causes "red cyanosis."
- Methemoglobinemia and sulfhemoglobinemia: cyanosis in the setting of normal PaO_2.
- Cherry-red flush (not cyanosis) is caused by carboxyhemoglobinemia.

Clubbing

Clubbing is the bulbous enlargement of the distal segment of a digit (fingers or toes) caused by increased soft tissue mass. Its mechanisms are neurogenic, humoral/hormonal, hereditary, and idiopathic. The mnemonic *CLUBBING* is a reminder of common causes for clubbing including the following: **C**yanotic heart diseases and cystic fibrosis; **L**ung cancer and lung abscess; **U**lcerative colitis; **B**ronchiectasis; **B**enign mesothelioma; **I**nfective endocarditis, idiopathic pulmonary fibrosis, idiopathic, and inherited; **N**eurogenic tumors; and **G**astrointestinal diseases (e.g., cirrhosis and regional enteritis). Clubbing can be the presenting manifestation of any of the above entities, and it may precede other clinical features of lung cancer.

- Clubbing may precede other clinical features of lung cancer.
- Common causes: pulmonary fibrosis, congenital heart disease with right-to-left shunt, cystic fibrosis, and idiopathic.

Hypertrophic Pulmonary Osteoarthropathy

Hypertrophic pulmonary osteoarthropathy (HPO) is characterized by clubbing, painful periosteal hypertrophy of long bones, and symmetrical arthralgias of large joints (usually knees, elbows, and wrists). Other features include gynecomastia, fever, and an increased erythrocyte sedimentation rate (ESR). The mechanisms of HPO are neurogenic (vagal afferents), hormonal, and idiopathic. The most common cause is bronchogenic carcinoma, usually adenocarcinoma or large cell carcinoma. HPO is an early sign of pulmonary metastasis from nasopharyngeal carcinoma. Clubbing is present in 30% of patients with non–small cell lung cancer; it is more common in women than in men (40% vs. 19%). Radiographs of long bones show thickened and raised periosteum. Bone scans show increased uptake of radionuclide by the affected periosteum. If HPO does not resolve after tumor resection, treatment options include the administration of a somatostatin analogue or ipsilateral vagotomy.

- Common causes of HPO: idiopathic and adenocarcinoma or large cell carcinoma of the lung.
- Radionuclide bone scans show characteristic changes.
- Therapy: resection of the tumor, somatostatin analogue, or ipsilateral vagotomy.
- Typical clinical scenario: An adult with clubbing, pain in the long bones, symmetrical arthralgias of large joints, increased ESR, and fever.

Horner Syndrome

Horner syndrome consists of ipsilateral miosis, anhidrosis, and ptosis on the side of the lesion. It is a complication of a superior sulcus tumor (Pancoast tumor) of the lung.

- Horner syndrome: ipsilateral miosis, anhidrosis, and ptosis.
- Superior sulcus tumor (Pancoast tumor).

Other Signs and Symptoms of Pulmonary Disease

Conjunctival suffusion is seen in severe hypercarbia, superior vena cava syndrome, and conjunctival sarcoidosis. Mental obtundation is seen with hypercarbia. Asterixis is seen in severe acute or subacute hypercarbia. Telangiectasia of the skin and mucous membranes occurs in patients with pulmonary arteriovenous malformation. Skin lesions of various types occur in patients with pulmonary involvement of Langerhans cell granulomatosis (eosinophilic granuloma or histiocytosis X), tuberous sclerosis, sarcoidosis, or lung cancer.

- Asterixis is seen in severe acute or subacute hypercarbia.
- Mental obtundation is seen with hypercarbia.

History and Examination

An approach to the history and physical examination of patients with pulmonary disease is outlined in Table 22-1. Percussion and auscultation findings associated with various pulmonary conditions are also listed in Table 22-1.

Diagnostic Tests

Radiology

Plain CXR, CT, magnetic resonance imaging (MRI), pulmonary angiography, and bronchial angiography are among the tests performed in the diagnosis of chest diseases.

Plain Chest Radiography

Internists should become familiar with the interpretation of common abnormalities on a plain CXR. Even normal CXRs should be viewed so that reading CXRs becomes routine. Many of the radiographic diagnoses such as pneumothorax, pleural effusion, and lung nodule can be established by CXR. It is essential to correlate clinical and other laboratory data with CXR findings.

It is important to compare the present film with previous films, particularly in assessing the seriousness of a newly identified abnormality. A lateral CXR is of most help in identifying retrocardiac and retrodiaphragmatic abnormalities.

- Develop the habit of reading CXRs.
- Obtain earlier CXRs for comparison.
- Lateral CXRs are important in identifying retrocardiac and retrodiaphragmatic abnormalities.

The ability to identify normal radiographic anatomy is essential. A routine step-by-step method of interpretation should be developed so that subtle abnormalities are not missed (Table 22-2). Initially, the CXR should be eyeballed, without focusing on any one area or abnormality. This is to ensure that the technical aspects are adequate and the patient identification markers and the orientation of the CXR (identification of the left and right sides) are correct. Next, the extrapulmonary structures are viewed. For instance, destructive arthritis of a shoulder joint seen on a CXR may be the result of rheumatoid arthritis and may prompt the CXR reader to look for pulmonary manifestations of this disease. The absence of a breast shadow on the CXR of a female patient suggests the need to look for signs of pulmonary metastases. The visualization of a tracheostomy stoma or cannula on the CXR may indicate previous laryngeal cancer, suggesting the possibility of complications such as aspiration pneumonia

Table 22-1 History and Physical Examination of Patients With Pulmonary Disease

- History
  - Smoking
  - Occupational exposure
  - Exposure to infected persons or animals
  - Hobbies and pets
  - Family history of diseases of lung and other organs
  - Past malignancy
  - Systemic (nonpulmonary) diseases
  - Immune status (corticosteroid therapy, chemotherapy, cancer)
  - History of trauma
  - Previous chest radiography
- Examination
  - Inspection
    - Respiratory rate, hoarseness of voice
    - Respiratory rhythm (abnormal breathing pattern)
    - Accessory muscles in action (FEV_1 <30%)
    - Postural dyspnea (orthopnea, platypnea, trepopnea)
    - Intercostal retraction
    - Paradoxical motions of abdomen/diaphragm
    - Cough (type, sputum, blood)
    - Wheeze (audible with or without stethoscope)
    - Pursed lip breathing/glottic wheeze (patients with chronic obstructive pulmonary disease)
    - Cyanosis (central vs. peripheral)
    - Conjunctival suffusion (CO_2 retention)
    - Clubbing
    - Thoracic cage (e.g., anteroposterior diameter, kyphoscoliosis, pectus carinatum)
    - Trachea, deviation
    - Superior vena cava syndrome
    - Asterixis, central nervous system status
    - Cardiac impulse, jugular venous pressure, pedal edema (signs of cor pulmonale)
  - Palpation
    - Clubbing
    - Lymphadenopathy
    - Tibial tenderness (hypertrophic pulmonary osteoarthropathy)
    - Motion of thoracic cage (hand or tape measure)
    - Chest wall tenderness (costochondritis, rib fracture, pulmonary embolism)
    - Tracheal deviation, tenderness
    - Tactile (vocal) fremitus
    - Subcutaneous emphysema
    - Succussion splash (effusion, air-fluid level in thorax)
  - Percussion
    - Thoracic cage (dullness, resonance)
    - Diaphragmatic motion (normal, 5-7 cm)
    - Upper abdomen (liver)
  - Auscultation
    - Tracheal auscultation
    - Normal breath sounds
    - Bronchial breath sounds
    - Expiratory slowing
    - Crackles
    - Wheezes
    - Pleural rub
    - Mediastinal noises (mediastinal crunch)
    - Heart sounds
    - Miscellaneous (muscle tremor, etc.; see text—"Other Signs and Symptoms of Pulmonary Disease" section)

Percussion/auscultation finding	Chest expansion	Fremitus	Resonance	Breath sounds	Egophony	Bronchophony
Pleural effusion	Decreased	Decreased	Decreased	Decreased	Absent>>present	Absent>>present
Consolidation	Decreased	Increased	Decreased	Bronchial	Present	Present
Atelectasis	Decreased	Decreased	Decreased	Decreased	Absent>present	Absent>present
Pneumothorax	Variable	Decreased	Increased	Decreased	Absent	Absent

Note: The trachea is shifted ipsilaterally in atelectasis and contralaterally in effusion. Whispered pectoriloquy is present in consolidation.
FEV_1, forced expiratory volume in 1 second.

and lung metastases. Infradiaphragmatic abnormalities such as calcifications in the spleen, displacement of the gastric bubble and colon, and signs of upper abdominal surgery (metal staples or feeding tubes) may indicate the cause of a pleuropulmonary process.

- Initially look at the entire CXR.
- Look for the absence of a breast shadow, infradiaphragmatic abnormalities, and extrapulmonary skeletal abnormalities.

The skeletal thorax should be viewed to exclude rib fracture, osteolytic and other lesions of the ribs, rib notching, missing ribs, and vertebral abnormalities. Changes due to a previous thoracic surgical procedure such as coronary artery bypass, thoracotomy, lung resection, or esophageal surgery may provide clues to the pulmonary disease. Next, the intrathoracic but extrapulmonary structures such as the mediastinum (great vessels, esophagus, heart, lymph nodes, and thymus) should be assessed. The superior mediastinum should

Table 22-2 Systematic Approach to Evaluation of a Chest Radiograph

1. Check for patient identifier
2. Evaluate extrapulmonary structures
   - Destructive arthritis
   - Absence of breast shadow
   - Evidence of previous surgery: sternal wires, valvular prosthesis, surgical staples demarking previous lobectomy, etc.
   - Tracheostomy
3. Infradiaphragmatic abnormalities
4. Skeletal changes: rib fractures, notching, osteolytic lesions, etc.
5. Intrathoracic, extrapulmonary structures: mediastinum, thyroid calcification, achalasia, aortopulmonary window, hilum, calcified adenopathy
6. Pleural region: blunting, calcification
7. Lung parenchyma: infiltrates, air bronchogram, nodules, cysts, abscess, pneumothorax
8. Lateral views to evaluate retrocardiac and retrodiaphragmatic spaces

be viewed to see whether the thyroid gland extends into the thoracic cage. A calcified mass in the region of the thyroid almost always indicates a goiter. The esophagus can produce important abnormalities in the CXR. A large esophagus, as in achalasia, may mimic a mass, and a large hiatal hernia with an air-fluid level may mimic a lung abscess. The aortopulmonary window (a notch below the aortic knob on the left, just above the pulmonary artery), if obliterated, may indicate a tumor or lymphadenopathy. Right paratracheal and paramediastinal lymphadenopathy can be subtle. Hilar regions are difficult to interpret because lymphadenopathy, vascular prominence, or tumor may make the hila appear larger. The retrocardiac region may show hiatal hernia with an air-fluid level; this may be helpful in the diagnosis of reflux or aspiration.

- Rib lesions: osteolytic, expansile, notching, or absence of a rib.
- Note changes due to previous surgical procedures.
- Assess the mediastinum: the esophagus, thyroid, thymus, and great vessels.

The pleural regions should be examined for pleural effusion, pleural thickening (particularly in the apices), blunting of costophrenic angles, pleural-based lesions such as pleural plaques or masses, and pneumothorax. A lateral decubitus film may be necessary to confirm the presence of free fluid in the pleural space. An air bronchogram depicting the major airways may indicate a large tumor (cut-off of air bronchogram), deviation of airways, signs of compression or stenosis, and the relation of major airways to the esophagus. Finally, the lung parenchyma should be evaluated. Nearly 15% of the pulmonary parenchyma is located behind the heart and diaphragm; a lateral CXR is helpful in examining this region. It is important not to overinterpret increased interstitial lung markings. Oligemia of the lung fields is difficult to assess because the clarity of the film depends on the duration of the exposure of the film. Generally, bronchovascular markings should be visible throughout the lung parenchyma. The complete absence of any markings within the lung parenchyma should suggest a bulla or an air-containing cyst. Apical areas should be evaluated carefully for the presence of pleural thickening, pneumothorax, small nodules, and subtle infiltrates. If the apices cannot be visualized properly with a standard CXR, a lordotic view should be obtained.

- Look for small pneumothorax, nodules, and large airway lesions.
- Examine the apices for thickening, pneumothorax, nodules, and subtle infiltrates.
- Examine the lung parenchyma behind the heart and diaphragm.

Some of the common CXR abnormalities are depicted in Figures 22-1 through 22-26.

Fluoroscopy

Fluoroscopy is useful in localizing lesions during biopsy and aspiration procedures. It also is valuable in assessing diaphragmatic motion and in diagnosing diaphragmatic paralysis by the sniff test. Paradoxic motion of the diaphragm suggests diaphragmatic paralysis (but it is present in up to 6% of healthy subjects).

- Up to 6% of healthy subjects exhibit paradoxic diaphragmatic motion.

Computed Tomography

Standard CT is useful in the staging of lung cancer and in assessing mediastinal and hilar lesions, solitary nodules, calcification in nodules, diffuse lung disease, and pleural processes. High-resolution CT (HRCT) demonstrates characteristic findings in pulmonary bronchiectasis (HRCT has replaced bronchography for diagnosing bronchiectasis), Langerhans cell granulomatosis (nodular-cystic spaces in the upper lung fields), lymphangitic carcinomatosis (nodular interlobular septal thickening), lymphangioleiomyomatosis (well-defined cystic spaces in lung parenchyma), and idiopathic pulmonary fibrosis (subpleural honeycombing). HRCT findings in pulmonary fibrotic diseases are more than 90% accurate; honeycombing may be seen in up to 90% of patients, as compared with 30% with traditional CXR. HRCT is also helpful in diagnosing certain granulomatous lung diseases (sarcoidosis and mycobacterial infections), asbestosis, pulmonary alveolar phospholipoproteinosis, chronic eosinophilic pneumonia, and bronchiolitis obliterans. Ultrafast CT with contrast media is better than a ventilation-perfusion (V/Q) scan in detecting pulmonary emboli in the main and lobar arteries.

- HRCT demonstrates characteristic features in pulmonary Langerhans cell granulomatosis, lymphangioleiomyomatosis, idiopathic pulmonary fibrosis, and lymphangitic pulmonary metastasis.
- HRCT has replaced bronchography for diagnosing bronchiectasis.

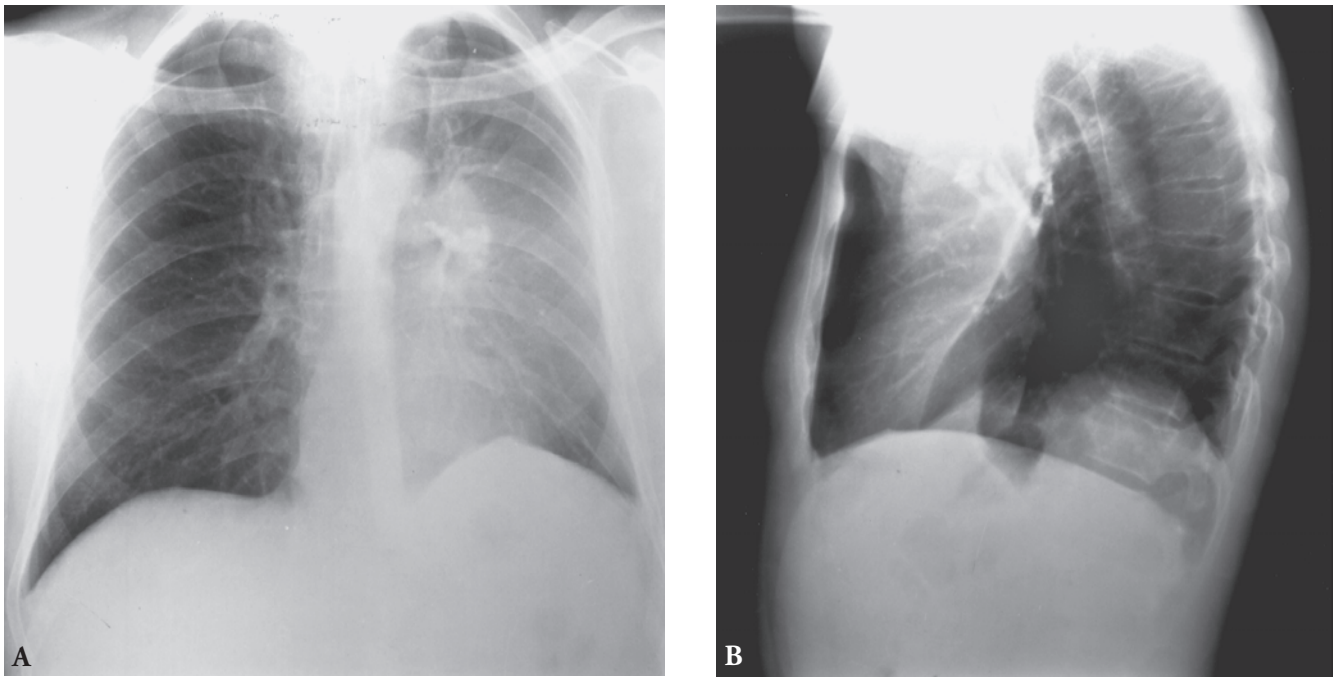

Fig. 22-1. Collapsed left upper lobe. *A*, PA CXR and, *B*, lateral CXR. The ground-glass haze over the left hemithorax is typical of a partially collapsed left upper lobe. In more than 50% of patients with collapsed lobes, loss of volume is evidenced by left hemidiaphragmatic elevation; the mediastinum is shifted to the left and the left hilus is pulled cranially. Also, the left main bronchus deviates cranially. Calcification in the left hilar mass represents an unrelated, old granulomatous infection. In *B*, the density from the left hilus down toward the anterior portion of the chest represents the partially collapsed left upper lobe. The radiolucency substernally is the right lung.

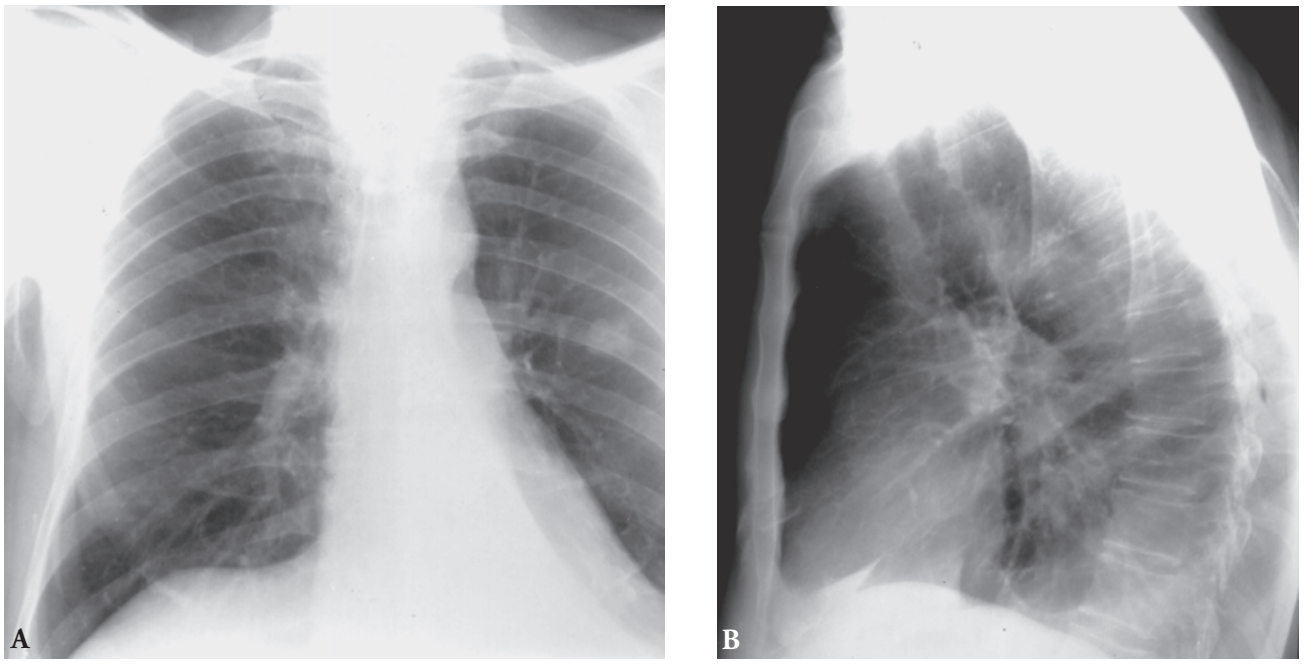

Fig. 22-2. Collapsed left lower lobe. *A*, PA CXR and, *B*, lateral CXR. Note nodule in left mid lung field plus collapsed left lower lobe, seen as a density behind the heart. This entity represents two separate primary lung cancers: synchronous bronchogenic carcinomas. Do not stop with the first evident abnormality, such as the nodule in the mid lung field, without looking carefully at all other areas. *B* demonstrates an increased density over the lower thoracic vertebrae without any obvious wedge-shaped infiltrate. Over the anterior portion of the hemidiaphragm, the small wedge-shaped infiltrate is not fluid in the left major fissure because the left major fissure is pulled away posteriorly. Instead, it is an incidental normal variant of fat pushed up into the right major fissure.

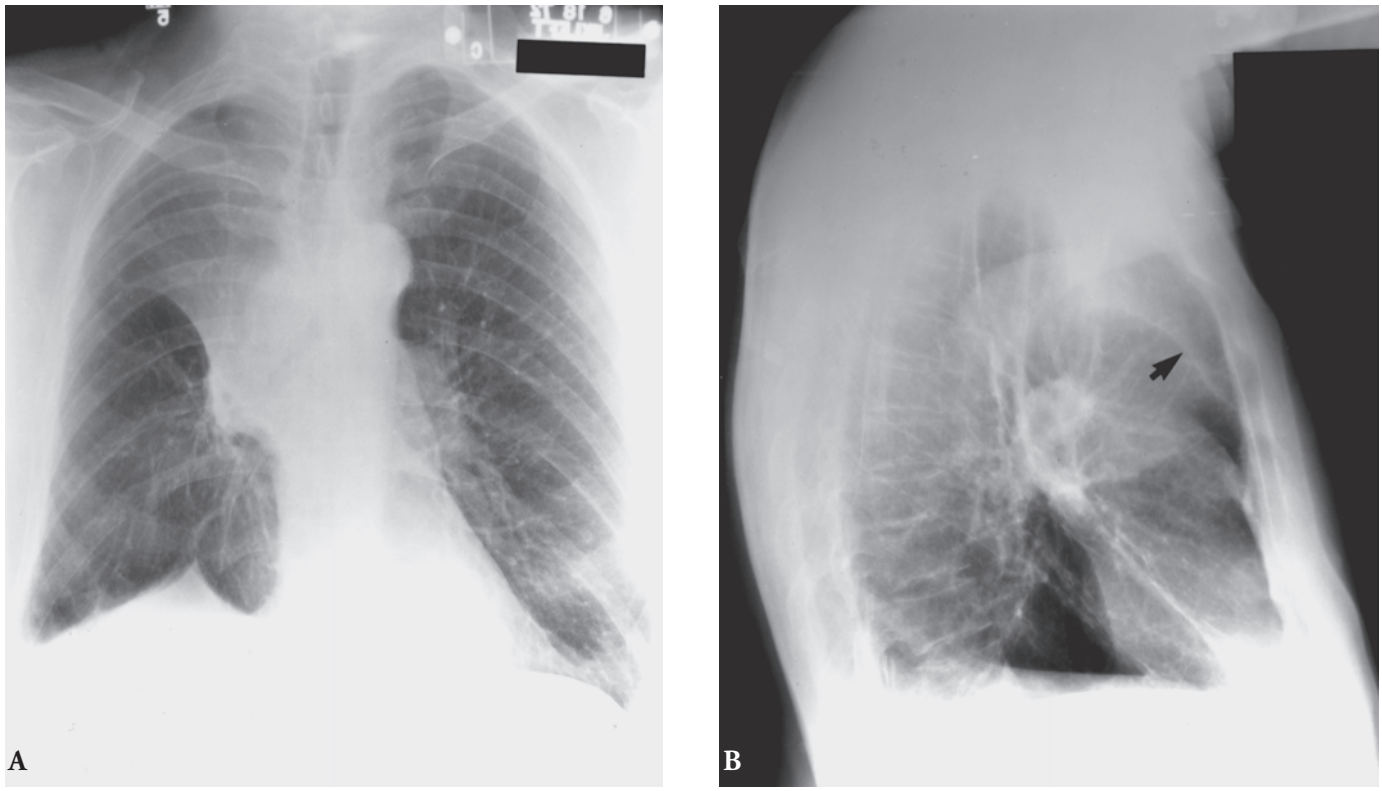

Fig. 22-3. Collapsed right upper lobe. *A*, PA CXR and, *B*, lateral CXR. *A*, This is a classic "reversed S" mass in the right hilus with partial collapse of the right upper lobe. Loss of volume is evident with the elevation of the right hemidiaphragm. In *B*, the partially collapsed right upper lobe is faintly seen in the upper anterior portion of the hemithorax (*arrow*).

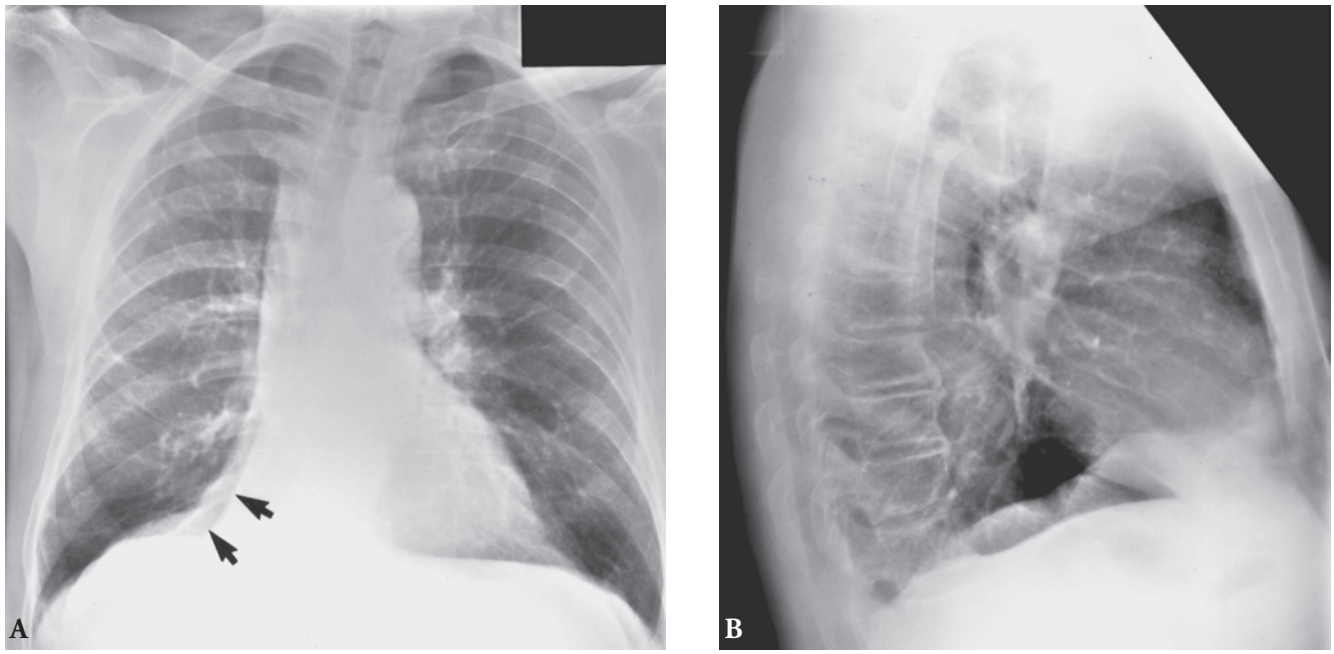

Fig. 22-4. Collapsed right lower lobe. *A*, PA CXR and, *B*, lateral CXR. *A*, This 75-year-old smoker had hemoptysis for 1.5 years; his CXR had been read as "normal" on several occasions. Note the linear density (*arrows*) projecting downward and laterally along the right border of the heart. It projects below the diaphragm and is not a normal line. Also, the right hilus is not evident; it has been pulled centrally and downward because of carcinoma obstructing the bronchus of the right lower lobe. Note the very slight shift in the mediastinum to the right, indicative of some loss of volume. *B*, In the lateral view, in spite of notable collapse of the right lower lobe, only a subtle increased density over lower thoracic vertebrae represents this collapse.

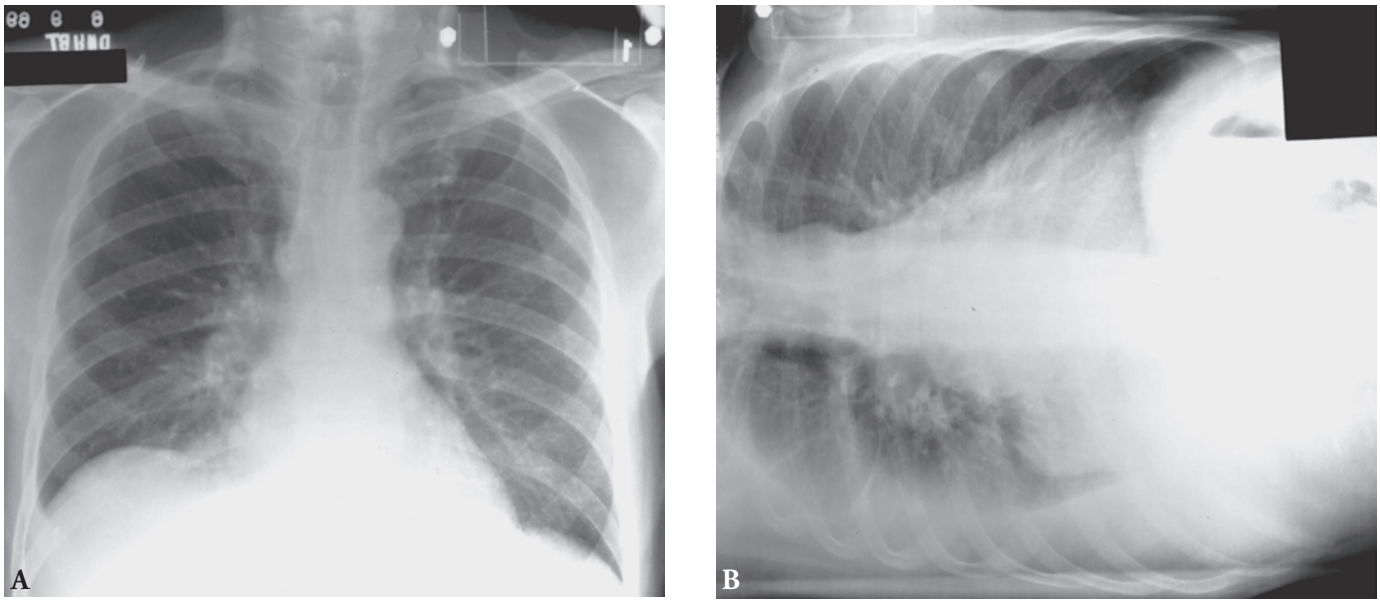

Fig. 22-5. *A*, PA CXR and, *B*, decubitus CXR. *A*, "Elevated right hemidiaphragm" that is really an infrapulmonic effusion, or subpulmonic, as seen on the decubitus film. *B*, For unknown reasons, a meniscus is not formed in some people with infrapulmonic pleural effusion. Thus, any seemingly elevated hemidiaphragm should be examined with the suspicion that it could be an infrapulmonic effusion. Subpulmonic effusions occur more frequently in patients with nephrotic syndrome. Decubitus CXR or ultrasonography would disclose the free fluid.

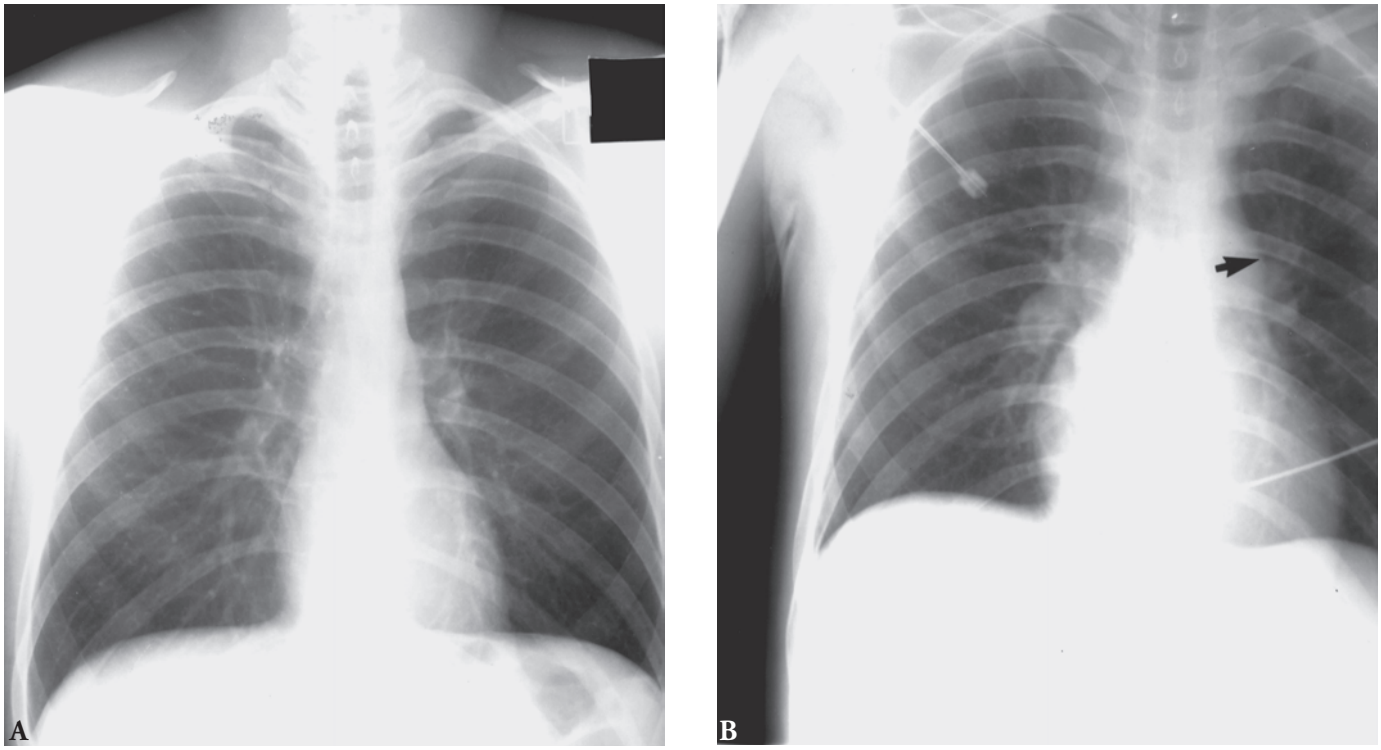

Fig. 22-6. *A*, Normal, prepulmonary embolism on PA CXR; *B*, pulmonary embolism. The CXR is read as "normal" in up to 30% of patients with angiographically proven pulmonary embolism. In comparison with *A*, *B* shows a subtle elevation of the right hemidiaphragm. In *A*, the right and left hemidiaphragms are equal. In some series, an elevated hemidiaphragm is the most common finding with acute pulmonary embolism. Also, note the plumpness of the right pulmonary artery, prominent pulmonary outflow tract on the left (*arrow*), and subtle change in cardiac diameter. At the time of CXR, this 28-year-old man was in shock from massive pulmonary emboli as a result of major soft tissue trauma produced by a motorcycle accident 7 days earlier.

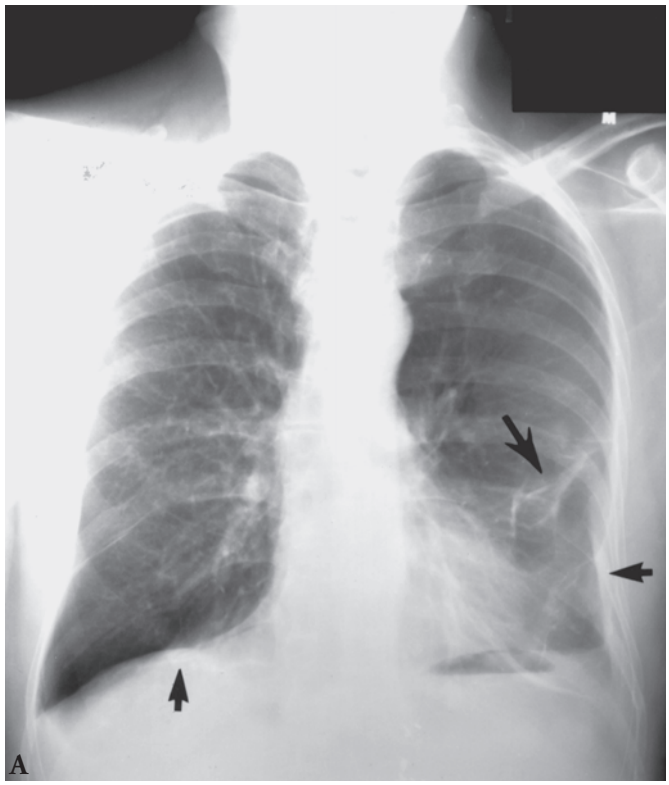

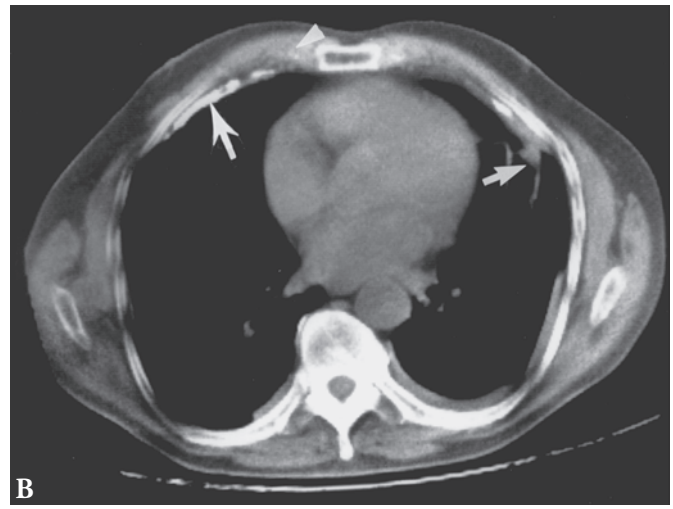

Fig. 22-7. Abnormal CXR, *A*, in a 68-year-old asymptomatic man. *Small arrows* indicate areas of pleural calcification, particularly on the right hemidiaphragm. This is a tip-off to previous asbestos exposure. The process in the left mid lung was worrisome (*large arrow*), perhaps indicating a new process such as bronchogenic carcinoma in this smoker. However, CT, *B*, disclosed rounded atelectasis (*small arrow*). The "comma" extending from this mass is characteristic of rounded atelectasis, which is the result of subacute-to-chronic pleural effusion resolving and trapping some lung as it heals. Also note pleural calcification in *B* (*large arrow*).

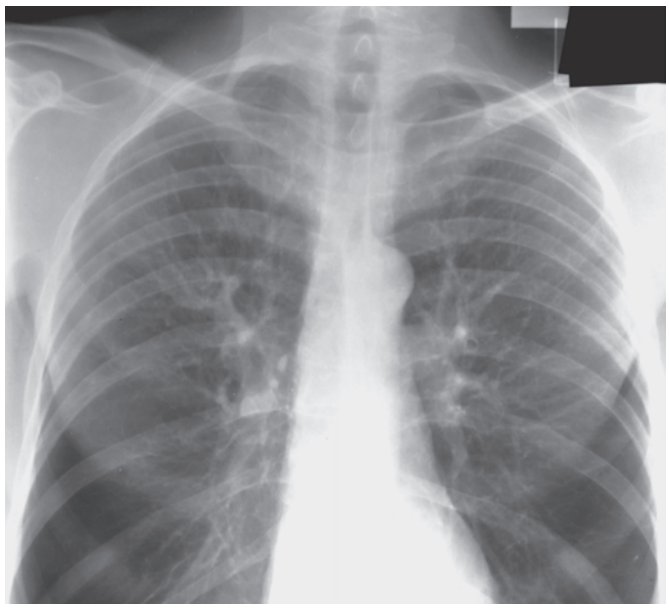

Fig. 22-8. Panlobular emphysema at the bases consistent with the diagnosis of α_1-antitrypsin deficiency. Emphysema should not be read into a CXR because all it usually represents is hyperinflation that can occur with severe asthma as well. However, in this setting, there are markedly diminished interstitial markings at the bases, with radiolucency. Also, blood flow is increased to the upper lobes because that is where most of the viable lung tissue is. Note the flattening of the hemidiaphragms from hyperinflation.

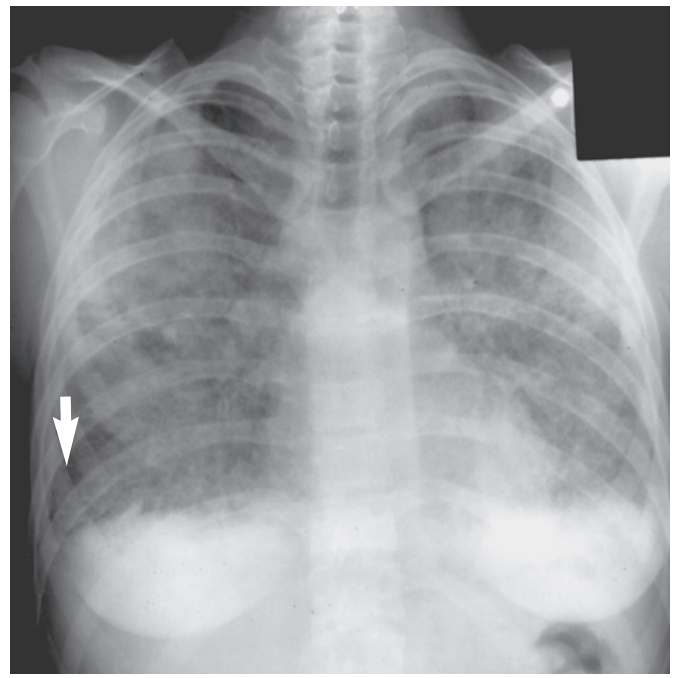

Fig. 22-9. Lymphangitic carcinoma in a 27-year-old woman with a 6-week history of progressive dyspnea and weight loss. Because of her young age, neoplasm may not be considered initially. However, the CXR features suggest it, viz., bilateral pleural effusions, Kerley B lines as evident in the right base (*arrow*), and mediastinal and hilar lymphadenopathy in addition to diffuse parenchymal infiltrate.

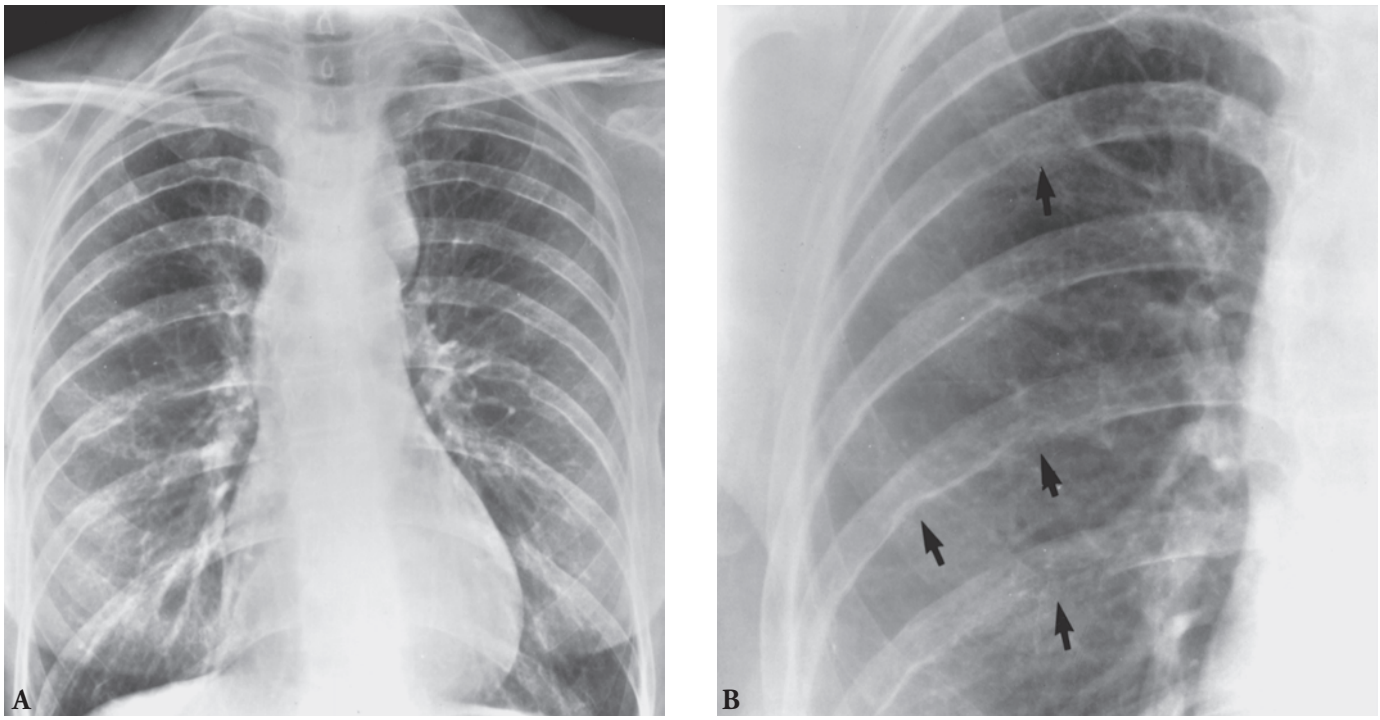

Fig. 22-10. *A* and *B*, PA CXR showing coarctation with a tortuous aorta mimicking a mediastinal mass. This occurs in about one-third of patients with coarctation. Rib notching is indicated by the *arrows* in *B*.

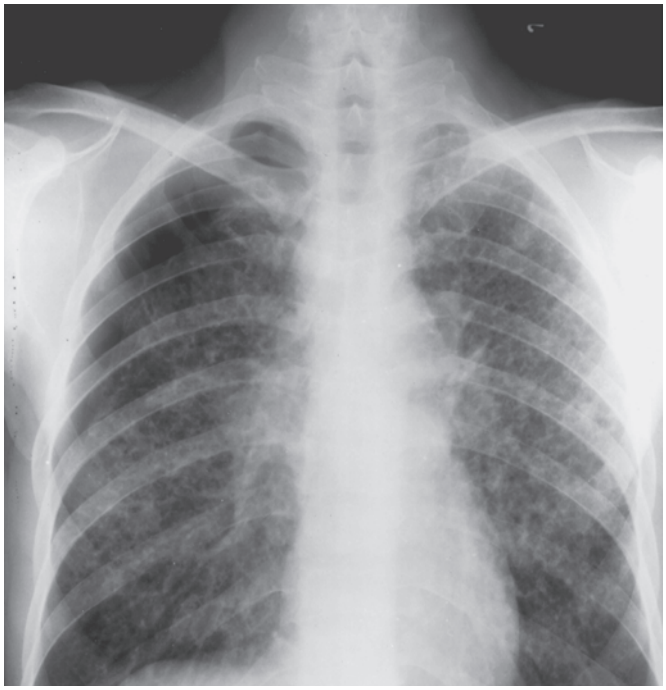

Fig. 22-11. Histiocytosis X, or eosinophilic granuloma, shows extensive change but predominantly in the upper two-thirds of the lung fields. Eventually 25% of these patients have pneumothorax, as seen on this CXR. The honeycombing, also described as microcysts, is characteristic of advanced histiocytosis X.

Fig. 22-12. Sarcoidosis in a 35-year-old patient. This CXR shows the predominant upper two-thirds parenchymal pattern seen in many patients with stage II or III sarcoidosis. The pattern can be interstitial, alveolar (which this one is predominantly), or a combination. There probably is some residual adenopathy in the hila and right paratracheal area.

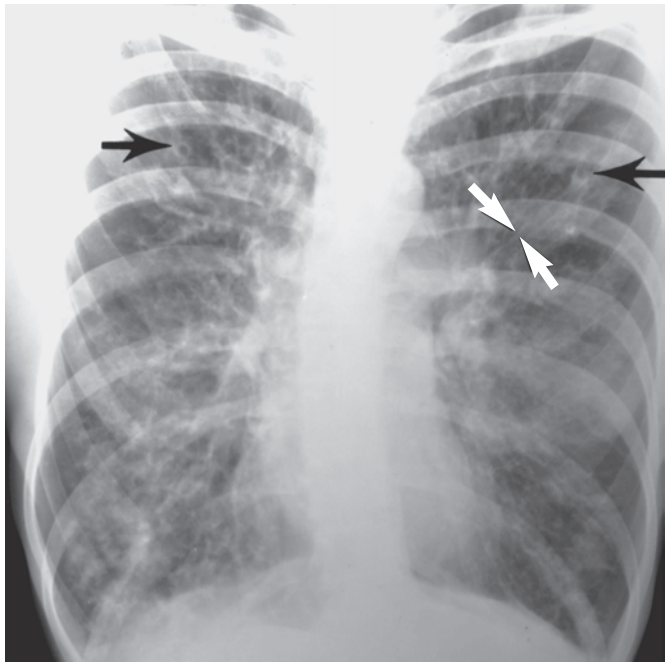

Fig. 22-13. Advanced cystic fibrosis showing hyperinflation with low-lying hemidiaphragms, bronchiectasis (*white arrows* pointing to parallel lines), and microabscesses (*black arrows*) representing small areas of pneumonitis distal to the mucous plug that has been coughed out. Cystic fibrosis almost always begins in the upper lobes.

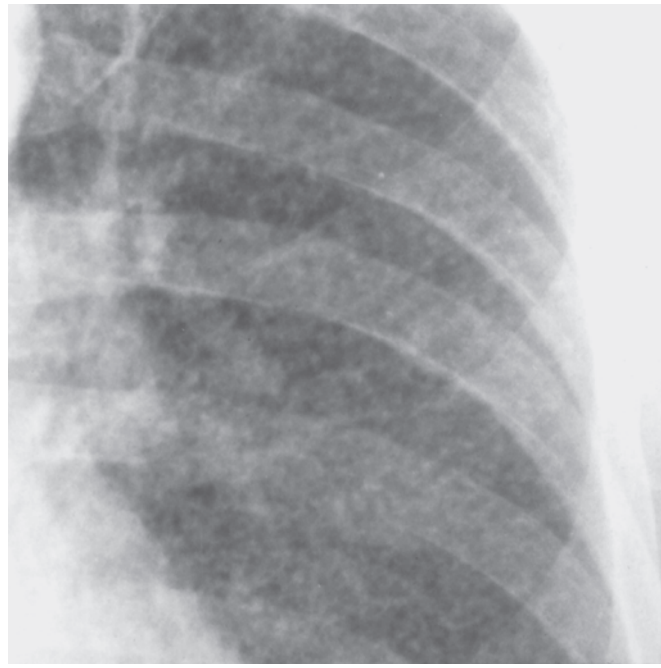

Fig. 22-14. Miliary tuberculosis. CXR shows a miliary pattern of relatively discrete micronodules, with little interstitial (linear or reticular) markings. Disseminated fungal disease has a similar appearance, as does bronchoalveolar cell carcinoma; however, these patients do not usually have the systemic manifestations of miliary tuberculosis. Other, less common differential diagnoses include lymphoma, lymphocytic interstitial pneumonitis, and pulmonary edema. *Pneumocystis carinii* pneumonia usually has a more interstitial reaction.

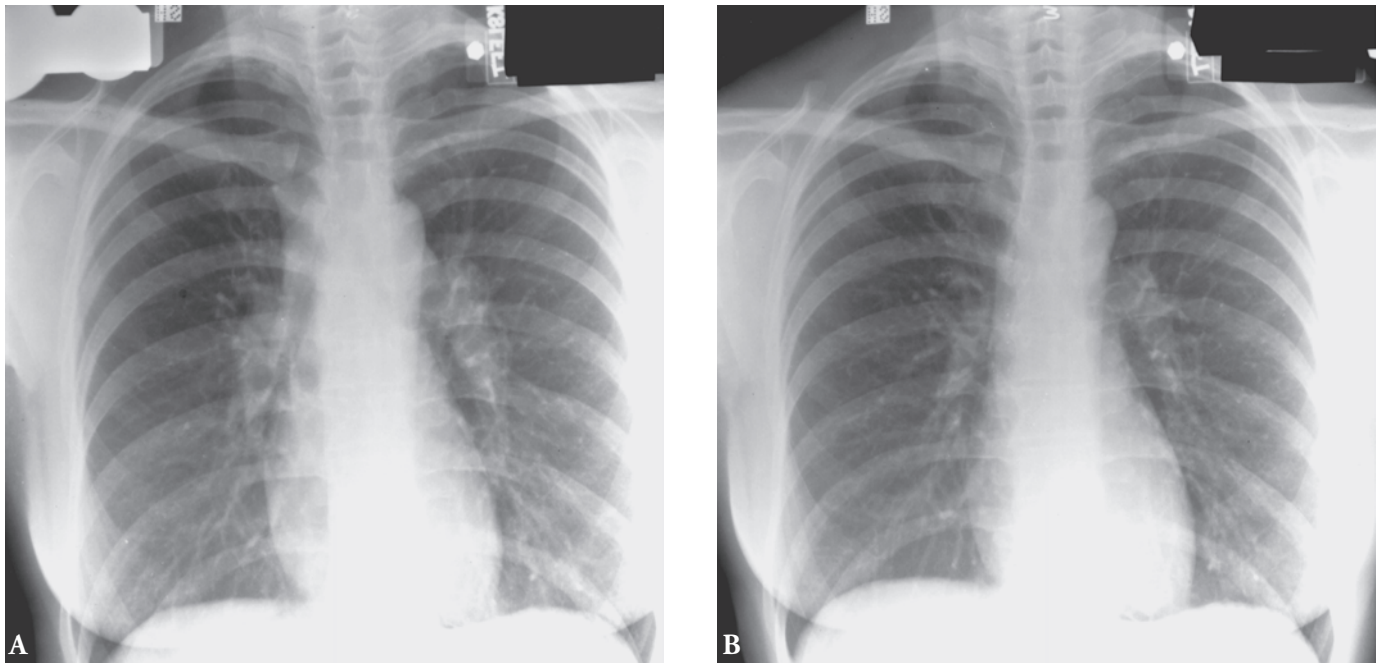

Fig. 22-15. *A*, CXR of a 30-year-old woman with stage I pulmonary sarcoidosis with subtle bilateral hilar and mediastinal adenopathy, particularly right paratracheal and left infra-aortic adenopathy. *B*, CXR 1 year later, after spontaneous regression of sarcoidosis.

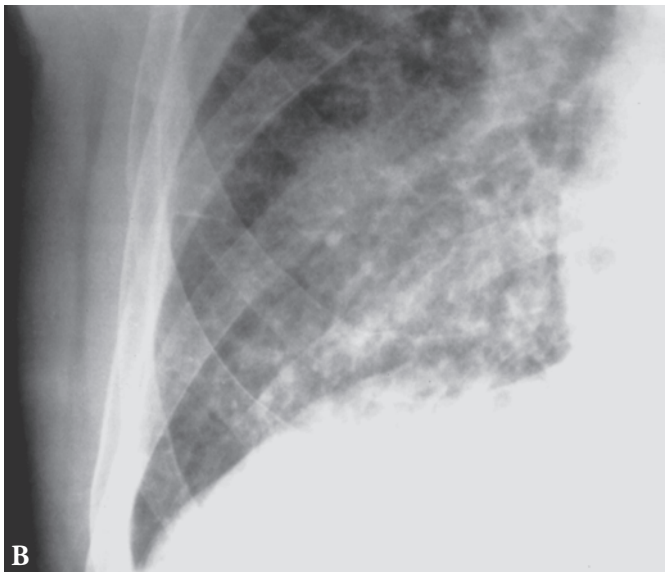

Fig. 22-16. *A* and *B*, Two examples of Kerley B lines that can be helpful in interpreting CXRs. *A*, Kerley B lines in a 75-year-old man with colon cancer. *B*, Kerley B lines are from metastatic adenocarcinoma of the colon and were a tip-off that the parenchymal process in this patient was due to metastatic carcinoma and not to a primary pulmonary process such as pulmonary fibrosis, which was the working diagnosis.

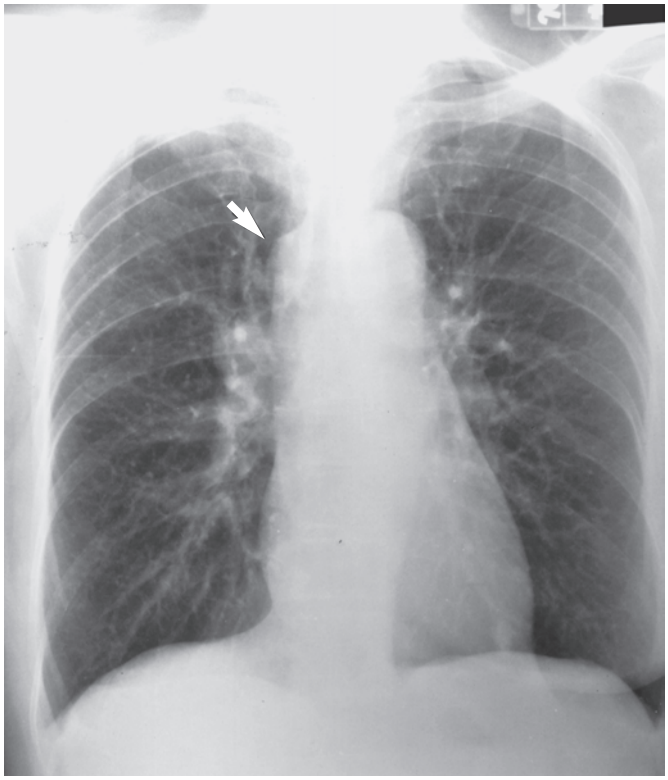

Fig. 22-17. CXR of a 55-year-old woman who had had a right mastectomy for breast carcinoma now shows subtle but definite right paratracheal (*arrow*) and right hilar adenopathy from metastatic carcinoma of the breast.

Fig. 22-18. The nodule in the left mid lung field is technically not a "solitary pulmonary nodule" because of another abnormality in the thorax that might be related to it, left infra-aortic adenopathy. The differential diagnosis would be bronchogenic carcinoma with hilar nodal metastasis or, as in this case, acute primary pulmonary histoplasmosis. Had this patient been in an area with coccidioidomycosis, it would also be included in the differential diagnosis.

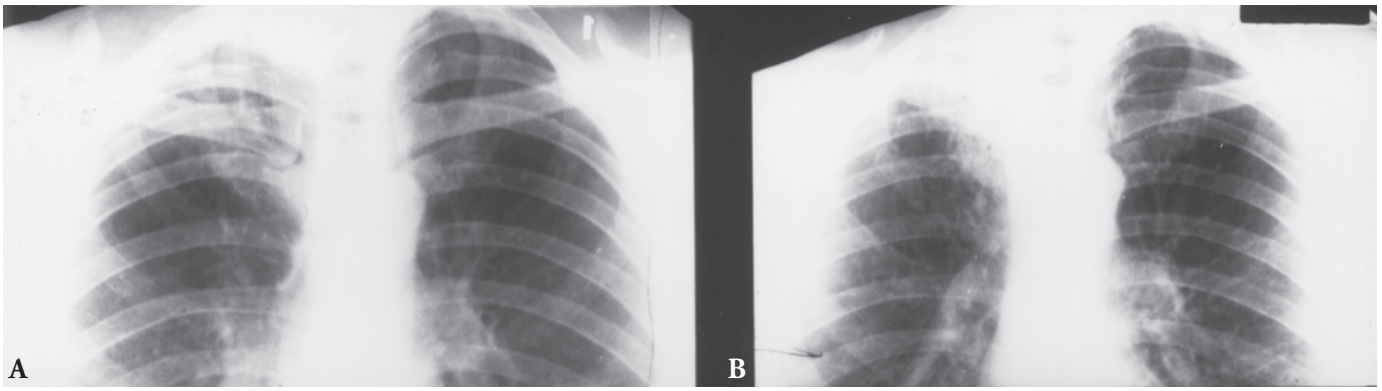

Fig. 22-19. Pancoast tumor. *A*, Subtle asymmetry at the apex of the right lung was more obvious 3.5 years later, *B*, at the time the Pancoast lesion (primary bronchogenic carcinoma) was diagnosed. The patient was symptomatic at the time of the initial CXR, with the symptoms attributed to a cervical disk.

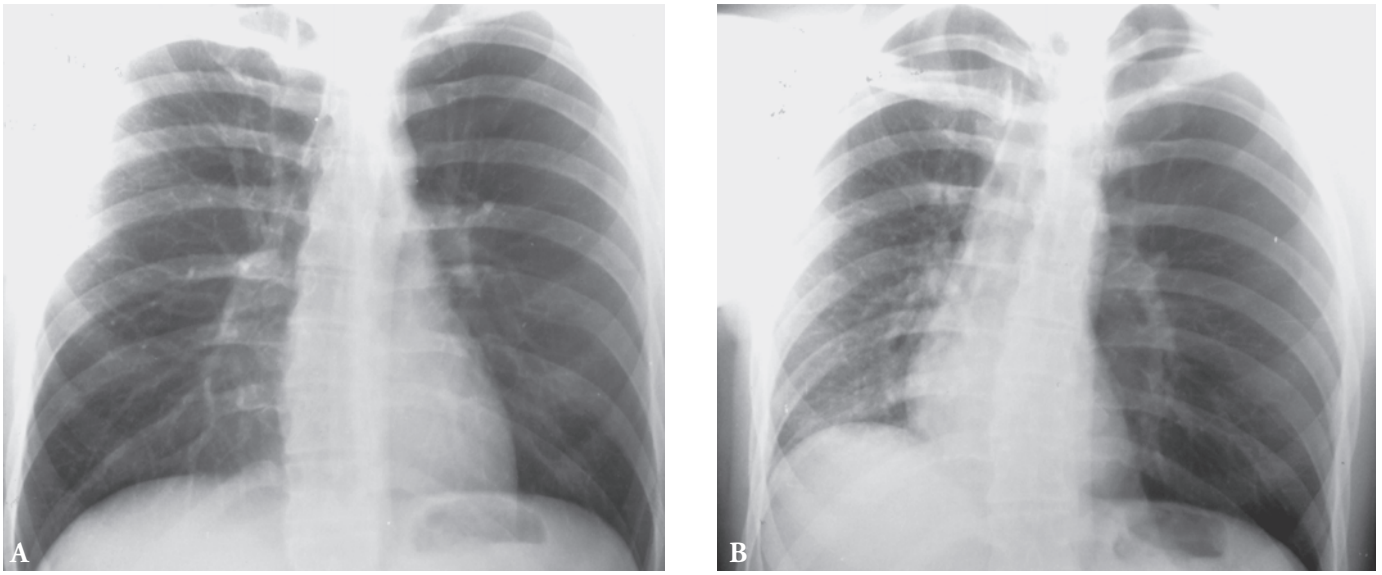

Fig. 22-20. The adage that "not all that wheezes is asthma" should be remembered every time a patient with asthma is encountered and the condition does not seem to improve. In the case shown here, *A*, wheezes were predominant over the left hemithorax. A forced expiration film, *B*, showed air trapping in the left lung. Bronchial carcinoid of the left main bronchus was diagnosed at bronchoscopy.

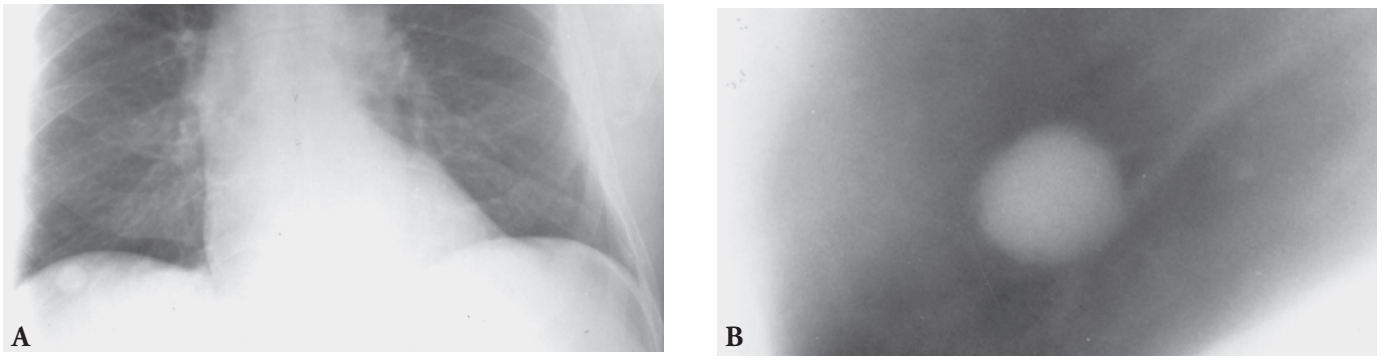

Fig. 22-21. *A*, A solitary pulmonary nodule is evident below the right hemidiaphragm, where at least 15% of the lung is obscured. *B*, Tomography shows that the nodule has a discrete border but is noncalcified. It was not present 18 months earlier. This is an adenocarcinoma.

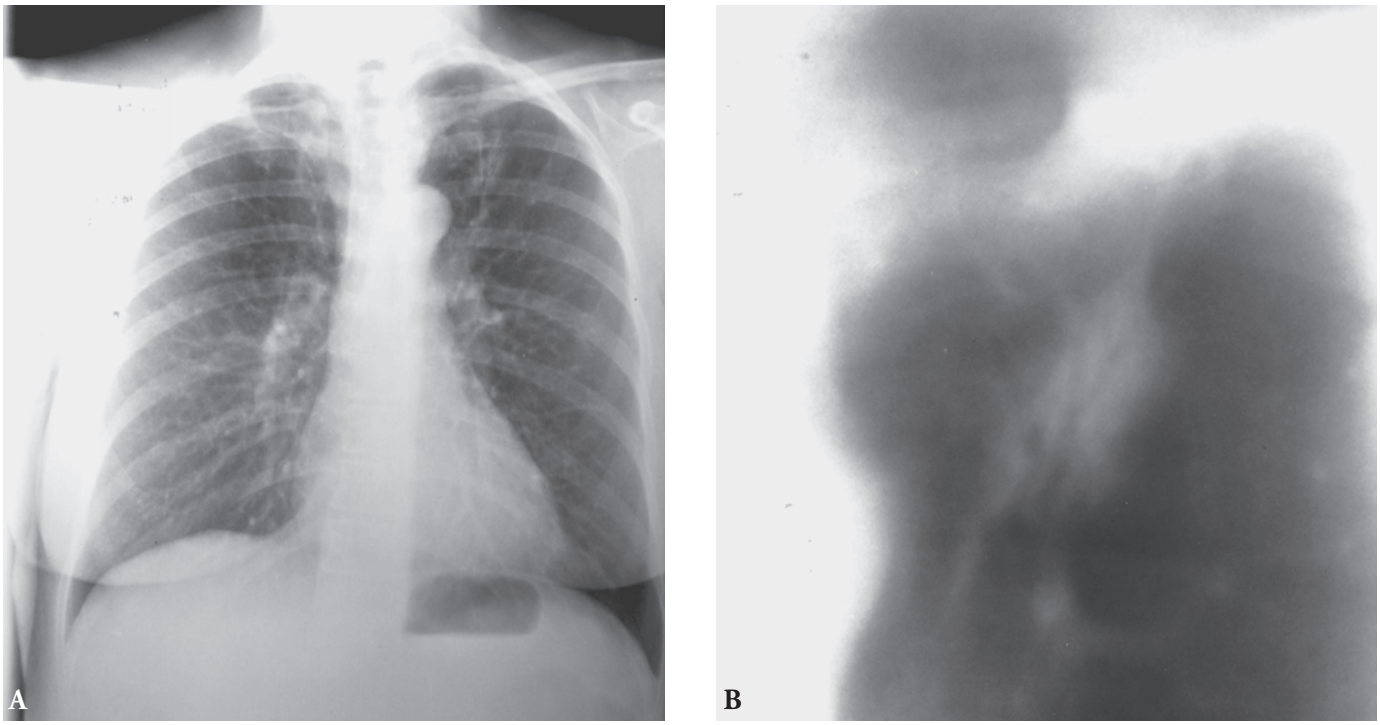

Fig. 22-22. *A*, Solitary infiltrate in the left upper lobe with air bronchogram, as evident on tomography or CT. *B*, Air bronchogram should be considered a sign of bronchoalveolar cell carcinoma or lymphoma until proved otherwise.

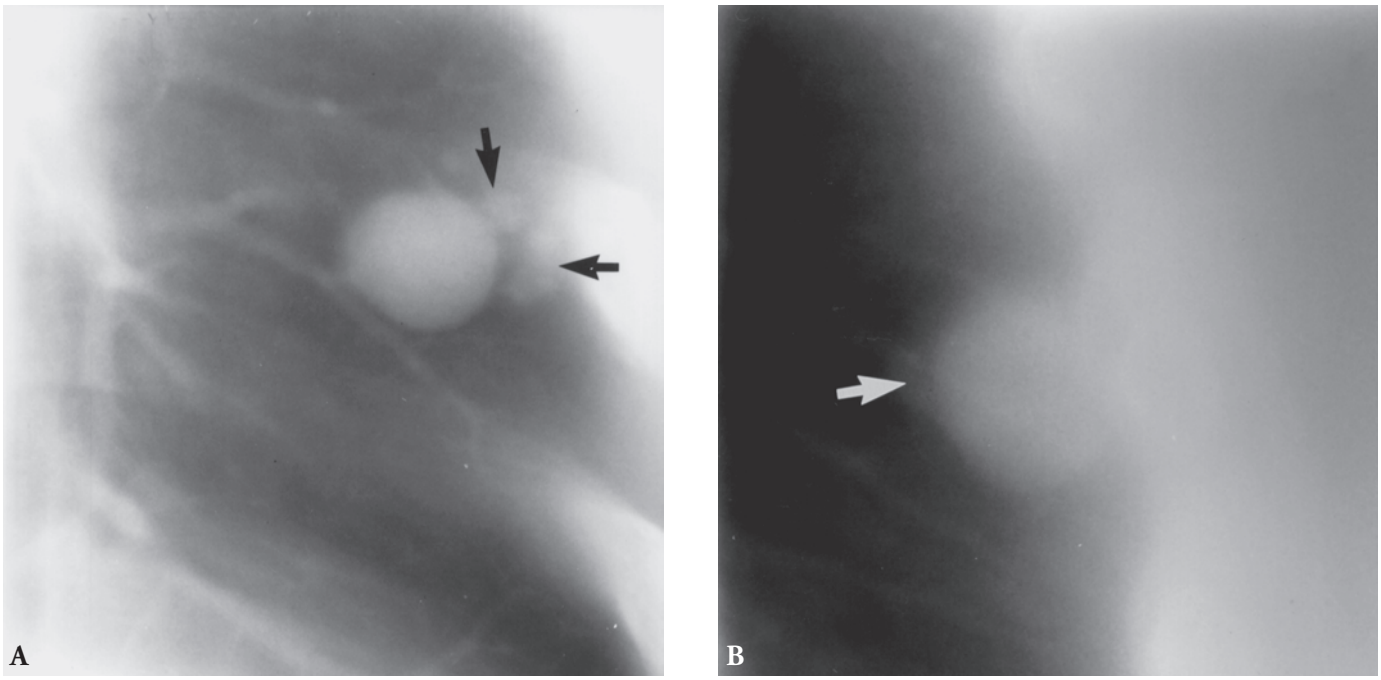

Fig. 22-23. *A* and *B*, Tomography of solitary pulmonary nodules showing satellite nodules (*arrows*). This is characteristic of granulomas.

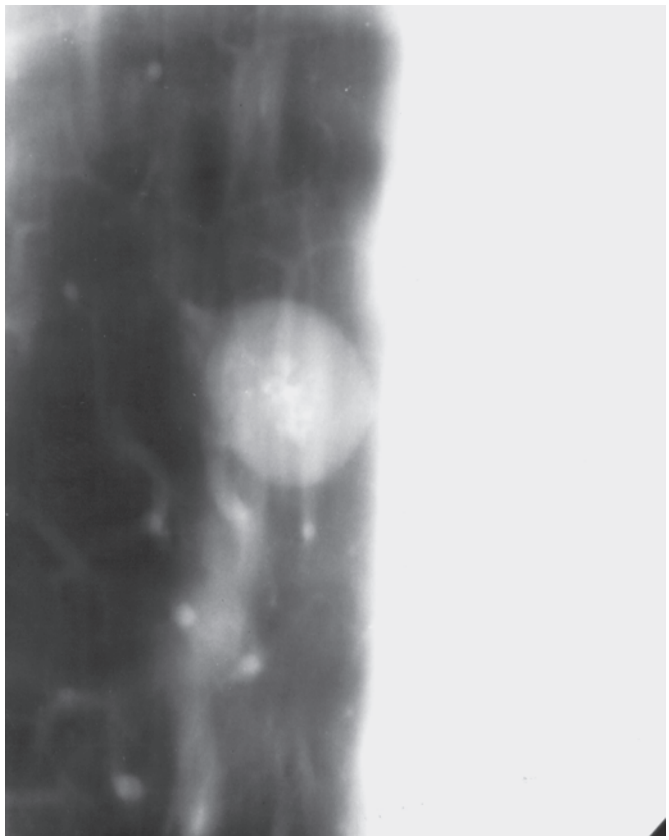

Fig. 22-24. Popcorn calcification of hamartoma. This can be seen also in granuloma and represents a benign process.

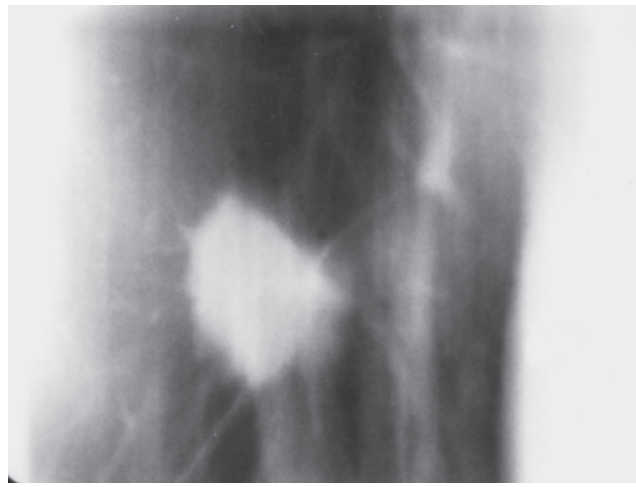

Fig. 22-25. Tomography of a solitary nodule showing spiculation, or sunburst effect, characteristic of primary bronchogenic carcinoma. Spicules represent extension of the tumor into septa. CT showed a similar appearance.

Fig. 22-26. *A* and *B*, Bull's-eye calcification characteristic of granuloma in a solitary pulmonary nodule. These nodules occasionally enlarge but even then almost never warrant removal.

- CT is helpful in the staging of lung cancer.
- CT is useful in evaluating the presence of solitary pulmonary nodule, multiple lung nodules (metastatic), and calcification in the nodule(s).
- Ultrafast CT with contrast media is better than a V/Q scan for diagnosing pulmonary emboli.

Magnetic Resonance Imaging

MRI is recommended for the initial evaluation of superior sulcus tumors (Pancoast tumor), lesions of the brachial plexus, and paraspinal masses that on CXR appear most consistent with neurogenic tumors. MRI is superior to CT in the evaluation of chest wall masses and in the search for small occult mediastinal neoplasms (e.g., ectopic parathyroid adenoma). MRI is useful when CT with contrast media is contraindicated for patients with renal failure or contrast allergy. MRI may be superior to CT in evaluating pulmonary sequestration, arteriovenous malformation, vascular structures, and tumor recurrence in patients with total pneumonectomy.

- MRI: useful for the evaluation of superior sulcus tumors and neurogenic tumors.

Pulmonary Angiography

The main indication for pulmonary angiography is to detect pulmonary emboli. However, small peripheral emboli may not be seen. Pulmonary angiography is also useful in the diagnosis of pulmonary arteriovenous fistulas and malformations, and it is usually a prerequisite if embolotherapy is planned.

- Common indications: pulmonary embolism and pulmonary arteriovenous malformations and fistulas.
- Pulmonary angiography may not detect a peripheral or tiny pulmonary embolism.

Bronchial Angiography

Bronchial angiography is used to determine whether the bronchial arteries are the cause of massive pulmonary hemorrhage or massive hemoptysis. It is a prerequisite if bronchial arterial embolotherapy is planned.

- Main indication: suspected bronchial arterial bleeding in massive hemoptysis.
- Both pulmonary and bronchial angiography may be needed for some patients who have massive hemoptysis.

Radionuclide Lung Scans

The V/Q scan is still commonly used in the diagnosis of pulmonary embolism, although CT angiography is assuming an increasingly larger diagnostic role. The likelihood of pulmonary embolism in a V/Q scan that shows "high probability" and a scan that shows "low probability" is greater than 90% and less than 5%, respectively. An "intermediate probability" scan usually is an indication for a CT scan with contrast medium or for pulmonary angiography. However, clinical suspicion of pulmonary embolism should guide the decision. The quantitative V/Q scan is used to assess unilateral and regional pulmonary function by measuring V/Q relationships in different regions of the lungs. It is indicated for patients who are poor surgical candidates for lung resection because of underlying pulmonary dysfunction. If the lung region to be resected shows minimal or no lung function on a quantitative V/Q scan, the resection is unlikely to impair further the patient's pulmonary reserve. The gallium scan is of minimal or no use in the diagnosis of diffuse lung diseases. The technetium 99m scan is useful in detecting diffuse pulmonary calcification associated with chronic hemodialysis.

- Quantitative V/Q scan is used to assess unilateral or regional pulmonary function.
- The gallium scan has no role in the diagnosis of diffuse lung disease.
- The technetium 99m lung scan detects diffuse pulmonary calcification.

Sputum Microscopy

Simple microscopy with a "wet" slide preparation of sputum is helpful in assessing the degree of sputum eosinophilia and detecting the presence of Charcot-Leyden crystals. Gram staining of sputum should be used to evaluate suspected bacterial infections. However, routine examination with Gram stain is not necessary for all patients with COPD who present with acute exacerbations. Induced sputum is helpful in identifying mycobacteria, fungi, *Pneumocystis carinii*, and malignant cells. Gastric washings are used to identify mycobacteria and fungi. Hemosiderin-laden macrophages in sputum do not always indicate alveolar hemorrhage; smokers can have a large number of hemosiderin-laden macrophages in their sputum.

- A sputum "wet prep" detects eosinophilia and Charcot-Leyden crystals.
- Induced sputum is excellent for identifying *P. carinii*.

Pulmonary Function Tests

The major indication for PFTs is dyspnea. PFT results do not diagnose lung disease, but they are used to assess the mechanical function of the respiratory system and to quantify the loss of lung function. They can be used to separate obstructive dysfunction, which indicates airflow limitation (as in asthma, bronchitis, and emphysema) from restrictive phenomena. In restrictive phenomena, the lungs cannot fully expand because of a large pleural effusion or disease in the lung parenchyma, chest wall, or diaphragm, and the volumes are diminished. A combination of obstructive and restrictive patterns is also possible (e.g., COPD with pulmonary fibrosis). Bronchoprovocation testing with agents such as methacholine is useful in detecting airway hyperresponsiveness. An increase in flow rates (>12% and 200 mL) after bronchodilator therapy suggests reversible component airway disease, although the absence of response does not preclude a clinical trial with inhaled bronchodilator medications. Results of previous PFTs are helpful in following the course of lung disease.

- Obstructive dysfunction: indicates airflow limitation, as in asthma, bronchitis, and emphysema.

- An increase in flow rates (>12% and 200 mL) after bronchodilator therapy suggests reversible component airway disease, although the absence of response does not preclude a clinical trial with inhaled bronchodilator medications.
- Restrictive dysfunction: limitation to full expansion of the lungs because of a large pleural effusion or disease in the lung parenchyma, chest wall, or diaphragm; volumes are diminished.
- A combination of obstructive and restrictive patterns is also possible (e.g., COPD with pulmonary fibrosis).

Provocation Inhalational Challenge

Provocation inhalational challenge is useful when the diagnosis of asthma or hyperreactive airway disease is uncertain. The test uses agents that elicit a bronchospastic response, for example, methacholine, carbachol, histamine, industrial irritants, exercise, isocapneic hyperventilation, and cold air. A 20% decrease in forced expiratory volume in 1 second (FEV_1) from baseline is considered a positive test result. Up to 10% of healthy subjects may exhibit a positive response to provocation challenge without symptoms of asthma. Thus, the strength of the test is in its high negative predictive value.

- A 20% decrease in FEV_1 from baseline is considered a positive test result.
- Up to 10% of healthy subjects exhibit a positive response to an inhalational challenge.
- A negative test is helpful in ruling out hyperreactive airway disease.

Interpretation of Pulmonary Function Tests

A simplified step-by-step approach to interpretation of PFT results is as follows:

1. Evaluate volumes and flows separately.
2. Total lung capacity (TLC), functional residual capacity (FRC), and residual volume (RV) indicate volumes. TLC = VC (vital capacity) + RV. Increases in TLC and RV suggest hyperinflation (asthma or COPD). If TLC and VC are decreased, consider restrictive lung disease (fibrosis) or loss of lung volume (surgery, diaphragmatic paralysis, or skeletal problems).
3. VC measured during a slow (not forced) expiration is not affected by airway collapse in COPD. Forced VC (FVC) may be low with forced expiration because of airway collapse. In healthy subjects, VC = FVC.
4. FEV_1 and forced expiratory flow (FEF) between 25% and 75% of VC ($FEF_{25\%-75\%}$) indicate flow rates. Flow rates are diminished in COPD, but smaller decreases can occur if lung volumes are low. Decreased FEV_1/FVC (<70%) indicates obstruction to airflow.
5. The maximal voluntary ventilation (MVV) test requires rapid inspiratory and expiratory maneuvers and, thus, tests airflow through major airways and muscle strength. Disproportionately reduced MVV (MVV = $FEV_1 \times 35$) may be from poor effort, variable extrathoracic obstruction, and respiratory muscle weakness. Respiratory muscle weakness can be assessed by maximal inspiratory pressure ($P_{I}max$) and maximal expiratory pressure ($P_{E}max$). Clinical features should be correlated with the results of PFTs.

- MVV is decreased in obstructive disease (i.e., MVV = $FEV_1 \times 35$).
- Respiratory muscle weakness can be assessed by maximal inspiratory pressure ($P_{I}max$) and maximal expiratory pressure ($P_{E}max$).
- Clinical features should be correlated with the results of PFTs.

6. Diffusing capacity for carbon monoxide (DLCO) is dependent on the thickness of the alveolocapillary membrane (T); the area of the alveolocapillary membrane (A), which is also influenced by number of capillaries and blood volume/flow; and the driving pressure (i.e., the difference in carbon monoxide tension between the alveolar gas and venous blood (ΔP_{CO}). Thus, DLCO is represented by the following:

$$DLCO \sim \frac{A \times \Delta P_{CO}}{T}$$

DLCO is low in anatomical emphysema (↓A), anemia (effectively ↓A), restrictive lung diseases (↓A or ↓T in pulmonary fibrosis or other interstitial lung diseases), pneumonectomy (↓A), pulmonary hypertension (effectively ↓T), and recurrent pulmonary emboli (effectively ↓A). DLCO is increased in the supine posture (↑A due to increased blood volume in upper lobes), after exercise (↑A due to increased blood volume), in polycythemia (↑A), in obesity (↑A due to increased blood volume), in left-to-right shunt (↑A), and in some patients with asthma. Isolated low DLCO (with normal results on PFT) is seen in pulmonary hypertension, multiple pulmonary emboli, combined diseases such as pulmonary fibrosis with COPD, and anemia. A decrease in hemoglobin by 1 g diminishes DLCO by 7%. Flow-volume curves are helpful to distinguish between intrathoracic and extrathoracic major airway obstructions.

- DLCO is decreased in anatomical emphysema.
- An isolated decrease in DLCO (normal volumes and flows) may occur in pulmonary hypertension, multiple pulmonary emboli, combined restrictive and obstructive lung diseases, and severe anemia.
- A decrease in hemoglobin by 1 g diminishes DLCO by 7%.
- Flow-volume curves are helpful to distinguish between intrathoracic and extrathoracic major airway obstructions.

Explanation of Table 22-3

Patient 1. Typical features of hyperinflation (high TLC and RV). VC is low because of high RV (TLC – RV = VC). Flow rates are very low, and MVV is moderately reduced. The very low DLCO suggests parenchymal damage. Without inhalational challenge, it is not possible to discern a bronchospastic component. Clinical diagnosis: moderately severe obstructive disease with severe anatomical emphysema.

Patient 2. Young nonsmoker with hyperinflation (high TLC and RV). Flow rates and MVV are also severely decreased. These suggest obstructive lung disease. The low DLCO suggests parenchymal

Table 22-3 Try to Interpret These Results of Pulmonary Function Tests Before Reading the Explanations*

$FEF_{25\%-75\%}$, forced expiratory flow between 25% and 75% of vital capacity; FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity; NS, nonsmoker; PY, pack-years of smoking.
*Values of 80%-120% of predicted are considered normal.

damage (emphysema). Clinical diagnosis: severe emphysema caused by familial deficiency of α_1-antitrypsin.

Patient 3. Flow rates and lung volumes are decreased only slightly but are within normal limits. MVV is severely decreased. In this patient, PImax and PEmax are severely decreased, suggesting muscle weakness. Clinical diagnosis: severe thyrotoxicosis with proximal muscle weakness (thyrotoxic myopathy). This pattern of PFT results can also occur in neuromuscular diseases such as amyotrophic lateral sclerosis and myasthenia gravis.

Patient 4. Slightly increased but normal TLC and slightly diminished VC. Flow rates are moderately decreased. This patient has a mild-to-moderate obstructive phenomenon. Normal DLCO excludes anatomical emphysema or other parenchymal problems. Bronchodilator testing elicited improvement in lung volumes and flow rates. Clinical diagnosis: typical asthma.

Patient 5. Mild hyperinflation (increased TLC and RV). Because these are within normal limits (80%-120% of predicted), true hyperinflation is not present. Flow rates are slightly reduced, and MVV and DLCO are normal. Bronchodilator inhalation showed no improvement. Note the slightly diminished FEV_1/FVC ratio. This together with a slightly diminished $FEF_{25\%-75\%}$ suggests a mild obstructive lung disease of a nonasthmatic type. Because of normal DLCO, marked anatomical emphysema can be excluded. Clinical diagnosis: nonasthmatic bronchitis.

Patient 6. Normal lung volumes and flow rates (80%-120% of predicted normal). A former "superathlete," he recently noted cough and chest tightness after exertion. Previous PFT results were unavailable. The following are important points: 1) In a young, otherwise healthy patient, the lung volumes and flow rates are usually above normal, more so in an athlete. 2) This patient may have had very high volumes and flow rates in the past, but without previous PFT results, no comparison can be made (if earlier PFT results were available, the new results might represent a severe decrease in pulmonary function). 3) The history suggests the possibility of exercise-induced asthma; spirometry after an exercise test showed a 28% reduction in flow rates 5 to 10 minutes after termination of exercise. 4) Note the relatively high DLCO in this patient, a phenomenon seen in patients with asthma. Clinical diagnosis: exercise-induced asthma.

Patient 7. Moderately severe decrease in lung volumes and normal flow rates. MVV is normal, but DLCO is severely diminished. These suggest severe restrictive lung disease. The slightly diminished flow rates are the result of decreased lung volumes. Clinical diagnosis: biopsy-proven idiopathic pulmonary fibrosis. Patients who have had lung resection also have low lung volumes and decreased DLCO.

Patient 8. Moderately decreased lung volumes. Flow rates are also diminished more than expected from the decreases in lung volumes. Reduction in the FEV_1/FVC ratio suggests the presence of obstructive dysfunction. MVV is also reduced, and DLCO is severely decreased. Compared with patient 7, this patient has obstructive disease plus severe restrictive lung disease. A very low DLCO suggests parenchymal disease. CXR showed bilaterally diffuse nodular interstitial changes, especially in the upper two-thirds of the lungs. Biopsy specimens of the bronchial mucosa and lung showed extensive endobronchial sarcoidosis. Clinical diagnosis: severe restrictive lung disease from parenchymal sarcoidosis and obstructive dysfunction caused by endobronchial sarcoidosis.

Patient 9. Normal lung volumes and flow rates. MVV is slightly reduced but within normal limits. DLCO is very low. PaO_2 is 56 mm Hg. Clinical diagnosis: primary pulmonary hypertension.

Patient 10. Normal lung volumes and flow rates. Previous PFT results were not available. DLCO is abnormally high. This patient was extremely obese, and all the abnormal PFT results can be

explained on the basis of this. Abnormally high DLCO is reported to be a result of increased VC. Clinical diagnosis: obesity-related pulmonary dysfunction.

Preoperative Evaluation of Lung Functions

If patients scheduled to undergo lung resection have suspected or documented lung disease, PFT results should be obtained preoperatively. A patient can tolerate pneumonectomy if the values are more than 50% of predicted for FEV_1, MVV, RV/TLC, and DLCO. If the values are less than 50% of predicted, a quantitative V/Q scan will help assess regional lung functions. Preoperative bronchodilators, chest physiotherapy, incentive spirometry, and physical conditioning decrease the risk of postoperative pulmonary complications. Increased morbidity and mortality are associated with severe COPD and arterial carbon dioxide tension ($PaCO_2$) greater than 45 mm Hg (hypoxemia is not a reliable indicator). Upper abdominal operations (gallbladder and abdominal aortic aneurysm repair) have higher rates of pulmonary complications than lower abdominal procedures.

It would also be advisable to obtain smoking history and recommend smoking cessation ideally several weeks before elective surgery. Also, screening for and treatment of sleep-related breathing disorder (especially for the postoperative period) would be beneficial.

Exercise Testing

Exercise testing can assess cardiopulmonary function. Indications for cardiopulmonary exercise testing include unexplained dyspnea or effort intolerance, ability-disability evaluation, quantification of severity of pulmonary dysfunction, differentiation of cardiac from pulmonary causes of disability, evaluation of progression of a disease process, estimation of operative risks before cardiopulmonary surgery (lung resection or heart-lung or lung transplantation), rehabilitation, and evaluation of need for supplemental oxygen. Special equipment and expertise are required to perform an optimal cardiopulmonary exercise study.

Blood Gases and Oximetry

The interpretation of blood gas abnormalities is discussed in Chapter 4, "Critical Care Medicine."

Overnight oximetry may be helpful in screening for sleep-related breathing disorders. Owing to a decrease in oxygen reserve during sleep, a brief episode of insufficient respiration can result in desaturation. Frequent oscillatory desaturations suggest sleep-related breathing disorder.

Bronchoscopy

Common diagnostic indications for bronchoscopy include persistent cough, hemoptysis, suspected cancer, lung nodule, atelectasis, diffuse lung disease, and lung infections. Diagnostic yield is low in pleural effusion. Therapeutic indications include atelectasis, retained secretions, tracheobronchial foreign bodies, airway stenosis (dilatation), and obstructive lesions (laser therapy or stent placement). Bronchoscopy is valuable in the staging of lung cancer. Complications from bronchoscopy are minimal and include bleeding from mucosal or lung biopsy, pneumothorax (from lung biopsy), and hypoxemia.

- Bronchoscopy: low diagnostic yield in pleural effusion.
- Useful in the diagnosis and staging of lung cancer.

Bronchoalveolar Lavage

Bronchoalveolar lavage (BAL) is performed by instilling 100 to 150 mL of sterile normal saline into the diseased segment(s) of the lung. The instilled saline is aspirated back via the bronchoscope. The aspirated effluent can be analyzed for cells, chemical constituents, and cultures for infectious agents. BAL in healthy subjects shows alveolar macrophages (93%±3%) and lymphocytes (7%±1%). Other types of leukocytes (neutrophils <1%) are rarely found in healthy subjects.

- BAL can quantify and identify cell morphology at the alveolar level.
- Healthy subjects: macrophages (93%), lymphocytes (7%), and neutrophils (<1%).

BAL may be helpful in diagnosing alveolar proteinosis, pulmonary Langerhans cell granulomatosis, and lymphangitic pulmonary metastasis. The CD4/CD8 ratio in BAL effluent is reversed in patients with acquired immunodeficiency syndrome (AIDS) complicated by lymphocytic interstitial pneumonitis and in many patients with hypersensitivity pneumonitis. BAL is extremely helpful in the diagnosis of infections in immunocompromised hosts, *P. carinii* infection, tuberculosis, mycoses, and other infections. BAL has a limited role in the diagnosis of sarcoidosis and idiopathic pulmonary fibrosis. It is diagnostic in more than 60% of patients with pulmonary lymphangitic carcinomatosis.

- BAL is helpful in diagnosing opportunistic lung infections.
- BAL has a limited role in the diagnosis of sarcoidosis and idiopathic pulmonary fibrosis.
- BAL is diagnostic in >60% of patients with pulmonary lymphangitic carcinomatosis.

Lung Biopsy

Lung biopsy can be performed via bronchoscopy, thoracoscopy, or thoracotomy. The indications for lung biopsy in diffuse lung disease should be based on the clinical features, treatment planned, and risks from biopsy and from treatment without a pathologic diagnosis. Bronchoscopic lung biopsy can provide a diagnostic yield of up to 80% to 90% in sarcoidosis, pulmonary Langerhans cell granulomatosis, eosinophilic pneumonitis, lymphangioleiomyomatosis, infections, pulmonary alveolar proteinosis, lymphangitic carcinomatosis, drug-induced lung disease, and hypersensitivity pneumonitis, especially when performed in combination with special stains. The major complications after bronchoscopic lung biopsy are pneumothorax (<2%) and hemorrhage (<3%).

Obstructive Lung Diseases

A common pathophysiologic feature of obstructive lung diseases is the obstruction to flow of air. Obstructive lung diseases include emphysema, bronchitis, asthma, bronchiectasis, cystic fibrosis, bronchiolitis, bullous lung disease, and airway stenosis. The three most

prevalent obstructive lung diseases are emphysema, chronic bronchitis, and asthma; they affect at least 25 to 30 million people in the United States. The salient features of these diseases are compared in Table 22-4. COPD represents the fourth leading cause of chronic morbidity and mortality in the United States. The current working definition of COPD is a disease state characterized by airflow limitation that is not fully reversible. This implies that asthma, which is considered fully reversible (at least in its early stages), is separate from COPD. Although there is airway inflammation in both diseases, the inflammation characteristics of COPD appear to be different from those of asthma. In some instances, however, the two diseases can coexist. A classification of the severity of COPD has been proposed and should guide management at various stages of the disease (Table 22-5).

Etiology

Tobacco smoking is the major cause of COPD. Nearly 10% to 20% of smokers exhibit an accelerated rate of decrease in FEV_1. This decrease is proportional to the number of pack-years of smoking. Smokers have 10 times the risk of nonsmokers of dying of COPD. Pipe and cigar smokers have between 1.5 and 3 times the risk of nonsmokers. Smoking increases the risk of developing COPD in persons who have α_1-antitrypsin deficiency. Smokers have an increased incidence of COPD, atherosclerosis, abdominal aortic aneurysm, and carcinoma of the lung, larynx, esophagus, and bladder. Diseases associated with or aggravated by smoking include asthma, some forms of interstitial lung diseases, calcification of pleural plaques in asbestosis, pulmonary alveolar phospholipoproteinosis, pulmonary Langerhans cell granulomatosis, and lung hemorrhage in Goodpasture syndrome. Sidestream tobacco exposure (secondhand smoke) is also carcinogenic. Other increased risks (particularly in children) include infections of the lower respiratory tract, fluid collection in the middle ear, decreased lung function, increased severity of preexistent asthma, and increased risk of asthma.

- Nearly 10%-20% of smokers exhibit an accelerated rate of decrease in FEV_1.
- Pulmonary Langerhans cell granulomatosis and pulmonary alveolar proteinosis are more common in smokers.
- Sidestream smoke is also carcinogenic.

Air pollution caused by oxidants, oxides of nitrogen, hydrocarbons, and sulfur dioxide has an important role in exacerbating COPD. Occupational exposures, heredity (α_1-antitrypsin deficiency), infections, allergy (in asthma), and other factors are also involved in the etiology of COPD.

Pathology

Obstruction to airflow in COPD can result from damage of lung tissue by mucus hypersecretion and hypertrophy, airway narrowing (bronchospasm) and fibrosis, destruction of lung parenchyma, and pulmonary vascular changes. The premature collapse of airways leads

Table 22-4 Salient Differential Features of Bronchial Asthma, Chronic Bronchitis, and Emphysema*

Differential feature	Bronchial asthma	Chronic bronchitis	Emphysema
Onset	70% <30 y old	≥50 y old	≥60 y old
Cigarette smoking	0	++++	++++
Pattern	Paroxysmal	Chronic, progressive	Chronic, progressive
Dyspnea	0 to ++++	+ to ++++	+++ to ++++
Cough	0 to +++	++ to ++++	+ to +++
Sputum	0 to ++	+++	+ to ++
Atopy	50% (adult)	15%	15%
Infections	↑ Symptoms	↑↑↑ Symptoms	↑ Symptoms
Chest radiograph	Usually normal	↑ Marking	Hyperinflation
$PaCO_2$	Normal or ↓ in attack	↑	Normal or ↑
PaO_2	Normal or ↓ in attack	Low	Low
DLCO	Normal	Normal or slight ↓	↓
FEV_1, %	↓↓ in attack or normal	↓↓	↓↓
Total lung capacity	Normal or ↑ in attack	Normal or slight ↑	↑↑↑
Residual volume	Normal or ↑ in attack	Normal or slight ↑	↑↑↑
Cor pulmonale	Rare	Common	Rare
Hematocrit	Normal	Normal or ↑	Normal or ↑

*↑ indicates increase; ↓, decrease; ↑↑, increased more; ↓↓, decreased more; ↑↑↑, increased greatly; ↓↓↓, decreased greatly; +, present; ++, bothersome; +++, major problem; ++++, significant problem; DLCO, diffusion capacity:total lung capacity ratio; and FEV_1, %, percentage of vital capacity expired in 1 second.

Table 22-5 Practical Aspects of Managing Chronic Obstructive Pulmonary Disease (COPD)

Steps in management
Identify the type of COPD
Identify pathophysiology
Assess lung dysfunction
Eliminate causative/exacerbating factors
Aim drug therapy at underlying pathophysiology
Anticipate and treat complications
Enroll in a rehabilitation program
Educate patient and family
Stepped care approach
Mild COPD (FEV_1/FVC <70%, FEV_1 ≥80% of predicted)
Short activity bronchodilators as needed
Moderate COPD
IIA (FEV_1/FVC <70%, 50% ≤FEV_1 <80% of predicted)
Scheduled use of bronchodilators with/without inhaled steroids if marked symptoms and lung function response, rehabilitation
IIB (FEV_1/FVC <70%, 30% ≤FEV_1 <50% of predicted)
Scheduled use of bronchodilators with/without inhaled steroids if repeated exacerbations or lung function response, rehabilitation
Severe COPD (FEV_1/FVC <70%, FEV_1 <30% of predicted or presence of respiratory failure or right heart failure)
Regular use of bronchodilators with or without inhaled steroids, rehabilitation, long-term oxygen if respiratory failure

FEV_1, forced expiratory volume in 1 second; FVC, forced vital capacity.

to air-trapping and hyperinflation of the lungs (barrel chest). Bronchospasm in susceptible persons occurs from increased bronchomotor tone in the smooth muscles of the airways. Bronchospasm can occur as a result of many underlying complex mechanisms mediated by the vagus nerve, extrinsic allergens, release of intrinsic chemicals, external physical and chemical injury, hypothermia of airways, and other factors. Mucous gland hypertrophy occurs in chronic bronchitis, asthma, and other airway diseases as a result of direct or indirect stimulation of mucous glands. Increased bronchomotor tone can be elicited by the provocation inhalational challenge (see above). Histologically, centrilobular emphysema is the most common type of COPD and usually starts in the upper lobes. The panlobular type usually starts in the lower lobes and is often seen in COPD associated with α_1-antitrypsin deficiency.

- Causes of airway obstruction: expiratory collapse of airways, bronchospasm, mucosal inflammation, pulmonary vascular changes, and mucous gland hypertrophy.
- Upper lobe centrilobular emphysema is the most common type of emphysema in susceptible smokers.
- Lower lobe panlobular emphysema is the usual pattern in patients with α_1-antitrypsin deficiency.

Physiology

Decreased flow rates are characteristic of COPD. Lung compliance is increased in emphysema, and elastic recoil of the lung is decreased (the opposite occurs in restrictive lung disease). DLCO is diminished in emphysema (as well as in most restrictive lung diseases). Hyperexpansion is manifested by increased total lung capacity and residual volume. As COPD progresses, continued parenchymal destruction and pulmonary vascular abnormalities result in hypoxemia, which eventually may progress to hypercapnia.

- Lung compliance is increased in emphysema (decreased in restrictive lung disease).

Emphysema

Emphysema, a pathology term, is characterized by enlargement of the airspaces distal to the terminal bronchioles and destruction of the alveolar walls. This entity describes only one of several structural abnormalities present in patients with COPD. CT of the lungs is excellent for documenting emphysema and bullous lung disease. Severe weight loss is a relatively common finding in severe emphysema. Carbon dioxide retention does not occur until late in the disease.

Bullous Lung Disease

Small apical bullae are present in many healthy persons. Bullous lung disease can be congenital or acquired. Bullous changes may be seen in Marfan and Ehlers-Danlos syndromes, burned-out sarcoidosis, and cadmium exposure. Panlobular emphysema may look like a bulla. Lack of communication with bronchi may cause air-trapping. Complications include pneumothorax, COPD, infection and formation of lung abscess, bleeding into a bulla, and compression of adjacent normal lung. Surgical therapy may improve lung function by 5% to 10% in 10% to 15% of patients. The incidence of lung cancer is increased in patients with bullous emphysema.

- Panlobular emphysema may look like a bulla.
- Bullous changes may be seen in Marfan and Ehlers-Danlos syndromes, burned-out sarcoidosis, and cadmium exposure.
- Bullous lung disease is associated with an increased risk of lung cancer.

α_1-Antitrypsin Deficiency

The synthesis of α_1-antitrypsin, a secretory glycoprotein, by hepatocytes is determined by the α_1-antitrypsin gene on chromosome 14. α_1-Antitrypsin inhibits many proteolytic enzymes and, thus, protects the lungs from destructive emphysema. α_1-Antitrypsin deficiency is an autosomal recessive disease; the phenotypes are normal (P_IMM), heterozygote (P_IMZ), homozygote (P_IZZ), and null (P_INull). Other phenotypes with either no increased risk or a slightly increased risk of disease are P_ISS and P_ISZ, respectively. The threshold for disease is set at a plasma α_1-antitrypsin level of less than 11

μmol/L (normal, 20-53 mmol/L). The prevalence of P_IZZ in the United States is 1:1,670 to 1:5,097. Up to 10% of patients with P_IZZ α_1-antitrypsin deficiency do not develop lung disease. Up to 95% of those with the P_IZZ phenotype may have an unrecognized deficiency because they are asymptomatic or the disease is unrecognized. In nonsmoking P_IZZ persons, lung function decreases with increasing age, especially after age 50. Men are at greater risk of deterioration of lung function than women. Smoking hastens the onset of emphysema. Signs and symptoms may appear during the third or fourth decade of life. Features include basal emphysema on CXR, absence of α_1-globulin on protein electrophoresis, patient with COPD, and family history of COPD. Hepatic cirrhosis develops in up to 3% of patients. In young patients with clinical features of COPD, consider asthma, α_1-antitrypsin deficiency, cystic fibrosis, ciliary dyskinesia, and bronchiectasis. A lack of α_1-antitrypsin seems to increase the propensity to develop asthma. Replacement therapy for symptomatic persons with the P_IZZ phenotype should be considered when the serum level of α_1-antitryptsin is less than 11 μmol/L. α_1-Antitrypsin derived from human plasma has been used as replacement therapy; minimal decreases in the rate of decrease of FEV_1 (~27 mL per year) have been observed in patients with severe emphysema.

- In α_1-antitrypsin deficiency, smoking hastens the onset of emphysema.
- Features of the disease: basal emphysema on CXR, absence of α_1-globulin on protein electrophoresis, patient with COPD, and family history of COPD.
- Hepatic cirrhosis develops in up to 3% of patients.
- In young patients with clinical features of COPD, consider asthma, α_1-antitrypsin deficiency, cystic fibrosis, ciliary dyskinesia, and bronchiectasis.
- Replacement therapy for symptomatic persons with the P_IZZ phenotype should be considered when the serum level of α_1-antitrypsin is <11 mmol/L.

Asthma

Asthma is discussed in Chapter 2, "Allergy."

Treatment of COPD

The therapeutic approach to COPD consists of reducing risk factors (e.g., smoking cessation), identifying the severity of COPD, quantification of pulmonary dysfunction and response to bronchodilator therapy, selection of appropriate bronchodilators, anticipation and appropriate treatment of complications, and initial as well as continued education of the patient and family about long-term therapy. Pulmonary rehabilitation decreases disability and improves the handicap, but PFT results show minimal improvement.

Reducing Risk Factors

Because cigarette smoking represents a major risk factor in the development and progression of COPD, smoking cessation should be discussed and programs offered to those who continue to smoke. Smoking cessation can prevent or delay the onset of symptoms in persons without disease and slow the progression in those with disease. Brief physician intervention can be effective in 5% to 10% of smokers. A formal multidisciplinary program with the use of skills training, problem solving, social support, and medications (nicotine replacement therapy or bupropion, or both) can increase smoking cessation in up to 35% of smokers. Reduction in occupational dusts, gases, and fumes and other pollutants is also important in the management of COPD.

- Smoking cessation is vital in the treatment of COPD.
- Minimize exposure to other occupational and environmental pollutants.
- Formal smoking cessation programs can be effective in up to 35% of smokers.

Bronchodilators

Bronchodilator drugs are administered to reverse bronchoconstriction (bronchospasm). They can be divided into β-adrenergic agonists (β_2-selective agonists), anticholinergics (ipratropium), adrenergic agonists (sympathomimetics), phosphodiesterase inhibitors (theophylline), mast cell inhibitors (cromolyn), leukotriene modifiers, antihistamines, anti-inflammatory agents (corticosteroids and methotrexate), and other agents (troleandomycin, gamma globulin, and mucolytics).

Short-Acting β-Adrenergic (β_2-Selective) Agonists

Short-acting β-adrenergic agonists are the most commonly used bronchodilators. They include albuterol, bitolterol, metaproterenol, pirbuterol, and terbutaline. They produce bronchodilatation by stimulating the production of cyclic adenosine monophosphate (cAMP) through activation of adenyl cyclase in the cell membrane. In most patients, single doses of these agents produce clinically important bronchodilatation within 5 minutes, a peak effect 30 to 60 minutes after inhalation, and a beneficial effect that lasts for 3 to 4 hours. The standard dosage for inhalation therapy is two inhalations four times daily. It is essential to tailor the dosage on the basis of the clinical features and the potential side effects. Adverse effects include tremor, anxiety, restlessness, tachycardia, palpitations, increased blood pressure, and cardiac arrhythmias. Prostatism may become exacerbated. Side effects are more likely in the elderly and in the presence of cardiovascular, liver, or neurologic disorders and in patients taking other medications for nonpulmonary diseases (e.g., β-blockers for cardiac disease). Rarely, paradoxic bronchospasm may result from tachyphylaxis (a rapidly decreasing response to a drug after a few doses) or from exposure to preservatives and propellants. A newer single-isomer β-agonist, levalbuterol, binds to β-adrenergic receptors with 100-fold greater affinity than albuterol. Because of the narrow therapeutic window for methylxanthines (i.e., theophylline) and the wide range of toxic effects (e.g., cardiac arrhythmias and grand mal convulsions) and drug interactions, the use of theophylline has decreased. The use of inhaled bronchodilators is preferred.

- β-Adrenergic agonists stimulate cAMP.
- Standard dosage: two inhalations four times daily.
- Side effects: tremor, anxiety, tachycardia, palpitations, increased blood pressure, cardiac arrhythmias, exacerbated prostatism.

Long-Acting β-Adrenergic (β_2-Selective) Agonists

Long-acting β-adrenergic agonists include salmeterol and formoterol. Salmeterol is more β_2-selective than isoproterenol, a short-acting bronchodilator that has approximately equal agonist activity on β_1- and β_2-adrenergic receptors. Albuterol has a β_2- to β_1-adrenergic receptor selectivity ratio of 1:1,400. Salmeterol is at least 50 times more selective for β_2-adrenergic receptors than albuterol. Salmeterol is highly lipophilic (albuterol is hydrophilic), hence the depot effect in tissues. Salmeterol has a prolonged duration of action (10-12 hours) and inhibits the release of proinflammatory and spasmogenic mediators from respiratory cells. It has a persistent effect in inhibiting histamine release for up to 20 hours, as compared with the short duration of action of isoproterenol, and albuterol. Salmeterol and formoterol are also effective in preventing exercise-induced asthma, methacholine-induced bronchospasm, and allergen challenge. The dosage of salmeterol is two inhalations (100 µg) twice daily. The dosage of formoterol is one inhalation (12 µg capsule) twice daily. The longer duration of action may aid in the management of nocturnal asthma. The side effects are similar to those of other β-adrenergic agents. However, tachyphylaxis is distinctly uncommon. Salmeterol and other β-adrenergic bronchodilators may potentiate the actions of monoamine oxidase inhibitors and tricyclic antidepressants.

- Salmeterol is lipophilic (albuterol is hydrophilic).
- Salmeterol and formoterol: long-acting bronchodilator (>12 hours).
- Salmeterol dosage: two inhalations (100 µg) twice daily.
- Formoterol dosage: one inhalation (12 µg) twice daily.

Anticholinergic Agents

Anticholinergic agents (e.g., ipratropium, tiotropium, and atropine) prevent the increase in intracellular concentration of cyclic guanosine monophosphate (cGMP) caused by the muscarinic receptors in bronchial smooth muscle. They also inhibit vagally mediated reflexes by blocking the effects of acetylcholine. Anticholinergic agents are useful in treating chronic bronchitis or asthmatic bronchitis, but they may not be as beneficial in pure emphysema. Ipratropium is a synthetic quaternary ammonium congener of atropine. As a single agent, it is only modestly effective in the management of acute or chronic airway disease. Ipratropium prevents bronchoconstriction caused by cholinergic agents such as methacholine and carbachol. It does not protect against bronchoconstriction produced by tobacco smoke, citric acid, sulfur dioxide, or carbon dust. Allergen-induced bronchospasm also responds poorly to ipratropium therapy. Ipratropium has no effect on mucus production, mucus transport, or ciliary activities. The usual dosage is two inhalations four times daily. The duration of action is 3 to 5 hours. No more than 12 inhalations should be permitted in 24 hours. Side effects include nervousness, headache, gastrointestinal tract upset, dry mouth, and cough. The drug may aggravate narrow-angle glaucoma, prostatic hypertrophy, and bladder neck obstruction.

Tiotropium has been shown to improve bronchodilation in patients with asthma or COPD. It appears to be more effective than ipratropium in asthma and in reducing the number of COPD exacerbations. The usual dosage is one inhalation (18 µg capsule) once daily.

- Ipratropium inhibits vagally mediated reflexes by blocking the effects of acetylcholine.
- It has minimal or no benefit in pure emphysema.
- It is only modestly effective if used alone.
- Tiotropium appears to be more effective than ipratropium in asthma and COPD.

Phosphodiesterase Inhibitors

Theophylline (methylxanthine) is the main phosphodiesterase inhibitor. The proposed mechanisms of action include inhibition of cGMP, augmentation of adrenergic terminal output to airway smooth muscle, adenosine receptor antagonism, and stimulation of endogenous catecholamine. The result is a decrease in free calcium levels in smooth muscle. Overall, the use of theophylline has diminished, with β-agonists being given more often in its place. Theophylline is effective in combination with β_2-agonists in the management of moderate and severe asthma. It increases the contractility of respiratory muscles in a dose-related fashion. The effects of various substances and circumstances on the clearance of theophylline are shown in Table 22-6.

- The exact mechanism of action of theophylline is unclear.
- Theophylline is effective in combination with β_2-agonists.

The recommended blood level of theophylline is 10 to 15 µg/mL. The loading dose is 6 mg/kg (range, 5-7 mg/kg); the maintenance dosage is 0.5 mg/kg per hour or 1.15 g/24 h. The normal adult dosage is usually less than 1,000 mg daily. Longer acting preparations may be given in a single dose of 300 to 600 mg. The dose should be decreased by 50% if the patient has received theophylline in the preceding 24 hours or has heart failure, severe hypoxemia, hepatic insufficiency, or seizures. Each dose should be increased by 50 to 100 mg if the therapeutic effect is suboptimal and in smokers

Table 22-6 Theophylline Clearance

Increased by	Decreased by
β-Agonists	Allopurinol
Carbamazepine	Antibiotics—macrolides, ciprofloxacin, norfloxacin, isoniazid
Dilantin	
Furosemide	
Hyperthyroidism	β-Blocker—propranolol
Ketoconazole	Caffeine
Marijuana	Cirrhosis
Phenobarbital	Congestive heart failure
Rifampin	H_2-blocker—cimetidine
Tobacco smoke	Mexiletine
	Oral contraceptives
	Viral infection

who can tolerate the increased dose. Each dose should be decreased by 50 to 100 mg if toxic effects develop or if progressive heart or liver failure develops. Tobacco smoking decreases the efficacy (half-life) of theophylline. In clinical practice, it is not necessary to measure frequently the serum levels of theophylline. The main side effects are tremor, aggravation of prostatism, tachycardia, and arrhythmias. Owing to its narrow therapeutic window, theophylline should be used with caution.

- Tobacco smoking decreases the half-life of theophylline.
- The recommended blood level is 10-15 μg/mL.
- In clinical practice, it is not necessary to measure frequently the serum levels of theophylline.

Antileukotrienes

The efficacy of antileukotrienes in the treatment of COPD is not known.

Corticosteroids

Corticosteroids have no bronchodilating effect in patients with emphysema. Patients with bronchitis, however, may benefit from the anti-inflammatory action. Systemic corticosteroid therapy in nonasthmatic COPD has a limited role; only about 15% of patients have improvement. Inhaled corticosteroids can be given in conjunction with systemic (oral) corticosteroids, especially during the weaning period of long-term or high-dose systemic (oral) corticosteroids. All inhaled corticosteroids, when given at higher doses, are associated with greater side effects and fewer benefits. The most common side effect with aerosolized corticosteroids is oral candidiasis. Inhaled corticosteroids in dosages greater than 1.5 mg per day (0.75 mg daily for fluticasone propionate) may lead to slowing of linear growth velocity in children, decrease in bone density (particularly in perimenopausal women), posterior subcapsular cataracts, or glaucoma. The use of corticosteroids, inhaled or oral, in the treatment of stable COPD is limited. A short course of oral corticosteroids may be tried for stable COPD, but studies have suggested that, unlike in patients with asthma, the response to a short course of treatment is a poor predictor of a long-term response in patients with COPD. Steroid myopathy in those receiving long-term treatment with oral corticosteroids may lead to worsening respiratory muscle function and eventually to hastened respiratory failure. Several large studies on the use of inhaled corticosteroids have suggested that their regular use may be appropriate for patients who have a documented FEV_1 response to inhaled corticosteroids or for those with moderate-to-severe COPD who have repeated exacerbations requiring oral corticosteroid therapy. A short course of corticosteroid is essential in the treatment of acute COPD exacerbation since it has been shown to reduce duration and severity of the illness.

- Oropharyngeal candidiasis is a complication of aerosolized corticosteroids.
- The use of corticosteroids in the treatment of stable COPD is limited, whereas it is very effective in the treatment of acute exacerbation of COPD.

Adjuvant Therapy

Antibiotic therapy is helpful for patients with symptoms suggestive of bacterial infection, especially during COPD exacerbations. Maintenance of good oral hydration, avoidance of tobacco smoking and other respiratory irritants, annual influenza vaccination, and prompt treatment of respiratory infections are equally important.

Oxygen

Low-flow oxygen (<2 L/min) therapy is recommended when the PaO_2 is 55 mm Hg or less, arterial oxygen saturation (SaO_2) is 88% or less, or PaO_2 is 59 mm Hg or less if there is polycythemia or clinical evidence of cor pulmonale. The lack of carbon dioxide retention should be assured before recommending oxygen. Continuous oxygen therapy is more useful than nocturnal-only treatment. The need for chronic or indefinite oxygen therapy should be reassessed after 3 months of treatment. For each liter of oxygen administered, the fraction of inhaled oxygen (FIO_2) is increased by approximately 3%. Exercise therapy (i.e., pulmonary rehabilitation) improves exercise tolerance and maximal oxygen uptake but does not improve PFT results.

- Oxygen therapy is recommended if PaO_2 is ≤55 mm Hg and/or SaO_2 is ≤88%.
- FIO_2 increases by approximately 3% for each liter of supplemental oxygen.
- An exercise program does not improve PFT results.

Practical aspects of managing COPD are outlined in Table 22-5.

Complications and Causes of Exacerbation of COPD

The complications and causes of exacerbation of COPD include viral and bacterial respiratory infections (commonly *Haemophilus influenzae*, *Moraxella catarrhalis*, and *Streptococcus pneumoniae*), cor pulmonale, myocardial infarction, cardiac arrhythmias, pneumothorax, pulmonary emboli, bronchogenic carcinoma, environmental exposure, oversedation, neglect of therapy, excessive oxygen use (suppression of hypoxemic drive and worsening V/Q mismatch), and excessive use of β_2-agonist (tachyphylaxis). Nocturnal oxygen desaturation is common in those with emphysema as are premature ventricular contractions and episodic pulmonary hypertension. A decrease in SaO_2 correlates with an increase in pulmonary artery pressure. Severe weight loss, sometimes more than 50 kg, is noted in 30% of patients with severe COPD.

- Bacterial infections in COPD are caused by *H. influenzae*, *M. catarrhalis*, and *S. pneumoniae*.
- Nocturnal oxygen desaturation is more common in those with emphysema.
- A decrease in SaO_2 correlates with an increase in pulmonary artery pressure.
- Severe weight loss is seen in 30% of patients with severe COPD (emphysema).

Other Topics in COPD

Nicotine gum and patch help maintain nicotine blood levels while a smoker tries to cope with the psychologic and other aspects of

nicotine addiction. Nearly 25% of smokers require treatment for more than 12 months to remain tobacco-free. Nicotine from gum is absorbed more slowly from the buccal mucosa and stomach than from the airways with inhaled smoke. Side effects include mucosal burning, light-headedness, nausea, stomachache, and hiccups. The patch causes a rash in a large number of patients. Use of the nicotine patch with continued smoking aggravates heart problems. Bupropion has been shown to be effective either as a single agent or in combination with nicotine replacement therapy in achieving smoking cessation. This medication is contraindicated for persons who have a seizure disorder, anorexia nervosa, or bulimia. The most common side effects of bupropion include insomnia, headache, and dry mouth.

- Nicotine gum and patch are important aspects of a tobacco cessation program.
- The simultaneous use of cigarette and nicotine products aggravates heart problems.
- Bupropion is effective in achieving smoking cessation, but its use is contraindicated for those who have a seizure or eating disorder.

Lung volume reduction surgery (resection of 20%-30% of peripheral lung parenchyma) in patients with emphysema appears to improve pulmonary function in selected individuals with COPD. The benefit is thought to be the result of regaining normal or near-normal mechanical function of the thoracic cage that was compromised by the severe hyperinflation of the lungs. However, lung volume reduction surgery is associated with increased mortality for patients whose FEV_1 is less than 20% of predicted and who have either DLCO less than 20% of predicted or homogeneous changes on chest CT. Lung transplantation is used to treat various end-stage pulmonary diseases. It does not confer a survival advantage for patients with advanced emphysema, but it may confer a survival advantage for patients with cystic fibrosis or idiopathic pulmonary fibrosis. Regardless of the underlying disease for which a transplantation is performed, the procedure improves the quality of life.

- Lung volume reduction surgery is beneficial in selected individuals with COPD.
- It is associated with increased mortality for those with severe disease.

Cystic Fibrosis

Cystic fibrosis is the most common lethal autosomal recessive disease among whites in the United States. The locus of the responsible gene is on the long arm of chromosome 7. This gene codes for cystic fibrosis transmembrane conductance regulator (CFTR), a protein that regulates the function of epithelial cell chloride channels. The most common genetic mutation is the DeltaF(508) mutation, which results in the omission of a phenylalanine residue at the regulatory site. Cystic fibrosis develops in 1 in 2,000 to 3,500 live births among whites; about 1 in 20 (2%-5%) whites is a heterozygous carrier. There is no sex predominance. Occurrence in African Americans is 1 in 15,300 and in Asian Americans, 1 in 32,100. Siblings of such a child have a 50% to 65% chance of being heterozygotes. The diagnosis is made in 80% of patients before the age of 10 years. Obstruction of exocrine glands, with the exception of sweat glands, by viscous secretions causes almost all the clinical manifestations. Mucociliary clearance is normal in patients with minimal pulmonary dysfunction and is decreased in those with obstructive phenomena.

- Cystic fibrosis: the most common lethal autosomal recessive disease among whites.
- In 20% of patients, the diagnosis is not made until the adolescent years.
- Siblings of children with cystic fibrosis have a 50%-65% chance of being heterozygotes.
- All exocrine glands, except sweat glands, are affected; this accounts for the majority of symptoms.

Up to 10% of patients with cystic fibrosis and heterozygous carriers demonstrate nonspecific airway hyperreactivity and an increased susceptibility to asthma and atopy. Because of chronic airway obstruction from viscous secretions, bacteria such as *H. influenzae*, *Staphylococcus aureus*, and *Pseudomonas aeruginosa* often colonize the airways. Also, defective CFTR protein may be responsible for the ineffective clearance of *P. aeruginosa*. Positive serologic reactions to *Aspergillus* species and *Candida albicans* occur with higher frequency in patients with cystic fibrosis than in those with asthma. Allergic bronchopulmonary aspergillosis occurs in up to 10% of patients with cystic fibrosis, and up to 57% of patients with cystic fibrosis become colonized with *Aspergillus fumigatus*.

- Up to 10% of patients with cystic fibrosis and carriers exhibit increased airway response.
- Up to 10% of patients show increased susceptibility to asthma and atopy.
- Allergic bronchopulmonary aspergillosis occurs in up to 10% of patients.
- Organisms such as *H. influenzae*, *S. aureus*, *P. aeruginosa*, and *A. fumigatus* often colonize the airways.

There is no evidence for a primary defect in sodium transport. However, the epithelial cells in cystic fibrosis are poorly permeable to chloride ions because of the defect in CFTR protein in most cases. There is a marked increase in the electrical potential difference across the nasal and tracheobronchial epithelium compared with that of healthy subjects and heterozygote relatives. The normally negative potential difference across the cell membrane becomes more negative (because of chloride impermeability) in cystic fibrosis. This leads to defects in intracellular chloride and, secondarily, to sodium homeostasis.

- No evidence for a primary defect in sodium transport.
- Because of a defect in CFTR protein, chloride ion transport is defective.
- There is a marked increase in the electrical potential difference across the nasal and tracheobronchial epithelium compared with that of healthy subjects and heterozygote relatives.

Diagnosis in adults requires at least three of the following: clinical features of cystic fibrosis, positive family history, sweat chloride >80 mEq/L, and pancreatic insufficiency. Quantitative pilocarpine iontophoresis is helpful in making the diagnosis; abnormal results on at least two tests are necessary for the diagnosis (abnormal sweat chloride: adult, >80 mEq/L; child, >60 mEq/L). Note that normal sweat chloride values do not exclude cystic fibrosis. This test must be performed with extreme care because inaccurate collection is a common source of misdiagnosis. Conditions associated with high levels of sodium and sweat chloride include smoking, chronic bronchitis, malnutrition, hereditary nephrogenic diabetes insipidus, adrenal insufficiency, hypothyroidism, hypoparathyroidism, pancreatitis, hypogammaglobulinema, and ectodermal dysplasia. The concentrations of sodium and sweat chloride increase with age. Heterozygotes may have normal sodium and sweat chloride values. False-negative test results are common in edematous states or in persons receiving corticosteroids. When sweat chloride levels are normal in a patient in whom cystic fibrosis is highly suspected, alternative diagnostic tests (e.g., nasal transepithelial voltage measurements and genotyping) should be considered. Respiratory manifestations include sinusitis, nasal polyps, progressive cystic bronchiectasis, purulent sputum, atelectasis, hemoptysis, and pneumothorax.

- Diagnosis in adults requires at least three of the following: clinical features of cystic fibrosis, positive family history, sweat chloride >80 mEq/L, and pancreatic insufficiency.
- Respiratory manifestations: sinusitis, nasal polyps, progressive cystic bronchiectasis, purulent sputum, atelectasis, hemoptysis, and pneumothorax.

Cystic fibrosis is the most common cause of COPD and pancreatic deficiency in the first 3 decades of life in the United States. COPD is present in 97% of adults with cystic fibrosis, and COPD is the major cause of morbidity and mortality in adults. Men constitute 55% of the adult patients. Adults with cystic fibrosis have a higher incidence of minor hemoptysis (60% of patients), major hemoptysis (5%), pneumothorax (16%), and sinusitis and nasal polyposis (48%). Pancreatic insufficiency is present in 95% of patients, but it is seldom symptomatic. Intussusception and fecal impaction (similar to meconium ileus) are more frequent (21%) in adults than in children. Both hyperinflation of lungs on CXR and lobar atelectasis are less frequent in adults than in children. The mean age at onset of massive hemoptysis is 19 years, and median survival from the initial episode of hemoptysis is about 3.5 years. The mean age at occurrence of pneumothorax in adults is 22 years. Azoospermia occurs in 95% of male patients.

- COPD is present in 97% of adults with cystic fibrosis; COPD is the major cause of morbidity and mortality.
- Adults with cystic fibrosis: minor hemoptysis (60% of patients), major hemoptysis (5%), pneumothorax (16%), and sinusitis and nasal polyposis (48%).
- Pancreatic insufficiency occurs in 95% of patients; it is seldom symptomatic.

Nearly 50% of patients with cystic fibrosis survive to age 25, and the overall survival rate for patients older than 17 years is approximately 50%. Survival and quality of life are improved with aggressive chest physical therapy, prompt treatment of upper and lower respiratory tract infections, intensive nutritional support, and conditioning. Poor prognostic factors include female sex, residence in a non-northern climate, pneumothorax, hemoptysis, recurrent bacterial infections, presence of *B. cepacia*, and systemic complications.

Respiratory therapy for cystic fibrosis includes management of obstructive lung disease, chest physiotherapy, postural drainage, immunization against influenza, and hydration. *P. aeruginosa* is the dominant organism and is difficult to eradicate. The presence of *Burkholderia cepacia* is associated with rapid deterioration in lung function. Inhaled antipseudomonal antibiotic therapy, such as inhaled tobramycin, is an option; it has been associated with an increase in FEV_1 and a decrease in the likelihood of hospitalization. Its role in management of acute exacerbation is not well defined. The sputum of patients with cystic fibrosis contains high concentrations of extracellular DNA, a viscous material released by leukocytes. Aerosolized recombinant human DNase I (dornase alfa) reduces sputum viscosity by degrading the DNA. Results of DNase I therapy have shown decreased risk of lung infections, improvement in FEV_1, and reduced antibiotic requirement. The usual dosage is 2.5 mg once daily via nebulizer; patients older than 21 years may benefit from 2.5 mg twice daily. However, recent studies have suggested that alternate-day dosing may have equivalent clinical outcomes. Serum antibodies to dornase alfa develop in about 2% to 4% of patients, but anaphylaxis has not been noted. Side effects of dornase alfa have included voice alteration, hoarseness, rash, chest pain, pharyngitis, and conjunctivitis. Although systemic glucocorticoids are administered during acute exacerbations or to those with allergic bronchopulmonary aspergillosis, routine use has been associated with notable side effects and is not recommended. Small studies have shown some benefit with inhaled glucocorticoids, which may be beneficial for patients with airway hyperreactivity. If examination of the sputum does not show nontuberculous mycobacteria, treatment with azithromycin (500 mg three times a week) appears to sustain the improvement in FEV_1 and to decrease the frequency of pulmonary exacerbations. The risk of death from cystic fibrosis is 38% to 56% within 2 years when FEV_1 has reached 20% to 30% of predicted. Patients younger than 18 years have worse survival rates after FEV_1 deteriorates. Bilateral lung transplantation is an option for patients with declining lung function. Survival rates are comparable to those of patients who undergo lung transplantation for other reasons. Presence of *B. cepacia*, however, is a contraindication for transplantation. The 5-year survival rate is between 40% and 60%.

- Nearly 50% of patients with cystic fibrosis survive to age 25.
- The overall survival rate for patients older than 17 years is approximately 50%.
- Aggressive chest physical therapy, prompt treatment of upper and lower respiratory tract infections, intensive nutritional support, and conditioning improve survival and quality of life.
- Poor prognostic factors: female sex, residence in a non-northern climate, pneumothorax, hemoptysis, recurrent bacterial infections, presence of *B. cepacia*, and systemic complications.

- Bilateral lung transplantation is an option for patients with declining lung function.

Bronchiectasis

Bronchiectasis is ectasia, or dilatation, of the bronchi due to irreversible destruction of bronchial walls. Its clinical features are similar to those of COPD. Airway inflammation in bronchiectasis is characterized by tissue neutrophilia, a mononuclear cell infiltrate composed mainly of $CD4^+$ T cells and $CD68^+$ macrophages, and increased interleukin-8 expression. Bronchiectasis is reversible when it results from severe bronchitis, acute pneumonia, or allergic bronchopulmonary aspergillosis. Bronchiectasis most commonly occurs in the lower lung fields. Mild cylindrical bronchiectasis seen in many heavy smokers with chronic bronchitis may be diffuse. Distal bronchial segments (second- to fourth-order bronchi) are involved in most cases of bronchiectasis. An exception is proximal bronchial involvement in allergic bronchopulmonary aspergillosis. Disease is bilateral in 30% of patients. Upper lobes are involved in cystic fibrosis and chronic mycotic and mycobacterial infections, and lower lobe involvement predominates in idiopathic bronchiectasis. Perihilar involvement is suggestive of allergic bronchopulmonary aspergillosis.

- Bronchiectasis is reversible in chronic bronchitis, acute pneumonia, and allergic bronchopulmonary aspergillosis.
- Upper lobes are involved in cystic fibrosis and chronic mycotic and mycobacterial infections.
- Central (perihilar) involvement is suggestive of allergic bronchopulmonary aspergillosis.
- Lower lobe predominance is suggestive of idiopathic bronchiectasis.

Most cases are diagnosed on clinical grounds (chronic cough with purulent sputum expectoration). Some patients with *dry bronchiectasis* caused by tuberculosis do not have productive cough, but episodes of severe hemoptysis may develop (this presentation is uncommon). Many mildly symptomatic or asymptomatic patients with atelectatic segments of the right middle lobe (*right middle lobe syndrome*) and lingular segments of the left upper lobe have minor degrees of bronchiectasis. Other signs suggestive of bronchiectasis include fetor oris, anorexia, weight loss, clubbing, and HPO. CXR shows segmental atelectasis, loss of lung volume, dilated and thickened airways (manifested as "tram tracks" or parallel lines), and air-fluid levels (if cystic bronchiectasis is present). HRCT can have a diagnostic sensitivity as high as 97%; it is the preferred test to confirm the presence of bronchiectasis. Findings include signet-ring shadows (a dilated bronchus, with bronchial artery forming the "stone"), bronchial wall thickening, dilated bronchi extending to the periphery (lack of tapering), bronchial obstruction due to inspissated purulent secretions, loss of volume, and air-fluid levels if cystic or saccular changes are present. The HRCT diagnosis of *nodular bronchiectasis* usually indicates peribronchial granulomatous infiltration caused by secondary infection by *Mycobacterium avium* complex. High seroprevalence of *Helicobacter pylori* has been reported in active bronchiectasis, but the clinical implications are unclear.

- Nonpulmonary symptoms: fetor oris, anorexia, weight loss, arthralgia, clubbing, and HPO.
- HRCT of the chest has replaced bronchography in making the diagnosis.
- PFT results usually indicate obstructive phenomena.
- Typical clinical scenario: A patient has asymptomatic or chronic cough, and HRCT shows signet-ring shadows and bronchial wall thickening.
- Dry bronchiectasis with episodes of marked hemoptysis without sputum is usually due to bronchiectasis in an area of old tuberculous damage.

Causes and Associations of Bronchiectasis

Infections

In adults, many cases of bronchiectasis are related to adenoviral or bacterial infections (measles, influenza, adenovirus, or pertussis) in childhood. Various infections, including *Mycoplasma pneumoniae*, nontuberculous mycobacteria, and anaerobic organisms, have also been associated with bronchiectasis. Tuberculosis is a common cause of bronchiectasis, particularly in the upper lobes. Occasionally, chronic histoplasmosis and coccidioidomycosis cause bronchiectasis. However, in patients with chronic stable bronchiectasis, *P. aeruginosa* is the predominant organism in respiratory secretions.

- Bronchiectasis may result from a chronic infection or be a complication of a previous viral infection.

Ciliary Dyskinesia (Immotile Cilia) Syndrome

Cilia are normally present in many organs, and their absence or abnormality may cause clinical problems (which are listed in parentheses): nasal mucosa (nasal polyps), paranasal sinuses (chronic sinusitis), eustachian tube (inner ear infection or deafness), and tracheobronchial tree (chronic bronchitis or bronchiectasis). Many types of ciliary abnormalities (loss of radial spokes, eccentric tubules, absence of tubules, and adhesion of multiple cilia) occur. Although the term *immotile cilia* is commonly used, the cilia do move, but their motion is abnormal; thus, the preferred term is *primary ciliary dyskinesia* (PCD).

- Many forms of ciliary abnormalities can occur.
- Ciliary dyskinesia—not ciliary immotility—is the main abnormality.

Kartagener syndrome, a classic example of PCD, is an autosomal recessive disorder that involves the triad of situs inversus, sinusitis, and bronchiectasis or at least bronchitis. Loss of the dynein arm—the fundamental defect—is an inherited abnormality involving a single protein. The prevalence of Kartagener syndrome is 1 in 40,000 to 60,000 persons, whereas the prevalence of PCD is approximately 1 in 20,000 to 40,000 persons. The loss of the dynein arm results in sinusitis and otitis (less common in adults), nasal polyposis, bronchiectasis (in 75% of adults), situs inversus, and infertility in males. Infertility is not a universal phenomenon, and, in fact, approximately 50% of women with PCD are often fertile. Kartagener

syndrome accounts for 0.5% of the cases of bronchiectasis and 15% of the cases of dextrocardia.

- Kartagener syndrome is an autosomal recessive disorder.
- Loss of the dynein arm is the fundamental defect.
- Typical clinical scenario: A patient presents with situs inversus, sinusitis, and bronchiectasis.

Diagnosis of PCD depends on the clinical features and documentation of ciliary abnormalities by electron microscopic examination of the nasal mucosa, bronchial mucosa, or semen. At least 20 types of axonemal defects have been described. Ciliary defects are not always inherited; acquired forms occur in smokers and patients with bronchitis, viral infections, or other pulmonary diseases. However, these acquired defects are different from those of PCD.

- Ciliary defects are not always inherited but are separate from PCD.
- Acquired ciliary defects occur in smokers, in patients with bronchitis, and after viral infections.

Hypogammaglobulinemia

Bruton agammaglobulinemia (X-linked agammaglobulinemia) predisposes to recurrent bacterial infections and bronchiectasis. The bacteria that are isolated include *H. influenzae*, *S. aureus*, and *S. pneumoniae*. Acquired (common variable) agammaglobulinemia may be manifested as sinopulmonary infections in the second or third decade. Selective IgA deficiency is the most common immunoglobulin deficiency; most of these patients are asymptomatic. IgA deficiency is frequently associated with IgG subclass (IgG2 and IgG4) deficiency. Despite the inability to form antibody, most patients have a normal number of circulating B cells, which fail to dedifferentiate into plasma cells that make immunoglobulins. Pulmonary disease occurs more commonly and is more severe than in patients with X-linked agammaglobulinemia. Infections caused by encapsulated bacteria are more common. Bronchiectasis and obstructive airway disease occur in up to 73% of patients.

- The overall incidence of bronchiectasis in hypogammaglobulinemia and agammaglobulinemia can be as high as 73%.
- Typical clinical scenario: Selective IgA deficiency is the most common immunoglobulin deficiency; most of these patients are asymptomatic or minimally symptomatic.

Right Middle Lobe Syndrome

Right middle lobe syndrome is recurrent atelectasis associated with localized bronchiectasis of the right middle lobe. Mechanisms include compression of the middle lobe bronchus by lymph nodes, acute angulation of the origin of the bronchus, narrow opening of the bronchus, lengthy bronchus, and lack of collateral ventilation. CXR usually points to the diagnosis, although many patients are asymptomatic.

- Typical clinical scenario for right middle lobe syndrome: An asymptomatic patient has chronic atelectasis and volume loss in the right middle lobe.
- The diagnosis is frequently made as an incidental CXR finding.

Allergic Bronchopulmonary Aspergillosis

Central bronchiectasis is present in 85% of patients with allergic bronchopulmonary aspergillosis at the time of the initial diagnosis and has been used as a diagnostic criterion of the disease.

Allergic bronchopulmonary aspergillosis also occurs in about 10% of patients with cystic fibrosis. The disease is caused by both IgG- and IgE-mediated immune responses directed at *Aspergillus* species. Type I (bronchospasm), type III (pulmonary-destructive changes), and type IV (parenchymal granuloma and mononuclear cell infiltrates) reactions are involved. The major criteria are asthma, blood eosinophilia (>1 × 10^9/L), immediate skin reactivity (type I reaction—IgE dependent) to *Aspergillus* antigen, IgG antibodies (type III reaction) to *Aspergillus* antigen, high IgE titer (>1,000 ng/mL), transient or fixed pulmonary infiltrates, and central bronchiectasis (noted in 85% of patients). A normal IgE level in a symptomatic patient virtually excludes allergic bronchopulmonary aspergillosis.

Minor criteria include the presence of *Aspergillus* in sputum, expectoration of brownish mucous plugs, and late-phase (Arthus) skin test reactivity to *Aspergillus* antigen. CXR shows fleeting infiltrates ("gloved finger" sign, "tram-track" line lesions, and "toothpaste shadows") in 85% of patients, mucoid impaction in 15% to 40%, atelectasis, and central bronchiectasis. Although generally associated with *A. fumigatus*, allergic bronchopulmonary mycosis can be caused by *C. albicans*, *Aspergillus terreus*, *Curvularia lunata*, *Helminthosporium* species, and *Stemphylium lanuginosum*. Systemic corticosteroid therapy for more than 6 months is required for most patients.

- Allergic bronchopulmonary aspergillosis may develop in 10% of patients with cystic fibrosis.
- Types I, III, and IV immune reactions may be involved.
- An increased IgE level is the most useful laboratory finding.
- Presence of *A. fumigatus* is only a minor criterion for the diagnosis.
- Therapy consists of long-term systemic corticosteroids.
- Typical clinical scenario: A patient has refractory asthma, expectoration of brownish mucous plugs, segmental atelectasis, and eosinophilia.

Miscellaneous Causes and Associations

Bronchiectasis develops in approximately 20% of patients with yellow nail syndrome. This syndrome is thought to arise from lymphatic hypoplasia or atresia. It consists of yellow-green discoloration of the nails (with a thickened and curved appearance) of all extremities, lymphedema of the lower extremities, and lymphocyte-predominant pleural effusion.

Nearly 10% of patients with bronchiectasis may have an abnormal α_1-antitrypsin phenotype, with serum levels less than 66% of normal. Other causes and associations include rheumatoid arthritis (Felty syndrome), toxic chemicals, recurrent aspiration, heroin, inflammatory bowel disease, foreign body, sequestrated lung, relapsing polychondritis, chronic tracheoesophageal fistula, heart-lung transplantation, chronic granulomatous disease of childhood, obstructive azoospermia (Young syndrome), unilateral hyperlucent lung

syndrome (Swyer-James or Macleod syndrome), and postobstructive status (tumors, long-standing foreign body, or stenosis).

- Uncommon causes of bronchiectasis include α_1-antitrypsin deficiency, Felty syndrome, inflammatory bowel disease, toxic inhalation, and chronic tracheobronchial stenosis.

Complications of Bronchiectasis

Complications of bronchiectasis include hemoptysis from bronchial vessels (in 50% of patients), progressive respiratory failure with hypoxemia and cor pulmonale, and secondary infections by fungi and noninfectious mycobacterioses. The presence of these organisms usually represents a saprophytic state, but active infection has to be excluded. The most commonly isolated bacterium in bronchiectasis is *P. aeruginosa*. As in cystic fibrosis, it is impossible to eradicate this bacterium. Patients with bronchiectasis infected by *P. aeruginosa* have more extensive bronchiectasis than those without this infection. Routine culture of respiratory secretions is not warranted for all patients.

- The source of bleeding in bronchiectasis is the bronchial (systemic) circulation; hence, it can be brisk.
- The presence of mycobacteria and fungi may represent saprophytic growth.

Treatment

Treatment of bronchiectasis is aimed at controlling the symptoms and preventing complications. Predisposing conditions should be sought and treated aggressively (gamma globulin injections, removal of foreign body or tumor, control of aspiration, and treatment of infections of paranasal sinuses, gums, and teeth). Postural drainage, chest physiotherapy, humidification, bronchodilators, and cyclic antibiotic therapy are effective in many patients. Surgical treatment is reserved for patients with troublesome symptoms, localized disease, and severe hemoptysis. High-dose inhaled corticosteroid therapy (fluticasone) is reportedly effective in reducing the sputum inflammatory indices in bronchiectasis.

Occupational Lung Disease

The points to remember about occupational lung diseases are summarized in Table 22-7.

Pleural Effusion

The normal volume of pleural fluid is 0.2 to 0.3 mL/kg of body weight. Excess pleural fluid collects in the pleural space when fluid collection exceeds normal removal mechanisms. Hydrostatic, oncotic, and intrapleural pressures regulate fluid movement in the pleural space. Any of the following mechanisms can produce pleural

Table 22-7 **Pulmonary Diseases: Causes and Associations**

Pulmonary disease	Causes and associations
Progressive massive fibrosis	Silicosis, coal, hematite, kaolin, graphite, asbestosis
Autoimmune mechanism	Silicosis, asbestosis, berylliosis
Monday morning sickness	Byssinosis, bagassosis, metal fume fever
Metals and fumes producing asthma	Bakers' asthma, meat wrappers' asthma, printers' asthma, nickel, platinum, toluene diisocyanate, cigarette cutters' asthma
Increased incidence of tuberculosis	Silicosis, hematite lung
Increased incidence of carcinoma	Asbestos, hematite, arsenic, nickel, uranium, chromate
Welder's lung	Siderosis, pulmonary edema, bronchitis, emphysema
Centrilobular emphysema	Coal, hematite
Generalized emphysema	Cadmium
Silo filler's lung	Nitrogen dioxide
Farmer's lung	*Thermoactinomyces*, *Micropolyspora*
Asbestos exposure	Mesothelioma, bronchogenic cancer, gastrointestinal tract cancer
Eggshell calcification	Silicosis, sarcoid
Sarcoid-like disease	Berylliosis
Diaphragmatic calcification	Asbestosis (also ankylosing spondylitis)
Nonfibrogenic pneumoconioses	Tin, emery, antimony, titanium, barium
Minimal abnormality in lungs	Siderosis, baritosis, stannosis
Bullous emphysema	Bauxite lung
Occupational asthma	Toluene diisocyanate, laboratory animals, grain dust, biologic enzymes, gum acacia, tragacanth, silkworm, anhydrides, wood dust, platinum, nickel, formaldehyde, Freon, drugs

effusion: changes in capillary permeability (inflammation), increased hydrostatic pressure, decreased plasma oncotic pressure, impaired lymphatic drainage, increased negative intrapleural pressure, and movement of fluid (through diaphragmatic pores and lymphatic vessels) from the peritoneum. The principal causes of pleural effusion are listed in Table 22-8. The diagnosis may be suggested by certain characteristics of the effusion. For example, obvious pus suggests empyema; lupus erythematosus cells and a ratio of pleural fluid to serum antinuclear antibody greater than 1 suggests lupus pleuritis; a high level of salivary amylase level with pleural fluid acidosis suggests esophageal rupture; and a ratio of pleural fluid hematocrit to blood hematocrit greater than 0.5 suggests hemothorax. On the basis of clinical suspicion, testing of the effusion should be selective. Despite thorough testing of pleural fluid, the cause of up to one-third of pleural effusions is unknown.

Transudate Versus Exudate

Traditionally, an effusion with any *one* of the following is considered an exudate:

1. Ratio of pleural fluid protein to serum protein >0.5
2. Ratio of pleural fluid lactate dehydrogenase (LDH) to serum LDH >0.6
3. Pleural fluid LDH >2/3 the upper limit of serum LDH

A recent meta-analysis found that any *one* of the following findings can also be used to identify the fluid as an exudate:

1. Pleural fluid protein >2.9 g/dL
2. Pleural fluid cholesterol >45 mg/dL
3. Pleural fluid LDH >60% of the upper limit of normal serum LDH

An increased level of LDH in the fluid is nonspecific, but it is increased in pulmonary embolism, rheumatoid effusion, lymphoma, and most exudative effusions. The classification of pleural fluid into transudates and exudates does not permit the consideration of all causes. The most common cause of a transudate is congestive heart failure (pulmonary artery wedge pressure >25 mm Hg). The most common cause of an exudate is pneumonia (parapneumonic effusion).

- It is not necessary to perform all the above tests to differentiate a transudate from an exudate.
- Clinically, it is more useful to classify the cause by considering the source (organ system) of the fluid (Table 22-8).
- The classification of pleural fluid into transudates and exudates does not permit the consideration of all causes.
- The most common cause of a transudate is congestive heart failure (pulmonary artery wedge pressure >25 mm Hg).
- The most common cause of an exudate is pneumonia (parapneumonic effusion).

Glucose and pH

When the pleural fluid glucose concentration is high, the pH is usually high, and when the glucose concentration is low, the pH is usually low. Pleural fluid hypoglycemia (<60 mg/dL or ratio of fluid glucose to plasma glucose <0.5) is found in rheumatoid effusion, malignant mesothelioma, empyema, systemic lupus erythematosus, esophageal rupture, and tuberculous pleurisy. In some cases of rheumatoid pleurisy and empyema, pleural fluid glucose may not be detectable. The pH of normal pleural fluid, which should be determined with a blood gas machine instead of a pH meter, is

Familial Mediterranean fever†

*Usually a transudate.
†Usually an exudate.

approximately 7.60. A pleural fluid pH less than 7.30 is found in empyema, esophageal rupture, rheumatoid effusion, tuberculosis, malignancy, and trauma. If the pH is low (<7.20) and clinical suspicion is high for infection, drainage with a chest tube should be considered. Empyema caused by *Proteus* species produces a pH greater than 7.8 (because of the production of ammonia).

- The pleural fluid glucose concentration and pH usually go together (i.e., if glucose is low, so is pH).
- Glucose levels are low in rheumatoid effusion, malignant mesothelioma, and empyema.

Amylase

The concentration of amylase in the pleural fluid is increased (ratio of pleural fluid amylase to serum amylase >1.0) in pancreatitis, pseudocyst of the pancreas, malignancy (typically a primary tumor in the lung), and rupture of the esophagus (with leakage of salivary amylase) or abdominal viscera. The amylase level in the fluid remains higher for longer periods than in the serum. Rare causes include ruptured ectopic pregnancy, hydronephrosis, cirrhosis, and pneumonia. In any unexplained left-sided effusion, consider pancreatitis and measure the amylase level in the pleural fluid.

- The concentration of amylase in the pleural fluid is increased in esophageal rupture because of leakage of salivary amylase.
- In any unexplained left-sided effusion, consider pancreatitis and measure the amylase level in the pleural fluid.

Chylous Effusion

Chylous effusion is suggested by a turbid or milky white appearance of the fluid. However, chylothorax is confirmed by the presence of chylomicrons. Supportive evidence includes a pleural fluid triglyceride concentration greater than 110 mg/dL. A concentration less than 50 mg/dL excludes chylothorax. Chylous effusions occur in numerous conditions: Kaposi sarcoma with mediastinal adenopathy, after Valsalva maneuver, during childbirth, amyloidosis, esophagectomy, esophageal sclerotherapy, tuberous sclerosis (lymphangiomyomatosis), and thrombosis of the superior vena cava or the innominate or subclavian vein. Lymphoma is the most common nontraumatic cause of chylothorax. Cholesterol effusions (fluid cholesterol >250 mg/dL, triglyceride <110 mg/dL, and absence of chylomicrons) are not true chylous effusions but are known as *pseudochylothorax*. They are seen in the setting of chronic pleural effusions and in some cases of nephrotic syndrome; the more common causes are old tuberculous effusions and rheumatoid effusions.

- Chylous effusion is seen in the "5 Ts": **t**horacic duct, **t**rauma, **t**umor (lymphoma), **t**uberculosis, and **t**uberous sclerosis (lymphangiomyomatosis).
- True chylous effusions contain chylomicrons.
- Cholesterol effusions are not true chylous effusions.

Complement

Total complement and C3 and C4 components in the pleural fluid are decreased in systemic lupus erythematosus (80% of patients), including the drug-induced form, and in rheumatoid arthritis (40%-60% of patients), carcinoma, pneumonia, and tuberculosis. Increased pleural fluid antinuclear antibody (>1:160) is strongly suggestive of lupus erythematosus. The presence of lupus erythematosus cells in the pleural fluid is diagnostic of systemic lupus erythematosus. Rheumatoid factor is greater than 1:320 in rheumatoid pleural effusion.

- Low pleural fluid complement: systemic lupus erythematosus (also in the drug-induced form).

Cell Counts

A hemorrhagic effusion (pleural fluid hematocrit >50% of serum hematocrit) is seen in trauma, tumor, asbestos effusion, pancreatitis, pulmonary embolism with infarctions, and other conditions. A bloody effusion in lung cancer usually denotes pleural metastasis, even if the cytologic results are negative. Pleural fluid eosinophilia (>10%) is nonspecific and occurs in trauma (air or blood in the pleural space), pulmonary infarction, psittacosis, drug-induced effusion, pulmonary infiltrate with eosinophilia-associated effusions, benign asbestos pleural effusion, and malignancy. Pleural fluid lymphocytosis occurs in tuberculosis, chronic effusions, lymphoma, sarcoidosis, chylothorax, and some collagenoses such as yellow nail syndrome and chronic rheumatoid pleurisy.

- A bloody effusion in lung cancer usually denotes pleural metastasis, even if the cytologic results are negative.

Cytology

Most effusions in adults should be examined cytologically if the clinical features do not suggest an obvious benign cause. Cytologic findings are positive in 60% of all malignant effusions, and pleural biopsy results are positive in less than 50%. Cytologic examination and biopsy give a slightly higher yield than either one alone, and repeated cytologic examination from sequential thoracentesis increases the diagnostic yield. Cytologic examination is less helpful in malignant mesothelioma and lymphoma, and an open biopsy is often necessary. Positive fluid cytologic findings in primary lung carcinoma imply unresectability (stage IIIB disease).

- Cytologic examination is an important test in most adults with an "unknown" effusion.
- The overall yield from a cytologic examination is 60%, less in cases of mesothelioma and lymphoma.

Cultures

Tuberculous effusions (fluid alone) yield positive cultures in less than 15% of cases. Pleural biopsy (histology and culture) has a higher (>75%) diagnostic yield in tuberculosis. Culture is of value if the effusion is due to actinomycosis or *Nocardia* infection. Culture is less helpful in mycoses, but if fungal infection of the pleural space is suspected, the pleural fluid should be cultured. Cultures for viruses and certain bacteria (influenza A, chlamydia, coxsackievirus B, and mycoplasma) are often negative. Paragonimiasis causes pleural effusion. The diagnosis of tuberculous pleuritis is strongly suggested

by a high adenosine deaminase level in the pleural fluid. Another relatively sensitive test for the diagnosis of tuberculous pleuritis is the level of interferon-γ in the pleural fluid.

- In tuberculosis, it is important to culture pleural biopsy specimens.
- The adenosine deaminase level is increased in tuberculous pleural effusion.
- Poor yield in viral infections.

Pleural Biopsy

Pleural biopsy, now most commonly performed through a thoracoscope, is indicated if tuberculous involvement of the pleural space is suspected. The diagnostic rate from pleural biopsy in tuberculosis is greater than 75%, whereas pleural fluid alone has a much lower yield (<15%). With thoracoscopy, the overall diagnostic yield is higher in pleural effusion of unknown cause, mesothelioma, and lung cancers than with pleural fluid analysis alone. Use of the thoracoscope also offers the advantage of being able to proceed to pleurodesis depending on the findings during the procedure.

- Pleural biopsy is indicated if tuberculous pleural disease is suspected.
- Pleural biopsy through a thoracoscope improves the diagnostic yield of pleural effusions.

Miscellaneous

Nearly 30% of all effusions are undiagnosed despite extensive studies, including open pleural biopsy. At least 350 to 400 mL of fluid must be present to be seen on CXR. It is important to look for subpulmonic effusions, elevated hemidiaphragms, and blunting of the costophrenic angle. When in doubt, obtain a lateral decubitus CXR. Ultrasonography is helpful in tapping small amounts of fluid and loculated fluid collections. Small effusions are common after abdominal operations and the normal labor of pregnancy; almost all resolve spontaneously. Assess for signs of trauma (rib fracture), abdominal surgery, acute abdomen, pancreatitis, and cirrhosis. Asbestos-induced effusions frequently mimic malignant pleural mesothelioma, with pain, bloody fluid, and recurrence. Mesothelioma should be excluded by repeated thoracentesis, pleural biopsy, or thoracotomy. Consider drug-induced pleural effusion (nitrofurantoin, methysergide, drug-induced systemic lupus erythematosus, and busulfan) on the basis of an accurate history of all medications used, suggestive correlation of symptom onset with initiation of the suspected drug, and pleural fluid eosinophilia (>10%) with or without peripheral eosinophilia.

- Small effusions are common after abdominal operations and the normal labor of pregnancy; almost all resolve spontaneously.
- Drug-induced pleural effusion: nitrofurantoin, methysergide, drug-induced systemic lupus erythematosus, and busulfan.
- Nearly 30% of all effusions are undiagnosed despite extensive studies, including open pleural biopsy.

Complications

Complications of thoracentesis include pneumothorax (in 3%-20% of patients), hemothorax, pulmonary edema, intrapulmonary hemorrhage, hemoptysis, vagal inhibition, air embolism, subcutaneous emphysema, bronchopleural fistula, empyema, seeding of a needle tract with malignant cells, and puncture of the liver or spleen.

Sleep-Related Breathing Disorders

Sleep-related breathing disorders (SRBD) encompass various abnormal breathing patterns that occur during sleep. These patterns can be in the form of reduced tidal volumes with or without resultant hypoventilation or complete cessation of airflow resulting in apnea. Complications from SRBD can include sleepiness, an increase in cardiovascular morbidity, an influence on various endocrine factors, and increase in overall mortality (Table 22-9). Diagnosis is confirmed through an overnight polysomnogram, which defines the presence and severity of SRBD and, in many cases, helps with treatment by titration of noninvasive positive pressure devices.

Obstructive Sleep Apnea Hypopnea Syndrome

Obstructive sleep apnea (OSA) is defined as periodic cessation of airflow (≥10 seconds in duration) during sleep due to obstruction of the upper airway in the setting of continued respiratory effort. This event is typically terminated with a temporary arousal from sleep and return

of normal upper airway patency. *Hypopnea* is defined as reduction in airflow for at least 10 seconds, usually with resultant desaturation of at least 4%, which is also typically terminated by an arousal. Such periodic episodes of apnea and hypopnea usually result in fragmented sleep and periodic desaturations. This entity should be suspected in those who are obese (although not always), known to snore, and complain of daytime sleepiness. An overnight PSG is required to make the diagnosis of OSA, which is defined as having more than 5 episodes of apnea and hypopnea per hour of sleep. *Obstructive sleep apnea hypopnea syndrome* implies the presence of OSA accompanied by other symptoms such as excessive daytime sleepiness. Although overnight oximetry may suggest the presence of OSA, it alone is neither sensitive enough nor specific enough for confirmation of the diagnosis.

OSA has been associated with multisystemic dysfunction as noted in Table 22-9. Several studies suggest there is an increase in postoperative complications and overall mortality for those with OSA who remain untreated.

Central Sleep Apnea

Central sleep apnea (CSA) is defined as periodic cessation of airflow (≥10 seconds) during sleep in the absence of upper airway obstruction, presumably due to lack of respiratory muscle stimulation. Airflow is gradually resumed and is not always associated with an arousal from sleep. This entity may be seen in those with neurologic abnormalities (e.g., cerebrovascular accident, amyotrophic lateral sclerosis, and postpolio syndrome) or endocrine dysfunctions (e.g., acromegaly and hypothyroidism), or it may be idiopathic. Within CSA, a specific respiratory pattern cycles between crescendo-decrescendo respirations followed by a pause. This pattern is known as *Cheyne-Stokes respiration* or *periodic respiration* and is often seen in those with congestive heart failure (especially during acute exacerbation), at high altitude, and after a cerebrovascular event.

Sleep Hypoventilation Syndrome

Sleep hypoventilation syndrome is characterized by a reduction in respiration, resulting in hypercapnia and usually hypoxemia during sleep, but is most pronounced during rapid eye movement (REM) sleep. Most affected persons have daytime hypercapnia and pulmonary hypertension or even cor pulmonale. Sleep hypoventilation syndrome may be seen in those who are significantly obese (known as *obesity-hypoventilation syndrome*) or who have severe respiratory (including chest wall defects) or neurologic diseases.

Treatment

Treatment typically involves use of noninvasive positive pressure devices such as continuous positive airway pressure (CPAP) and bilevel positive airway pressure (BiPAP) devices. Adequate titration can be achieved during a polysomnogram, but, in certain circumstances, an autotitrating CPAP device may be used. In severe cases, tracheostomy may be required, but, in most cases, these disorders can be managed noninvasively with or without addition of supplemental oxygen. Treatment of CSA, however, can be difficult, and positive airway pressure devices may not always be effective.

Part II

Timothy R. Aksamit, MD

Diffuse Lung Disease

Diffuse lung disease includes a wide range of parenchymal lung diseases that have infectious, inflammatory, malignant, drug, occupational/environmental, and other causes. Although many identifiable causes are recognized, the cause of most cases of diffuse lung disease in many published series is idiopathic. The clinical course may be acute or prolonged and may progress rapidly to life-threatening respiratory failure with death, or it may be indolent over many years. In most instances, a differential diagnosis can readily be formulated by taking the medical history, with emphasis on the nature of the symptoms, duration, and pertinent environmental, occupational, drug, and travel exposures. The physical examination, blood tests, pulmonary function tests (PFTs), chest radiography (CXR), and computed tomography (CT) often provide clues to the diagnosis. The diagnosis may be confirmed on clinical grounds but may also require bronchoscopy with bronchoalveolar lavage (BAL) and transbronchial biopsy or open lung biopsy via video-assisted thoracoscopy (VATS).

This overview of diffuse lung disease emphasizes the differential diagnosis, classification schemes, clinical clues to diagnosis, and available diagnostic tools and summarizes a diagnostic strategy for approaching diffuse lung disease in clinical practice.

Some of the numerous causes of diffuse lung disease and the diseases associated with them are listed in Figure 22-27. The numerous idiopathic causes are listed in Table 22-10. The relative proportions of the causes of diffuse lung disease are given in Table 22-11. In a typical internal medicine practice, approximately three-fourths of the cases of diffuse lung disease represent one of three diagnoses: idiopathic pulmonary fibrosis (IPF) (also called *usual interstitial pneumonia* [UIP]), sarcoidosis, or collagen vascular disease–associated interstitial lung disease (especially nonspecific interstitial pneumonia [NSIP]). Many of the causes of diffuse lung disease usually described in textbooks are uncommon in clinical practice.

The abbreviations and clinicopathologic correlates of diffuse lung disease are listed in Tables 22-12 and 22-13, respectively. In most instances, the histopathologic findings alone are not sufficient to establish a specific clinical diagnosis of diffuse lung disease. The pathology findings are common to several diagnostic possibilities and need to be correlated with the clinical history and laboratory test and radiographic results to establish the diagnosis. Similarly, different disease entities have overlapping histopathologic features. The histopathologic features of IPF/UIP or NSIP may be found separately or together, as in collagen vascular disease–associated interstitial diffuse lung disease. In other instances, the histopathologic features are specific for a particular diagnosis, for example, lymphangioleiomyomatosis. The histopathologic features may also have prognostic and therapeutic implications. For example, the histopathologic findings of IPF/UIP, compared with those of NSIP, are consistently correlated with less responsiveness to corticosteroid therapy and poorer prognosis. In contrast, NSIP–interstitial diffuse lung disease is more common in younger persons, is often associated with drug-induced or collagen vascular disease–associated diffuse lung disease, and has a more cellular inflammatory process.

Thus, the physician needs to formulate a systematic approach to diffuse lung disease that involves a complete medical history, physical examination, PFTs, blood tests, and radiographic studies before considering bronchoscopy with BAL and transbronchial biopsy or open

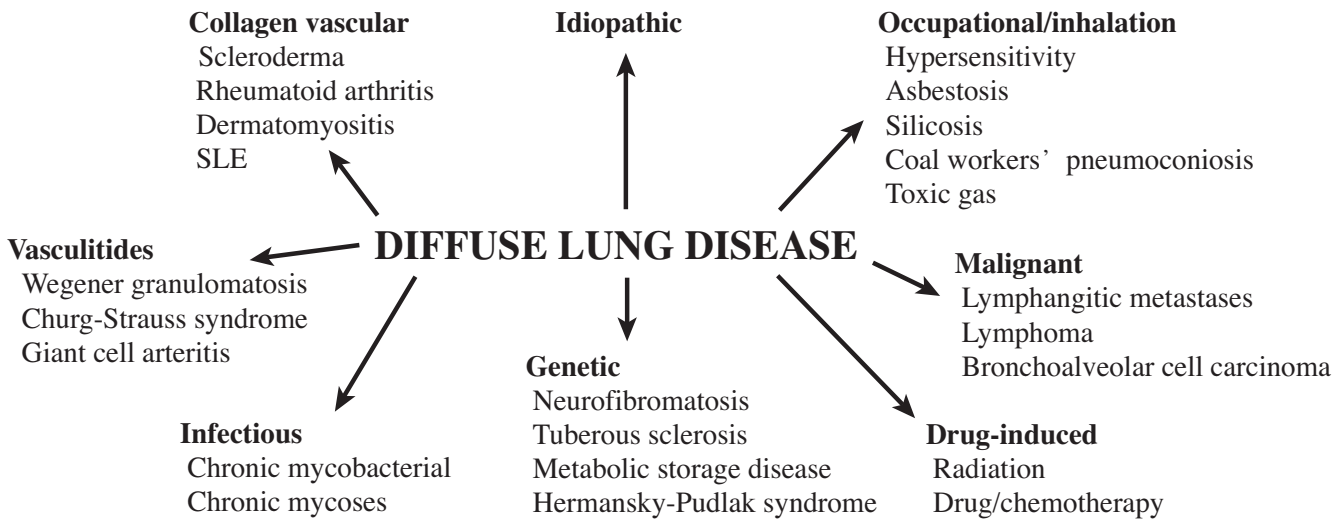

Fig. 22-27. Causes of diffuse lung disease. SLE, systemic lupus erythematosus.

Table 22-10 Idiopathic Diffuse Lung Disease

IPF/UIP
Nonspecific interstitial pneumonia
Sarcoidosis
Bronchiolitis obliterans with organizing pneumonia/cryptogenic organizing pneumonia
Eosinophilic lung diseases
Lymphocytic interstitial pneumonitis
Alveolar microlithiasis
Lymphangioleiomyomatosis
Langerhans cell histiocytosis/eosinophilic granulomatosis
Pulmonary alveolar proteinosis
Acute respiratory distress syndrome/acute lung injury
Others

IPF, idiopathic pulmonary fibrosis; UIP, usual intersitital pneumonia.

Table 22-11 Epidemiology of Diffuse Lung Disease*†

Diagnosis	%
IPF	12-42
Sarcoidosis	8-41
ILD-CVD	10-17
Hypersensitivity	2-8
Vasculitides	2-8
Histiocytosis	1-11
Drug/radiation	1-10
Pneumoconioses	5-10
BOOP	1-3
LAM	1-2
Lymphangitic cancer	1-2
LIP	1-2

BOOP, bronchiolitis obliterans with organizing pneumonia; CVD, collagen vascular disease; ILD, interstitial lung disease; IPF, idiopathic pulmonary fibrosis; LAM, lymphangioleiomyomatosis; LIP, lymphocytic interstitial pneumonitis.

*Prevalence is 2 to 200 per 100,000 persons.

†Prevalence of IPF is higher among males and the elderly.

Data from American Thoracic Society (ATS), European Respiratory Society (ERS). Idiopathic pulmonary fibrosis: diagnosis and treatment. International consensus statement. Am J Respir Crit Care Med. 2000;161:646-64; Coultas DB, Zumwalt RE, Black WC, Sobonya RE. The epidemiology of interstitial lung diseases. Am J Respir Crit Care Med. 1994;150:967-72; Grenier P, Chevret S, Beigelman C, Brauner MW, Chastang C, Valeyre D. Chronic diffuse infiltrative lung disease: determination of the diagnostic value of clinical data, chest radiography, and CT and Bayesian analysis. Radiology. 1994;191:383-90.

lung biopsy via VATS. Occasionally, specific patterns of diagnostic test results provide additional clues to assist the physician.

In diffuse lung disease, PFTs generally demonstrate restrictive change, with various degrees of gas exchange abnormalities and hypoxemia. A component of obstructive change may be found in some cases. Specifically, the causes of diffuse lung disease that demonstrate various degrees of airflow obstruction on PFTs with or without restrictive change and gas exchange abnormalities include rheumatoid arthritis, Langerhans cell histiocytosis, lymphangioleiomyomatosis, tuberous sclerosis, sarcoidosis, bronchiectasis, cystic fibrosis, eosinophilic pneumonia, and hypersensitivity pneumonitis.

CXR is the initial radiographic study for virtually all patients who present with respiratory symptoms attributed to diffuse lung disease. The findings may include interstitial or alveolar patterns or both. However, the differences between alveolar and interstitial infiltrates can be subtle; also, they are sufficiently nonspecific to be of limited usefulness. Nonetheless, alveolar infiltrates generally predominate in processes of diffuse lung disease that include diffuse alveolar damage (which is the histopathologic diagnosis that corresponds to acute respiratory distress syndrome [ARDS], the clinical diagnosis), pulmonary edema (cardiogenic and noncardiogenic), aspiration pneumonia, alveolar hemorrhage syndromes, pulmonary alveolar proteinosis, bronchoalveolar cell carcinoma, toxic gas exposure, desquamative interstitial pneumonia, infectious pneumonitis, and hematogenous metastases. Infiltrates may be nodular, cavitary, or mixed. An upper versus lower predominance may be suggestive of specific diagnoses. Upper predominance often occurs in diffuse lung disease related to ankylosing spondylitis, silicosis/coal workers' pneumoconiosis, sarcoidosis, Langerhans cell histiocytosis, tuberculosis and mycotic lung disease, cystic fibrosis, and allergic bronchopulmonary aspergillosis. Basilar predominance is common in IPF/UIP, asbestosis, desquamative interstitial pneumonia, lymphocytic interstitial pneumonitis, and hematogenous metastatic disease.

Chest CT, including high-resolution chest CT (HRCT, thin-section CT), is commonly used to evaluate patients who present with diffuse lung disease. In conjunction with a "characteristic" clinical history, physical examination, blood tests, and PFTs, HRCT findings may preclude the need for bronchoscopy or VATS open lung biopsy (or both) to establish the clinical diagnosis, to outline a therapeutic strategy, and to provide prognostic information. Similarly, specific chest CT findings alone may suggest the diagnosis of Langerhans cell histiocytosis, lymphangioleiomyomatosis, IPF/UIP, and lymphangitic metastases and, occasionally, sarcoidosis, bronchiolitis obliterans with organizing pneumonia (BOOP), eosinophilic pneumonia, asbestosis, and mycobacterial disease. Ground-glass opacities seen with HRCT are patchy, hazy areas of increased attenuation with preserved bronchial and vascular margins. They may represent airspace or interstitial abnormalities, although rarely they are seen in nondisease states because of technical limitations. In the case of airspace opacification and interstitial lung disease, ground-glass opacities have been correlated with increased cellularity, as in NSIP. In contrast, interlobular septal thickening and subpleural "reticular" honeycombing with traction bronchiectasis reflect a less cellular lesion that is more fibrotic, with scattered fibroblastic foci, and are characteristic of IPF/UIP. Both ground-glass opacities and peripheral reticular honeycombing occur in many cases of interstitial diffuse lung disease.

Table 22-12 Abbreviations for Diffuse Lung Disease

AIP	Acute interstitial pneumonia (Hamman-Rich syndrome)
BOOP/COP	Bronchiolitis obliterans with organizing pneumonia/cryptogenic organizing pneumonia
DAD	Diffuse alveolar damage (acute respiratory distress syndrome)
DIP	Desquamative interstitial pneumonia
GIP	Giant cell pneumonitis
ILD	Interstitial lung disease
IPF	Idiopathic pulmonary fibrosis
NSIP	Nonspecific interstitial pneumonia
RB-ILD	Respiratory bronchiolitis–associated interstitial lung disease
UIP	Usual interstitial pneumonia

Flexible fiberoptic bronchoscopy has dramatically improved the ability to sample the airway and lung in stabilized outpatients and in inpatients with hypoxemic respiratory failure due to diffuse lung disease. BAL generally can be performed safely in most settings, and the findings can be used to quickly identify the cause of diffuse lung disease, especially atypical or typical infectious causes or lymphangitic metastases. BAL is safe for patients who have thrombocytopenia or hypoxemia. Nonetheless, BAL has a limited role in establishing many specific diagnoses of diffuse lung disease, including IPF, sarcoidosis, hypersensitivity pneumonitis, and asbestosis. In many cases, transbronchial biopsy can be performed in combination with BAL, resulting in a diagnostic yield greater than 70% for sarcoidosis, hypersensitivity pneumonitis, Langerhans cell histiocytosis, pulmonary alveolar proteinosis, lymphangitic metastases, diffuse pulmonary lymphoma, bronchoalveolar cell carcinoma, mycobacterial and mycotic lung disease, pneumoconioses, and lung rejection after transplantation. The complication rates with transbronchial biopsy are 1% to 5% for pneumothorax, 1% to 2% for hemorrhage, and less than 0.2% for death. In comparison, the mortality rate with BAL is 0.04%.

In most cases, the results of blood tests provide supportive but not definitive diagnostic information. Results that are often abnormal but nonspecific, and thus not helpful diagnostically, include the leukocyte count, antinuclear antibody titer, rheumatoid factor, and gamma globulins. Moreover, an increase in the angiotensin-converting enzyme (ACE) level is neither specific nor sensitive enough to establish the diagnosis of sarcoidosis. The level may be increased in many other causes of granulomatous lung disease. When the ACE level is increased in sarcoidosis, it may be a marker of disease activity and thus be helpful in follow-up evaluations. In other cases, blood test abnormalities are specific but lack sensitivity; these include fungal serologic tests (e.g., for histoplasmosis, blastomycosis, coccidioidomycosis, and cryptococcal disease), serum precipitins (for hypersensitivity pneumonitis), and specific autoantibody titers in connective tissue diseases or vasculitis. An exception is the test for cytoplasmic antinuclear cytoplasmic antibody (cANCA), which has an estimated overall sensitivity of 81% and a specificity of 98% for Wegener granulomatosis when performed in an experienced laboratory. This antibody is directed specifically against proteinase 3 (PR3). The perinuclear antinuclear cytoplasmic antibody (pANCA) is directed against myeloperoxidase and may also be positive in Wegener granulomatosis as well as in microscopic polyangiitis, Churg-Strauss syndrome, and other vasculitides. Higher sensitivity and specificity rates may be expected during disease activity.

The pretest probability, including medical history and laboratory data, and radiographic findings need to be combined to optimize the diagnostic yield. The diagnostic yield increases from 27% to 53% and 61% when clinical information is added to CXR and HRCT findings, respectively. An algorithm for diagnosing diffuse lung disease is given in Figure 22-28. With this strategy, including HRCT, the diagnostic yield may approach 90% if the diffuse lung disease is rapidly progressive. The likelihood of establishing a specific diagnosis using this algorithm is greatest for sarcoidosis, Langerhans cell histiocytosis, hypersensitivity pneumonitis, asbestosis,

Table 22-13 Clinicopathologic Classification of Diffuse Lung Disease

Idiopathic pulmonary fibrosis
Usual interstitial pneumonia: idiopathic > collagen-vascular disease, others
Nonspecific interstitial pneumonia: collagen-vascular disease, drugs
DIP/RB-ILD: smokers
Lymphocytic interstitial pneumonitis: Sjögren syndrome, AIDS, lymphoma, dysproteinemia, inflammatory bowel disease/Crohn disease, primary biliary cirrhosis, lymphomatoid granulomatosis
Acute interstitial pneumonia: Hamman-Rich syndrome, diffuse alveolar damage-ARDS
BOOP (idiopathic): also drugs, collagen-vascular disease
Hypersensitivity pneumonitis: drugs, avian, mold

AIDS, acquired immunodeficiency syndrome; ARDS, acute respiratory distress syndrome; BOOP, bronchiolitis obliterans with organizing pneumonia; DIP, desquamative interstitial pneumonia; RB-ILD, respiratory bronchiolitis–associated interstitial lung disease.

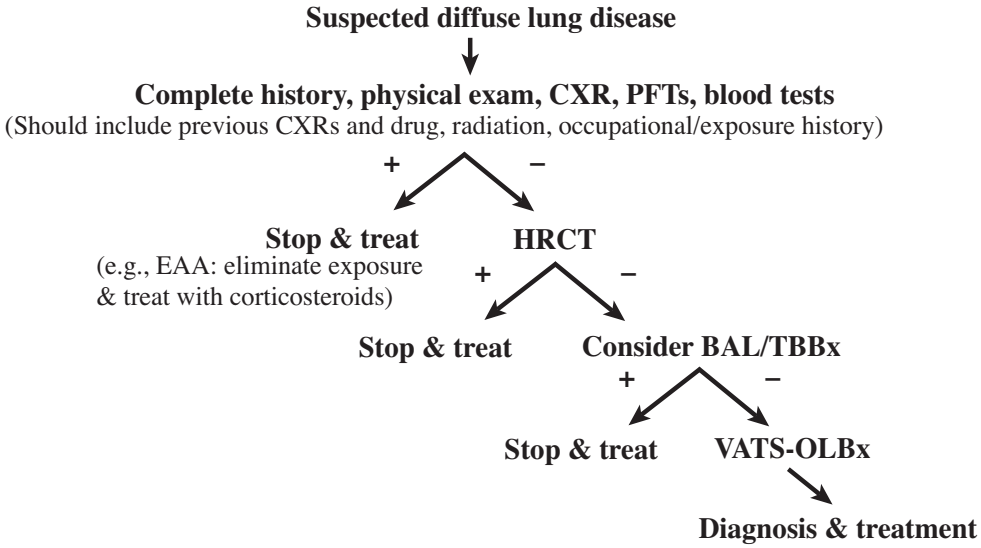

Fig. 22-28. Strategy for diagnosing diffuse lung disease. BAL, bronchoalveolar lavage; CXR, chest radiography; EAA, extrinsic allergic alveolitis; HRCT, high-resolution computed tomography; OLBx, open lung biopsy; PFT, pulmonary function test; TBBx, transbronchial biopsy; VATS, video-assisted thoracoscopy.

lymphangitic metastases, silicosis, and possibly IPF/UIP. VATS open lung biopsy may still be required in up to one-third of patients.

Specific Diagnoses

IPF/UIP

The onset of IPF/UIP is insidious and involves a dry progressive cough. It affects persons 50 to 70 years old. Serologic tests are too nonspecific to be helpful diagnostically. Antinuclear antibody, erythrocyte sedimentation rate, rheumatoid factor, and gamma globulins are often mildly abnormal. HRCT findings vary but typically include lower lobe predominance of interlobular septal thickening with subpleural fibrosis and honeycombing with few, if any, ground-glass opacities. In many cases of IPF/UIP, peripheral honeycombing and ground-glass opacities are seen together. Classic HRCT findings in combination with a compatible clinical presentation suggest IPF/UIP and may obviate the need for bronchoscopy or biopsy. PFTs are expected to demonstrate restrictive abnormalities, with reduced diffusing capacity and abnormal gas exchange with various degrees of hypoxemia. By the time the diffusing capacity is about 50% of predicted or less, hypoxemia with exercise is usually present. As a rule, the response to treatment is poor. Corticosteroids, other immunosuppressive agents (e.g., azathioprine and cyclophosphamide), and antifibrotic drugs (e.g., colchicine and penicillamine) have not been shown clearly to be of benefit. Some data suggest that corticosteroids worsen the outcome of IPF/UIP if more than a low dose (prednisone equivalent of ≥10 mg/day) is administered. Whether newer therapies, including interferon-γ and antifibrotic agents, will be effective is not known, but they are being studied in large multicenter trials. The overall prognosis is poor, with 5-year survival from the time of diagnosis estimated to be 20%.

Nonspecific Interstitial Pneumonia

NSIP represents a distinct histopathologic type of interstitial lung disease. Its pathologic features often are found in drug-induced or collagen vascular disease–associated interstitial diffuse lung disease. However, in many cases, it appears to be idiopathic. NSIP generally occurs in younger patients (≤50 years) and has a female-male ratio of 2:1. HRCT often shows ground-glass opacities, in contrast to the basilar subpleural honeycombing, fibrosis, and traction bronchiectasis typical of IPF/UIP. The course usually includes various degrees of cough, dyspnea, and fever over weeks or months. The cellularity detected with BAL and the inflammatory components seen in biopsy specimens tend to be greater than those of IPF/UIP. Thus, NSIP tends to be more responsive to corticosteroid therapy and to have a better prognosis overall, with a 5-year survival rate of approximately 65% to 80%.

Sarcoidosis

Sarcoidosis is a granulomatous disease of patients who generally are younger than 50 years. It may present as lung disease, either as acute inflammatory disease or chronic end-stage diffuse fibrotic lung disease. The development of sarcoidosis has not been linked to tobacco use. Although the lymph nodes and lungs are the most commonly involved organs, the disease can affect virtually any organ, including the heart, liver, spleen, eye, bone, skin, bone marrow, parotid glands, pituitary, reproductive organs, and the nervous system. If the disease is systemic, hypercalcemia, anemia, and increased liver enzyme levels may be noted. Familial clusters of sarcoidosis have been reported. The incidence, clinical course, and prognosis are influenced by ethnic and genetic factors. Stages 0 through IV correlate with the severity of pulmonary disease and the prognosis. Radiographic stage 0 indicates a normal CXR; stage I, hilar adenopathy; stage II, hilar adenopathy with pulmonary

infiltrates; stage III, infiltrates without adenopathy; and stage IV, fibrotic lung disease. CXRs may also demonstrate characteristic right paratracheal, bilateral hilar, or mediastinal lymphadenopathy (or a combination of these) with or without eggshell calcification. Chest CT may show small nodules with a bronchovascular and subpleural distribution, thickened intralobular septa, architectural distortion, or conglomerate masses.

A diagnosis of acute sarcoidosis (Löfgren syndrome) can be made on the basis of clinical findings in a young patient who presents with fever, erythema nodosum, polyarthritis, and hilar adenopathy. For the diagnosis in most other cases, granulomatous histopathologic features need to be demonstrated and other causes of granulomatous inflammation need to be excluded, primarily infectious (mycotic and mycobacterial) causes. If hilar adenopathy and parenchymal infiltrates are present, bronchoscopy with biopsy confirms granulomatous changes in more than 90% of cases. Thus, sarcoidosis must be considered a diagnosis of exclusion after other causes of granulomatous disease have been ruled out.

Although rales may be present when acute parenchymal interstitial changes occur, the lung fields typically are clear on auscultation even if parenchymal infiltrates are substantial. The serum levels of ACE are not sufficiently sensitive or specific to be of diagnostic value, but they may be helpful as a marker of disease activity.

Corticosteroids are first-line therapy. However, whether any immunosuppressive therapy, including corticosteroids, alters the natural course of the disease is debated. Other immunosuppressive regimens used as second-line therapy for pulmonary sarcoidosis have included methotrexate, azathioprine, pentoxifylline, and cyclosporine. Treatment is reserved for progressive disease or advanced-stage disease with active granulomatous inflammation. In up to 90% of patients with stage I pulmonary sarcoidosis, the disease is expected to remain stable or to resolve spontaneously with no treatment. Stage III pulmonary sarcoidosis is expected to spontaneously remit in only 10% of patients. Pregnancy does not alter disease activity, although a flare in disease activity may occur post partum. Pulmonary sarcoidosis is expected to progress within 2 to 5 years after diagnosis, although increased disease activity can occur at any time. Indefinite long-term follow-up is recommended for patients with stage II or higher pulmonary or extrapulmonary sarcoidosis.

Desquamative Interstitial Pneumonia and Respiratory Bronchiolitis–Associated Interstitial Lung Disease

Desquamative interstitial pneumonia and respiratory bronchiolitis–associated interstitial lung disease (RB-ILD) likely represent similar entities along a spectrum of disease. Both are diagnosed universally in current or former smokers who present with worsening cough and dyspnea over weeks or months. Crackles may be present. In desquamative interstitial pneumonia, chest CT demonstrates diffuse ground-glass opacities, but in RB-ILD, it shows a mix of diffuse, fine reticular, or nodular interstitial abnormalities. PFTs may show restrictive, obstructive, or mixed abnormalities, with various degrees of reduced diffusing capacity and hypoxemia. Macrophages are thought to be an integral part of the disease process. Abnormal accumulations of macrophages are seen in the alveoli in desquamative interstitial pneumonia and in the peribronchiolar airway–respiratory bronchioles in RB-ILD. Mild fibrosis of the peribronchiolar area is more prominent in RB-ILD than in desquamative interstitial pneumonia, in which little fibrosis is noted. Cellularity, including lymphocytic infiltration, is also more prominent in the airway-oriented lesions of RB-ILD than the relatively bland macrophage accumulations seen in the alveoli in desquamative interstitial pneumonia. Smoking cessation is the mainstay of therapy, although corticosteroids have been used in some instances. Overall, prognosis is better for both of these conditions than for IPF/UIP. The expected 10-year mortality rate for desquamative interstitial pneumonia is approximately 30%.

Lymphangioleiomyomatosis

This is a disease of women of childbearing age. It is characterized clinically by a history of recurrent pneumothoraces, chylous pleural effusions, diffuse infiltrates with hypoxemia, and airflow obstruction. HRCT typically demonstrates well-defined cysts scattered throughout the lungs, without nodules or interstitial fibrosis. Hemoptysis is common. Pregnancy or exogenous estrogens may worsen the course of the disease. The histopathologic features, similar to those of tuberous sclerosis, include a distinctive proliferation of atypical interstitial smooth muscle and thin-walled cysts within the lung. Extrapulmonary involvement may include uterine leiomyomas and renal angiomyolipomas. The response to treatment with hormonal manipulation has been limited. Currently, lung transplantation is the definitive treatment.

Langerhans Cell Histiocytosis

Langerhans cell histiocytosis is a rare diffuse lung disease of young white smokers. Spontaneous pneumothoraces are common. CXR demonstrates diffuse interstitial infiltrates with classic cystic and nodular changes, predominantly in the upper lobe. The distinctive nodular component with cystic change seen on HRCT differentiates Langerhans cell histiocytosis from lymphangioleiomyomatosis. Airflow obstruction with decreased diffusing capacity and hypoxemia is expected. In the systemic variant of the disease, bone may be involved, especially in children. Pituitary insufficiency with central diabetes insipidus has been described, as it has been for other granulomatous processes, including sarcoidosis. Peripheral blood eosinophilia is not expected, although eosinophilia may be detected on BAL. PFTs often demonstrate restrictive, obstructive, or mixed changes, with reduced diffusing capacity and various degrees of gas exchange abnormality and hypoxemia. Aggregates of Langerhans cells interspersed with normal lung parenchyma are the characteristic histopathologic finding. An increase in the number of Langerhans cells can be detected by staining BAL specimens for OKT6, which is overexpressed in these cells. Absolute cessation from smoking is mandatory. The response to abstinence from all tobacco products varies, with stabilization or improvement noted in as many as two-thirds of patients. Langerhans cell histiocytosis increases the risk of bronchogenic cancer. The success of corticosteroid treatment and chemotherapy has been limited. Transplantation is reserved for advanced, progressive disease.

Hypersensitivity Pneumonitis (Extrinsic Allergic Alveolitis): Farmer's Lung Disease, Hot-Tub Lung, and Bird Fancier's Lung Disease

Hypersensitivity pneumonitis is an uncommon but often discussed form of diffuse lung disease. It respresents an allergic sensitization to various antigens, including molds, grain dusts (farmer's lung), pets and birds (bird fancier's lung), and mycobacterial antigens (hot-tub lung). Serum precipitins for specific antigens are inconsistently specific and have poor sensitivity for diagnostic purposes. In many cases, serum precipitins are tested but the results are not helpful diagnostically except for patients who have a clear history of exposure to birds and positive serologic results to testing with an avian panel of antigens. Other blood tests are expected to demonstrate nonspecific and various degrees of leukocytosis and eosinophilia and an increase in the erythrocyte sedimentation rate and rheumatoid factor and a mild increase in antinuclear antibodies. Patients may present with acute inflammatory disease, subacute mixed inflammatory–fibrotic disease, or chronic fibrotic lung disease. The symptoms and clinical course are related temporally to antigen exposure. Acutely, patients may experience dyspnea, cough, fever, chest pain, headache, malaise, fatigue, and flulike illness. Clinically, radiographically, histopathologically, or bronchoscopically, chronic diffuse fibrotic lung disease may be indistinguishable from IPF/UIP.

The histopathologic features of hypersensitivity pneumonitis show a range of bronchiolar-oriented, loosely organized, noncaseating granulomas with lymphocytic-predominant centrilobular infiltrates and various degrees of fibrosis, depending on how long the disease has been present. PFTs show restrictive abnormalities, although an airway component may also be present and result in an obstructive component. Gas exchange abnormalities and hypoxemia may be profound in more severe cases of acute or chronic disease. Bronchodilators may be needed to treat airflow obstruction. CXR generally demonstrates reticulonodular changes, with various amounts of alveolar infiltrates. HRCT findings often include nonspecific nodules and ground-glass opacities, predominantly in the upper lobe. Diffuse fibrotic changes indistinguishable from those of IPF/UIP may be seen in chronic disease. Acute symptoms generally improve after the patient is removed from antigen exposure. Severe cases require treatment with corticosteroids.

Asbestos-Related Lung Disease

Asbestos-related lung disease manifests as diffuse interstitial lung disease (asbestosis), but it may also present as benign pleural plaques and effusions, malignant mesothelioma, pulmonary nodules, or rounded atelectasis. The asbestos fibers usually associated with the disease are the amphibole type, of which the crocidolite subtype is the most fibrogenic and carcinogenic. A dose-response relation has been reported consistently between the intensity and duration of exposure to asbestos fibers and the development of asbestosis. A long dormant period between exposure and symptomatic disease is common. The dormant period for interstitial disease, pleural plaques, and malignant mesothelioma is generally longer (20-40 years) than for the development of benign pleural effusions (<15 years). Progressive isolated pleural disease may lead to restrictive pulmonary function without parenchymal change. Asbestos-related interstitial lung disease is characterized by a progressive course of dry cough, dyspnea, and basilar rales in association with restrictive abnormalities detected with PFTs, decreased diffusing capacity, and hypoxemia. Smoking greatly increases the risk of bronchogenic cancer for patients with asbestos-related interstitial disease and may accelerate the rate of progression of parenchymal lung disease. A basilar predominance of interstitial infiltrates seen on CXR resembles that of IPF/UIP. Pleural plaques, when present, may differentiate asbestosis from IPF/UIP. Although HRCT is not needed as often to establish the diagnosis of asbestosis as it is for IPF/UIP, it is able to detect parenchymal changes earlier than CXR and it demonstrates the characteristic subpleural lines, parenchymal bands, thickened interlobular septal lines, and honeycombing. Treatment, including corticosteroids, is not effective.

Silicosis

Silicosis-related diffuse lung disease may result from acute or chronic exposure to silica dust. Generally, the disease affects predominantly the upper lobe, with typical 1- to 3-mm nodular infiltrates. Coalescence may lead to conglomerate masses and fibrosis. Dry cough and dyspnea are typical symptoms. Eggshell calcifications of mediastinal and hilar lymph nodes may be seen, as in sarcoidosis. The antinuclear antibodies are often high titer, but their role in disease progression is unclear. PFTs are usually normal, unless the disease is advanced. Restrictive changes and a decrease in diffusing capacity without obstructive change are expected. Patients with silicosis are at increased risk of *Mycobacterium tuberculosis* infection and should have screening tests for latent tuberculosis infection and active disease. The risk of bronchogenic cancer is less for silicosis than for asbestosis.

BOOP

BOOP is a specific histopathologic entity that can occur with collagen vascular- and drug-induced diffuse lung disease, various infections, radiation injury, and other conditions. Idiopathic BOOP appears to represent a distinct clinical diagnosis, assuming that other secondary causes have been excluded. It generally affects men and women between 50 and 70 years old. The presentation is more acute, occurring over days or weeks, than that of IPF/UIP, which occurs over months or years. Approximately 75% of cases of idiopathic BOOP present within 8 weeks after symptoms appear. Most often, the symptoms are cough, dyspnea, fever, fatigue, and flulike illness not responsive to antibiotics. CXR findings include consolidation, interstitial infiltrates, alveolar infiltrates, or mixed infiltrates. Often, the infiltrates are predominantly peripheral, resembling chronic eosinophilic pneumonia. Diagnosis is usually confirmed by transbronchial or VATS open lung biopsy. The response to corticosteroid therapy is generally dramatic. Overall, the prognosis is favorable. Long-term outcome studies do not usually indicate progression.

Diffuse Alveolar Damage, ARDS, and Acute Interstitial Pneumonitis

Diffuse alveolar damage is a specific pathologic diagnosis made on the basis of lung biopsy findings. When diffuse alveolar damage is found in combination with causes of the systemic inflammatory

response syndrome, including sepsis, pneumonia, pancreatitis, and trauma, the clinical diagnosis is ARDS or, if it is less severe, acute lung injury. If a patient presents with acute or subacute hypoxemic respiratory failure and diffuse lung disease without any identifiable cause and the histopathologic features of diffuse alveolar damage, the diagnosis is acute interstitial pneumonitis. The mortality rate is high (>50%-80%), and the disease is not very responsive to treatment, including high-dose corticosteroids or other aggressive immunosuppressive regimens. Treatment is largely supportive.

Eosinophilic Pneumonia

Acute and chronic eosinophilic pneumonias are two of several forms of eosinophilic lung disease. Acute eosinophilic pneumonia has acute onset (days) of severe dyspnea and cough associated with fulminant hypoxemic respiratory failure and diffuse alveolar and interstitial infiltrates and, usually, pleural effusions. Peripheral blood eosinophilia is not necessarily present, but marked eosinophilia is expected in BAL and pleural fluid specimens. Typically, the response to corticosteroid therapy is complete and without relapse. The long-term prognosis is excellent. In comparison, chronic eosinophilic pneumonia presents with cough, dyspnea, and fever over months or years and, clinically and radiographically, may be essentially indistinguishable from IPF/UIP or chronic BOOP. In the subacute form of the disease, CXR typically shows pulmonary edema, which may also be seen in some cases of BOOP and occasionally in sarcoidosis and drug reactions. BAL fluid eosinophilia with peripheral blood eosinophilia (88% of patients) is expected. Usually, long-term corticosteroid therapy is required to prevent disease relapse.

Lymphocytic Interstitial Pneumonitis

Lymphocytic interstitial pneumonitis is an unusual form of interstitial diffuse lung disease that is related to several hematologic diseases (e.g., lymphoma), autoimmune disorders (e.g., Sjögren syndrome), dysproteinemia, human immunodeficiency virus infection, and transplant rejection (graft-versus-host disease). The response to treatment is highly variable and depends primarily on the underlying disease process.

Giant Cell Pneumonitis

Another rare form of interstitial diffuse lung disease, giant cell pneumonitis is most often associated with hard-metal (e.g., cobalt) pneumoconioses.

Pulmonary Alveolar Proteinosis

Pulmonary alveolar proteinosis is a rare and idiopathic form of diffuse lung disease characterized by the filling of alveoli with proteinaceous material consisting mostly of phospholipoprotein (dipalmitoyl lecithin). A defect in the signaling of granulocyte-macrophage colony-stimulating factor is thought to contribute to the clinical manifestations. Most patients are smokers younger than 50 years, with a male predominance (male-female ratio of 3:1). Symptoms of dyspnea, cough, and low-grade fever are common. Many infectious, occupational, inflammatory, and environmental secondary causes of pulmonary alveolar proteinosis-like presentations have been recognized. Increased predisposition to *Nocardia* infections has been reported. CXR may demonstrate an alveolar filling pattern infiltrate that resembles "bat wings," mimicking pulmonary edema. A nonspecific but characteristic alveolar filling pattern seen with HRCT, described as a "crazy paving" pattern with airspace consolidation and thickened interlobular septa, is suggestive of pulmonary alveolar proteinosis. A milky white return of BAL fluid or lung biopsy findings usually indicate the diagnosis. In addition to smoking cessation, therapy has involved whole lung lavage and, more recently, trials of granulocyte-macrophage colony-stimulating factor.

Alveolar Microlithiasis

Alveolar microlithiasis, a rare form of idiopathic familial (autosomal recessive) diffuse lung disease, is characterized by interstitial infiltrates. Fine miliary nodular changes due to the deposition of microliths occur throughout all lung fields. Most patients are asymptomatic through the third to fourth decades of life. Symptoms of dyspnea may progress to cor pulmonale as the disease advances. No therapy has been shown to be effective.

Summary

In summary, diffuse lung disease represents a wide range of idiopathic and secondary disease processes of the lung that have various presentations and prognoses. A directed, complete medical history and physical examination in combination with judicious use of laboratory data, PFTs, chest imaging, bronchoscopy, and open lung biopsy when needed can considerably narrow the differential diagnosis and provide important therapeutic and prognostic information.

Part III

Karen L. Swanson, DO

Pulmonary Neoplasms

Solitary Pulmonary Nodule

A *solitary pulmonary nodule* is defined as a solitary lesion seen on plain chest radiography (CXR). It is less than 4 cm in diameter and is round, ovoid, or slightly lobulated. The lesion is located in lung parenchyma, is at least moderately circumscribed, and is uncalcified on plain CXRs. It is not associated with satellite lesions or other abnormalities on plain CXRs. Common causes include carcinoma of the lung (15%-50% of patients), mycoses (5%-50%), tuberculosis, uncalcified granulomas, resolving pneumonia, hamartoma, and metastatic lesions. Granulomas and hamartomas make up 40% to 60% of all solitary pulmonary nodules and 90% of nonmalignant solitary pulmonary nodules. Hamartomas alone comprise less than 10% of nonmalignant nodules. Uncommon causes include carcinoid tumors, bronchogenic cysts, resolving infarction, rheumatoid and vasculitic nodules, and arteriovenous malformations.

- Granulomas and hamartomas make up 40%-60% of all solitary pulmonary nodules and 90% of nonmalignant solitary pulmonary nodules.
- Hamartomas alone comprise <10% of nonmalignant nodules.

Clinical Evaluation

The following are important in the evaluation of solitary pulmonary nodules: age of patient, availability of previous CXRs, smoking history, previous malignancy, exposure to tuberculosis, travel to areas endemic for mycoses, recent respiratory infection, recent pulmonary embolism (suggestive of infarction), recent trauma to the chest, asthma, mucoid impaction, systemic diseases (congestive heart failure or rheumatoid arthritis), ear-nose-throat symptoms (Wegener granulomatosis), exposure to mineral oil or oily nose drops, immune defense mechanisms, and family history (arteriovenous malformation seen in hereditary hemorrhagic telangiectasia).

- History: old CXRs for comparison, age, smoking history, previous malignancy, and exposure history are important.

Diagnosis

Physical examination, routine blood tests, chemistry group, and the exclusion of obvious causes (e.g., congestive heart failure, vasculitis, and rheumatoid arthritis) are important for making the diagnosis. Obtain an earlier CXR for comparison if possible. Generally, sputum cytology, skin tests, serologic studies, and cultures are unrewarding in evaluating asymptomatic patients. Bronchoscopy has a 60% diagnostic yield in cancer. Transthoracic needle aspiration with computed tomographic (CT) or fluoroscopic guidance has an 85% diagnostic yield in cancer but a 20% risk of pneumothorax. CT detects 30% more nodules than CXR and is helpful in assessing the location of a solitary pulmonary nodule, calcification, cavitation, satellite lesions, margins, density, and multiple nodules (particularly in evaluating metastatic malignancy) and in the staging of lung cancer. A nodule is more likely to show contrast enhancement on CT if it is malignant. For nodules larger than 1 cm, dynamic positron emission tomography (PET) with fludeoxyglucose F 18 imaging reportedly differentiates malignant from benign pulmonary lesions more accurately than CT and may be helpful in evaluation and staging. It is important to remember that enhancement on PET scanning can be seen with malignancy as well as with inflammatory or infectious processes, so it is not diagnostic. Similarly, carcinoid tumors and bronchoalveolar cell carcinoma may not enhance on PET scanning, leading to a false-negative result. For asymptomatic patients who have a single lung nodule, extensive studies (gastrointestinal tract series, intravenous pyelography, and scans of bone, brain, liver, and bone marrow) are not indicated because of the low diagnostic yield (<3%).

- CT detects 30% more nodules than CXR.
- A nodule is more likely to show contrast enhancement on CT if it is malignant.
- Bronchoscopy has a 60% diagnostic yield in cancer.
- Transthoracic needle aspiration (CT- or fluoroscopy-guided) has an 85% diagnostic yield in cancer but a 20% risk of pneumothorax.

Decision Making

General guidelines for decision making are given in Table 22-14. If a benign cause cannot be firmly established after complete clinical, imaging, culture, and biopsy evaluations, the following clinical decisions advocate surgical resection: 1) the solitary pulmonary nodule is probably malignant because little or no other clinical information is available to indicate a benign diagnosis or 2) the nodule may be benign but must be resected now because the benign nature cannot be established. If the clinical information firmly indicates a benign cause, follow-up CXR is recommended. If the nodule is followed clinically, serial CXR or CT (or both) should be performed for at least 2 years to ensure no change. If the patient is a poor surgical risk, repeat CXR or CT (or both) every 3 to 6 months (enlargement of the lesion may alter the decision).

- If the nodule is followed clinically, serial CXR or CT (or both) should be performed for at least 2 years to ensure no change.
- If the patient is a poor surgical risk, repeat CXR or CT (or both) every 3-6 months (enlargement of the lesion may alter the decision).

Primary Lung Cancer

Lung cancer is the most common malignant disease and the most common cause of cancer death in the United States. The estimated incidence of new lung cancer cases in 2004 was 13% (of all cancers)

Table 22-14 Likelihood of Benign or Malignant Single Pulmonary Nodule According to Clinical and Radiographic Variables

Clinical factor or radiographic result	More likely benign	More likely malignant
Patient age, y	<35	≥35
Sex	Female	Male
Smoking	No	Yes
Symptoms	No	Yes
Exposure to tuberculosis, cocci, etc.	Yes	No
Previous malignancy	No	Yes
Nodule size, cm	<2.0	≥2.0
Nodule age, y	≥2	<2
Doubling time, d	<30	≥30
Nodule margins	Smooth	Irregular
Calcification	Yes	No
Satellite lesions	Yes	No

for both men and women. It was estimated that more than 170,000 new cases would be diagnosed and more than 160,000 deaths would be attributable to lung cancer. The risk factors include cigarette smoking (25% of cancers may result from passive smoking), other carcinogens, cocarcinogens, radon exposure (uranium mining), arsenic (glass workers, smelters, and pesticides), asbestos (insulation, textile, and asbestos mining), coal dust (coke oven, road work, and roofing work), chromium (leather, ceramic, and metal), vinyl chloride (plastic), chloromethyl ether (chemical), and chronic lung injury (idiopathic pulmonary fibrosis and chronic obstructive pulmonary disease [COPD]). Genetic and nutritional factors (perhaps deficiency of vitamin A) have been implicated.

The World Health Organization (WHO) classification of pathologic types of pulmonary neoplasms is given in Table 22-15 and the TNM classification for staging of non–small cell lung carcinoma, in Table 22-16.

Small cell carcinoma is staged as follows:

1. Limited: single hemithorax, mediastinum, ipsilateral supraclavicular nodes
2. Extensive: anything beyond limited stage

Overall Survival

The overall 5-year survival for all stages of lung cancer is 14%. The overall survival rate for patients with occult and in situ cancers is greater than 70%. The overall survival for other stages is as follows: stage I, 50%; stage II, less than 20%; and stage III, less than 10%. One-year survival for stage I cancer is greater than 80%. In small cell cancer, the median survival is less than 12 months; the 5-year survival for limited cancer is 15% to 20% and for extensive disease, 1% to 5%.

- The overall 5-year survival for all lung cancers is 14%.

Cell Types

Primary lung cancer is broadly divided into non–small cell lung carcinoma (adenocarcinoma, 35%; squamous cell carcinoma, 30%; and large cell carcinoma, 1%-15%), small cell carcinoma (20%-25%), mixed (small and large cell), and others (metastatic lesions).

Clinical Features

Most patients are older than 50 years. Only 5% of patients with lung cancer are asymptomatic. The presentation is highly variable and depends on the cell type, location, rate of growth, paraneoplastic syndromes, systemic symptoms, and other factors. Cough is the most frequent symptom and is more likely in squamous cell carcinoma and small cell lung carcinoma than in other types of lung cancer. Hemoptysis occurs in 35% to 50% of patients and is more common with squamous cell, small cell, carcinoid, and endobronchial metastases than with other types of tumors. Wheezing is due to intraluminal tumor or extrinsic compression. Dyspnea depends on the extensiveness of the tumor, COPD, degree of bronchial obstruction, and other factors. Persistent chest pain may suggest rib metastasis, local extension, or pleural involvement. Superior vena cava syndrome may suggest small cell carcinoma, lymphoma, squamous cell carcinoma, or Pancoast tumor. Horner syndrome is indicative of Pancoast tumor. Fever, postobstructive pneumonitis, nonthoracic skeletal pain, central nervous system symptoms, abdominal pain or discomfort, and hepatomegaly are indicative of possible distant metastases. During the course of the disease, central nervous system metastasis is found in 15% of patients with squamous cell carcinoma, in 25% with

Table 22-15 World Health Organization Classification of Pulmonary Neoplasms

Type	Histologic type
I	Squamous cell carcinoma
II	Small cell carcinoma
	Oat cell carcinoma
	Intermediate cell carcinoma
	Combined oat cell carcinoma
III	Adenocarcinoma
	Acinar adenocarcinoma
	Papillary adenocarcinoma
	Bronchoalveolar carcinoma
	Solid carcinoma with mucus formation
IV	Large cell carcinoma
	Giant cell carcinoma
	Clear cell carcinoma
V	Combined cell types
VI	Carcinoid
VII	Bronchial gland tumors
	Cylindroma
	Mucoepidermoid
VIII	Papillary tumors

Table 22-16 Staging of Lung Cancer: TNM Classification

T, primary tumor	
T0	No evidence of primary tumor
TX	Cancer cells in respiratory secretions; no tumor on chest radiographs or at bronchoscopy
Tis	Carcinoma in situ
T1	Tumor ≤3 cm in greatest dimension, surrounded by lung tissue; no bronchoscopic evidence of tumor proximal to lobar bronchus
T2	Tumor >3 cm in diameter, or tumor of any size that involves visceral pleura, or associated with atelectasis extending to hilum (but not involving entire lung); must be ≥2 cm from main carina
T3	Tumor involves chest wall, diaphragm, mediastinal pleura, or pericardium, or is <2 cm from main carina (but does not involve it)
T4	Tumor involves main carina or trachea, or invades mediastinum, heart, great vessels, esophagus, or vertebrae, or malignant pleural effusion
N, nodal involvement	
NX	Regional lymph nodes cannot be assessed
N0	No demonstrable lymph node involvement
N1	Ipsilateral peribronchial or hilar lymph nodes involved
N2	Metastasis to ipsilateral mediastinal lymph nodes or to subcarinal lymph nodes
N3	Metastasis to contralateral mediastinal and/or hilar lymph nodes or to scalene and/or supraclavicular lymph nodes
M, metastasis	
MX	Presence of distant metastasis cannot be assessed
M0	No known distant metastasis
M1	Distant metastasis present (specify site or sites)

Stage Grouping—TNM Subsets*

Stage 0	Carcinoma in situ	Stage IIIB	T4 N0 M0
			T4 N1 M0
Stage IA	T1 N0 M0		T4 N2 M0
Stage IB	T2 N0 M0		T1 N3 M0
			T2 N3 M0
Stage IIA	T1 N1 M0		T3 N3 M0
Stage IIB	T2 N1 M0		T4 N3 M0
	T3 N0 M0		
		Stage IV	Any T, any N, M1
Stage IIIA	T3 N1 M0		
	T1 N2 M0		
	T2 N2 M0		
	T3 N2 M0		

*Staging is not relevant for occult carcinoma, designated TX N0 M0.

adenocarcinoma, in 28% with large cell carcinoma, and in 30% with small cell carcinoma.

- Cough and hemoptysis are more common in squamous cell carcinoma and carcinoid.
- Chest pain may indicate pleural effusion, pleural metastasis, or rib lesion.
- Nonpulmonary symptoms may indicate distant metastases or paraneoplastic syndromes.
- Central nervous system metastasis is more common with small cell carcinoma.

Squamous Cell Carcinoma

Two-thirds of squamous cell carcinomas arise in the proximal tracheobronchial tree (first four subdivisions). They also may arise in the upper airway and esophagus. Symptoms appear early in the course of the disease because of proximal bronchial involvement and consist of cough, hemoptysis, and lobar or segmental (or both) collapse with postobstructive pneumonia. CXR findings include atelectasis (23% of patients), obstructive pneumonitis (13%), hilar adenopathy (38%), and cavitation (35%). One-third of cases present as peripheral masses. Bronchoscopy is indicated in almost all patients. One-third of squamous cell carcinomas have thick-walled irregular

cavities. Treatment is resection in combination with either irradiation or chemotherapy (or both). Laser bronchoscopy and endobronchial brachytherapy are palliative measures.

- Squamous cell carcinoma: proximal airway disease in 66% of cases, peripheral mass in 33%, and cavitation in 35%.
- Bronchoscopy is an important test.

Adenocarcinoma

Most adenocarcinomas arise in the periphery and, thus, remain asymptomatic and undetected until they have spread locally or distally. This means that the chance of dissemination to extrapulmonary sites is higher for these tumors. However, incidentally detected peripheral carcinomas tend to be in an early stage. Adenocarcinoma is the most common type of peripheral primary lung cancer. Sputum cytology has a low diagnostic yield. The most common presentation is as a solitary peripheral nodule. A small number cavitate. Clubbing and hypertrophic pulmonary osteoarthropathy are more common than in other kinds of primary lung cancer. The response to radiotherapy and chemotherapy is generally poor.

- Adenocarcinoma: A solitary pulmonary nodule in the periphery of the lung.
- The symptomatic stage usually denotes advanced disease.
- Sputum cytology has a low diagnostic yield.
- Clubbing and hypertrophic pulmonary osteoarthropathy are more common than in squamous cell carcinoma.

Bronchoalveolar Cell Carcinoma

Bronchoalveolar cell carcinoma is thought to arise from alveolar type II pneumocytes or Clara cells (or both) and is unrelated to tobacco smoking. The tumor presents in two forms: as a localized solitary nodular lesion and as a diffuse alveolar process. More than 60% of patients are asymptomatic. The cancer presents as a solitary nodule in the majority of patients and as lobar pneumonitis or a diffuse infiltrate in a minority. The solitary form has the best prognosis of all types of lung cancer, with a 1-year survival rate greater than 80% after resection. Patients with the diffuse form have a mean survival of less than 6 months. Bronchorrhea (>100 mL of a thin, serous mucous secretion in 24 hours) is seen in 20% of patients (usually with the diffuse form). CXR shows a solitary nodule, localized infiltrate with vacuoles (on tomography), or pneumonic lesions. Both forms of bronchoalveolar cell carcinoma can mimic ordinary pneumonia. Because of the slow growth, the chronic course of the disease may suggest a benign process; thus, close surveillance is imperative. The treatment of a solitary lesion is resection. The response to radiotherapy and chemotherapy is poor, although bronchorrhea seems to respond to radiotherapy in some patients.

- Bronchoalveolar cell carcinoma: unrelated to tobacco smoking.
- The solitary form grows slowly and may mimic a benign lung nodule.
- The solitary (localized) form has a 1-year survival rate >80% after resection.
- The diffuse form has a mean survival of <6 months.
- Bronchorrhea occurs in 20% of patients (usually with the diffuse form).

Large Cell Carcinoma

Large cells are seen on histologic examination, and CXR shows large masses. Large cell carcinoma grows more rapidly than adenocarcinoma. Cavitation occurs in 20% to 25% of patients. Clubbing and hypertrophic pulmonary osteoarthropathy are more common than in other tumors except for adenocarcinoma. The treatment is surgical. The response to irradiation and chemotherapy is poor.

- Large cell carcinoma: A large, rapidly growing lung mass, with cavitation in 25% of patients; clubbing and hypertrophic pulmonary osteoarthropathy are common.

Small Cell Carcinoma

Small cell carcinoma (oat cell carcinoma) accounts for 25% of all bronchogenic carcinomas. Smokers and uranium miners are at high risk. It is associated with many paraneoplastic syndromes, including the syndrome of inappropriate antidiuretic hormone (SIADH), corticotropin (ACTH) production, and myasthenic syndrome (Eaton-Lambert syndrome). The tumor originates from neuroendocrine cells, invades the tracheobronchial tree, and spreads submucosally. Later, it breaks through the mucosa and produces changes similar to those seen in squamous cell carcinoma. CXR shows a unilateral, rapidly enlarging hilar or perihilar mass or widening of the mediastinum. Less than 20% of these tumors are peripheral. Bronchoscopy may show heaped-up or thickened mucosa. This tumor responds better to radiotherapy and chemotherapy than do other lung tumors. Brain metastasis is common. Prophylactic brain irradiation is standard at many medical centers; this decreases the frequency of brain metastasis but does not prolong survival. Peripheral nodules that are found after resection to be small cell carcinoma should be treated as any small cell carcinoma.

- Small cell carcinoma: smokers and uranium miners are at high risk; it is associated with many paraneoplastic syndromes, including SIADH, ACTH production, and myasthenic syndrome (Eaton-Lambert syndrome).
- Surgical treatment is not a standard therapeutic option; radiotherapy and chemotherapy are.

Carcinoid

Carcinoid arises from the same cells as small cell carcinoma, but its clinical behavior is different. Typically, carcinoid presents with cough, with or without hemoptysis, in young adults. CXR may show a solitary nodule or segmental atelectasis. Paraneoplastic syndromes in pulmonary carcinoid are rare (occurring in <1% of patients with bronchial carcinoid) but can develop from hormonal secretion (ACTH and parathyroid hormone [PTH]). Treatment is surgical resection of the tumor without lung resection. The diagnosis of malignant carcinoid is based on the extent of spread noted at resection or on clinical behavior.

- Typical clinical scenario for carcinoid: A young adult presents with cough and hemoptysis; symptoms may be related to the production of ACTH (Cushing syndrome and hypertension) and PTH (hypercalcemia).
- Carcinoid "syndrome" is rare, occurring in <1% of patients with bronchial carcinoid.

Bronchial Gland Tumors

Cylindroma (adenoid cystic carcinoma) and mucoepidermoid tumors usually are located centrally and cause cough, hemoptysis, and obstructive pneumonia. Distant metastasis is unusual. Cylindromas arising in salivary glands can metastasize to the lungs after many years. Surgical treatment is used for lesions causing major airway obstruction. The response to radiotherapy and chemotherapy is poor.

- Cylindromas arising in salivary glands can metastasize to the lungs after many years.

Mesenchymal Tumors

This group of tumors includes lymphoma, lymphosarcoma, carcinosarcoma, fibrosarcoma, mesothelioma, and soft tissue sarcomas. Many of these present as large peripheral masses, homogeneous densities, and cavitated lesions.

Lymphoma

Patients with Hodgkin or non-Hodgkin lymphoma may have pulmonary involvement. CXR findings include bilateral hilar adenopathy, chylous pleural effusion, segmental atelectasis from endobronchial lesions, a diffuse nodular process, fluffy infiltrates, and diffuse interstitial or alveolar infiltrates (or both). Almost all cases of lymphocytic interstitial pneumonitis represent low-grade lymphomas that originate from the mucosa-associated lymphoid tissue (MALToma). They are very responsive to chemotherapy.

- Intrathoracic involvement is common in Hodgkin lymphoma.
- Bilateral hilar lymphadenopathy and chylous pleural effusion may occur.
- Hodgkin lymphoma can produce any type of CXR abnormality.

Diagnostic Tests

Sputum cytology findings are positive in up to 60% of patients with squamous cell carcinoma, in 21% with small cell carcinoma, in 16% with adenocarcinoma, and in 13% with large cell carcinoma. More tumors are diagnosed with CXR than with sputum cytology, but CXR is not recommended as a surveillance tool for all patients. Lung cancer screening using chest CT scanning continues to be studied but is currently not endorsed by the American Cancer Society. Bronchoscopy is helpful in diagnosing the cell type, in assessing staging and resectability, in using laser treatment for large airway tumors, and in brachytherapy. Transthoracic needle aspiration has an 85% to 90% yield, but the incidence of pneumothorax is 25%. CT is helpful in assessing the number of nodules in patients with pulmonary metastasis and in examining the hila and mediastinum. Positive results on pleural fluid cytology establish stage IIIB disease. Mediastinoscopy and mediastinotomy (Chamberlain procedure) are staging procedures that are often used before thoracotomy is performed.

- More lung tumors are diagnosed with CXR than with sputum cytology.
- Sputum cytology findings are positive in up to 60% of patients with squamous cell cancer.
- Routine surveillance of all susceptible persons (heavy smokers) with CXR and sputum cytology or with chest CT is not recommended.

Paraneoplastic Syndromes

As a group, primary lung tumors are the most common cause of paraneoplastic syndromes. The presence of a paraneoplastic syndrome does not indicate metastatic spread of lung cancer. It is more helpful to consider paraneoplastic manifestations based on each organ system (see below).

- Primary lung tumors cause most of the paraneoplastic manifestations.
- A paraneoplastic syndrome does not indicate metastatic spread of lung cancer.

Endocrine

Small cell carcinoma is associated with SIADH and ACTH production. Hypokalemia, muscle weakness, and CXR abnormality should suggest ACTH production. These patients do not survive long enough for the typical Cushing syndrome to develop. The ACTH levels are high and not suppressed by dexamethasone. ACTH is also produced by bronchial carcinoid. Hypercalcemia is not associated with small cell carcinoma. The overall frequency of hypercalcemia is 13%, with squamous cell cancer as the cause in 25% of patients, large cell carcinoma in 13%, and adenocarcinoma in 3%. Bony metastasis may also cause hypercalcemia. Hyperpigmentation from melanocyte-stimulating hormone occurs in small cell carcinoma. Calcitonin is secreted in 70% of patients with small cell carcinoma and in adenocarcinoma. SIADH is also seen in some patients with alveolar cell carcinoma and adenocarcinoma. Hypoglycemia with insulin-like polypeptide is found in patients with squamous cell carcinoma and mesothelioma. The human chorionic gonadotropin, luteinizing hormone, and follicle-stimulating hormone secreted by adenocarcinoma and large cell carcinoma may be responsible for gynecomastia.

- Abnormal CXR, hypokalemia, and muscle weakness: small cell carcinoma (ACTH).
- ACTH is also produced by bronchial carcinoid.
- Hypercalcemia: squamous cell carcinoma and carcinoid.

Nervous System

The mechanisms for encephalopathy, myelopathy, sensorimotor neuropathies, and polymyositis are unknown but may include toxic, nutritional, autoimmune, and infectious causes. Cerebellar ataxia is similar to alcohol-induced ataxia and is more common with squamous cell carcinoma. Myasthenic syndrome (Eaton-Lambert syndrome)

is closely associated with small cell carcinoma; the proximal muscles are initially weak, but strength returns to normal with repeated stimulation on electromyography. This differentiates Eaton-Lambert syndrome from myasthenia gravis. Focal neurologic signs should suggest central nervous system metastasis. Acute and rapidly progressive lower extremity signs should indicate spinal cord compression by tumor. Antineuronal nuclear antibody (ANNA)-1 is positive in many patients with small cell carcinoma.

- Myasthenic syndrome may precede the clinical detection of small cell carcinoma.
- Cerebellar ataxia (similar to alcohol-induced ataxia) is more common in squamous cell carcinoma.

Skeletal

Hypertrophic pulmonary osteoarthropathy (HPO) indicates periosteal bone formation and is associated with clubbing and symmetrical arthralgias. Other features include fever, gynecomastia, and an increased erythrocyte sedimentation rate (ESR). The proposed mechanisms include neural (vagal afferents), hormonal, and others. HPO is more common in adenocarcinoma and large cell carcinoma than in squamous cell and small cell lung carcinoma, and it may precede detection of the tumor by months. Clubbing may be the only feature. Removal of the tumor relieves the HPO, but ipsilateral vagotomy may be indicated if the HPO persists after resection of the tumor. Octreotide appears to be effective in treating HPO.

- HPO is more common in adenocarcinoma and large cell carcinoma.
- Tumor resection relieves HPO.
- Treatment: octreotide (somatostatin analogue) or ipsilateral vagotomy if the HPO persists after resection of the tumor.

Others

Other paraneoplastic manifestations include malignant cachexia, marantic endocarditis, increased incidence of thrombophlebitis, fever, erythrocytosis, leukocytosis, lymphocytopenia, eosinophilia, thrombocytosis, leukemoid reaction, disseminated intravascular coagulation, dysproteinemia, fever, acanthosis nigricans (adenocarcinoma), epidermolysis bullosa (squamous cell carcinoma), and nephrotic syndrome.

Pulmonary Metastases

Nearly 30% of all cases of malignant disease from extrapulmonary sites metastasize to the lung. More than 75% present with multiple lesions, and the rest may present as a solitary pulmonary nodule, a diffuse process, lymphangitic spread (breast, stomach, thyroid, pancreas, and the lung itself), or endobronchial metastases (kidney, colon, Hodgkin lymphoma, and breast). Solitary metastases are more common with carcinoma of the colon, kidneys, testes, and breast and with sarcoma and melanoma. The estimated occurrence of pulmonary metastasis by primary tumor is as follows: choriocarcinoma, 80%; osteosarcoma, 75%; kidney, 70%; thyroid, 65%; melanoma, 60%; breast, 55%; prostate, 45%; nasopharyngeal, 20%; gastrointestinal tract, 20%; and gynecologic malignancies, 20%.

Vascular Diseases

Pulmonary Embolism

Pulmonary embolism (PE) is the cause of death of 5% to 15% of patients who die in hospitals in the United States. In a multicenter study of PE, the mortality rate at 3 months was 15% and important prognostic factors included age older than 70 years, cancer, congestive heart failure, COPD, systolic arterial hypotension, tachypnea, and right ventricular hypokinesis. PE is detected in 25% to 30% of routine autopsies. Antemortem diagnosis is made in less than 30% of cases. Among hospitalized patients, the prevalence of PE is 1%. The risk of death from untreated PE is 8%. In about 90% of patients who die of PE, death occurs within 1 to 2 hours. The risk of fatal PE is greater among patients with severe deep venous thrombosis (DVT).

- PE is a common problem; consider PE in all patients who have lung problems.
- Antemortem diagnosis is made in <30% of cases.
- The risk of death from untreated PE is 8%.

Etiology

The factor responsible for most PEs is DVT of the lower extremities. Among patients with fatal PE, DVT has been identified clinically in only 40%. In those with a large angiographically diagnosed PE, DVT is detected in about 35%. About 60% of patients with PE have asymptomatic lower extremity DVT. Approximately 45% of femoral and iliac DVTs embolize to the lungs. Other sources of emboli include thrombi in the upper extremities, right ventricle, and indwelling catheters. In up to 20% of patients, DVTs from the calves propagate to the thigh and iliac veins, and up to 10% of cases of superficial thrombophlebitis are complicated by DVT. The risk of recurrent DVT is similar among carriers of factor V Leiden and patients without this mutation. The primary and secondary coagulation abnormalities that predispose to the development of DVT and PE are listed in Table 22-17.

- DVT is detected in only 40% of cases of PE.
- Consider factor V Leiden mutation and deficiencies of antithrombin III, protein S, and protein C and the presence of lupus anticoagulant among predisposing factors for DVT and PE.

The incidence of DVT in various clinical circumstances is listed in Table 22-18. Idiopathic DVT, particularly when recurrent, may indicate the presence of neoplasm in 10% to 20% of patients. The presence of varicose veins does not increase the risk of DVT.

- In idiopathic, recurrent DVT, look for an occult neoplasm.
- Risk of DVT: thoracic surgery, 25%-60%; hip surgery, 50%-75%; post–myocardial infarction, 20%-40%; congestive heart failure, 70%; and stroke with paralysis, 50%-70%.

DVT is diagnosed in only 50% of clinical cases. A diagnosis based on physical examination findings is unreliable. The Homan sign (pain and tenderness on dorsiflexion of the ankle) is elicited in less

Table 22-17 Coagulation Disorders Predisposing to the Development of Deep Venous Thrombosis and Pulmonary Embolism

Primary hypercoagulable states	Secondary hypercoagulable states
Activated protein C resistance* (factor V Leiden carriers)	Cancer
Antithrombin III deficiency†	Postoperative states (stasis)
Protein C deficiency†	Lupus anticoagulant syndrome
Protein S deficiency†	Increased factor VII and fibrinogen
Fibrinolytic abnormalities	Pregnancy
Hypoplasminogenemia	Nephrotic syndrome
Dysplasminogenemia	Myeloproliferative disorders
TPA release deficiency	Disseminated intravascular coagulation
Increased TPA inhibitor	Acute stroke
Dysfibrinogenemia	Hyperlipidemias
Homocystinuria	Diabetes mellitus
Heparin cofactor deficiency	Paroxysmal nocturnal hemoglobinuria
Increased histidine-rich glycoprotein	Behçet disease and vasculitides
	Anticancer drugs (chemotherapy)
	Heparin-induced thrombocytopenia
	Oral contraceptives
	Obesity

TPA, tissue plasminogen activator.

*Prevalence of factor V Leiden in patients with deep venous thrombosis is 16%; presence of factor V Leiden is associated with a 40% risk of recurrent deep venous thrombosis (N Engl J Med. 1997;336:399-403).

†Prevalence of these protein deficiencies in patients with deep venous thrombosis is 5% to 10%.

From Prakash UBS. Pulmonary embolism. In Murphy JG, editor. Mayo Clinic Cardiology Review. 2nd ed. Philadelphia: Lippincott Williams & Wilkins; 2000. p. 379-406. Used with permission.

than 40% of cases of DVT, and a false-positive Homan sign occurs in 30% of high-risk patients. Impedance plethysmography (IPG) and duplex ultrasonography together are the most commonly used noninvasive tests and have a diagnostic accuracy of 90% to 95% in detecting iliac and femoral DVTs. They are clinically unreliable in the diagnosis of calf vein thrombosis. Serial (daily) IPG or duplex ultrasonography (or both) is recommended for high-risk patients, because of a 15% detection rate of DVT after an initial negative study. Currently, IPG is performed less often than ultrasonography. Duplex ultrasonography is less accurate for the diagnosis of chronic DVT and less useful in pelvic DVT than in the diagnosis of acute femoral DVT. Venography is considered nearly 100% sensitive and specific. Venography should be performed when other tests are nondiagnostic or cannot be performed. Magnetic resonance imaging (MRI) has a high sensitivity and specificity for the diagnosis of pelvic DVT.

- DVT is diagnosed in only 50% of clinical cases.
- IPG plus duplex ultrasonography is up to 95% accurate for detecting iliac and femoral DVTs.

Clinical Features

PE has no pathognomonic clinical symptoms and signs. Tachypnea and tachycardia are observed in nearly all patients. Other symptoms include dyspnea in 80% of patients, pleuritic pain in up to 75%, hemoptysis in less than 25%, pleural friction rub in 20%, and wheezing in 15%. The differential diagnosis of PE includes myocardial infarction, pneumonia, congestive heart failure, pericarditis, esophageal spasm, asthma, exacerbation of COPD, intrathoracic malignancy, rib fracture, pneumothorax, pleurisy from any cause, pleurodynia, and nonspecific skeletal pains. Acute cor pulmonale occurs if more than 65% of the pulmonary circulation is obstructed by emboli. PE should be suspected in the setting of syncope or acute hypotension.

- PE has no pathognomonic signs or symptoms.
- Acute cor pulmonale occurs when >65% of the pulmonary circulation is obstructed by PE.

Diagnostic Tests

Clinical examination, electrocardiography, CXR, blood gas abnormalities, and increased plasma D-dimer level have low specificity and sensitivity for the diagnosis of PE. Clinical suspicion is the most important factor in steering a clinician toward the appropriate tests to diagnose PE. CXR may show diaphragmatic elevation in 60% of patients, infiltrates in 30%, focal oligemia in 10% to 50%, effusion in 20%, an enlarged pulmonary artery in 20%, and normal findings in 30%. Nonspecific electrocardiographic changes are noted in 80%, ST and T changes in 65%, T inversion in 40%, S_1Q_3 pattern in 15%, right bundle branch block in 12%, and left axis deviation in 12%. In patients in critical condition, echocardiography should be performed early to assess right ventricular hypokinesia or dysfunction.

Table 22-18 Incidence of Deep Venous Thrombosis (DVT) in Various Clinical Circumstances

Clinical circumstance	Incidence of DVT, %
Major abdominal surgery*	14-33
Thoracic surgery	25-60
Gynecologic surgery	
Patient age ≤40 y	<3
Patient age >40 y	10-40
Patient age >40 y + other risks	40-70
Urologic surgery	10-40
Hip surgery	50-75
Post–myocardial infarction	20-40
Congestive heart failure	70
Stroke with paralysis	50-70
Post partum	3
Trauma	20-40

*Odds are 1:20 without prophylaxis and 1:50 with prophylaxis.

- Normal CXR in 30% of patients with PE.
- The classic S_1Q_3 pattern is seen in only 15% of patients.

Both the partial pressure of arterial oxygen (PaO_2) and the alveolar-arterial difference in partial pressure of oxygen, $P(A\text{-}a)O_2$ gradient, may be normal in 15% to 20% of patients. The $P(A\text{-}a)O_2$ gradient shows a linear correlation with the severity of PE. A normal $P(A\text{-}a)O_2$ gradient does not exclude PE. Indeed, in the Prospective Investigation of Pulmonary Embolism Diagnosis (PIOPED) study, about 20% of patients with angiographically documented PE had a normal $P(A\text{-}a)O_2$ gradient (≤20 mm Hg). Most patients with acute PE demonstrate hypocapnia.

- The $P(A\text{-}a)O_2$ gradient correlates linearly with the severity of PE.
- Of patients with PE, 20% have a normal $P(A\text{-}a)O_2$ gradient (≤20 mm Hg).

The plasma levels of D-dimer (a specific fibrin degradation product) are increased in DVT and in PE. However, high levels themselves have no positive predictive value for PE. A normal level of D-dimer does not exclude PE but makes it unlikely in patients with a low pretest probability of PE. Age and pregnancy are associated with increased levels. Levels less than 300 µg/L (by enzyme-linked immunosorbent assay [ELISA]) or less than 500 µg/L (by latex agglutination) are considered to reliably exclude PE in patients with an abnormal but not high-probability ventilation-perfusion (V/Q) lung scan. A plasma concentration of D-dimer of less than 500 µg/L allows the exclusion of PE in less than 30% of patients with suspected PE. Currently, the D-dimer test cannot be recommended as a standard part of the PE or DVT diagnostic algorithm.

- Increased D-dimer levels have no positive predictive value for PE.
- Normal D-dimer levels (<500 µg/L) exclude PE in <30% of cases.

Echocardiography can identify thrombi in the right side of the heart in up to 15% of patients with PE. Dysfunction of the right ventricle, frequently seen in massive as well as recurrent PE, can be detected with echocardiography. Although the echocardiographic findings are abnormal in more than 80% of patients with documented PE, the findings are nonspecific. The presence of associated abnormalities (intracardiac tumors or myxoma) poses a difficulty in distinguishing among the lesions. A highly mobile intracavitary thrombus-in-transit has a 98% risk of acute PE and a 1-week mortality of 50%. Transesophageal echocardiography is reportedly 97% sensitive and 86% specific for the diagnosis of centrally located pulmonary arterial thrombi. Currently, the role of echocardiography in the diagnosis of acute PE is undefined.

The V/Q scan is commonly used in the diagnosis of PE. A "high-probability" lung scan has a sensitivity of 41% and a specificity of 97%. A "low-probability" lung scan excludes the diagnosis of PE in more than 85% of patients. A normal lung scan excludes PE in 100% of cases. An "intermediate-probability" or "indeterminate-probability" scan is associated with PE in 21% to 30% of patients. Therefore, patients with an intermediate-probability lung scan usually require pulmonary angiography. A negative or normal perfusion-only scan (excluding ventilation scan) rules out PE with a very high probability.

- High-probability scan: 90% probability of PE.
- Intermediate-probability scan: 30% probability of PE.
- Low-probability scan: 15% probability of PE.
- Normal scan excludes PE in 100% of cases.

CT permits ultrafast scanning of pulmonary arteries during contrast injection. In some institutions, spiral (helical) CT with intravenous contrast (CT angiography) is being used more frequently than V/Q scans to detect PE. Sensitivity and specificity rates greater than 95% have been reported. Spiral CT has the greatest sensitivity in the diagnosis of PE in the main, lobar, or segmental arteries. Lymph node enlargement may result in false-positive studies. MRI may have the advantage of detecting both DVT and PE.

- Spiral CT has the greatest sensitivity in the diagnosis of PE in the main, lobar, or segmental arteries.

Pulmonary angiography is the best diagnostic test. It should be performed within 24 to 48 hours after the diagnosis has been considered. However, it is nondiagnostic in 3% of cases. Major and minor complications following pulmonary angiography occur in 1% and 2% of patients, respectively, and mortality from the procedure is 0.5%. Pulmonary angiography followed by therapy with tissue plasminogen activator (TPA) is associated with a 14% risk of major hemorrhage.

- Major and minor complications from pulmonary angiography are 1% and 2%, respectively.

Treatment

The therapy for uncomplicated DVT is identical to that for PE. For acute disease, treatment can begin simultaneously with both heparin (low-molecular-weight heparin [LMWH] or unfractionated heparin [UFH]) and warfarin unless warfarin is contraindicated. When treatment with both drugs is begun simultaneously, an overlap for 4 to 5 days is recommended. For patients with acute disease, UFH (80 IU/kg) is administered as a bolus, followed by a maintenance dose of 18 IU/kg per hour intravenously. The dose should be adjusted to maintain an activated partial thromboplastin time (APTT) of 1.5 to 2 times the control value. With LMWH regimens, indications for outpatient therapy include stable proximal DVT or PE, normal vital signs, low risk of bleeding, and availability of appropriate monitoring.

- In acute DVT or PE, heparin (LMWH or UFH) and warfarin treatment can begin simultaneously.
- UFH dose: bolus, 80 IU/kg; maintenance, 18 IU/kg per hour.
- APTT in uncomplicated cases: 1.5-2 times normal.

Long-term anticoagulant therapy can be maintained with either heparin or warfarin. LMWH has been prescribed for patients who have difficulty monitoring the APTT. Warfarin at a dose to achieve an international normalized ratio (INR) of 2.0 to 3.0 is recommended. The loading dose of warfarin is usually 10 mg daily for 1 or 2 days, followed by adjustment of the dose to maintain an INR of 2.0 to 3.0. Recurrent and complicated cases (e.g., coagulopathies) may require lifelong anticoagulation, maintenance of higher APTT or prothrombin time (PT), and other measures such as the inferior vena cava filter. The recommended duration of treatment of venous thromboembolic disease is given in Table 22-19.

- PT in uncomplicated cases: INR of 2.0-3.0.
- Duration of treatment for first episode of idiopathic DVT or PE: 3-6 months.

Thrombolytic agents are administered in cases of massive PE and massive iliofemoral thrombosis. The indications are debated, although these drugs generally are indicated for patients with massive DVT or PE (or both). The 1-year mortality among those treated with heparin alone is 19% and among those treated with thrombolytic agents, 9%. The rate of recurrent PE in heparin-alone therapy is 11% and in thrombolytic therapy, 5.5%. Ideally, thrombolytic agents should be administered within 24 hours after PE. The doses for different agents are as follows: streptokinase, loading dose of 250,000 IU infused over 30 minutes, followed by a maintenance dose of 100,000 IU per hour for up to 24 hours; urokinase, loading dose of 4,400 IU/kg infused over 10 minutes, followed by continuous infusion of 4,400 IU/kg per hour for 12 hours; and TPA, a total dose of 100 mg given intravenously over a 2-hour period. The adequacy of thrombolytic therapy is monitored with the thrombin time. Heparin infusion is begun or resumed if the APTT is less than 80 seconds after thrombolytic therapy.

- Thrombolytic agents should be administered within 24 hours after PE.
- Heparin therapy is necessary after thrombolytic therapy.

Among patients receiving chronic warfarin therapy, the cumulative incidence of fatal bleeding is 1% at 1 year and 2% at 3 years. A greater risk of major hemorrhage exists when anticoagulation is continued indefinitely. The presence of malignant disease at the initiation of warfarin therapy is significantly associated with major hemorrhage. Patients with PE treated with thrombolytic drugs have about a 1% risk of intracranial bleeding.

- Thrombolytic therapy: 1% risk of intracranial bleeding.

Drugs that prolong the effect of warfarin include, among others, salicylates, heparin, estrogen, antibiotics, clofibrate, quinidine, and cimetidine. Drugs that decrease the effect of warfarin include glutethimide, rifampin, barbiturates, and ethchlorvynol. This is only a partial list of drugs that interfere with warfarin metabolism. Therefore, the physician recommending warfarin therapy should ascertain the drug-drug interaction or consult a pharmacist.

- Knowledge of the interaction of warfarin with other drugs is important.

Inferior Vena Cava Interruption

Inferior vena cava interruption is aimed at preventing PE while maintaining blood flow through the inferior vena cava. It is indicated if anticoagulant therapy is contraindicated, complications result from anticoagulant therapy, anticoagulant therapy fails, a predisposition to bleeding is present, chronic recurrent PE and secondary pulmonary hypertension occur, or surgical pulmonary thromboendarterectomy has been performed or is intended to be performed. Inferior vena cava plication does not replace anticoagulant therapy; many patients require both. After the filter has been inserted, anticoagulant therapy is aimed at preventing DVT at the insertion site,

Table 22-19 Recommended Duration of Treatment of Venous Thromboembolic Disease

Patient characteristic	Duration of treatment, mo
First event, with a reversible or time-limited risk factor*	≥3
First episode of idiopathic DVT or PE	3-6
Recurrent idiopathic DVT or PE or a continuing risk factor†	≥12

DVT, deep venous thrombosis; PE, pulmonary embolism.
*Surgery, trauma, immobilization, or estrogen use.
†Cancer, antithrombin deficiency, anticardiolipin antibody syndrome.
Modified from Hyers TM, Agnelli G, Hull RD, Morris TA, Samama M, Tapson V, et al. Antithrombotic therapy for venous thromboembolic disease. Chest. 2001;119:176S-93S. Used with permission.

inferior vena cava thrombosis, cephalad propagation of a clot from an occluded filter, or propagation or recurrence of lower extremity DVT. PE occurs in 2.5% of patients despite inferior vena cava interruption.

- Inferior vena cava plication does not replace chronic anticoagulant therapy.
- PE occurs in 2.5% of patients despite inferior vena cava interruption.

Prophylaxis

Prophylaxis against DVT and PE includes early ambulation after surgery or immobilization, intermittent pneumatic compression of the lower extremities, active and passive leg exercises, and a low dose of heparin given subcutaneously. A low dose of heparin decreases the incidence of DVT from 25% to 8%. Prophylactic enoxaparin, 40 mg daily subcutaneously, safely reduces the risk of DVT in patients with acute medical illnesses. LMWH has been approved in the United States for prophylaxis against DVT and PE after total hip arthroplasty and total knee arthroplasty. A postoperative, fixed-dose LMWH (enoxaparin, 30 mg subcutaneously every 12 hours) is more effective than adjusted-dose warfarin (INR 2.0-3.0) in preventing DVT after total hip or knee arthroplasty. LMWH has a rapid onset of action, is safe, and is approximately 50% more effective than standard heparin. Also, heparin-induced thrombocytopenia is reduced with LMWH. Because of a more predictable dose response to LMWH, it is not necessary to monitor the APTT.

- LMWH has been approved in the United States for DVT and PE prophylaxis after total hip arthroplasty.
- LMWH therapy does not require measuring APTT.
- Heparin-induced thrombocytopenia is reduced with LMWH.

Complications of PE

Pulmonary infarction occurs in less than 10% of patients with PE. Pulmonary infarction and hemorrhage occur more frequently in patients with disseminated intravascular coagulation. Complications of pulmonary infarction include secondary infection, cavitation, pneumothorax, and hemothorax. Recurrent PE (in 8% of patients) is a common cause of secondary pulmonary hypertension (in 0.5% of patients). Mechanical obstruction of one-half to two-thirds of the pulmonary vascular bed by emboli is necessary for this complication to develop.

- Pulmonary infarction occurs in <10% of patients.
- Recurrent PE occurs in 8%.
- Secondary pulmonary hypertension occurs in 0.5%.

Pulmonary Vasculitides

The vasculitides are a heterogeneous group of disorders of unknown cause characterized by various degrees of inflammation and necrosis of the arteries and, sometimes, veins. Immunologic factors, the absence or deficiency of certain chemical mediators in the body, and mycotic infectious processes, particularly those caused by *Aspergillus* and *Mucor*, are associated with vasculitis. The common vasculitides and their frequency in North America are as follows: giant cell (temporal) arteritis, 26.5%; polyarteritis nodosa, 14.6%; Wegener granulomatosis, 10.5%; Schönlein-Henoch purpura, 10.5%; Takayasu arteritis, 7.8%; and Churg-Strauss syndrome, 2.5%.

Wegener Granulomatosis

Wegener granulomatosis is a systemic vasculitis of arteries and veins characterized by necrotizing granulomatous vasculitis of the upper and lower respiratory tract, glomerulonephritis, and variable degrees of small-vessel vasculitis. The Wegener triad consists of necrotizing granulomas of the upper or lower respiratory tract (or both), generalized focal necrotizing vasculitis of arteries and veins in the lungs, and glomerulonephritis. Bronchiolitis obliterans with organizing pneumonia (BOOP), bronchocentric inflammation, a marked eosinophilic infiltrate, and alveolar hemorrhage are atypical features. Pulmonary capillaritis occurs in up to 40% of patients. Eosinophilic infiltrates are seen in tissue samples, but peripheral blood eosinophilia is not a feature of Wegener granulomatosis. The term *limited Wegener granulomatosis* is used to describe the disease involving the lungs only.

- Typical clinical scenario for Wegener granulomatosis: systemic disease with major respiratory manifestations and renal involvement with focal segmental glomerulonephritis.

The cause of Wegener granulomatosis is unknown. Occupational exposure has been suggested as an etiologic factor; a sevenfold risk for development of Wegener granulomatosis was observed in persons with a history of inhalation of silica-containing compounds and grain dust. Heterozygotes for the P_I*Z variant of the α_1-antitrypsin gene are reported to have a sixfold greater risk of developing the disease than the general population. The prevalence of Wegener granulomatosis in the United States is approximately 3 per 100,000 persons. Some have noted associations between disease exacerbations during the winter months and during pregnancy.

The mean age at the onset of symptoms is 45.2 years (the male-female ratio is 2:1); 91% of the patients are white. The initial symptoms are nonspecific: fever, malaise, weight loss, arthralgias, and myalgias. The organs affected are the ear, nose, and throat (initial complaints in 90% of patients are rhinorrhea, purulent or bloody nasal discharge, sinus pain, nasal mucosal drying and crust formation, epistaxis, and otitis media); skin (40%-50% of patients); and eyes (43%) and the central nervous system (25%). Arthralgias occur in 58% of patients and frank arthritis in 28%. Patients older than 60 have a relatively low incidence of upper respiratory tract complaints but a high incidence (4.5-fold) of neurologic involvement. Two important signs of Wegener granulomatosis are nasal septal perforation and ulceration of the vomer bone. The differential diagnosis of the "saddle-nose" deformity includes Wegener granulomatosis, relapsing polychondritis, and leprosy.

- Major organs affected are represented by the mnemonic *ELKS* (**e**ar, nose, and throat; **l**ungs; **k**idney; and **s**kin).
- Ear-nose-throat symptoms are the initial complaints in 90% of patients.

- Nasal septal perforation and ulceration of the vomer bone are two important signs.
- Differential diagnosis of "saddle-nose" deformity: Wegener granulomatosis, relapsing polychondritis, and leprosy.

Ulcerated lesions of the larynx and trachea occur in 30% of untreated patients, and subglottic stenosis occurs in 8% to 18% of treated patients. The pulmonary parenchyma is affected in more than 60% of patients. Symptoms include cough, hemoptysis, and dyspnea. The clinical manifestations can range from subacute to rapidly progressive respiratory failure. Most patients with pulmonary symptoms have associated nodular infiltrates on CXR. Hemoptysis is seen in 98% of patients and CXR abnormalities are seen in 65% (unilateral in 55% and bilateral in 45%), including infiltrates (63%), nodules (31%), infiltrates with cavitation (8%), and nodules with cavitation (10%). CXR shows rounded opacities (from a few millimeters to several centimeters large). The nodules are usually bilateral and one-third cavitate. Solitary nodules occur in 30% to 40% of patients. Pneumonic infiltrates, lobar consolidation, and pleural effusions are also seen. Diffuse alveolar infiltrates indicate alveolar hemorrhage. Massive pulmonary alveolar hemorrhage is occasionally a life-threatening emergency. Benign stenoses of the tracheobronchial tree (15% of patients) are more likely in chronic cases and in patients whose disease is stable. The shape of the inspiratory and expiratory flow volume loop should be assessed.

- Hemoptysis occurs in almost all patients.
- CXR: multiple nodules in 31% of patients or masses with cavitation in 10% of patients who have CXR abnormalities.
- Diffuse alveolar infiltrates indicate alveolar hemorrhage.
- Tracheobronchial stenosis occurs in 15% of patients. Assess the shape of the inspiratory and expiratory flow volume loop.

Laboratory tests demonstrate mild or moderate normochromic normocytic anemia, mild leukocytosis, mild thrombocytosis, positive rheumatoid factor, and elevations of immunoglobulins IgG and IgA and circulating immune complexes. A highly increased ESR (often >100 mm/h) is a consistent finding. Peripheral blood eosinophilia is not a feature. All these abnormalities are nonspecific. Urinalysis is an important test because hematuria, proteinuria, and red cell casts are found in 80% of patients.

- Increased ESR.
- Hematuria, proteinuria, and red cell casts occur in 80% of patients.

The antineutrophil cytoplasmic autoantibodies (ANCAs) are used to corroborate the diagnosis of Wegener granulomatosis. The two main patterns of ANCA are cytoplasmic (c-ANCA) and perinuclear (p-ANCA). Almost all c-ANCAs are directed to proteinase 3 (PR3), whereas myeloperoxidase (MPO) is the major target antigen of p-ANCA. Also, c-ANCA is highly specific and sensitive for Wegener granulomatosis and is present in more than 90% of patients with systemic Wegener granulomatosis. In active disease, the sensitivity and specificity are 91% and 98%, respectively, whereas in inactive disease, the values are 63% and 99.5%. The following points are important:

1. A positive c-ANCA without clinical evidence of disease does not establish the diagnosis.
2. Some patients with active disease have negative results for c-ANCA.
3. Some patients have persistently positive c-ANCA results despite inactive disease or disease in remission.
4. c-ANCA titers may increase without evidence of an increase in disease activity.
5. c-ANCA is present in other diseases, such as hepatitis C virus infection, some cases of microscopic polyangiitis, and ulcerative colitis and as a manifestation of sulfasalazine toxicity.

- c-ANCA is generally considered specific for Wegener granulomatosis.
- Positive c-ANCA without clinical evidence of disease does not establish the diagnosis.
- c-ANCA can be positive in other diseases.

p-ANCA is positive in various diseases, including inflammatory bowel disease, autoimmune liver disease, rheumatoid arthritis, and many other vasculitides. Reportedly, p-ANCA with specificity against MPO is closely associated with microscopic polyangiitis, mononeuritis multiplex, leukocytoclastic vasculitis of the skin, pauci-immune necrotizing-crescentic glomerulonephritis, and other vasculitides affecting small vessels. Some cases of Churg-Strauss syndrome may demonstrate p-ANCA with specificity for MPO.

- p-ANCA has been noted in other vasculitides and collagen diseases.
- p-ANCA with specificity for MPO should suggest small-vessel vasculitis (microscopic polyangiitis).

The combination of corticosteroids and cyclophosphamide produces complete remission in more than 90% of patients. The usual dosage of each drug is up to 2 mg/kg daily orally. In milder cases, corticosteroids alone may be sufficient. Because of immunosuppression, the overall incidence of *Pneumocystis jiroveci* (formerly *Pneumocystis carinii*) pneumonia in these patients is approximately 6%. Respiratory infection, particularly from *Staphylococcus aureus*, is more common. The nasal carriage rate for this bacteria is higher in patients with Wegener granulomatosis. Disease relapse usually is associated with viral or bacterial infections. A combination of trimethoprim, 160 mg daily, and sulfamethoxazole, 800 mg daily, is an effective prophylactic regimen to prevent disease relapse; 82% of treated patients remain in remission for 24 months compared with 60% who do not receive prophylaxis. Stenosis of large airways may require bronchoscopic interventions, including dilation by rigid bronchoscope, YAG-laser treatment, and placement of silicone airway stents.

- Cyclophosphamide and corticosteroids are effective.
- Trimethoprim-sulfamethoxazole is effective in preventing relapse.

Giant Cell (Temporal) Arteritis

Giant cell arteritis, also known as *temporal arteritis*, *cranial arteritis*, and *granulomatous arteritis*, is a vasculitis of unknown cause. It usually

affects middle-aged or older persons. Pulmonary complications include cough, sore throat, and hoarseness. Nearly 10% of the patients have prominent respiratory symptoms, and respiratory symptoms are the initial manifestation in 4%. Giant cell arteritis should be considered in older patients who have a new cough or throat pain without obvious cause. Pulmonary nodules, interstitial infiltrations, pulmonary artery occlusion, and aneurysms have been described. Virtually all patients have a favorable response to systemic corticosteroid therapy.

- Giant cell arteritis: nearly 10% of patients have prominent respiratory symptoms.
- Cough, sore throat, and hoarseness may be the presenting features.

Churg-Strauss Syndrome

Churg-Strauss syndrome, also called *allergic granulomatosis* and *angiitis*, is among the least common of the vasculitides. It is characterized by pulmonary and systemic vasculitis, extravascular granulomas, increased levels of IgE, and eosinophilia, which occur exclusively in patients with asthma or a history of allergy. Patients have progressive respiratory distress. Allergic rhinitis, nasal polyps, nasal mucosal crusting, and septal perforation occur in more than 70% of patients. Nasal polyposis is a major clinical finding. The chief pulmonary manifestation is refractory asthma, which is noted in almost all patients. CXR abnormalities are noted in more than 60% of patients: patchy and occasionally diffuse alveolar-interstitial infiltrates in the perihilar area, with a predilection for the upper two-thirds of the lung fields. Up to one-third of patients with Churg-Strauss vasculitis develop pleural effusions. A dramatic response can be expected with high doses of systemic corticosteroids.

- Churg-Strauss syndrome: Refractory asthma, progressive respiratory distress, allergic rhinitis, nasal polyps, nasal mucosal crusting, septal perforation in >70% of patients, tissue and blood hypereosinophilia, and increased IgE.

Behçet Disease

Behçet disease is a chronic, relapsing, multisystemic inflammatory disorder characterized by aphthous stomatitis along with two or more of the following: aphthous orogenital ulcerations (in >65% of patients), uveitis, cutaneous nodules or pustules, synovitis, and meningoencephalitis. Superficial venous thrombosis and DVT of the upper and lower extremities and thrombosis of the inferior and superior venae cavae occur in 7% to 37% of patients. Pulmonary vascular involvement produces severe hemoptysis. Severe hemoptysis, initially responsive to therapy with corticosteroids, tends to recur; death is due to hemoptysis in 39% of patients. CXR may show lung infiltrates, pleural effusions, prominent pulmonary arteries, and pulmonary artery aneurysms. Aneurysms of the pulmonary artery communicating with the bronchial tree (bronchovascular anastomosis) should be considered in patients with Behçet disease and massive hemoptysis. Because of the high incidence of DVT of the extremities and the venae cavae, PE commonly occurs in these patients. Corticosteroids and chemotherapeutic agents have been used to treat Behçet disease. The prognosis is poor if marked hemoptysis develops.

- Behçet disease: aphthous stomatitis, uveitis, cutaneous nodules, and meningoencephalitis.
- Severe hemoptysis is the cause of death in 39% of patients.
- A fistula between the airway and vascular structures is common.
- High incidence of DVT and PE.

Takayasu Arteritis

Takayasu arteritis, also known as *pulseless disease*, *aortic arch syndrome*, and *reversed coarctation*, is a chronic inflammatory disease of unknown cause that affects primarily the aorta and its major branches, including the proximal coronary arteries and renal arteries and the elastic pulmonary arteries. The pulmonary arteries are involved in more than 50% of patients, with lesions in medium-size and large arteries. Early abnormalities occur in the upper lobes, whereas the middle and lower lobes are involved in later stages of the disease. Perfusion lung scans have shown abnormalities in more than 75% of patients; pulmonary angiography has demonstrated arterial occlusions in 86%. Corticosteroid therapy has produced symptomatic remission within days to weeks. Pulmonary involvement signifies a poor prognosis.

- Takayasu arteritis: pulmonary artery involvement in >50% of patients.

Mixed Cryoglobulinemia

Mixed cryoglobulinemia is characterized by recurrent episodes of purpura, arthralgias, weakness, and multiorgan involvement. Frequently, levels of cryoglobulin and rheumatoid factor are increased. Biopsy findings in vascular structures are similar to those in leukocytoclastic vasculitis. The most serious complication is glomerulonephritis caused by deposition of immune complexes. Pulmonary insufficiency, Sjögren syndrome-like illness with lung involvement, subclinical T-lymphocytic alveolitis, diffuse pulmonary vasculitis with alveolar hemorrhage, BOOP, and bronchiectasis have been described in isolated cases.

- Mixed cryoglobulinemia: lymphocytic alveolitis, BOOP, alveolar hemorrhage.

Polyarteritis Nodosa

Polyarteritis nodosa is characterized by a necrotizing arteritis of small and medium-size muscular arteries involving multiple organ systems. This disease seldom affects the lungs. Arteritis affecting bronchial arteries and producing diffuse alveolar damage has been reported. Lung involvement is rare also in Schönlein-Henoch purpura.

- Polyarteritis nodosa and Schönlein-Henoch purpura rarely affect the lungs.

Secondary Vasculitis

Many of the rheumatologic diseases (e.g., systemic lupus erythematosus, rheumatoid arthritis, and scleroderma) demonstrate

secondary vasculitic processes in the tissues involved. Certain infectious processes, particularly mycoses, may cause secondary vasculitis. For treatment of vasculitic lesions, the well-known etiologic agents such as drugs and chemicals should be considered.

- Collagen diseases are common causes of secondary vasculitis.

Alveolar Hemorrhage Syndromes

Diffuse hemorrhage into the alveolar spaces is called *alveolar hemorrhage syndrome*. Disruption of the pulmonary capillary lining may result from damage caused by different immunologic mechanisms (e.g., Goodpasture syndrome, renal-pulmonary syndromes, glomerulonephritis, and systemic lupus erythematosus), direct chemical or toxic injury (e.g., toxic or chemical inhalation, penicillamine, mitomycin, abciximab, all-*trans*-retinoic acid, trimellitic anhydride, and smoked crack cocaine), physical trauma (pulmonary contusion), and increased vascular pressure within the capillaries (mitral stenosis and severe left ventricular failure). The severity of hemoptysis, anemia, and respiratory distress depends on the extent and rapidity with which bleeding occurs in the alveoli. Alveolar hemorrhage is indicated, reportedly, if hemosiderin-laden macrophages constitute more than 20% of the total alveolar macrophages recovered with bronchoalveolar lavage. Pulmonary alveolar hemorrhage is strongly associated with thrombocytopenia ($\leq 50 \times 10^9$/L), other abnormal coagulation variables, renal failure (creatinine ≥2.5 mg/dL), and a history of heavy smoking.

- Alveolar hemorrhage syndrome is caused by different mechanisms.
- Hemoptysis is not a consistent feature.
- Increased risk with platelets $\leq 50 \times 10^9$/L, other coagulopathy, creatinine ≥2.5 mg/dL, and heavy smoking.
- Drugs that cause alveolar hemorrhage: penicillamine, abciximab, all-*trans*-retinoic acid, and mitomycin.

Goodpasture Syndrome

Goodpasture syndrome is a classic example of a cytotoxic (type II) disease. The Goodpasture antigen (located in type IV collagen) is the primary target for the autoantibodies. The highest concentration of Goodpasture antigen is in the glomerular basement membrane (GBM). The alveolar basement membrane is affected by cross-reactivity with the GBM. Lung biopsy specimens show diffuse alveolar hemorrhage. Immunofluorescent microscopy shows linear deposition of IgG and complement along basement membranes. Anti-GBM antibody is positive in more than 90% of patients, but it is also present in persons exposed to influenza virus, hydrocarbons, or penicillamine and in some patients with systemic lupus erythematosus, polyarteritis nodosa, or Schönlein-Henoch purpura. The cause of Goodpasture syndrome is unknown, but influenza virus, hydrocarbon exposure, penicillamine, and unknown genetic factors are known to stimulate anti-GBM antibody production. Inadvertent exposure to hydrocarbons has resulted in the exacerbation of Goodpasture syndrome. The treatment of rheumatoid arthritis and other diseases with penicillamine and carbimazole has been associated with Goodpasture syndrome, circulating anti-GBM antibodies, and focal necrotizing glomerulonephritis with crescents. Azathioprine hypersensitivity may mimic pulmonary Goodpasture syndrome.

- Goodpasture syndrome: a classic example of a cytotoxic (type II) disease.
- Anti-GBM antibody is positive in >90% of patients.
- Anti-GBM antibody is also present in persons exposed to influenza virus, hydrocarbons, or penicillamine and in some patients with collagen diseases.
- Exposure to hydrocarbons may exacerbate the disease.

Patients with anti-GBM antibody–mediated nephritis demonstrate two principal patterns of disease: 1) young men presenting in their 20s with Goodpasture syndrome (glomerulonephritis and lung hemorrhage) and 2) elderly patients, especially women, presenting in their 60s with glomerulonephritis alone. In the classic form (in younger patients) of Goodpasture syndrome, men are affected more often than women (male-female ratio, 7:1) and the average age at onset is approximately 27 years. Recurrent hemoptysis, pulmonary insufficiency, renal involvement with hematuria and renal failure, and anemia are the classic features. Pulmonary hemorrhage almost always precedes renal manifestations. Active cigarette smoking increases the risk of alveolar hemorrhage. Frequent initial clinical features include hemoptysis, hematuria, proteinuria, and an increased serum level of creatinine.

- Typical clinical scenario for the classic form: A young man with glomerulonephritis and lung hemorrhage.
- Typical clinical scenario for the atypical form: An elderly patient, especially a woman, with glomerulonephritis alone.
- Pulmonary hemorrhage almost always precedes renal manifestations.
- Active cigarette smoking increases the risk of alveolar hemorrhage.

CXR demonstrates a diffuse alveolar filling process, with sparing of the costophrenic angles. One-third of the patients with anti-GBM disease (Goodpasture syndrome) test positive for p-ANCA–MPO. These patients are more prone to develop fulminant pulmonary hemorrhage than those who are p-ANCA–negative. Plasmapheresis is the treatment of choice for Goodpasture syndrome. Although complete recovery can be expected in most patients treated with systemic corticosteroids, immunosuppressive agents, or plasmapheresis, relapse occurs in up to 7% of them. A previous history of pulmonary hemorrhage markedly decreases the diffusing capacity of the lung for carbon monoxide without affecting other variables of pulmonary function.

- One-third of the patients with anti-GBM disease test positive for p-ANCA–MPO.
- Patients with positive p-ANCA–MPO are more likely to have fulminant pulmonary hemorrhage.
- Plasmapheresis is the treatment of choice.

Glomerulonephritis

Rapidly progressive glomerulonephritis, in the absence of anti-GBM antibody, is a major cause of pulmonary alveolar hemorrhage. Nearly 50% of the patients with alveolar hemorrhage syndromes caused by a renal mechanism do not have anti-GBM antibody. Alveolar

hemorrhage is mediated by immune-complex disease. Several vasculitic syndromes, including Wegener granulomatosis and microscopic polyangiitis, belong to this group. ANCAs have been detected in patients with idiopathic crescentic glomerulonephritis and alveolar hemorrhage syndrome. The alveolar hemorrhage syndrome in systemic lupus erythematosus and other vasculitides is discussed elsewhere.

- Glomerulonephritis: a major cause of pulmonary alveolar hemorrhage.
- Alveolar hemorrhage is mediated by immune-complex disease.

Vasculitides

Diffuse alveolar hemorrhage is present sometimes in patients with vasculitis. Alveolar hemorrhage is rare as an initial symptom of Wegener granulomatosis and is more common in Churg-Strauss syndrome and Schönlein-Henoch purpura. Alveolar hemorrhage is more common in Behçet disease than in other vasculitides. Pulmonary capillaritis is a distinct histologic lesion characterized by extensive neutrophilic infiltration of the alveolar interstitium, and subclinical alveolar hemorrhage may occur in patients with this disease. This lesion can be seen in various vasculitides such as Wegener granulomatosis, microscopic polyarteritis, systemic lupus erythematosus, and other collagen diseases.

Microscopic Polyangiitis

Microscopic polyangiitis is distinct from classic polyarteritis nodosa, which typically affects medium-size arteries. Pulmonary capillaritis is the most common lesion in microscopic polyangiitis but does not occur in classic polyarteritis nodosa. Microscopic polyangiitis is a systemic vasculitis associated with renal involvement in 80% of patients, characterized by rapidly progressive glomerulonephritis. Other features include weight loss (70% of patients), skin involvement (60%), fever (55%), mononeuritis multiplex (58%), arthralgias (50%), myalgias (48%), and hypertension (34%). Males are affected more frequently than females; the median age at onset is 50 years. Pulmonary alveolar hemorrhage is observed in 12% to 29% of patients and is an important contributory factor to morbidity and mortality. ANCA is detected in 75% of patients with microscopic polyangiitis, and the majority are the p-ANCA–MPO type.

- Microscopic polyangiitis: progressive glomerulonephritis is a major feature.
- Pulmonary alveolar hemorrhage is observed in 12%-29% of patients.
- p-ANCA–MPO is positive in 75% of patients.

Mitral Valve Disease

Diffuse alveolar hemorrhage is a well-known feature of mitral stenosis, even though the possibility is rarely considered in clinical practice. Severe mitral insufficiency can also produce alveolar hemorrhage. Hemoptysis can be the presenting feature. It is caused by the rupture of dilated and varicose bronchial veins early in the course of mitral stenosis, or it is the result of stress failure of pulmonary capillaries. In patients not treated surgically, recurrent episodes of alveolar hemorrhage may lead to chronic hemosiderosis of the lungs, fibrosis, and punctate calcification or ossification of the lung parenchyma.

- Mitral stenosis is an important cause of alveolar hemorrhage syndrome.

Idiopathic Pulmonary Hemosiderosis

Idiopathic pulmonary hemosiderosis is a rare disorder of unknown cause. The term *idiopathic pulmonary hemorrhage* has been suggested instead of the traditional name. Idiopathic pulmonary hemosiderosis is a diagnosis of exclusion. It manifests as recurrent intra-alveolar hemorrhage, hemoptysis, transient infiltrates on CXR, and secondary iron deficiency anemia. The cause is unknown, but many factors have been implicated: heritable defect, an immunologic mechanism based on the presence of antibodies to cow's milk (Heiner syndrome), cold agglutinins, increased serum IgA, viral infections, a primary disorder of airway epithelial cells, and a structural defect of pulmonary capillaries. Idiopathic pulmonary hemosiderosis has been described in association with idiopathic thrombocytopenic purpura, autoimmune hemolytic anemia, and nontropical sprue (celiac disease). A pediatric form of pulmonary hemosiderosis, presumed to be caused by the toxins of a spore growing in humid basements, has been described.

- Idiopathic pulmonary hemosiderosis: a diagnosis of exclusion.

Most cases begin in childhood. Although this disease is often fatal, a prolonged course is common. In children, the male-female ratio is 1:1 and in adults, 3:1. Pathologic features include hemosiderin-laden macrophages. No autoimmune phenomena are noted. Some patients have cold agglutinins. The iron content in the lung depends on the duration of the disease. Clinical features are chronic cough with intermittent hemoptysis, iron deficiency anemia, fever, weight loss, generalized lymphadenopathy (25% of patients), hepatosplenomegaly (20%), clubbing (15%), and eosinophilia (10%). The kidneys are not involved. CXR shows transient, blotchy, perihilar alveolar infiltrates in the mid and lower lung fields. Small nodules, fibrosis, and cor pulmonale may also be found. Intrathoracic lymphadenopathy occurs in up to 25% of patients. Treatment is repeated blood transfusions, iron therapy, corticosteroids, and, possibly, cytotoxic agents. A 30% mortality rate within 5 years after disease onset has been reported.

- Generalized lymphadenopathy in 25% of patients, hepatosplenomegaly in 20%, and clubbing in 15%.
- The kidneys are not involved.
- Eosinophilia in 10% of patients.

Toxic Alveolar Hemorrhage

Dust or fumes of trimellitic anhydride (a component of certain plastics, paints, and epoxy resins) cause acute rhinitis and asthma symptoms if exposure is minor. With greater exposure, alveolar hemorrhage occurs. The trimellitic anhydride–hemoptysis anemia syndrome (pulmonary hemorrhage–anemia syndrome) occurs after "high-dose exposure" to fumes. Antibodies to trimellitic anhydride, human proteins, and erythrocytes have been found in these patients.

Isocyanates have caused lung hemorrhage. Other toxins known to cause alveolar hemorrhage syndromes are penicillamine and mitomycin C. Lymphangiography has been complicated by pulmonary alveolar hemorrhage. Pulmonary lymphangioleiomyomatosis is an uncommon cause of alveolar hemorrhage syndrome. Alveolar hemorrhage occurs in many patients who have pulmonary veno-occlusive disease. Anticardiolipin antibody syndrome, tumor emboli, and bone marrow transplantation are other causes of alveolar hemorrhage.

- Alveolar hemorrhage occurs with penicillamine and mitomycin C.
- Trimellitic anhydride can cause pulmonary hemorrhage–anemia syndrome.
- Alveolar hemorrhage occurs with tumor emboli and after bone marrow transplantation.

Pulmonary Arterial Hypertension

Pulmonary arterial hypertension (PAH) is present when the mean pulmonary arterial pressure (MPAP) is greater than 25 mm Hg at rest (or >35 mm Hg with exercise). Pathologically, PAH is characterized by vasoconstriction, pulmonary vascular remodeling, and thrombosis in situ that leads to progressive increases in pulmonary vascular resistance, right-heart failure, and death. There are many causes of pulmonary hypertension, and Table 22-20 illustrates the revised clinical classification of pulmonary hypertension.

Typically a diagnosis of PAH is made initially with the finding of increased right ventricular systolic pressure on transthoracic echocardiography and is confirmed with right-heart catheterization. Hemodynamic measurements at right-heart catheterization are important to exclude pulmonary hypertension due to fluid overload (increased pulmonary capillary wedge pressure) or contributions from a high cardiac output (such as seen in liver disease). Nonspecific symptoms include progressive dyspnea, lower extremity edema, and fatigue. Patients who exhibit vasoreactivity at right-heart catheterization (a decrease in MPAP or pulmonary vascular resistance by 20% with vasodilator challenge) may benefit from a trial of calcium channel blockers.

To date, no cure exists; however, several treatment options are available that have been shown to improve quality of life and survival.

Table 22-20 Revised Clinical Classification of Pulmonary Hypertension (Venice 2003)*

1. Pulmonary arterial hypertension (PAH)
   - 1.1. **Idiopathic** (IPAH)
   - 1.2. Familial (FPAH)
   - 1.3. Associated with (APAH):
     - 1.3.1. Collagen vascular disease
     - 1.3.2. Congenital systemic-to-pulmonary shunts†
     - 1.3.3. Portal hypertension
     - 1.3.4. HIV infection
     - 1.3.5. Drugs and toxins
     - 1.3.6. **Other** (thyroid disorders, glycogen storage disease, Gaucher disease, hereditary hemorrhagic telangiectasia, hemoglobinopathies, myeloproliferative disorders, splenectomy)
   - 1.4. **Associated with significant venous or capillary involvement**
     - 1.4.1. Pulmonary veno-occlusive disease (PVOD)
     - 1.4.2. Pulmonary capillary hemangiomatosis (PCH)
   - 1.5. Persistent pulmonary hypertension of the newborn
2. Pulmonary hypertension with left heart disease
   - 2.1. Left-sided atrial or ventricular heart disease
   - 2.2. Left-sided valvular heart disease
3. Pulmonary hypertension associated with lung disease and/or hypoxemia
   - 3.1. Chronic obstructive pulmonary disease
   - 3.2. Interstitial lung disease
   - 3.3. Sleep-disordered breathing
   - 3.4. Alveolar hypoventilation disorders
   - 3.5. Chronic exposure to high altitude
   - 3.6. Developmental abnormalities
4. Pulmonary hypertension due to chronic thrombotic and/or embolic disease
   - 4.1. Thromboembolic obstruction of proximal pulmonary arteries
   - 4.2. Thromboembolic obstruction of distal pulmonary arteries
   - 4.3. Nonthrombotic pulmonary embolism (tumor, parasites, foreign material)
5. **Miscellaneous**
   Sarcoidosis, histiocytosis X, lymphangiomatosis, compression of pulmonary vessels (adenopathy, tumor, fibrosing mediastinitis)

Table 22-20 (continued)

*Main modifications to the previous Evian clinical classification are set in **bold** in table body. These include idiopathic pulmonary hypertension instead of primary hypertension; some newly identified possible risk factors and associated conditions have been added in the APAH subgroup (glycogen storage disease, Gaucher disease, hereditary hemorrhagic telangiectasia, hemoglobinopathies, myeloproliferative disorders, splenectomy); another subgroup has been added in the PAH category: PAH associated with significant venous or capillary involvement (PVOD and PCH); the last group, now termed "miscellaneous," includes some conditions associated with pulmonary hypertension of various and multiple etiologies (histiocytosis X, lymphangiomatosis, compression of pulmonary vessels by adenopathy, tumor, fibrosing mediastinitis).

†Guidelines for classification of congenital systemic-to-pulmonary shunts:

1. Type
   - Simple
     - Atrial septal defect (ASD)
     - Ventricular septal defect (VSD)
     - Patent ductus arterious
     - Total or partial unobstructed anomalous pulmonary venous return
   - Combined
     - Describe combination and define prevalent defect if any
   - Complex
     - Truncus arteriosus
     - Single ventricle with unobstructed pulmonary blood flow
     - Atrioventricular septal defects
2. Dimensions
   - Small (ASD ≤2.0 cm and VSD ≤1.0 cm)
   - Large (ASD >2.0 cm and VSD >1.0 cm)
3. Associated extracardiac abnormalities
4. Correction status
   - Noncorrected
   - Partially corrected (age)
   - Corrected: spontaneously or surgically (age)

From Simonneau G, Galiè N, Rubin LJ, Langleben D, Seeger W, Domenighetti G, et al. Clinical classification of pulmonary hypertension. J Am Coll Cardiol. 2004;43:5S-12S. Used with permission.

Oxygen, diuretics, digoxin, and anticoagulation may be useful in the treatment of PAH. Other treatment options approved by the Food and Drug Administration include intravenous, subcutaneous, and inhaled prostanoids (epoprostenol, treprostinil, iloprost), and oral endothelin receptor antagonists (bosentan). Phosphodiesterase type 5 inhibitors (sildenafil) are currently being studied and may be efficacious in the treatment of PAH.

- Consider the diagnosis of pulmonary hypertension in patients with a new onset of dyspnea.
- Transthoracic echocardiography can suggest the presence of PAH; however, right-heart catheterization is the diagnostic procedure of choice.
- Several treatment options exist for PAH that may improve quality of life and survival.

Part IV

Charles F. Thomas, Jr., MD

Pulmonary Infections

Viral Infections

The common cold is caused by rhinovirus, parainfluenza virus, adenovirus, respiratory syncytial virus, and coxsackievirus. The temporary interference with mucociliary clearance caused by acute viral infection may increase the risk of other infections. Viral respiratory tract infections constitute 80% of all acute infections. Nearly one-half of the general population has a viral respiratory tract infection in December through February and only 20% in June through August. Respiratory syncytial virus is an important cause of acute lower respiratory tract disease among children and the elderly. Coxsackieviruses are a more frequent cause of viral respiratory tract infections in the summer and autumn.

- Coxsackieviral infections are more frequent in the summer and autumn.
- Typical clinical scenario: Coxsackievirus B causes pleurodynia (Bornholm disease or "devil's grip")—fever, headache, malaise, and severe pleuritic pain lasting from several days to weeks.

Viral Pneumonia

Common causes of viral pneumonia are parainfluenza virus, adenovirus, and influenza viruses A and B. In adults, varicella (chickenpox) pneumonia is a severe illness, the resolution of which may be followed by nodular pulmonary calcification. In adults with chickenpox, cough (25% of patients), profuse rash, fever for more than 1 week, and age older than 34 years are the most important predictors of varicella pneumonia. Early aggressive therapy with intravenous acyclovir is recommended for patients at risk of pneumonia. Corticosteroids reportedly are of value in the treatment of previously well patients with life-threatening varicella pneumonia; however, this has not been tested in a large controlled trial since this condition is uncommon. Herpes simplex virus may cause pneumonia in an immunocompromised host or in patients with extensive burns. Cytomegalovirus (CMV) is seen more commonly in immunocompromised patients such as those with CD4 counts less than 50/μL from acquired immunodeficiency syndrome (AIDS) (also associated with *Pneumocystis jiroveci* [formerly *Pneumocystis carinii*] infection) or transplant recipients, in hematologic malignancy, and after multiple blood transfusions and cardiopulmonary bypass. Diffuse, small nodular, or hazy infiltrates are seen on chest radiography (CXR) in 15% of patients with pneumonia caused by CMV, but interstitial pneumonia due to CMV is seen in 50% of bone marrow graft recipients. Diagnosis of CMV is made by finding inclusion bodies in affected cells, isolating the virus, or detecting CMV antigens or nucleic acids.

- Typical clinical scenario for varicella pneumonia: An adult with a characteristic chickenpox rash has cough and fever lasting more than 1 week; acyclovir is recommended for patients at risk.
- CMV infection is associated with immunocompromised patients, such as those with AIDS (CD4 count <50/μL).
- Isolation of CMV from respiratory tract secretions does not always establish that infection is present.

Influenza

Influenza epidemics occur during winter in the United States and cause approximately 40,000 deaths per year. Worldwide pandemics can lead to increased morbidity and mortality from influenza. Although the rates of influenza infection are highest among children, the rates of serious morbidity and death are highest among adults older than 65 years and persons of any age with serious underlying medical conditions. These conditions include chronic cardiovascular disease such as rheumatic valvular disease, chronic pulmonary disease (asthma, chronic bronchitis, or emphysema), diabetes mellitus, kidney disease, chronic anemia, or immunosuppression due to medications or human immunodeficiency virus (HIV) infection. Women who are pregnant during the influenza season are at risk of infection. Influenza A and B cause human disease, but only influenza A is categorized into subtypes on the basis of the expression of the surface antigens hemagglutinin (H) and neuraminidase (N). Influenza is spread from person to person through respiratory secretions, and the average incubation period is 2 days. Adults are usually infectious until 5 days after symptom onset; however, virus shedding can be prolonged for weeks in immunocompromised patients. In the majority of adults, the symptoms of influenza (fever, myalgias and malaise, headaches, nonproductive cough, pharyngitis, and rhinitis) resolve after several days without specific treatment. In some patients, however, secondary bacterial pneumonia, primary influenza viral pneumonia, or coinfections may develop. Deaths due to influenza can result from pneumonia or from exacerbations of underlying cardiopulmonary diseases or other chronic conditions. The antiviral agents amantadine and rimantadine can decrease the duration of influenza A illness by several days if therapy is started within 2 days of infection; zanamivir and oseltamivir have similar efficacies for influenza A and B. It is uncertain whether antiviral agents have a role in preventing the development of serious complications from influenza. The use of the influenza vaccine is efficacious for preventing the disease and its complications. Vaccination is recommended for adults who have any of the following risk factors for influenza:

1. Age older than 65 years
2. Chronic cardiopulmonary diseases
3. Chronic diseases such as diabetes mellitus, kidney disease, chronic anemia, or immunosuppression due to medications or human immunodeficiency virus infection
4. Residents of nursing homes and long-term care facilities
5. Pregnant during the influenza season

Both the inactivated influenza vaccine and the live attenuated influenza vaccine are available for use in the United States. Persons with a

history of hypersensitivity to eggs or the components of the vaccines should not receive either vaccine. Persons older than 50 years, pregnant women, immunocompromised patients, persons with a history of Guillain-Barré syndrome, persons with chronic cardiopulmonary diseases, and persons with chronic diseases should not receive the live attenuated influenza vaccine.

- Typical clinical scenario for influenza A pneumonia: A 73-year-old woman with underlying valvular heart disease presents with fever, dyspnea, cyanosis, and mid-lung infiltrates.

Hantavirus Pulmonary Syndrome

Hantavirus pulmonary syndrome, first recognized in the southwestern United States in 1993, is caused by an RNA virus (family, Bunyaviridae; genus, *Hantavirus*). The rodent reservoir for this virus is the deer mouse (*Peromyscus maniculatus*). Infection occurs by inhalation of rodent excreta. No human-to-human transmission has been documented. The syndrome is more common in the southwestern United States. The demographic features are the following: median age of patients, 32 years (range, 12-69 years); males (52%); and Native Americans (55%). The illness is characterized by a short prodrome of fever, myalgia, headache, abdominal pain, nausea or vomiting (or both), and cough, followed by the abrupt onset of respiratory distress. Bilateral pulmonary infiltrates (noncardiogenic pulmonary edema) that occur within 48 hours after the onset of illness have been reported in all patients. Pleural effusions are common and can be transudates or exudates. Hemoconcentration, thrombocytopenia, and prolonged activated partial thromboplastin time (APTT) are common; however, disseminated intravascular coagulation is rare. Early thrombocytopenia may provide a clue to the diagnosis of the infection. Myocardial suppression is an important component of the infection. Autopsy has routinely documented serous pleural effusions and heavy edematous lungs, with interstitial mononuclear cells in the alveolar septa, alveolar edema, focal hyaline membranes, and occasional alveolar hemorrhage. *Hantavirus* antigens are detected with immunohistochemistry. Serologic (*Hantavirus*-specific IgM or increasing titers of IgG), polymerase chain reaction, and other studies are available. For those in shock and who have lactic acidosis, the prognosis is poor. No sequelae have been reported in survivors. The mortality rate has been 50% to 75%.

- The reservoir for *Hantavirus* is the deer mouse.
- Typical clinical scenario for hantavirus pulmonary syndrome: After a prodrome, a Native American male has abrupt onset of respiratory distress, shock, and hypoxemia. CXR demonstrates bilateral pulmonary infiltrates and pleural effusion. Laboratory studies demonstrate a left-shift neutrophilia, hemoconcentration, thrombocytopenia, and circulating immunoblasts.

Severe Acute Respiratory Syndrome

Severe acute respiratory syndrome (SARS) is a viral respiratory infection caused by a novel coronavirus that previously had infected only animals. SARS transmission is through aerosol and possibly fecal-oral routes. The majority of patients with SARS have been adults 25 to 70 years old who were previously healthy. Many of the cases have been reported in Asia, particularly Hong Kong, Taiwan, and the People's Republic of China; however, cases have been reported in other countries in Asia as well as in North America and Europe. SARS has an incubation period of 2 to 7 days and as long as 10 days in some patients. The illness begins with fever (>38.0°C) and associated chills and rigors. Other frequent symptoms are headache, malaise, and myalgia. No skin rash or neurologic symptoms are present. Diarrhea may occur in 10% to 20% of patients. Within the first 7 days, a dry nonproductive cough and dyspnea develop, with hypoxemia. This worsens in 20% of patients, who require mechanical ventilation and treatment in an intensive care unit. Currently, the fatality rate is approximately 15%. CXR shows interstitial infiltrates that progress to areas of consolidation. Leukocyte counts generally have been normal or decreased, with more than 50% of patients having lymphopenia and thrombocytopenia. Increased levels of liver aminotransferases and creatine kinase have been noted. Most patients have normal renal function during the illness. Treatment is primarily supportive, with no role for antivirals.

- SARS is caused by a coronavirus.
- Typical clinical scenario for SARS: After a febrile prodrome with associated myalgias, a dry nonproductive cough with dyspnea and hypoxemia develop in a 39-year-old traveler from Asia. CXR demonstrates bilateral interstitial pulmonary infiltrates. Laboratory studies demonstrate leukopenia, thrombocytopenia, and elevated levels of creatine kinase and liver aminotransferases.

Bacterial Infections

Sinusitis

Most bacterial sinus infections occur after an acute viral infection of the nasal mucosa. Bacteria in acute and chronic sinusitis are listed in Table 22-21. Most cases of acute sinusitis are due to viral infections and do not need treatment with antibiotics. However, distinguishing viral from bacterial sinusitis is often difficult. Although multiple sinuses are commonly affected, the maxillary sinus is most commonly involved. Approximately 10% of the cases of maxillary sinusitis are related to odontogenic infections. Sinus involvement is also seen in asthma, chronic bronchitis, bronchiectasis, cystic fibrosis, Kartagener syndrome, and Wegener granulomatosis. Cultures

Table 22-21 Bacteria in Acute and Chronic Sinusitis

	Sinusitis, % of patients	
Bacteria	Acute	Chronic
Pneumococci	20-35	5-15
Haemophilus influenzae	15-30	3-10
Streptococcus, anaerobes and aerobes	5-35	10-25
Staphylococcus aureus	3-6	5-15
No growth	2-25	25-60

of the nasal secretions from more than 90% of patients with chronic rhinosinusitis are positive for fungi. Computed tomography (CT) of the sinuses is better than traditional radiography for detecting sinusitis but is not routinely indicated in these patients unless persistent or recurrent symptoms develop. Iatrogenic nasal obstruction with nasogastric tubes or nasotracheal tubes can result in nosocomial sinusitis and serious infection. In these instances, a high degree of awareness is needed and CT of the sinus may be indicated for prompt diagnosis.

- Sinus involvement is also seen in asthma, chronic bronchitis, bronchiectasis, cystic fibrosis, Kartagener syndrome, and Wegener granulomatosis.
- Fungal sinusitis is common in chronic rhinosinusitis.

Otitis Media

The relation between otitis media and common viral infections is strong, especially in children. Nearly 10% of children with measles have otitis media. Bacteria are isolated from 70% to 80% of patients with otitis media and include pneumococci (25%-75% of patients), *Haemophilus influenzae* (15%-30%), anaerobes, peptococci and propionibacteria (20%-30%), group A streptococci (2%-10%), and *Staphylococcus aureus* (1%-5%). Ampicillin-resistant *H. influenzae* is found in 15% to 40% of patients. Otitis media in adults occurs in severe diabetes mellitus and cystic fibrosis.

- Otitis media in adults occurs in severe diabetes mellitus and cystic fibrosis.

Pharyngitis

Pharyngitis is caused by group A *Streptococcus pyogenes* (>30% of patients), *Neisseria gonorrhoeae*, *Corynebacterium diphtheriae*, and *Mycoplasma pneumoniae* (5%). Sore throat is also caused by adenovirus, Epstein-Barr virus, and other viruses.

Pneumonia

Streptococcus pneumoniae

S. pneumoniae is the most commonly isolated pathogen (identified in 20%-60% of cases) in adults with community-acquired pneumonia. In community-acquired pneumonia, a specific pathogen is not identified in as many as 50% of patients, even when extensive testing is performed. The incidence peaks in the winter and spring, when carrier rates in the general population may be as high as 70%. It is most common in infants and the elderly and in alcoholic or immunocompromised patients. At high risk are persons with cardiopulmonary disease (especially pulmonary edema), viral respiratory tract infections, or hemoglobinopathy and immunosuppression, including patients with hyposplenism. The incidence of bacteremic pneumonia among hospitalized patients is 25%, and the mortality rate is 20%. Of the elderly with bacteremic pneumonia, 30% do not have fever, 50% have minimal respiratory symptoms, 50% have altered mental state, and 50% have volume depletion. Leukocytosis of 10 to 30 × 10^9/L is common. Sputum may be blood-streaked or rusty. Early in the disease, CXR findings may be normal, but later, they may show classic lobar pneumonia. Pleurisy or effusion is common, and cavitation is rare. *S. pneumoniae* urinary antigen has a sensitivity of 80% and a specificity of 97% in patients with bacteremic pneumococcal pneumonia. The emergence of drug-resistant *S. pneumoniae* (DRSP) is an increasing problem in the United States. By in vitro measures of resistance, more than 40% of pneumococci are resistant to penicillin; however, in the absence of meningitis, treatment failure with high-dose β-lactam antibiotics is thought to be unlikely.

- *S. pneumoniae*: mortality rate of about 20% among hospitalized patients with bacteremic pneumonia.
- Of the elderly with bacteremic pneumonia, 30% do not have fever and 50% have minimal respiratory symptoms, 50% have altered mental state, and 50% have volume depletion.
- Typical clinical scenario for streptococcal pneumonia: A patient with cardiopulmonary disease has a recent viral respiratory tract infection, leukocytosis, and rusty sputum.

The pneumococcal vaccine consists of purified capsular polysaccharide from the 23 pneumococcal types accounting for at least 90% of pneumococcal pneumonias. It offers as much protection against drug-resistant pneumococci as against drug-sensitive ones. Vaccination decreases serious complications of pneumococcal infection by about one-half and reduces the carrier state among the general population. The overall efficacy of the pneumococcal vaccine is 60% for preventing invasive infections. Vaccine efficacy rates vary for certain diseases (diabetes mellitus, 84%; coronary artery disease, 73%; congestive heart failure, 69%; chronic obstructive pulmonary disease [COPD], 65%; and anatomical asplenia, 77%). Pneumovax decreases the incidence of pneumonia by 79% to 92%. Pneumococcal vaccination is recommended for elderly persons (older than 65) and for those with diabetes mellitus, heart and lung diseases, renal insufficiency, hepatic insufficiency, sickle cell anemia, asplenia or hyposplenia, hematologic and other malignancies, alcoholism, cerebrospinal fluid leakage, immunodeficiency states, organ transplants, or AIDS. Some recommend pneumococcal vaccination for all adults, especially health care workers. Guidelines for subsequent vaccinations are controversial. Patients with nephrotic syndrome and other protein-losing nephropathies rapidly lose pneumococcal antibody and, thus, should receive Pneumovax every 5 or 6 years. For persons older than 65, a single revaccination is suggested if the primary immunization was more than 5 years ago. Pneumococcal vaccination should be given to pregnant women only if clearly needed.

- The overall efficacy of the pneumococcal vaccine is 60% for preventing invasive infections.
- Vaccine efficacy rates vary for certain diseases (diabetes mellitus, 84%; coronary artery disease, 73%; congestive heart failure, 69%; COPD, 65%; and anatomical asplenia, 77%).
- Pneumovax decreases the incidence of pneumonia by 79%-92%.

Staphylococcus aureus

S. aureus may be isolated from the nasal passages of 20% to 40% of normal adults, but pneumonia is uncommon. *S. aureus* pneumonia

is more likely to occur in patients with severe diabetes mellitus or an immunocompromised state, in patients receiving dialysis, in drug abusers, and in those with influenza or measles. In drug addicts, it may begin as septic emboli from right-sided endocarditis. It is a nosocomial type of pneumonia. Consolidation, bronchopneumonia, abscess with air-fluid level, pneumatocele, pneumothorax, empyema, and a high mortality rate characterize staphylococcal pneumonia.

- Lung abscess and pneumatoceles are more common complications of *S. aureus* pneumonia.
- Associations with *Staphylococcus* pneumonia: diabetes mellitus, immunocompromised host, dialysis patients, influenza or measles infection, or drug abuse.

Pseudomonas aeruginosa

P. aeruginosa is a ubiquitous organism commonly isolated from patients with cystic fibrosis and bronchiectasis. Colonization may be difficult to distinguish from true infection. Pneumonia may occur in patients with COPD, congestive heart failure, diabetes mellitus, kidney disease, alcoholism, malignant otitis media, tracheostomy, or prolonged ventilation. It also may develop postoperatively and in immunocompromised hosts. *Pseudomonas* pneumonia results in microabscess, alveolar hemorrhage, and necrotic areas. CXR may show bilateral patchy infiltrates.

- *P. aeruginosa*: colonization may be difficult to distinguish from true infection.
- It is an important pathogenic organism in cystic fibrosis, bronchiectasis, malignant otitis media, immunocompromised state, and ventilator-associated pneumonia.

Klebsiella pneumoniae

Pneumonia due to *K. pneumoniae* is more likely in persons who are alcoholic, have diabetes, or are hospitalized and are receiving mechanical ventilation. It is more common in males. Dependent lobes are affected more frequently than nondependent ones. In lobar pneumonia caused by *K. pneumoniae*, CXR may show a "bulging fissure." Complications include abscess and empyema.

- Typical clinical scenario for *K. pneumoniae* pneumonia: A patient is alcoholic, has diabetes, or is hospitalized and has a "bulging fissure" sign on CXR.

Haemophilus influenzae

Unencapsulated strains of *H. influenzae* are present in the sputum of 30% to 60% of normal adults and 58% to 80% of patients with COPD. In contrast, bacteremia is almost always associated with encapsulated strains. Both strains cause pulmonary infections and otitis, sinusitis, epiglottitis, and pneumonia. Most patients with pneumonia have underlying COPD or alcoholism, even though *H. influenzae* pneumonia develops in healthy military recruits. Pneumonia is detected in the lower lobes more often than in the upper lobes. CXR findings are typical for bronchopneumonia or lobar pneumonia. Pleural effusions occur in 30% of patients, and cavitation is rare.

- Typical clinical scenario for *H. influenzae* pneumonia: A patient has COPD or is alcoholic; 30% of patients have pleural effusions, and cavitation is rare.

Moraxella catarrhalis

M. catarrhalis, a gram-negative diplococcus, is part of the normal flora. Colonization is more common in the winter. It causes sinusitis, otitis, and pneumonia. The latter is more likely in patients who have alcoholim, COPD, diabetes mellitus, or immunocompromised status. Bacteremia is rare. Infection produces segmental patchy bronchopneumonia in the lower lobes. Cavitation and pleural effusion are rare. These bacteria produce β-lactamase, and most are resistant to penicillin and ampicillin.

- Typical clinical scenario for *M. catarrhalis* pneumonia: A patient has COPD, immunocompromised status, or alcoholism and has gram-negative diplococci that are β-lactamase–positive.

Legionella pneumophila

Legionella is a gram-negative bacillus whose natural habitat is water. Infection results from the inhalation of aerosolized organisms, aspiration, and contaminated respiratory equipment. Epidemics have occurred from contaminated air-conditioning cooling towers, construction or excavation in contaminated soil, and contaminated hospital showers. Most cases occur in the summer and early autumn. Risk factors include COPD, smoking, cancer, diabetes mellitus, immunosuppression, and chronic heart and kidney diseases. Almost all cases of pneumonia are caused by *L. pneumophila* (85% of patients) and *Legionella micdadei* (10%). *Legionella* is the most common atypical organism resulting in severe pneumonia. Bacteria can be demonstrated in tissue with the Dieterle and fluorescent antibody stains. The incubation period is 2 to 10 days. Symptoms, in decreasing order of frequency, are abrupt onset of cough (hemoptysis in 30% of patients), chills, dyspnea, headache, myalgia, arthralgia, diarrhea, and relative bradycardia. Common signs include high fever, diarrhea, and change in mental status. Measurement of the *Legionella* urinary antigen is diagnostically valuable, since it is positive in the majority of patients with acute *Legionella* pneumonia. The fluorescent antibody stain is positive in the sputum in 20% of infected patients. Bacteria can be cultured from tissue or other samples. Serologic testing takes from 1 to 3 weeks before a titer of 1:64 is seen; the peak titer is reached in 5 to 6 weeks. A titer of 1:128 is suspicious, and a fourfold increase in titer is diagnostic. A false-positive serologic titer can be seen in plague, tularemia, leptospirosis, and adenovirus infections.

- Typical clinical scenario for *L. pneumophila* pneumonia: A 67-year-old with COPD, diabetes mellitus, and chronic heart failure presents with hyponatremia and hypophosphatemia, lobar consolidations on CXR, leukocytosis (>10×10^9/L), proteinuria, and increased serum level of aspartate aminotransferase (AST).
- The *Legionella* urinary antigen is detected in the majority of patients with acute *Legionella* pneumonia.
- A false-positive serologic titer can be seen in plague, tularemia, leptospirosis, and adenovirus infections.

Anaerobic Bacteria

Bacteroides melaninogenicus, *Fusobacterium nucleatum*, anaerobic cocci, and anaerobic streptococci are responsible for most cases of anaerobic pneumonia. *Bacteroides fragilis* is recovered from 15% to 20% of patients with anaerobic pneumonia. Most of these anaerobes reside in the oropharynx as saprophytes. Common factors responsible for aspiration of anaerobes include altered consciousness, tooth extraction, poor dental hygiene, oropharyngeal infections, and drug overdose. Anaerobic bacterial infections may complicate underlying pulmonary problems (e.g., cancer, bronchiectasis, or foreign body). More than 50% of patients have foul-smelling sputum. Patchy pneumonitis in dependent segments may progress to lung abscess and empyema.

- Typical clinical scenario for anaerobic bacterial pneumonia: Aspiration of anaerobes is facilitated by altered consciousness, tooth extraction, poor dental hygiene, oropharyngeal infections, and drug overdose; the patient has cavitated lung abscesses in dependent lobes.

Community-Acquired "Atypical" Pneumonia

The classification of pneumonia into "atypical" and "typical" arose from the clinical observation that in some patients pneumonia had a different course from that of pneumococcal pneumonia. The appreciation that numerous organisms, each with varied manifestations, can cause atypical pneumonia limits the clinical usefulness of such a classification. Organisms causing atypical community-acquired pneumonia include *L. pneumophila*, *M. pneumoniae*, *Chlamydia psittaci*, *Chlamydia pneumoniae*, *Coxiella burnetii*, and *Francisella tularensis*. In atypical pneumonia, the CXR abnormalities are often disproportionate to the pulmonary symptoms, and sputum analysis may reveal numerous leukocytes and no organisms. Community-acquired typical pneumonias are caused by *S. pneumoniae* (45% of patients), gram-negative bacilli (15%), and *H. influenzae* (15%). For patients not admitted to the hospital, the mortality from community-acquired pneumonia is less than 1%. However, the overall mortality for patients admitted to the hospital is 14%; for elderly patients, 18%; and for those with bacteremia, 20%. The mortality of patients with community-acquired pneumonia who are admitted to an intensive care unit is 37%.

- Community-acquired atypical pneumonia is caused by *M. pneumoniae*, *C. psittaci*, *C. pneumoniae*, *C. burnetii*, and *Legionella* species.

Mycoplasma

Mycoplasma species is spread from person to person by droplet nuclei. Infections occur in epidemic and endemic forms, and outbreaks occur in closed populations (e.g., military camps and colleges). Epidemics are more common in the summer and autumn. Illness is more common in school-aged children and young adults. The incubation period is 2 to 3 weeks. Clinical features include cough (>95% of patients), fever (85%), pharyngitis (50%), coryza, and tracheobronchitis. Bullous myringitis (20%) is a rare but unique feature of this disease. Other rare complications include pleural effusion, hemolytic anemia, erythema multiforme, hepatitis, thrombocytopenia, and Guillain-Barré syndrome. Nearly 20% of all community-acquired pneumonias and 50% of all pneumonias in healthy young adults in close living quarters (e.g., military recruits and dormitory students) may be caused by *M. pneumoniae*. Pneumonia occurs in only 3% to 10% of infected persons and is more likely in younger adults (military recruits or children in summer camps); it causes interstitial pneumonia and acute bronchiolitis. CXR shows unilateral bronchopneumonia, lower lobe involvement (65% of patients), and pleural effusion (5%). Cold agglutinins (>1:64 in 50% of patients) appear during the second or third week after the onset of symptoms, and the titer decreases to insignificant levels by 4 to 6 weeks. With complement fixation serologic testing, a fourfold increase in titer is noted in 50% to 80% of patients.

- Typical clinical scenario for *Mycoplasma* pneumonia: Cough, fever, pharyngitis, coryza, and tracheobronchitis, with bullous myringitis, hemolytic anemia, erythema multiforme, or Guillain-Barré syndrome; it causes interstitial pneumonia and acute bronchiolitis.
- Cold agglutinins (>1:64 in 50% of patients) appear during the second or third week.

Chlamydia pneumoniae (TWAR Strain)

C. pneumoniae is confined to the human respiratory tract; no reservoirs are known. Person-to-person spread occurs among schoolchildren, family members, and military recruits. The incubation period is 10 to 65 days (mean, 31 days). Reinfection is common, with cycles of disease every few years. *C. pneumoniae* is the cause of at least 10% of all cases of community-acquired pneumonia. About 15% of patients are symptomatic and have clinical features that include pharyngitis (90% of patients), pneumonia (10%), bronchitis (5%), and sinusitis (5%). Pharyngeal erythema and wheezing are common. CXR shows unilateral segmental patchy opacity. The complement fixation test is insensitive and nonspecific. *C. pneumoniae* is considered an etiologic agent in coronary artery disease.

- *C. pneumoniae*: person-to-person spread among schoolchildren, family members, and military recruits.
- Pneumonia in 10% of patients, and bronchitis in 5% of symptomatic patients.
- *C. pneumoniae* is considered an etiologic agent in coronary artery disease.

Chlamydia psittaci

C. psittaci causes psittacosis (ornithosis) in humans. The organism is found in psittacine birds (parrots and lories), turkeys, pigeons, and other birds. Asymptomatic infection of these birds with continued shedding of the organism is common. Infected birds have anorexia, weight loss, diarrhea, ruffled feathers, conjunctivitis, and rhinitis, and they are not able to fly. In humans, the incubation period is 1 to 6 weeks. Clinical features include myalgias, fever, headache, pharyngitis, lethargy, confusion, delirium, neutropenia (in 25% of patients), and splenomegaly (in 1%-10%). Pulmonary symptoms are late and mild. CXR shows patchy unilateral or bilateral lower lobe pneumonia

and an occasional small pleural effusion. Laboratory findings include a normal leukocyte count, increased creatine kinase level, and a fourfold increase in complement fixation over more than 2 weeks. Whereas psittacosis is transmitted from birds to humans, *C. pneumoniae* pneumonia is transmitted between people. Pigeon-breeder's lung (bird fancier's lung) is hypersensitivity pneumonnitis caused by an immune reaction to avian proteins.

- Typical clinical scenario for psittacosis: Exposure to sick birds that harbor *C. psittaci*; patients have myalgias, fever, headache, lethargy, confusion, delirium, and splenomegaly.
- Note the differences: *C. pneumoniae* pneumonia (human-to-human transmission), psittacosis (bird-to-human transmission), and pigeon-breeder's or bird fancier's lung (hypersensitivity pneumonitis caused by immune reaction to avian proteins).

Coxiella burnetii

C. burnetii, a rickettsia shed in the urine, feces, milk, and birth products of sheep, cattle, goats, and cats, is responsible for Q fever. However, epidemiologic factors such as contact with cats or farm animals are identified for only 40% of patients. Humans are infected by inhalation of dried aerosolized material. The incubation period is 10 to 30 days. Clinical features include fever, myalgias, chills, chest pain, and cough (late). The leukocyte count is normal, and the erythrocyte sedimentation rate is increased. CXR findings may be normal or show unilateral bronchopneumonia and small pleural effusions. Lobar consolidation is seen in 25% of patients. Hepatitis and endocarditis can occur. Hyponatremia occurs in more than 25% of patients. Liver enzyme levels may increase. Indirect immunofluorescence is the immunologic test of choice.

- *C. burnetii*: rickettsial illness (Q fever).
- Inhalation of dried inoculum from urine, feces, milk, or birth products of sheep, cattle, goats, or cats.
- Bronchopneumonia and pleural effusion.

Francisella tularensis

F. tularensis is a gram-negative bacillus transmitted to humans from wild animals and by bites of ticks or deer flies. Aerosol inhalation can occur (e.g., laboratory workers), and it is a potential bioterrorism agent. The incubation period for tularemia is 2 to 5 days. Cutaneous ulcer and lymphadenopathy are common features. Cough, fever, and chest pain are frequent, but many patients are asymptomatic. CXR shows unilateral lower lobe patchy infiltrates (bilateral in 30% of patients) and pleural effusion (30% of patients). The leukocyte count is normal; the organism is not seen with Gram staining of the sputum. Serologic testing (agglutinins), showing a fourfold rise in titer in paired samples 2 to 3 weeks apart or a single titer greater than 1:160, is considered diagnostic.

- Tularemia: transmitted from wild rabbits, squirrels, and other wild animals.
- Typical clinical scenario for tularemia: Patients may be asymptomatic or have cough and fever, with cutaneous ulcer, lymphadenopathy, bronchopneumonia, and pleural effusion.

Yersinia pestis

Y. pestis is a gram-negative bacillus that causes plague. It is more prevalent in New Mexico, Arizona, Colorado, and California than in other states. It is spread from wild rodents (occasionally cats), either directly or by fleas, usually in May to September. The incubation period is 2 to 7 days. Clinical features include fever, headache, bubo (groin or axilla), cough, and tachypnea. Pneumonia occurs in 10% to 20% of patients. Pneumonic plague is the most serious and fulminant form of this disease. CXR shows bilateral lower lobe alveolar infiltrates. Pleural effusion is common, and nodules and cavities can occur. The leukocyte count is higher than 15×10^9/L. The organism is seen with Giemsa or direct fluorescent antibody staining and in cultures of blood, lymph node, or sputum. Serologic testing gives positive results.

- Typical clinical scenario for *Y. pestis* pneumonia: A patient from the southwestern United States has alveolar infiltrates and pleural effusion; the leukocyte count is $>15 \times 10^9$/L.

Burkholderia pseudomallei

B. pseudomallei is a gram-negative rod responsible for melioidosis. The disease is most prevalent in parts of Southeast Asia; sporadic cases have been reported in the United States. The organism is widely distributed in water and soil, and infection occurs after direct inoculation through the skin or, less commonly, by inhalation. Although the incubation period can be as short as 3 days, the disease remains latent and may become evident months to years later. Up to 2% of U.S. Army personnel stationed in Vietnam were seropositive for *B. pseudomallei*, even though the majority of them were free of clinical disease. Clinical features include acute community-acquired pneumonia, pleurisy, subacute presentation with upper lobe lesions (sometimes with cavitation), or chronic cavitary lung disease that resembles tuberculosis. Diagnosis is by positive findings on culture.

- Melioidosis may resemble chronic cavitary tuberculosis.

Nocardia Pneumonia

Nocardia asteroides, *Nocardia brasiliensis*, and *Nocardia otitidis-caviarum* can cause pneumonia in susceptible persons. *N. asteroides* is a weakly acid-fast saprophytic bacteria present in the soil, dust, plants, and water. Infection is more common in immunosuppressed patients and in those with pulmonary alveolar proteinosis. Primary infection leads to necrotizing pneumonia with abscess formation. No inflammatory response or granuloma formation occurs. Pulmonary nodules suggestive of cancer metastases and dense alveolar infiltrates are common CXR findings. Infection may produce pleural effusion. Lymphohematogenous spread occurs in 20% of patients; nearly all such patients develop a brain abscess. The diagnosis is made at autopsy in 40% of cases. Isolation of the organism from the sputum of immunocompetent patients might represent colonization since the saprophytic state is well recognized; however, in an immunocompromised patient, this should be considered a true infection.

- Typical clinical scenario for *Nocardia* pneumonia: An immunocompromised patient or a patient with pulmonary alveolar proteinosis, necrotizing pneumonia, and lung abscess.

- Brain abscess is common in those with disseminated infection.

Actinomycosis

Actinomycosis is caused by *Actinomyces israelii* or *Actinomyces bovis*. The organism is easily isolated from scrapings around the teeth, gums, and tonsils in subjects with poor dental or oral hygiene. It is an opportunistic organism and becomes invasive with severe caries, tissue necrosis, and aspiration. In tissue, the organism grows into a "sulfur granule" caused by mycelial clumps in a matrix of calcium phosphate. The disease is more common in rural areas and has a male-female ratio of 2:1. Infection is always mixed with anaerobes. Skin abscesses, ulcers, sinus tracts, and cervicofacial node involvement are found in up to 40% of patients. Pulmonary involvement is seen in 20% of patients, along with cough, fever, pulmonary consolidation, pleurisy with effusion, and, eventually, draining sinuses.

- Typical clinical scenario for actinomycosis: A patient has severe dental caries, tissue necrosis, and aspiration, with cough, fever, pulmonary lesions, pleural effusion, and fistula and sinus tracts.

Hospital-Acquired (Nosocomial) Pneumonia

About 60% of the cases of nosocomial pneumonia are caused by aerobic gram-negative bacilli, 20% by *S. aureus*, 10% by *S. pneumoniae*, and the rest by anaerobes, *Legionella* species, and others. Risk factors include coma, hypotension, shock, acidosis, azotemia, prolonged treatment with antibiotics, major surgical operations, lengthy procedures, mechanical ventilation, and immunosuppressive therapy. Methicillin-resistant *Staphylococcus aureus* (MRSA) has become a prevalent nosocomial pathogen in the United States. By definition, MRSA is resistant to methicillin, oxacillin, penicillin, and amoxicillin. This infection occurs most frequently among patients with weakened immunity in hospitals, nursing homes, dialysis centers, or other long-term care facilities. Colonized patients are the most important reservoirs of MRSA in hospitals, and the main transmission of MRSA is by hands (particularly those of health care workers). Standard precautions (e.g., handwashing and use of gloves, masks, and gowns) should be implemented to control the spread of MRSA. Recently, community-associated MRSA (CA-MRSA) has been identified in persons who have not been hospitalized or had a medical procedure within the past year. Clusters of CA-MRSA skin infections have occurred among athletes, military recruits, children, prisoners, and others. Close contact seems to be a major risk factor. The identified CA-MRSA strains seem to have properties that differ from those of hospital-acquired MRSA.

- About 60% of cases of nosocomial pneumonia are caused by gram-negative bacilli, 20% by *S. aureus*, and 10% by *S. pneumoniae*.
- In hospital outbreaks involving a single type of organism, consider contaminated respiratory equipment.

Aspiration Pneumonia

Aspiration pneumonia can be either acute or chronic. The acute type usually results from aspiration of a volume larger than 50 mL, with a pH less than 2.4. It produces classic aspiration pneumonia that is usually sterile and does not require the use of antibiotics. Predisposing factors include nasogastric tube, anesthesia, coma, seizures, central nervous system problems, diaphragmatic hernia with reflux, and tracheoesophageal fistula. Nosocomial aspiration pneumonia is caused by *Escherichia coli*, *S. aureus*, *K. pneumoniae*, and *P. aeruginosa*. Community-acquired aspiration pneumonias are caused by infections due to anaerobes (*B. melaninogenicus*, *F. nucleatum*, and gram-positive cocci). Preventive measures are important. Chronic aspiration pneumonia results from recurrent aspiration of small volumes. Examples include patients with reflux aspiration who develop mineral oil granuloma. Symptoms include chronic cough, patchy lung infiltrates, and nocturnal wheeze.

- Acute aspiration pneumonia: from the aspiration of a volume >50 mL, with a pH <2.4. Usually sterile and antibiotics are not needed.
- Chronic aspiration pneumonia: from recurrent aspiration of small volumes.

Lung Abscess

Lung abscess is a circumscribed collection of pus in the lung that leads to cavity formation; the cavity has an air-fluid level on CXR. Lung abscess usually is caused by bacteria, particularly anaerobic bacilli (30%-50% of cases), aerobic gram-positive cocci (25%), and aerobic gram-negative bacilli (5%-12%). Polymicrobial infections are most common. Suppuration leading to lung abscess can result from primary, opportunistic, and hematogenous lung infection. Primary lung abscess is caused by oral infection; aspiration accounts for up to 90% of all abscesses. Alcohol abuse and dental caries also contribute. Lung abscesses caused by opportunistic infections are seen in elderly patients with a blood dyscrasia and in patients with cancer of the lung or oropharynx. Patients with advanced HIV infection can develop lung abscess that is associated with a broad spectrum of pathogens, including opportunistic organisms. This condition has a poor prognosis in these patients. Hematogenous lung abscesses occur with septicemia, septic embolism, and sterile infarcts (3% of patients). A history of any of these conditions in association with fever, cough with purulent or bloody sputum, weight loss, and leukocytosis suggests the diagnosis. CXR may show cavitated lesions. The abscess may rupture into the pleural space and cause empyema. Bronchoscopy may be necessary to obtain cultures, to drain the abscess, and to exclude obstructing lesions. High rates of morbidity and mortality (20%) are associated with lung abscess despite antibiotic therapy. The prognosis is worse for patients with a large abscess and for those infected with *S. aureus*, *K. pneumoniae*, and *P. aeruginosa*. Treatment includes drainage (physiotherapy, postural, and bronchoscopic), antibiotics for 4 to 6 weeks, and surgical treatment if medical therapy fails.

- Typical clinical scenario for primary lung abscess: A 54-year-old alcoholic male presents with fever. CXR demonstrates a cavity with an air-fluid level.
- Hematogenous lung abscess is seen in septicemia and septic embolism.
- Cause is often polymicrobial and prolonged antibiotic therapy is often needed.

Mycobacterial Diseases

Mycobacterium tuberculosis

M. tuberculosis causes the most common type of human-to-human chronic infection by mycobacteria worldwide. The most common mode of transmission is by inhalation of droplet nuclei from expectorated respiratory secretions. Of those exposed to *M. tuberculosis*, 30% become infected, and among the latter group, less than 5% develop active primary disease and less than 5% develop active disease from reactivation. Active infection is diagnosed by documenting the presence of *M. tuberculosis* in respiratory secretions or other body fluids or tissues. Sputum and gastric washings have approximately a 30% diagnostic yield. Bronchoscopy with bronchoalveolar lavage has an approximately 40% diagnostic yield, which increases to almost 95% if biopsy is performed. Culture of pleural fluid alone provides the diagnosis in less than 20% of cases, but culture of pleural biopsy specimens has a 70% diagnostic yield. Faster culture results are available with the use of broth culture systems (1.5-2 weeks) and nucleic acid amplification (8 hours). Culture-positive pulmonary tuberculosis with normal CXR findings is not uncommon, and the incidence of this presentation is increasing. *Latent tuberculosis infection* (LTBI) is the current term for a person who does not have active tuberculosis but has a positive purified protein derivative (PPD) skin test. Such a person is infected with mycobacteria but does not have active disease.

- The PPD skin test indicates infection with mycobacteria and not active disease.
- Active infection should be confirmed by the growth of *M. tuberculosis* in respiratory secretions or other body fluids or tissues.
- Bronchoscopically obtained specimens have a higher diagnostic yield.
- CXR findings can be normal in active tuberculosis.

A positive PPD tuberculin skin test is an example of a delayed (T-cell–mediated) hypersensitivity reaction. The test can be positive within 4 weeks after exposure to *M. tuberculosis*. The PPD test is negative in 25% of patients with active tuberculosis. A false-negative PPD result is also seen in infections with viruses or bacteria, live virus vaccinations, chronic renal failure, nutritional deficiency, lymphoid malignancies, leukemias, corticosteroid and immunosuppressive drug therapy, newborn or elderly patients, recent or overwhelming infection with mycobacteria, and acute stress. The specificity of a positive PPD reaction is variable and is dependent on the prevalence of infection with nontuberculous mycobacteria. The annual risk of active tuberculosis for those who are PPD-positive depends on the underlying medical condition (annual risk in parentheses): HIV-positive (8%-10%), recent converters (2%-5%), abnormal CXR (2%-4%), intravenous drug abuse (1%), end-stage renal disease (1%), and diabetes mellitus (0.3%). PPD skin testing should use a 5-tuberculin unit (TU) preparation; the widest induration is read at 48 and 72 hours. Prior vaccination with BCG is not a contraindication for the PPD skin test. There is no reliable method to distinguish positive PPD results caused by BCG vaccination from those caused by mycobacterial infections, although large reactions (≥20 mm) are not likely caused by BCG. The assay recently approved by the Food and Drug Administration, the QuantiFERON-TB Gold assay, may help in distinguishing tuberculous infection from nontuberculous mycobacterial infection and BCG vaccination since it measures interferon-γ production from a patient's blood sample incubated with the *M. tuberculosis*–specific antigens ESAT-6 and CFP-10.

- The PPD reaction is a delayed type of hypersensitivity reaction.
- The PPD skin test can become positive within 4 weeks after exposure to *M. tuberculosis*.
- The PPD skin test is negative in 25% of patients with active tuberculosis.

Targeted tuberculin testing for LTBI identifies persons at high risk of tuberculosis who would benefit from treatment of LTBI. Indications for the PPD skin test include persons with signs and symptoms suggestive of current tuberculous infection, recent contacts with known or suspected cases of tuberculosis, abnormal CXR findings compatible with past tuberculosis, patients with diseases that increase the risk of tuberculosis (silicosis, gastrectomy, diabetes mellitus, immune suppression, and HIV infection), and groups at high risk of recent infection with *M. tuberculosis* (immigrants and long-time residents and workers in hospitals, nursing homes, or prisons). The following criteria are used to diagnose LTBI (i.e., a positive PPD skin test):

1. Reaction ≥5 mm—persons with HIV infection, close contact with infectious cases, patients with organ transplants and other immunosuppressed patients (receiving the equivalent of 15 mg/d of prednisone for 1 month or more), and those with fibrotic lesions on CXR consistent with prior tuberculosis
2. Reaction ≥10 mm—immigrants within the past 5 years from high-prevalence countries; injection drug users; mycobacteriology laboratory workers; children younger than 4 years, or infants, children, and adolescents exposed to adults at high risk of tuberculosis; and employees and residents of high-risk congregate facilities including prisons, nursing homes, hospitals and other health care facilities, residential facilities for patients with AIDS, and homeless shelters; and patients with high-risk clinical conditions (diabetes mellitus, silicosis, chronic renal failure, leukemias and lymphomas, carcinoma of the head or neck and lung, weight loss ≥10% of ideal body weight, gastrectomy, and jejunoileal bypass)
3. Reaction ≥15 mm—any person without a defined risk factor for tuberculosis

Pleural tuberculosis used to be more common in younger (<40 years) patients; now, it is more common among the elderly. In the United States, 4% of all tuberculous patients have pleural involvement, and pleural tuberculosis constitutes 23% of the cases with extrapulmonary tuberculosis. Effusions usually occur 3 to 6 months after the primary infection. Acute presentation (cough, fever, and pleuritic chest pain) is more common in younger patients. Bilateral exudative effusions occur in up to 8% of patients, and the PPD skin test is positive in more than 66%. The effusions typically have high protein

levels (>5g/dL), lymphocytosis (>50%), and low levels of glucose (<50 mg/dL). A low pleural fluid pH occurs in 20% of patients. Measurement of levels of the enzyme adenosine deaminase (ADA) in the pleural fluid has a sensitivity of 70% to 90% for pleural tuberculosis, with a specificity that varies from less than 50% to 90%. The test is not diagnostic for pleural tuberculosis, and its main utility is to suggest tuberculosis infection if the ADA level is very high or to rule out the diagnosis of pleural tuberculosis if the ADA level is very low. Pleural biopsy specimens show caseous granulomas in up to 80% of patients, and cultures of biopsy specimens are positive in more than 75%. Cultures of pleural fluid are positive in only 20% to 40% of patients and the sputum is positive in 40%. Bronchopleural fistula is a complication.

- Pleural tuberculosis is more common among the elderly.
- Effusion occurs 3 to 6 months after primary infection.

Miliary tuberculosis constitutes 10% of cases of extrapulmonary tuberculosis. It is characterized by the diffuse presence of small (<2 mm) nodules throughout the body. The spleen, liver, and lung are frequently involved. The disease can be acute and fatal or insidious in onset and slowly progressive. CXR shows typical miliary lesions in more than 65% of patients. Sputum findings are negative in up to 80% of patients and the PPD skin test is negative in approximately 50% of patients with miliary tuberculosis. Mortality is high (30%) even with therapy. Tuberculous lymphadenitis (scrofula) is the most common form of extrapulmonary tuberculosis. It is more common in children and young adults than in older persons. Cervical lymph nodes are affected most commonly; one or more nodes (painless, nontender, and rubbery) may be palpable. Abscess and sinus formation may occur. Skeletal tuberculosis is becoming less common; when seen, it is more common in the young than in older adults. Any bone can be involved, but the vertebrae are involved in 50% of cases. Pott disease is tuberculous spondylitis and may produce severe kyphosis. Tuberculous meningitis is the most common form of central nervous system involvement and is localized mainly to the base of the brain. It occurs more commonly in intravenous drug users who are HIV-positive and in immunocompromised patients. Tuberculous meningitis is often insidious in onset. Abdominal tuberculosis frequently affects the peritoneum. Ileocecal tuberculosis can lead to ulcerative enteritis, strictures, and fistulas. Genitourinary tuberculosis is responsible for up to 13% of extrapulmonary disease. It is usually a late manifestation of the infection and is more common in older patients. The renal cortex is affected initially, and the infection can then spread to the renal pelvis, ureter, bladder, and genitalia. Sterile pyuria is an important feature. Laryngeal tuberculosis is usually a complication of pulmonary tuberculosis. Pericardial tuberculosis is usually due to hematogenous spread. Pericardial constriction may begin subacutely and become a chronic problem.

- Miliary tuberculosis is responsible for 10% of cases of extrapulmonary tuberculosis.
- Tuberculous lymphadenitis is the most common form of extrapulmonary tuberculosis.
- Tuberculous meningitis is often insidious in onset.

Tuberculosis is particularly prone to develop in HIV-positive persons. In this group of patients, a CD4 count less than 200/µL and a PPD-positive status increase the risk. Furthermore, there is an increased rate of reactivation, increased rate of progressive primary infection, increased incidence of multidrug resistance, atypical clinical features, and increased progression of HIV disease. Among those who are HIV-positive and are exposed to *M. tuberculosis*, nearly 40% develop primary tuberculosis, and the rate of reactivation is 8% to 10% per year. Tuberculous pleurisy and hilar and mediastinal lymphadenopathy are more common in AIDS than in non-AIDS patients with tuberculosis. The diagnosis of tuberculosis in a patient with AIDS can be difficult owing to the varied manifestations. These patients may lack cavitation and granuloma formation and have negative sputum findings and negative PPD skin tests. Treatment of tuberculosis in HIV-negative and HIV-positive patients is essentially identical with a few notable exceptions. Certain treatment schemes are contraindicated in HIV-infected patients because of a high rate of relapse due to resistant organisms or an increased risk of toxicity. Management of these patients is complex and requires expertise with both HIV and tuberculosis. Rifampin-containing regimens are effective in curing tuberculosis in HIV-positive patients. Initiation of HIV protease inhibitor therapy in patients who are HIV-positive or who have AIDS increases the symptoms and signs of the underlying mycobacterial infection. Rifampin accelerates the metabolism of protease inhibitors (decreased plasma levels) and leads to HIV resistance. Isoniazid prophylaxis for 12 months decreases the incidence of tuberculosis and increases the life expectancy for HIV-infected patients.

- Tuberculosis is particularly prone to develop in HIV-positive persons.
- The simultaneous presence of HIV and tuberculosis leads to increased severity of both infections.
- HIV protease inhibitor therapy may lead to worsening of the signs and symptoms of tuberculosis.

Definitive therapy is indicated for all patients with culture-positive tuberculosis. Treatment usually should include multidrug therapy (>2 drugs) for all patients who have active tuberculosis (Tables 22-22 to 22-24; Fig. 22-29 and 22-30). With rigidly administered 6-month regimens, more than 90% of patients are smear-negative after 2 months of therapy, more than 95% are cured, and less than 5% have relapse. A 9-month regimen provides a cure rate higher than 97% and a relapse rate less than 2%. All treatment programs should be recommended and preferably undertaken by physicians and health care workers experienced in the management of mycobacterial diseases. The most important impediment to lack of adequate therapy worldwide is the lack of adherence to the treatment.

Extrapulmonary tuberculosis can be treated effectively with either a 6- or 9-month regimen. However, miliary tuberculosis, bone and joint tuberculosis, and tuberculous meningitis in infants and children may require treatment for 12 or more months. Cavitary tuberculosis is often treated for 9 months. Systemic corticosteroid therapy may be useful in the prevention of pleural fibrosis, pericardial constriction, neurologic complications from tuberculous

Table 22-22 Drug Regimens for Culture-Positive Pulmonary Tuberculosis Caused by Drug-Susceptible Organisms

Initial phase			Continuation phase				Rating* (evidence)†	
Regimen	Drugs	Interval and doses‡ (minimal duration)	Regimen	Drugs	Interval and doses‡§ (minimal duration)	Range of total doses (minimal duration)	HIV-	HIV+
1	INH RIF PZA EMB	7 d/wk for 56 doses (8 wk) *or* 5 d/wk for 40 doses (8 wk)//	1a	INH/RIF	7 d/wk for 126 doses (18 wk) *or* 5 d/wk for 90 doses (18 wk)//	182-130 (26 wk)	A (I)	A (II)
			1b	INH/RIF	Twice weekly for 36 doses (18 wk)	92-76 (26 wk)	A (I)	A (II)#
			1c**	INH/RPT	Once weekly for 18 doses (18 wk)	74-58 (26 wk)	B (I)	E (I)
2	INH RIF PZA EMB	7 d/wk for 14 doses (2 wk), *then* twice weekly for 12 doses (6 wk) *or* 5 d/wk for 10 doses (2 wk),// *then* twice weekly for 12 doses (6 wk)	2a	INH/RIF	Twice weekly for 36 doses (18 wk)	62-58 (26 wk)	A (II)	B (II)#
			2b**	INH/RPT	Once weekly for 18 doses (18 wk)	44-40 (26 wk)	B (I)	E (I)
3	INH RIF PZA EMB	3 times weekly for 24 doses (8 wk)	3a	INH/RIF	3 times weekly for 54 doses (18 wk)	78 (26 wk)	B (I)	B (II)
4	INH RIF EMB	7 d/wk for 56 doses (8 wk) *or* 5 d/wk for 40 doses (8 wk)//	4a	INH/RIF	7 d/wk for 217 doses (31 wk) *or* 5 d/wk for 155 doses (31 wk)//	273-195 (39 wk)	C (I)	C (II)
			4b	INH/RIF	Twice weekly for 62 doses (31 wk)	118-102 (39 wk)	C (I)	C (II)

EMB, ethambutol; INH, isoniazid; PZA, pyrazinamide; RIF, rifampin; RPT, rifapentine.

*Definitions of evidence ratings: A, preferred; B, acceptable alternative; C, offer when A and B cannot be given; E, should never be given.

†Definitions of evidence ratings: I, randomized clinical trial; II, data from clinical trials that were not randomized or were conducted in other populations; III, expert opinion.

‡When directly observed therapy is used, drugs may be given 5 d/wk and the necessary number of doses adjusted accordingly. Although there are no studies that compare 5 with 7 daily doses, extensive experience indicates this would be an effective practice.

§Patients with cavitation on initial chest radiograph and positive cultures at completion of 2 months of therapy should receive a 7-month (31-week; either 217 doses [daily] or 62 doses [twice weekly]) continuation phase.

//Five-day-a-week administration is always given by directly observed therapy. Rating for 5 d/wk regimens is A (III).

#Not recommended for human immunodeficiency virus (HIV)-infected patients with CD4+ cell counts <100 cells/mL.

**Options 1c and 2b should be used only in HIV-negative patients who have negative sputum smears at the time of completion of 2 months of therapy and who do not have cavitation on the initial chest radiograph. For patients started on this regimen and found to have a positive culture from the 2-month specimen, treatment should be extended an extra 3 months.

Table 22-23 First-Line Drugs for Tuberculosis (TB)*†

Drug	Dose, mg/kg						Adverse reactions	Monitoring
	Daily		2 times/wk‡		3 times/wk‡			
	Children§	Adults	Children§	Adults	Children§	Adults		
INH// (maximal dose, mg)	10-20 (300)	5 (300)	20-40 (900)	15 (900)	20-40 (900)	15 (900)	Liver enzyme elevation, hepatitis, peripheral neuropathy, mild effects on central nervous system, drug interactions	Baseline measurements of liver enzymes for adults Repeat measurements if baseline results are abnormal, if patient is at high risk of adverse reactions, if patient has symptoms of adverse reactions
RIF¶ (maximal dose, mg)	10-20 (600)	10 (600)	10-20 (600)	10 (600)	10-20 (600)	10 (600)	GI upset, drug interactions, hepatitis, bleeding problems, flulike symptoms, rash	Baseline measurements for adults: complete blood cell count, platelets, liver enzymes Repeat measurements if baseline results are abnormal, if patient has symptoms of adverse reactions
PZA# (maximal dose, g)	15-30 (2)	15-30 (2)	50-70 (4)	50-70 (4)	50-70 (3)	50-70 (3)	Hepatitis, rash, GI upset, joint aches, hyperuricemia, gout (rare)	Baseline measurements for adults: uric acid, liver enzymes Repeat measurements if baseline results are abnormal, if patient has symptoms of adverse reactions
EMB**	15-25	15-25	50	50	25-30	25-30	Optic neuritis	Baseline and monthly tests: visual acuity, color vision
SM†† (maximal dose, g)	20-40 (1)	15 (1)	25-30 (1.5)	25-30 (1.5)	25-30 (1.5)	25-30 (1.5)	Ototoxicity (hearing loss or vestibular dysfunction), renal toxicity	Baseline and repeat as needed: hearing, kidney function

EMB, ethambutol; GI, gastrointestinal; INH, isoniazid; PZA, pyrazinamide; RIF, rifampin; SM, streptomycin.
*Adjust weight-based dosages as weight changes.
†INH, RIF, PZA, and EMB are administered orally; SM is administered intramuscularly.
‡Directly observed therapy should be used with all regimens administered 2 or 3 times a week.
§Younger than 12 years.
//Hepatitis risk increases with age and alcohol consumption. Pyridoxine can prevent peripheral neuropathy.
¶Severe interactions with methadone, oral contraceptives, and many other drugs. Drug colors body fluids orange and may permanently discolor soft contact lenses.
#Treat hyperuricemia only if patient has symptoms.
**Not recommended for children too young to be monitored for changes in vision unless TB is drug resistant.
††Avoid or decrease dose in adults older than 60 years.
From Centers for Disease Control and Prevention, Division of Tuberculosis Elimination: core curriculum on tuberculosis. 3rd ed. 1994.

Table 22-24 Targeted Tuberculin Testing for Latent Tuberculosis Infection

Prophylactic group description	PPD, mm
Persons with known or suspected HIV infection	≥5
Close contacts of person with infectious TB	≥5
Persons with chest radiographic findings suggestive of previous TB and inadequate or no treatment*	≥5
Persons who inject drugs and are known to be HIV-negative	≥10
Persons with certain medical conditions or factors	≥10
Diabetes mellitus, silicosis, prolonged corticosteroid or other immunosuppressive therapy, cancer of the head and neck, hematologic and reticuloendothelial diseases (e.g., leukemia and Hodgkin disease), end-stage renal disease, intestinal bypass or gastrectomy, chronic malabsorption syndromes, low body weight (≥10% below ideal)	
Persons in whom PPD converted from negative to positive within the past 2 y	†
Age <35 y in the following high-prevalence groups	≥10
Foreign-born persons from areas of the world where TB is common (e.g., Asia, Africa, Caribbean, and Latin America)	
Medically underserved, low-income populations including high-risk racial and ethnic groups (e.g., Asians and Pacific Islanders, African Americans, Hispanics, and American Indians)	
Residents of long-term care facilities (e.g., correctional facilities and nursing homes)	
Children <4 y	
Other groups identified locally as having an increased prevalence of TB (e.g., migrant farm workers or homeless persons)	
Persons <35 y with no known risk factors for TB	≥15
Occupational exposure to TB (e.g., health care workers and staff of nursing homes, drug treatment centers, or correctional facilities)	‡
Close contacts with an initial PPD <5 mm and normal findings on chest radiography	<5
Circumstances suggest a high probability of infection	
Evaluation of other contacts with a similar degree of exposure demonstrates a high prevalence of infection	
Child or adolescent	
Immunosuppressed (e.g., HIV infection)	

HIV, human immunodeficiency virus; PPD, purified protein derivative of tubercle bacillus; TB, tuberculosis.
*Isolated calcified granulomas are excluded.
†10 mm or greater increase if person is younger than 35 years or is a health care worker; 15 mm or greater increase if person is 35 years or older.
‡Appropriate cutoff for defining a positive reaction depends on the employee's individual risk factors for TB and on the prevalence of TB in the facility.
From Van Scoy RE, Wilkowske CJ. Antimicrobial therapy. Mayo Clin Proc. 1999;74:1038-48. Used with permission of Mayo Foundation for Medical Education and Research.

meningitis, tuberculous bronchial stenosis, and adrenal insufficiency caused by tuberculosis. Extrapulmonary tuberculosis confined to lymph nodes has no effect on obstetrical outcomes, but tuberculosis at other sites adversely affects the outcome of pregnancy.

- Miliary, skeletal, and meningeal tuberculosis may require >12 months of therapy.
- Corticosteroids are helpful in treating extrapulmonary tuberculosis.

Drug-resistant tuberculosis is a problem in many large cities; for example, a rate of 30% has been reported in New York City. Drug resistance can develop against a single drug or multiple drugs. Multidrug resistance is usually defined as *M. tuberculosis* resistance to at least isoniazid and rifampin. Multidrug resistance is more likely in the following settings: nonadherence to treatment guidelines and treatment "errors" by physicians and health care workers, lack of compliance by patients, homelessness, drug addiction, and exposure to multidrug-resistant tuberculosis (MDR-TB) in high-prevalence countries with inadequate tuberculosis control programs. Multidrug resistance occurs rapidly in HIV-infected persons. The American Thoracic Society (ATS) and the Centers for Disease Control and Prevention (CDC) recommend an intensive phase of therapy with four drugs if the local rate of resistance to isoniazid is more than 4%. Even though the mortality from MDR-TB is high in HIV-positive and HIV-negative patients, appropriate treatment produces a favorable outcome (>80%). MDR-TB is often treated for 18 to 24 months.

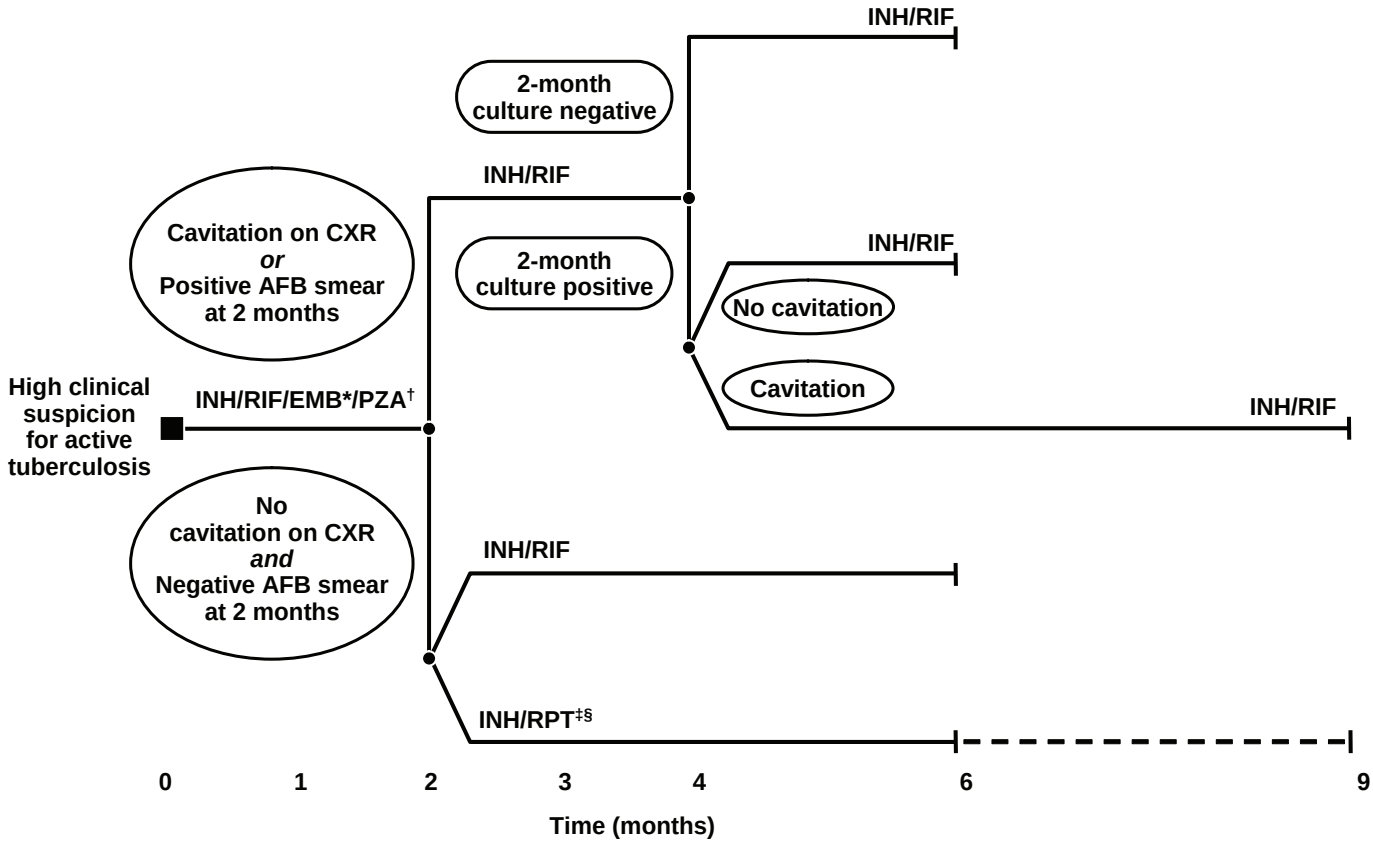

Fig. 22-29. Treatment algorithm for tuberculosis. Patients in whom tuberculosis is proved or strongly suspected should have treatment initiated with isoniazid, rifampin, pyrazinamide, and ethambutol for the initial 2 months. A repeat smear and culture should be performed when 2 months of treatment has been completed. If cavities were seen on the initial chest radiograph or the acid-fast smear is positive at completion of 2 months of treatment, the continuation phase of treatment should consist of isoniazid and rifampin daily or twice weekly for 4 months to complete a total of 6 months of treatment. If cavitation was present on the initial chest radiograph and the culture at the time of completion of 2 months of therapy is positive, the continuation phase should be lengthened to 7 months (total of 9 months of treatment). If the patient has HIV infection and the $CD4^+$ cell count is <100/μL, the continuation phase should consist of daily or 3-times-weekly doses of isoniazid and rifampin. In HIV-uninfected patients having no cavitation on chest radiograph and negative acid-fast smears at completion of 2 months of treatment, the continuation phase may consist of either once-weekly doses of isoniazid and rifapentine, or daily or twice-weekly doses of isoniazid and rifampin, to complete a total of 6 months (*bottom*). Patients receiving isoniazid and rifapentine, and whose 2-month cultures are positive, should have treatment extended by an additional 3 months (total of 9 months). *EMB may be discontinued when results of drug susceptibility testing indicate no drug resistance. †PZA may be discontinued after it has been taken for 2 months (56 doses). ‡RPT should not be used in HIV-infected patients with tuberculosis or in patients with extrapulmonary tuberculosis. §Therapy should be extended to 9 months if 2-month culture is positive. CXR, chest radiograph; EMB, ethambutol; INH, isoniazid; PZA, pyrazinamide; RIF, rifampin; RPT, rifapentine. (From Blumberg HM, Burman WJ, Chaisson RE, Daley CL, Etkind SC, Friedman LN, et al. American Thoracic Society/Centers for Disease Control and Prevention/Infectious Diseases Society of America: treatment of tuberculosis. Am J Respir Crit Care Med. 2004;167:603-62. Used with permission.)

- Drug-resistant tuberculosis may require multidrug (≥4 drugs) therapy.

To prevent drug resistance and to effectively decrease the number of cases of tuberculosis, many health care organizations recommend administration of antituberculous drugs by directly observed therapy (DOT) in which a health care provider monitors each patient as every dose of a 6-month regimen is taken. This approach makes a cure almost certain in those with drug-sensitive tuberculosis. The DOT regimen is particularly important for the homeless, chronic alcoholics, intravenous drug abusers, AIDS patients, and prison inmates. A fixed-dose combination should be considered in cases of newly diagnosed disease. Even though fixed-dose combinations of antituberculous drugs (Rifamate and Rifater) are available and have been strongly recommended by the World Health Organization, CDC, ATS, and the International Union Against Tuberculosis and Lung Disease, less than 25% of rifampin-containing therapies use the fixed-dose regimen. Treatment completion rates for pulmonary tuberculosis are most likely to exceed 90% with DOT. However, DOT may not increase the cure rate in areas where the rate of cure is high (without DOT).

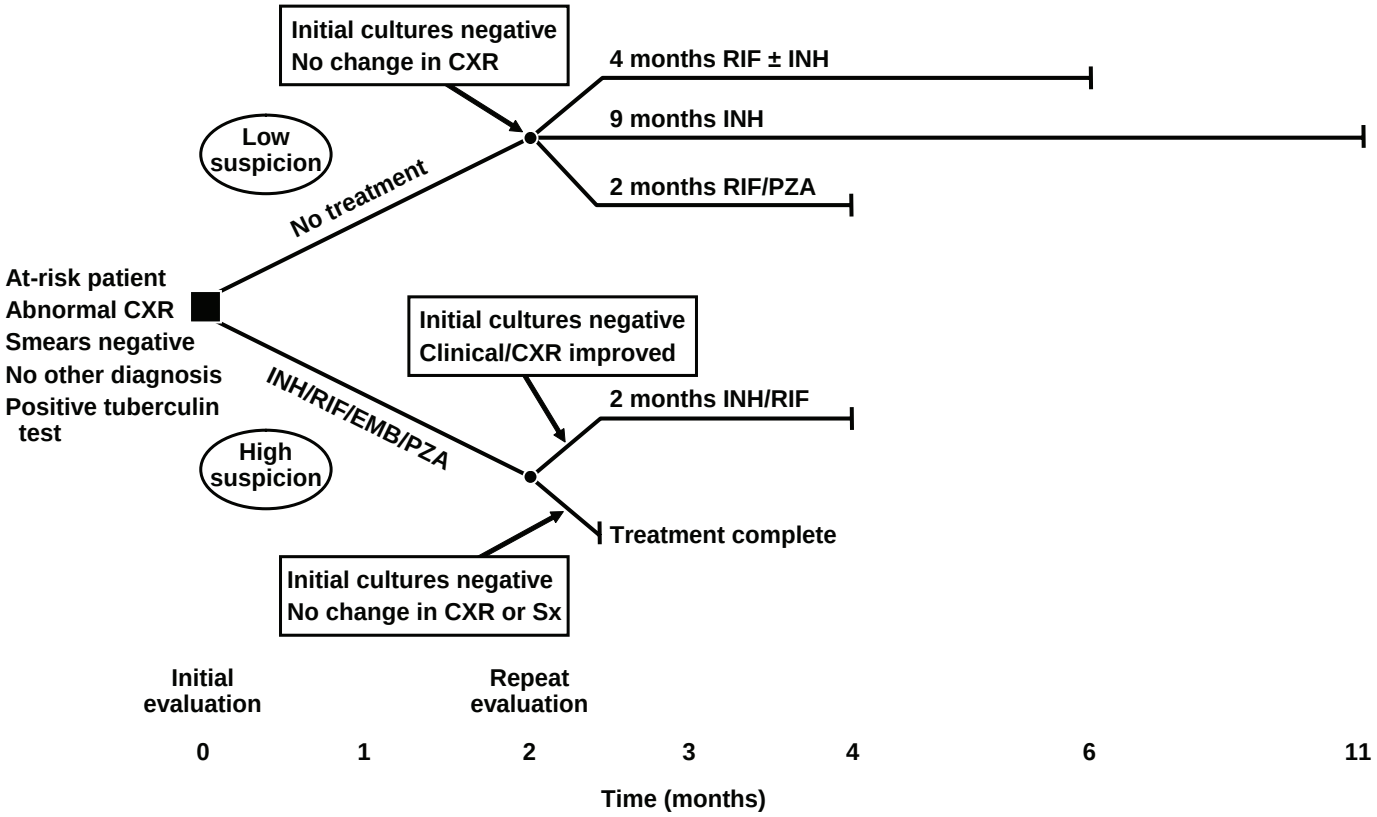

Fig. 22-30. Treatment algorithm for active, culture-negative pulmonary tuberculosis and inactive tuberculosis. The decision to begin treatment for a patient with sputum smears that are negative depends on the degree of suspicion that the patient has tuberculosis. If the clinical suspicion is high (*bottom*), multidrug therapy should be initiated before acid-fast smear and culture results are known. If the diagnosis is confirmed by a positive culture, treatment can be continued to complete a standard course of therapy (see Figure 22-29). If initial cultures remain negative and treatment has consisted of multiple drugs for 2 months, there are 2 options depending on repeat evaluation at 2 months (*bottom*): 1) If the patient demonstrates symptomatic or radiographic improvement without another apparent diagnosis, a diagnosis of culture-negative tuberculosis can be inferred. Treatment should be continued with isoniazid and rifampin alone for an additional 2 months. 2) If the patient demonstrates neither symptomatic nor radiographic improvement, prior tuberculosis is unlikely and treatment is complete after treatment including at least 2 months of rifampin and pyrazinamide has been administered. In low-suspicion patients not initially receiving treatment (*top*), if cultures remain negative, the patient has no symptoms, and the chest radiograph is unchanged at 2-3 months, the 3 treatment options are 1) isoniazid for 9 months, 2) rifampin with or without isoniazid for 4 months, or 3) rifampin and pyrazinamide for 2 months. CXR, chest radiograph; EMB, ethambutol; INH, isoniazid; PZA, pyrazinamide; RIF, rifampin; Sx, signs/symptoms. (It should be noted that the RIF/PZA 2-month regimen should be used only for patients who are not likely to complete a longer course of treatment and can be monitored closely.) (From Blumberg HM, Burman WJ, Chaisson RE, Daley CL, Etkind SC, Friedman LN, et al. American Thoracic Society/Centers for Disease Control and Prevention/Infectious Diseases Society of America: treatment of tuberculosis. Am J Respir Crit Care Med. 2004;167:603-62. Used with permission.)

- DOT for 6 months is effective in preventing relapses and emergence of drug-resistant tuberculosis.
- DOT is also useful in the treatment of drug-resistant tuberculosis and tuberculosis in immunocompromised patients.
- A fixed-dose combination should be considered in cases of newly diagnosed disease.

Treatment of LTBI is indicated for persons with a positive PPD skin test who do not have active infection (Table 22-24). If an isoniazid-sensitive organism is suspected to have caused LTBI, the treatment options include isoniazid 300 mg daily or 900 mg biweekly. Rifampin (600 mg daily) is an alternative option. If isoniazid resistance is suspected or known, the options include rifampin (600 mg daily) or rifabutin (300 mg daily). A short course of therapy (4 months) with rifampin and pyrazinamide was an alternative regimen for LTBI, but this is no longer routinely recommended because of the increased frequency of cases of fatal hepatitis. Therapy with this combination should be supervised by a specialist. The recommended duration for LTBI therapy is outlined below:

1. Isoniazid for HIV-positive adults and children: 12 months
2. Isoniazid for HIV-negative adults: at least 6 months
3. Isoniazid for HIV-negative children: 9 months
4. Rifampin or rifabutin: 12 months
5. Silicosis or old fibrotic lesion on CXR without active tuberculosis: 4-month therapy with isoniazid and rifampin, although 12 months of isoniazid alone is an acceptable alternative

In the United States, BCG vaccine is recommended for PPD-negative persons in the following categories:

1. Infants and children who are at high risk of intimate and prolonged exposure to persistently untreated or ineffectively treated patients with infectious pulmonary tuberculosis, who cannot be removed from the source of exposure, and who cannot be given long-term prophylactic therapy
2. Health care workers in settings in which the likelihood of transmission and subsequent infection with *M. tuberculosis* strains resistant to isoniazid and rifampin is high, provided comprehensive tuberculosis infection-control precautions have been implemented in the workplace and have not been successful.

BCG is not recommended for HIV-positive children and adults.

- BCG is indicated for children who are at high risk of intimate and prolonged exposure to *M. tuberculosis*.
- BCG is not recommended for HIV-positive adults or children.

Nontuberculous Mycobacteria

Mycobacteria other than *M. tuberculosis* and *Mycobacterium leprae* are commonly classified as *nontuberculous mycobacteria* (NTM) even though tubercle formation occurs. Most NTM have been isolated from natural water and soil. Human-to-human spread has not been documented. Natural waters are the source for most human infections caused by *Mycobacterium avium* complex; some cases are likely acquired from hospital tap water. Colonization or a saprophytic state of NTM is uncommon. NTM disease is not reportable in the United States.

- Human-to-human spread has not been documented.
- NTM disease is not reportable in the United States.

Chronic pulmonary disease is caused most frequently by *M. avium* complex and *Mycobacterium kansasii*. Pulmonary disease is more common in older adults, those with underlying COPD, smokers, alcohol abusers, and some children with cystic fibrosis. Another group of patients who develop pulmonary infection from *M. avium* complex are white women in their 60s who are HIV-negative without preexisting lung disease. Most of these patients (>90%) demonstrate bronchiectasis or small nodules without predilection for any lobe. High-resolution CT may show associated multifocal bronchiectasis with small (<5 mm) nodular infiltrates. Bilateral nodular or interstitial lung disease (or both) or isolated disease in the right middle lobe or lingular disease is more predominant in elderly nonsmoking women. Hypersensitivity pneumonitis caused by exposure to *M. avium* complex growing in a hot tub has been reported. *M. avium* complex is responsible for 5% of the cases of mycobacterial lymphadenitis in adults and more than 90% of the cases in children. Lymphadenopathy is usually unilateral and nontender. Disseminated disease caused by NTM presents as a fever of unknown origin in immunocompromised patients without AIDS.

- *M. avium* complex infection occurs in bronchiectasis.

HIV-infected persons are at high risk of NTM infections. More than 95% of NTM disease in HIV-infected persons is caused by *M. avium* complex. In those with AIDS, disseminated infection occurs in up to 40% and localized infection in 5%; dissemination is more likely in those with a CD4 cell count less than 50/μL. The risk of disseminated infection is 20% per year when the CD4 cell count is less than 100/μL. High fever and sweats are common, as are anemia and increased alkaline phosphatase levels. Dissemination is usually documented with positive blood cultures (sensitivity of 90%).

- Disseminated *M. avium* complex in AIDS is more likely when the CD4 count is <50/μL.
- A single blood culture in disseminated *M. avium* complex infection has a sensitivity of 90%.

M. kansasii is the second most common cause of nontuberculous mycobacterial pulmonary disease in the United States. It primarily affects adult white men. Approximately 90% of patients with *M. kansasii* disease have cavitary infiltrates. *M. kansasii* infection can be clinically indistinguishable from tuberculosis; however, symptoms may be less severe and more chronic than with tuberculosis. In HIV-negative patients, common symptoms are cough (90%), purulent sputum (85%), weight loss (55%), and dyspnea (50%). In immunocompromised patients, including those with AIDS, the lung is most commonly involved and symptoms include fever, chills, night sweats, cough, weight loss, dyspnea, and chest pain. Disseminated *M. kansasii* infection occurs in 20% of HIV-positive patients who have *M. kansasii* pulmonary disease.

- Cavitation occurs in 90% of patients with *M. kansasii* infection.

Specific skin tests are not available for the diagnosis of NTM. Routine cultures of sputum, blood, or stool are not recommended for asymptomatic patients. All specimens positive for acid-fast bacilli must be considered to indicate *M. tuberculosis* until final culture results are available. Bronchoscopy or open lung biopsy is required for diagnosis in nearly half the cases. Therapy fails in half the patients. More than 80% of patients remain symptomatic, and 60% do not tolerate the initial multidrug regimen. Treatment of infections caused by NTM should be undertaken by a physician who specializes in infections caused by mycobacteria. The macrolides azithromycin and clarithromycin are important in the treatment of infections with *M. avium* complex. Isoniazid is not used to treat infection with *M. avium* complex. The current recommendation for treatment of pulmonary disease caused by *M. kansasii* in adults is to use isoniazid, rifampin, and ethambutol. In patients who are unable to tolerate one of these three drugs, clarithromycin can be substituted. Pyrazinamide is avoided because all isolates are resistant.

- Isoniazid is not used to treat infection with *M. avium* complex.
- Macrolides are important in the therapy for infections with *M. avium* complex, and rifampin is clinically useful for *M. kansasii*.

Toxicity From Antituberculous Drugs

Isoniazid, rifampin, ethambutol, and pyrazinamide are considered first-line antituberculous medications. These four medications are the

foundation of numerous treatment regimens for tuberculosis. Each has its own potential toxicity, and each can potentiate toxicity when used in combination. Hepatitis (AST usually >5 times normal value) is the most common important adverse effect from antituberculous medications and is distinct from the mild elevation in transaminases which occur in up to 20% of patients receiving these medications (AST usually <3 times normal value). In adults receiving these medications, it is important to assess baseline liver function, creatinine level, complete blood cell count, and uric acid (if pyrazinamide is used) and to perform an ophthalmic examination (if ethambutol is used) before antituberculous therapy is begun. All patients should be evaluated periodically for adverse reactions to the drugs (Table 22-23).

Isoniazid

Clinically significant hepatitis is seen in less than 1% of patients receiving isoniazid, with the incidence increasing with age. Middle-aged and black females are at higher risk. Hepatitis is more likely in patients who are "rapid acetylators," and neuritis is more likely in those who are "slow acetylators." Isoniazid also causes skin rash, purpura, drug-induced systemic lupus erythematosus, seizures, optic neuritis, and arthritis. The addition of pyridoxine is recommended for patients with neuropathy (diabetes mellitus, uremia, alcoholism, and malnutrition), pregnancy, and seizure disorder. Before initiating treatment of LTBI, baseline laboratory testing is indicated in patients with known liver disease or HIV infection, in pregnant women, in women in the immediate postpartum period (within 3 months after delivery), and in persons who drink alcohol regularly. Routine monitoring of liver function during treatment is recommended for patients with abnormal baseline liver function tests or those at risk of liver disease. Therapy should be stopped if the AST value is more than five times normal or three times more than the baseline value. Alcohol consumption should be avoided.

- The incidence of isoniazid-induced hepatitis increases with age.
- Isoniazid causes hepatitis and peripheral neuropathy.
- Stop therapy if AST is >5 times normal or 3 times above baseline.

Rifampin

The overall incidence of serious side effects with rifampin is 1%. Gastrointestinal upset is the most common reaction. Larger or intermittent doses (>10 mg/kg) (or both) are associated with thrombocytopenia, flulike syndrome, hemolytic anemia, and cholestatic jaundice. Skin rash can occur, and use of the drug needs to be stopped for persistent rash. Hepatitis can also occur. Harmless orange discoloration of body secretions occurs. Rifampin induces liver microsomal enzymes, and it increases the metabolism of contraceptive pills, corticosteroids, warfarin, oral hypoglycemic agents, theophylline, anticonvulsant agents, ketoconazole, cyclosporine, methadone, and antiarrhythmic drugs (digitalis, quinidine, verapamil, and mexiletine); therefore, dosages of these drugs may have to be increased.

- Rifampin: gastrointestinal upset is the most common side effect.
- Rifampin induces liver microsomal enzymes.

Pyrazinamide

The most serious adverse reaction of pyrazinamide is liver damage. Hyperuricemia is common but gout is not, although arthralgias are reported occasionally. Skin rash and gastrointestinal upset are sometimes encountered.

- Pyrazinamide: liver damage is the most serious adverse reaction.

Ethambutol

Ethambutol in doses greater than 25 mg/kg causes retrobulbar neuritis in less than 3% of patients; symptoms usually are observed 2 months after therapy has been initiated. Because ophthalmoscopic findings are normal in these patients, symptoms are important (blurred vision, central scotoma, and red-green color blindness). These symptoms precede changes in visual acuity. Optic neuritis is best prevented by giving a lower dose (15 mg/kg) during the maintenance phase of treatment. Renal failure prolongs the half-life of the drug and increases the frequency of ocular toxicity.

- Ethambutol: Retrobulbar neuritis (dose-related) is the most frequent and serious side effect.
- Renal failure prolongs the half-life of the drug and increases the frequency of ocular toxicity.

Streptomycin

Because streptomycin is excreted by the kidneys, the dosage should be decreased in renal insufficiency. The most common adverse side effect is vestibular toxicity, which causes vertigo. Hearing loss may also occur. These side effects are more likely in the elderly (>60 years). Ototoxicity and nephrotoxicity are related to both the cumulative dose and the peak serum concentration. Streptomycin should be avoided in pregnancy.

- Streptomycin: nephrotoxicity and vestibular toxicity are more common in persons >60 years.
- Streptomycin should be avoided in pregnancy.

Fungal Diseases of the Lung

Serious fungal infections are found at autopsy in 2% of patients overall, in up to 10% of those with solid tumors, and in up to 40% of those dying of leukemia. Among renal transplantation patients, 15% have a fungal infection at some time during the posttransplantation course. Almost all fungi produce granulomas. The saprophytic state of fungi is a common problem, particularly with *Aspergillus* species. Pulmonary manifestations are described here. Treatment of the mycoses is discussed in Chapter 14 ("Infectious Diseases").

Histoplasmosis

Histoplasma capsulatum infections are more common in the Mississippi, Ohio, and St. Lawrence river valleys than elsewhere. Infection is by inhalation of fungal spores, which are especially numerous in chicken coops, dusty areas, starling roosts, bat-infested caves, and decayed wood. Clinically, patients may present with asymptomatic infection, acute pneumonia or acute respiratory distress

syndrome (ARDS), disseminated infection (AIDS or other immunocompromised hosts), chronic cavitary disease (underlying lung structural defects), or late complications of mediastinal granuloma, mediastinal fibrosis, broncholithiasis, or residual pulmonary nodules seen on CXR. The nodules may be calcified, and hilar adenopathy may be seen.

- Typical clinical scenario for *Histoplasma* pneumonitis: Exposure to chicken coops, dusty areas, starling roosts, bat-infested caves, and decayed wood in the Mississippi River Valley, with late complications that include chronic cavitary disease, mediastinal granulomas, calcified hilar adenopathy, and hilar adenopathy.

Coccidioidomycosis

The endemic zone for *Coccidioides immitis* extends from northern California to Argentina. Infections are more common when dry windy conditions exist, with epidemics occurring in the dry hot months after the rainy season, often after the soil has been disturbed. Clinically, patients may be asymptomatic, with CXR showing nodules or thin-walled cavities, or they may have a range of symptomatic disease: "valley fever" (erythema nodosum, erythema multiforme, arthralgia, arthritis, and eosinophilia), acute pneumonia (mildly symptomatic flulike illness in 40% of patients), disseminated disease (more common in Filipinos, African Americans, Mexicans, and immunocompromised patients), and chronic cavitary disease. Infection acquired late during pregnancy is associated with higher maternal and fetal mortality. Chronic thin-walled cavities are associated with increased risk of hemoptysis.

- Typical clinical scenario for coccidioidomycosis pneumonitis: A patient from the southwestern United States presents with erythema nodosum, arthalgias/arthritis, acute pneumonia, and chronic cavitary disease.

Blastomycosis

Blastomyces dermatitidis infections occur most commonly in the southern, south-central, and Great Lakes states. Persons and animals (canines) in contact with soil are more likely to be infected. The male-female ratio is 10:1. Patients with pulmonary infections can be asymptomatic or have acute pneumonia (mimicking an acute bacterial pneumonia), chronic progressive pneumonia, or extrapulmonary dissemination (typically to skin, bone, prostate, or central nervous system). The most characteristic CXR finding is a perihilar mass that mimics carcinoma. Sputum analysis with 10% potassium hydroxide is helpful in diagnosis. Laryngeal blastomycosis can resemble cancer.

- Typical clinical scenario for blastomycosis pneumonitis: A person has contact with the soil, lives in one of the Great Lakes states, and has the CXR finding of a perihilar mass mimicking carcinoma.

Cryptococcosis

Cryptococcus neoformans is a unimorphic fungus that is widely distributed in the soil and excreta of pigeons and other animals. In humans, it may exist as a saprophyte in preexisting lung disease, but one-third to one-half of patients with cryptococcosis are immunosuppressed. The lung is the portal of entry, but the most common clinical presentation is subacute or chronic meningitis (the common cause of death). Diseases that predispose to cryptococcosis include an immunocompromised state, Hodgkin and non-Hodgkin lymphomas, leukemia, sarcoidosis, and diabetes mellitus. The onset of neurologic symptoms, fever, nausea, and anorexia is insidious. Pulmonary features include chest pain (45%), dyspnea (25%), night sweats (25%), cough with scant sputum (15%), and hemoptysis (7%). Nodular infiltrates with cavitation, especially in the lower lobes, occasional hilar adenopathy, and a solitary mass may be found. In non-AIDS patients with pulmonary cryptococcosis, masses and air space consolidation are common and atelectasis, lymphadenopathy, and pleural effusion or empyema are relatively rare. The cerebrospinal fluid should be examined in almost all patients who have organisms in respiratory secretions.

- Typical clinical scenario for *C. neoformans* pneumonitis: An immunocompromised patient or a patient with diabetes who has nodular, cavitary, and patchy infiltrates on CXR, fever, and pulmonary and neurologic symptoms.
- The cerebrospinal fluid should be examined in almost all patients who have organisms in respiratory secretions.

Aspergillosis

Aspergillus fumigatus, *A. flavus*, and *A. niger* are responsible for several pulmonary manifestations. The clinical forms include 1) allergic bronchopulmonary aspergillosis, 2) hypersensitivity pneumonitis in red cedarwood workers, 3) mycetoma or fungus ball in preexisting lung disease, 4) locally invasive (chronic necrotizing) aspergillosis of lung tissue, 5) tracheobronchial form in immunocompromised or HIV-infected persons and lung transplant recipients (at anastomotic site), 6) disseminated, 7) bronchocentric granulomatosis, and 8) saprophytic. The organism frequently colonizes the respiratory tract in patients with lung disease. Invasive aspergillosis in immunosuppressed hosts is the most serious form of infection and occurs mainly in granulocytopenic patients with a hematologic malignancy. The occurrence of life-threatening complications in patients with invasive fungal pneumonia is closely related to rapid granulocyte recovery. The presence of *Aspergillus* in respiratory secretions is not diagnostic; tissue invasion should be documented.

Aspergilloma is a mass of fungal hyphae in preexisting lung cavities, almost always in the upper lobes. The major symptoms include hemoptysis, cough, low fever, and weight loss. CXR and CT show a meniscus of air around the fungus ball. Because surgical therapy of aspergilloma has a high morbidity and mortality, another therapeutic option is the intracavitary instillation of amphotericin.

- Typical clinical scenario for pulmonary invasive aspergillosis: Fever and pulmonary infiltrates with prolonged neutropenia in acute leukemias and Hodgkin disease.
- Aspergillosis: tissue invasion should be documented.
- Aspergilloma (fungus ball) occurs in previously damaged lung; hemoptysis is a serious complication.

Zygomycosis (Mucormycosis)

Zygomycosis is caused by fungi in the order Mucorales (class Phycomycetes). Serious infections of the upper respiratory tract, lungs, central nervous system, and skin occur in patients with severe diabetes mellitus, hematologic malignancy, skin or mucosal injury, or immunocompromised status. The organism invades blood vessels in the lungs and causes hemoptysis. CXR may show patchy infiltrates, consolidation, cavitation, and effusions. Bronchial stenosis is a peculiar complication of zygomycosis.

- Zygomycosis: immunocompromised and diabetic patients.
- Propensity to invade blood vessels; hemoptysis is common.

Candidiasis

Candida species are present in the oropharynx of 30% of normal persons, in the gastrointestinal tract of 65%, and in the vagina of up to 70% of women. Systemic candidiasis is found at autopsy in as many as 25% of patients with leukemia. Risk factors for developing candidiasis include diabetes mellitus, cancer, cirrhosis, renal failure, blood dyscrasia, cytotoxic therapy, intravenous or urinary catheters, intravenously administered antibiotics, prostheses, cachexia, burns, and HIV infection. Lung involvement is relatively rare, and CXR shows patchy or diffuse infiltrates. *Candida* bronchitis, an occupational disease of tea tasters, is manifested by low-grade fever, cough, and patchy infiltrates.

- Typical clinical scenario for candidiasis: A patient with hematologic malignancy and prolonged granulocytopenia.
- Lung involvement is uncommon; patchy or diffuse lung infiltrates.

Sporotrichosis

Sporothrix schenckii is a dimorphic fungus that exists as a saprophyte in soil, plants, wood, straw, sphagnum moss, decaying vegetation, cats, dogs, and rodents. Sporotrichosis is an occupational hazard of farmers, florists, gardeners, horticulturists, and forestry workers. Infection is by cutaneous inoculation and inhalation. Cutaneous nodules along lymphatic vessels may appear in 75% of patients. Hematogenous dissemination to the lungs is rare, but inhalation-induced pulmonary disease mimics cavitary tuberculosis.

- Sporotrichosis: occupational hazard of florists, horticulturists, and gardeners.
- Lymphangitis of the skin and subcutaneous nodules.
- Pulmonary infection mimics chronic tuberculosis.

Pneumocystis jiroveci Infection

Pneumocystis jiroveci (formerly *Pneumocystis carinii*) is a fungus with trophic and cyst forms. *P. jiroveci* infections occur in immunosuppressed patients, especially those with AIDS (CD4 <200/μL) or malignancy, and after organ transplantation. Infection causes alveolar and interstitial inflammation and edema with plasma cell infiltrates. Clinical features in patients with AIDS include the gradual onset of dyspnea, fever, tachypnea, and hypoxia. In patients without AIDS, the onset is more abrupt and progression to respiratory failure occurs quickly. Patients typically have relatively normal findings on lung examination and a patchy or diffuse interstitial or alveolar process on CXR. An upper lobe process is seen on CXR of patients receiving pentamidine aerosolized prophylaxis. The typical CT finding is ground-glass attenuation. However, this classic radiographic presentation is less frequent now and is being replaced by cystic lung disease, spontaneous pneumothorax, and an upper lobe distribution of parenchymal opacities. Routine laboratory data are unhelpful. The diagnosis can be made with induced sputum, bronchoalveolar lavage, or lung biopsy. Induced sputum or bronchoalveolar lavage is an excellent method for diagnosis, and the cyst stains best with methenamine silver nitrate. The number of organisms present in immunocompromised patients without AIDS is smaller and overall mortality is greater.

- Typical clinical scenario: AIDS patient with CD4 <200/μL and gradual onset of dyspnea, fever, tachypnea, hypoxia, cyanosis, cough; relatively normal findings on lung examination; and a patchy or diffuse interstitial or alveolar process on CXR.
- An upper lobe process is seen on CXR of patients receiving pentamidine aerosolized prophylaxis.

Parasitic Diseases

Parasitic infections of the lung are less common in the United States than in other parts of the world. Travelers to regions that are endemic for parasitic infestations may become infected and, when they return to the United States, present with difficult diagnostic problems. However, dirofilariasis is indigenous to the eastern and southeastern United States. Other parasitic infections, including helminthic infestations, also occur in the United States. The parasites most likely to cause pulmonary infections include *Paragonimus westermani* (paragonimiasis), *Echinococcus granulosus* (echinococcosis or hydatid disease), *Dirofilaria immitis* (dirofilariasis), *Schistosoma japonicum* and *Schistosoma mansoni* (schistosomiasis), and *Entamoeba histolytica* (amebiasis). Protozoal infections are more likely in patients whose cellular immunity is suppressed.

Dirofilariasis, caused by the heartworm that infects dogs, is transmitted to humans by mosquitoes. The disease is endemic to the Mississippi River Valley, the southeastern United States, and the Gulf Coast. Characteristically, the infection presents in the form of a well-defined solitary lung nodule or multiple lung nodules 1.5 to 2.5 cm in diameter. Eosinophilia occurs in less than 15% of patients. Serologic tests may aid in the diagnosis.

Echinococcosis has occurred in Alaska and the southwestern United States. Lung disease presents with the CXR findings of well-defined round or oval cystic or solid lesions up to 15 cm in diameter. Rupture of the cysts can cause anaphylactic shock, hypersensitivity reactions, and seeding of adjacent anatomical areas. Liver involvement (in 40% with lung disease) and positive serologic findings are common.

Paragonimiasis is more likely in immigrants from Southeast Asia, but sporadic cases occur in the United States. It is transmitted typically through consumption of raw or undercooked crabs or crayfish. Respiratory features resemble those of chronic bronchitis, bronchiectasis, or tuberculosis. Profuse brown-colored sputum and hemoptysis can be seen. Pleural effusion is relatively common, and

peripheral eosinophilia is common. Ova can be found in pleural fluid, bronchial wash, or sputum.

Schistosomiasis is not acquired in the United States. The infection leads to gradual development of secondary pulmonary hypertension caused by occlusion of the pulmonary arterial tree by the parasite. Cor pulmonale develops in 5% of patients.

Amebiasis may present as lobar pneumonia or lung abscess (pleuropulmonary complications are almost always right-sided). Rupture into the bronchial tree (hepatobronchial fistula) may be followed by expectoration of "anchovy paste" or "chocolate" sputum. Rupture of the liver abscess into the pleural space causes empyema along with respiratory distress in many patients. Pericardial involvement can also occur.

Strongyloidiasis involving the lungs can mimic asthma with eosinophilia. Risk factors include corticosteroid use, age older than 65, chronic lung disease, and chronic debilitating illness. Pulmonary signs and symptoms include cough, shortness of breath, wheezing, and hemoptysis in more than 90% of patients and pulmonary infiltrates in 90%. In a series of 20 patients with pulmonary strongyloidiasis, ARDS developed in 9 patients (45%). Preexisting chronic lung disease and the development of ARDS are important predictors of a poor prognosis.

- Typical clinical scenario for dirofilariasis: A patient from the Mississippi River Valley, southeastern United States, or Gulf Coast has a solitary lung nodule or multiple nodules. Dirofilariasis is transmitted by mosquitoes.
- Schistosomiasis: pulmonary hypertension.
- Amebiasis: pleuropulmonary complications are almost always right-sided; rupture into the bronchial tree, with "anchovy paste" or "chocolate" sputum.
- Strongyloidosis: mimics asthma with eosinophilia.

Noninfectious Pulmonary Complications in AIDS

Infectious pulmonary complications are discussed in Chapter 14 ("Infectious Diseases"). The noninfectious pulmonary complications in AIDS are discussed below (also see Chapter 12, "HIV Infection").

Nonspecific interstitial pneumonitis represents 30% to 40% of all episodes of lung infiltrates in patients with AIDS. Its incidence has decreased with the institution of highly active antiretroviral therapy (HAART). More than 25% of patients with this problem have concurrent Kaposi sarcoma, previous experimental treatments, or a history of *P. jiroveci* pneumonia or drug abuse. The clinical features are similar to those of patients with *P. jiroveci* pneumonia. Histologic examination of the lung may show various degrees of edema, fibrin deposition, and interstitial inflammation with lymphocytes and plasma cells. This condition is self-limited and often needs no therapy.

- Nonspecific interstitial pneumonitis occurs in up to 40% of patients with AIDS, and *P. jiroveci* pneumonia should be excluded.

Lymphocytic interstitial pneumonitis is caused by pulmonary infiltration with mature polyclonal B lymphocytes and plasma cells. It occurs most commonly in children and is diagnostic of AIDS when it occurs in a child younger than 13 years who is seropositive for HIV. Corticosteroid therapy may produce marked improvement. Pulmonary lymphoid hyperplasia has been reported in 40% of children with AIDS.

- Lymphocytic interstitial pneumonitis is diagnostic of AIDS when it occurs in a child younger than 13 years who is seropositive for HIV.

Cystic lung disease is more common in patients with *P. jiroveci* infections and in those receiving aerosolized pentamidine therapy. Cystic lesions are more common in the upper and mid lung zones. Chest CT identifies these small or medium-size cystic lesions.

- Cystic lung disease is more common in patients with *P. jiroveci* pneumonia receiving aerosolized pentamidine therapy.

Bilateral synchronous pneumothorax occurs with increasing frequency in patients with *P. jiroveci* pneumonia and in those receiving aerosolized pentamidine therapy. Other causes of pneumothorax include Kaposi sarcoma, tuberculosis, and other infections. Pneumothorax in patients with AIDS has a poor prognosis.

- High incidence of bilateral synchronous pneumothoraces.

Pleural effusion is found in 25% of hospitalized patients with AIDS. Nearly one-third of the pleural effusions are due to noninfectious causes. Hypoalbuminemia is the leading cause of these effusions. Other important noninfectious causes include Kaposi sarcoma and atelectasis. Among the infectious causes, bacterial pneumonias, *P. jiroveci* pneumonia, and *M. tuberculosis* are important. Fungal infections can also produce pleural effusion. Large effusions are caused by tuberculosis and Kaposi sarcoma.

- Pleural effusion is caused by infections in two-thirds of hospitalized patients with AIDS.
- Kaposi sarcoma and tuberculosis cause large effusions.

Pulmonary hypertension has been found in patients with AIDS. It is more common in those with HLA-DR6 alleles. The mechanism is not clear, but HIV is thought to affect the endothelium directly and to cause vascular changes. The clinical, physiologic, and pathologic features are identical to those of primary pulmonary hypertension.

- Pulmonary hypertension is clinically identical to idiopathic pulmonary hypertension.

Kaposi sarcoma occurs with greater frequency among homosexuals with AIDS than among other patients with AIDS. It is believed to be caused by human herpesvirus 8. The incidence of its occurrence has diminished. Cutaneous lesions usually precede pulmonary Kaposi sarcoma. Previous or concurrent pulmonary opportunistic infections have been noted in more than 70% of patients with Kaposi sarcoma. Kaposi sarcoma occurs in the lungs of up to 35% of patients who have this tumor. The lung may be the only site in about 15% of patients. In most patients, the diagnosis of pulmonary Kaposi

sarcoma is established only at autopsy. The diagnostic yield from bronchoscopy is 24% and from lung biopsy, 56%. Hemoptysis is an uncommon complication of Kaposi sarcoma, although endobronchial metastasis develops in 30% of patients. Multiple, discrete, raised, violaceous, or bright red tracheobronchial lesions can be seen on bronchoscopy. Bronchoscopic biopsy is associated with a high incidence of significant bleeding. CXR may show typical nodular infiltrates in less than 10% of patients. Pleural effusion is present in more than two-thirds of patients with lung involvement with Kaposi sarcoma. Clinically, pulmonary Kaposi sarcoma is indistinguishable from *P. jiroveci* pneumonia or opportunistic pneumonia.

- Pulmonary Kaposi sarcoma is usually preceded by cutaneous lesions.
- Lung involvement due to Kaposi sarcoma occurs in up to 35% of patients with this neoplasm.
- Clinically, pulmonary Kaposi sarcoma is indistinguishable from *P. jiroveci* pneumonia or opportunistic pneumonia.
- Multiple, discrete, raised, violaceous, or bright red tracheobronchial lesions can be seen on bronchoscopy.

Non-Hodgkin lymphoma involving the lungs is seen in less than 10% of patients with AIDS who develop lymphoma. The lymphoma in these patients is usually extranodal non-Hodgkin B-cell lymphoma. Lung involvement is a late occurrence. Nodules, masses, and infiltrates can be seen on CXR. A 6.5-fold increased incidence of primary lung cancer has been noted among HIV-infected and AIDS patients.

Pulmonary Diseases Pharmacy Review

Todd M. Johnson, PharmD

Drugs for Pulmonary Disease

Drug	Toxic/adverse effects	Drug interactions	Comment
Bronchodilators Levalbuterol (Xopenex) Salmeterol (Serevent) Albuterol (Proventil HFA, Ventolin HFA, Vospire ER) Isoetharine (Bronkosol) Metaproterenol (Alupent) Pirbuterol (Maxair) Terbutaline (Brethine) Isoproterenol (Isuprel) Epinephrine (Primatene)	Palpitations, tachycardia, hypertension, arrhythmia, tremor, nervousness, headache, insomnia, gastroesophageal reflux disease, or pharyngitis	β-Blockers may inhibit effect of bronchodilators in asthmatic patients Tricyclic antidepressants & sympathomimetics may cause hypertension Isoproterenol or epinephrine may sensitize the myocardium to the effects of general anesthetic	Bronchodilators must be used with caution in patients with diabetes mellitus, cardiovascular disorders, hyperthyroidism, or seizure Use of β-blockers in asthmatics may precipitate asthma
Ipratropium (Atrovent) Ipratropium & albuterol (Combivent) Tiotropium (Spiriva)	Ipatropium may cause blurred vision & dry mouth		
Leukotriene receptor antagonists Montelukast (Singulair) Zafirlukast (Accolate) Zileuton (Zyflo)	Rarely may cause systemic eosinophilia with vasculitis, consistent with Churg-Strauss syndrome	Zafirlukast & zileuton can increase warfarin effects Zileuton can double theophylline concentrations	
Anti-inflammatory inhalant products Beclomethasone (QVAR) Budesonide (Pulmicort) Flunisolide (Aerobid) Fluticasone (Flovent HFA) Fluticasone & salmeterol (Advair Diskus) Triamcinolone (Azmacort) Cromolyn (Intal) Nedocromil (Tilade)			Corticosteroids, cromolyn, & nedocromil are not effective for the relief of acute bronchospasm When systemic corticosteroids are withdrawn, inhaled corticosteroids do not provide systemic effects necessary to prevent symptoms of adrenal insufficiency

Pulmonary Diseases Pharmacy Review (continued)

Drugs for Pulmonary Tuberculosis

Drug	Toxic/adverse effects	Drug interactions
Isoniazid	Hepatitis, hypersensitivity reactions, lupus-like reactions, peripheral neuropathy	Carbamazepine, cycloserine, phenytoin, levodopa, prednisone, rifampin, theophylline, warfarin
Rifampin	Orange discoloration of body fluids, leukopenia, thrombocytopenia, proteinuria, hypersensitivity	Aminosalicylic acid, anticoagulants, azole antifungals, barbiturates, benzodiazepines, contraceptives (oral), corticosteroids, cyclosporine, delavirdine, digoxin, estrogens, haloperidol, hydantoins, isoniazid, macrolides, progestins, protease inhibitors, quinine, sulfones, tacrolimus, theophylline, thyroid replacement
Rifabutin (Mycobutin)	Neutropenia, body fluid discoloration, GI intolerance, rash, uveitis, increased liver enzymes	Anticoagulants, azole antifungals, cyclosporine, delavirdine, hydantoins, macrolides, methadone, nelfinavir, quinine, theophylline
Pyrazinamide	Hepatitis, hyperuricemia, nausea, anorexia, poly-arthralgia	Ethionamide, probenecid, zidovudine
Ethambutol (Myambutol)	Optic neuritis, hyperuricemia	Aluminum salts
Cycloserine (Seromycin)	CNS (somnolence, headache, tremor, psychosis, seizures)	Isoniazid
Para-aminosalicylic acid	Skin rash, GI intolerance, hypersensitivity	
Acyclovir (Zovirax)	Malaise, nausea, vomiting, diarrhea, phlebitis (IV)	
Famciclovir (Famvir)	Headache, dizziness, nausea, diarrhea, fatigue	Probenecid
Valacyclovir (Valtrex)	Nausea, headache, diarrhea, dizziness	
Amantadine	Nausea, dizziness, light-headedness, insomnia	
Rimantadine (Flumadine)	Insomnia, dizziness, nervousness, nausea, vomiting	
Foscarnet (Foscavir)	Renal impairment, leukopenia, electrolyte disturbances, seizures, fever, anemia, headache, nausea, vomiting	Nephrotoxic drugs
Cidofovir (Vistide)	Renal impairment, neutropenia, ocular hypotony, headache, asthenia, alopecia, rash, GI distress, anemia, infection, fever	Nephrotoxic drugs
Oseltamivir (Tamiflu)	Nausea, vomiting, diarrhea, bronchitis, abdominal pain, dizziness	
Zanamivir (Relenza)	Nausea, diarrhea, nasal signs & symptoms, bronchitis	

CNS, central nervous system; GI, gastrointestinal; IV, intravenous.

Kevin G. Moder, MD

Rheumatoid Arthritis

Rheumatoid arthritis is a chronic systemic inflammatory disease characterized by joint destruction. It affects 0.03% to 1.5% of the population worldwide. Its incidence peaks between the ages of 35 and 45 years; however, the age-related prevalence continues to increase even after age 65. It occurs 3 times more frequently in women than men. The cause remains unknown. The presentation of an unknown antigen to genetically susceptible persons is believed to trigger rheumatoid arthritis.

There is an immunogenetic predisposition to the development of rheumatoid arthritis. Class II major histocompatibility complex molecules on the surface of antigen-presenting cells are responsible for initiating cellular immune responses and for stimulating the differentiation of B lymphocytes into plasma cells that produce antibody. Most white patients with rheumatoid arthritis have class II major histocompatibility complex type HLA-DR4 or HLA-DR1 or both. HLA-DR4 can be divided into five subtypes, two of which independently promote susceptibility to rheumatoid arthritis ("shared epitope"). The risk of rheumatoid arthritis is increased 3 to 5 times in white Americans with HLA-DR4. The concordance of rheumatoid factor–positive rheumatoid arthritis is increased 6 times among dizygotic twins. The risk of rheumatoid arthritis in a monozygotic twin is increased 30 times when a sibling has the disease.

- Rheumatoid arthritis affects 0.03%-1.5% of the population.
- Most white patients with rheumatoid arthritis have class II major histocompatibility complex type HLA-DR4 or HLA-DR1 or both.
- The concordance of rheumatoid factor–positive rheumatoid arthritis is increased 6 times among dizygotic twins.
- The risk of rheumatoid arthritis in a monozygotic twin is increased 30 times when a sibling has the disease.

Pathogenesis of Rheumatoid Arthritis

The immune reaction begins in the synovial lining of the joint. The earliest pathologic changes in the disease are microvascular injury that increases vascular permeability and the accumulation of inflammatory cells (CD4+ lymphocytes, polymorphonuclear leukocytes, and plasma cells) in the perivascular space. Pro-inflammatory cytokines are released. Mediators of inflammation promote synovial angiogenesis and synovial cell proliferation, the accumulation of neutrophils in synovial fluid, and the maturation of B cells into plasma cells. Plasma cells in the joint locally synthesize rheumatoid factor and other antibodies that promote inflammation. Immune complexes activate the complement system, releasing chemotactic factors and promoting vascular permeability and opsonization. Phagocytosis releases lysosomal enzymes and fosters the digestion of collagen, cartilage matrix, and elastic tissues. The release of oxygen-free radicals injures cells. Damaged cell membranes set free phospholipids that fuel the arachidonic acid cascade.

The local inflammatory response becomes self-perpetuating. Cytokines continue to play an important role, including tumor necrosis factor-α, interleukin-1, and interleukin-6. Proliferating synovium of activated macrophages and fibroblasts polarizes into a centripetally invasive pannus, destroying the weakened cartilage and subchondral bone. Chondrocytes, stimulated in the inflammatory milieu, release their own proteases and collagenases.

Patients have swelling, pain, and joint stiffness with the onset of vascular injury of the synovial lining, angiogenesis, and cellular proliferation. Joint warmth, swelling, pain, and limitation of motion worsen as the synovial membrane proliferates and the inflammatory

reaction builds. Histologic and radiographic evidence of rheumatoid synovitis is found in clinically unaffected joints, suggesting that the disease may be present for a period of time before clinical manifestations appear.

Rheumatoid factor is an immunoglobulin not specific for rheumatoid arthritis. Rheumatoid factor may be detected in other inflammatory diseases such as primary Sjögren syndrome, systemic lupus erythematosus, hepatitis C, and systemic vasculitis. It also occurs with aging.

Anti-citrullinated protein antibodies (anti-CCP) are detected in the majority of patients with rheumatoid arthritis. These target antigens are found in peptides containing citrulline, an amino acid resulting from posttranslational enzyme modification of arginine. Unlike rheumatoid factor, these antibodies seem to be highly specific for rheumatoid arthritis. They are present at the onset of disease, and in high titer they are associated with progressive erosive disease.

- Swelling, pain, and joint stiffness occur with the onset of immune-mediated vascular injury of the synovial lining, angiogenesis, and cellular proliferation.
- Anti-CCP antibodies are equally sensitive and more specific than rheumatoid factor for the diagnosis of early, erosive rheumatoid arthritis.
- Cytokines, in particular tumor necrosis factor-α, and immune complexes, including rheumatoid factor, are important components of the joint inflammatory reaction.

Clinical Features of Rheumatoid Arthritis

The joints most commonly involved (more than 85% of patients) in rheumatoid arthritis are the metacarpophalangeal, proximal interphalangeal, wrist, and metatarsophalangeal joints (Fig. 23-1). The distal interphalangeal joints are typically spared. The distribution of involvement is symmetric and polyarticular (five or more joints); predominantly, small joints are involved. Ultimately, the knees (80% of patients), ankles (80%), shoulders (60%), elbows (50%), hips (50%), acromioclavicular joints (50%), atlantoaxial joint (50%), and temporomandibular joints (30%) can be involved. The sternoclavicular joints, cricoarytenoid joints, and the ear ossicles are affected infrequently. Joints affected with rheumatoid arthritis are warm and swollen. The joint enlargement feels spongy and occurs with the thickening of the synovium. An associated joint effusion may make the joint feel fluctuant. Patients describe deep aching and soreness in the involved joints, which are aggravated by use and can be present at rest. Prolonged morning joint stiffness and "gelling" throughout the body and recurrence of this stiffness after resting are some of the many constitutional features that complicate rheumatoid arthritis.

Fig. 23-1. Moderately active seropositive rheumatoid arthritis. The patient has soft tissue swelling across the entire row of metatarsophalangeal joints and proximal interphalangeal joints bilaterally and soft tissue swelling mounding up over the wrists. Note the nearly complete lack of change at the distal interphalangeal joints.

- The joints most commonly involved in rheumatoid arthritis are the metacarpophalangeal, proximal interphalangeal, wrist, and metatarsophalangeal joints.
- The distribution of involvement is symmetric and polyarticular; predominantly, small joints are involved.
- Hallmarks of joint inflammation: stiffness, heat, redness, soft tissue swelling, pain, and dysfunction.

Constitutional Features of Rheumatoid Arthritis

Fatigue, weight loss, muscle pain, excessive sweating, or low-grade fever may be reported by patients presenting with rheumatoid arthritis. Adult seropositive rheumatoid arthritis is not a cause of fever of unknown origin because temperatures greater than 38.3°C cannot be attributed to the disease. A high temperature should raise concern about another problem, such as infection or malignancy. Most patients with *active* arthritis have more than 1 hour of morning stiffness. The musculoskeletal complications of rheumatoid arthritis are listed in Table 23-1.

Musculoskeletal Complications of Rheumatoid Arthritis

Cervical Spine

Half of all patients with chronic rheumatoid arthritis have radiographic involvement of the atlantoaxial joint. It is diagnosed with cervical flexion and extension radiographs showing subluxation. Alternatively, some patients have subaxial subluxations, typically at two or more levels. The cervical instability is usually asymptomatic; however, patients may have pain and stiffness in the neck and occipital region. Patients may present dramatically with drop attacks or tetraplegia, but more commonly progression can be slow and subtle with symptoms of hand weakness or paresthesias or signs of cervical myelopathy. Interference with blood flow by ischemic compression of the anterior spinal artery or vertebral arteries (vertebrobasilar insufficiency) causes the neurologic symptoms. All patients with destructive rheumatoid arthritis should be managed with intubation precautions and the assumption that cervical instability is present. New neurologic symptoms mandate urgent neurologic evaluation, including magnetic resonance imaging of the cervical spine and consideration of surgical intervention. Indications for surgical treatment include neurologic or vascular compromise and intractable

Table 23-1 Musculoskeletal Complications of Rheumatoid Arthritis

Characteristic deformities include
Boutonnière deformity of the finger, with hyperextension of the distal interphalangeal joint and flexion of the proximal interphalangeal joint
Swan-neck deformity of the finger, with hyperextension at the proximal interphalangeal joint and flexion of the distal interphalangeal joint
Ulnar deviation of the metacarpophalangeal joints; it can progress to complete volar subluxation of the proximal phalanx from the metacarpophalangeal head
Compression of the carpal bones and radial deviation at the carpus
Subluxation at the wrist
Valgus of the ankle and hindfoot
Pes planus
Forefoot varus and hallux valgus
Cock-up toes from subluxation at the metatarsophalangeal joints

pain. In active patients, prophylactic cervical spine stabilization is recommended when there is evidence of extreme (>8 mm) subluxation of C1 over C2. The probability of cervical involvement is predicted by the severity of peripheral arthritis.

- Half of all patients with chronic rheumatoid arthritis have radiographic involvement of the atlantoaxial joint.
- Patients with cervical spine involvement may present with occipital pain, signs of myelopathy, weakness and paresthesias of the hands, or drop attacks.
- Indications for surgical treatment: neurologic or vascular compromise or intractable pain.
- The probability of cervical involvement is predicted by the severity of peripheral arthritis.

Popliteal Cyst

Flexion of the knee markedly increases the intra-articular pressure of a swollen joint. This pressure produces an out-pouching of the posterior components of the joint space, termed a *popliteal* or a *Baker* cyst. Ultrasonographic examination of the popliteal space can be diagnostic. A popliteal cyst should be distinguished from a popliteal artery aneurysm, lymphadenopathy, phlebitis, and (more rarely) a benign or malignant tumor. The cyst can rupture down into the calf or, rarely, superiorly into the posterior thigh. Rupture of the popliteal cyst with dissection into the calf may resemble acute thrombophlebitis and is called *pseudophlebitis*. Fever, leukocytosis, and ecchymosis around the ankle (crescent sign) can occur with the rupture. Treatment of an acute cyst rupture includes bed rest, elevation of the leg, ice massage or cryocompression, and an intra-articular injection of corticosteroid. Treatment of the popliteal cyst requires improvement in the knee arthritis.

- Popliteal cyst is also called Baker cyst.
- Rupture of a popliteal cyst may resemble acute thrombophlebitis (pseudophlebitis).
- Ultrasonography can distinguish a cyst from a popliteal artery aneurysm, lymphadenopathy, phlebitis, and tumor.

Tenosynovitis

Tenosynovitis of the finger flexor and extensor tendon sheaths is common. It presents with diffuse swelling between the joints and a palpable grating within the flexor tendon sheaths in the palm with passive movement of the digit. Other tenosynovial syndromes in rheumatoid arthritis include de Quervain and wrist tenosynovitis. Persistent inflammation can produce stenosing tenosynovitis, loss of function, and, ultimately, rupture of tendons. Treatment of acute tenosynovitis includes immobilization, warm soaks, nonsteroidal anti-inflammatory drugs, and local injections of corticosteroid in the tendon sheath.

- Tenosynovitis of the finger flexor and extensor tendon sheaths is common and can lead to tendon rupture.

Carpal Tunnel Syndrome

Rheumatoid arthritis is a common cause of carpal tunnel syndrome (pregnancy is the commonest cause). The sudden appearance of bilateral carpal tunnel syndrome should raise the question of an early inflammatory arthritis. This syndrome is associated with paresthesias of the hand in a typical median nerve distribution. Discomfort may radiate up the forearm or into the upper arm. The symptoms worsen with prolonged flexion of the wrist and at night. Late complications include thenar muscle weakness and atrophy and permanent sensory loss. Treatment includes resting splints, control of inflammation, and local injection of glucocorticosteroid. Surgical release is recommended for persistent symptoms.

- Rheumatoid arthritis is a common cause of carpal tunnel syndrome.
- Carpal tunnel syndrome: paresthesias of the hand in a typical median nerve distribution.

Extra-articular Complications of Rheumatoid Arthritis

Extra-articular complications of rheumatoid arthritis occur almost exclusively in patients who have high titers of rheumatoid factor. In general, the number and severity of the extra-articular features vary with the duration and severity of disease.

Rheumatoid Nodules

Rheumatoid nodules are the most common extra-articular manifestation of seropositive rheumatoid arthritis. More than 20% of patients have rheumatoid nodules, which occur over extensor surfaces and at pressure points. They are rare in the lungs, heart, sclera, and dura mater. The nodules have characteristic histopathologic features. A collagenous capsule and a perivascular collection of chronic inflammatory cells surround a central area of necrosis encircled by palisading fibroblasts. Breakdown of the skin over rheumatoid nodules, with ulcers and infection, can be a major source of morbidity. The

infection can spread to local bursae, infect bone, or spread hematogenously to joints.

- Extra-articular complications in rheumatoid arthritis occur almost exclusively in seropositive rheumatoid arthritis.
- Rheumatoid nodules are the most common extra-articular complication.
- Rheumatoid nodules occur over extensor surfaces and at pressure points and are prone to ulceration and infection.

Rheumatoid Vasculitis

Rheumatoid vasculitis usually occurs in persons with severe, deforming arthritis and a high titer of rheumatoid factor. The vasculitis is mediated by the deposition of circulating immune complexes on the blood vessel wall. At its most benign, it occurs as rheumatoid nodules, with small infarcts over the nodules and at the cuticles. Proliferation of the vascular intima and media causes this obliterative endarteropathy, which has little associated inflammation. It is best managed by controlling the underlying arthritis. Leukocytoclastic or small vessel vasculitis produces palpable purpura or cutaneous ulceration, particularly over the malleoli of the lower extremities. This vasculitis can cause pyoderma gangrenosum or peripheral sensory neuropathy. Secondary polyarteritis, which is clinically and histopathologically identical to polyarteritis nodosa, results in mononeuritis multiplex. Occasionally, the vasculitis occurs after the joint disease appears "burned out."

- Rheumatoid vasculitis usually occurs in the setting of severe, deforming arthritis and a high titer of rheumatoid factor.
- Rheumatoid vasculitis is mediated by the deposition of circulating immune complexes on the blood vessel wall.
- Rheumatoid vasculitis comprises a spectrum of vascular disease, including rheumatoid nodules and obliterative endarteropathy, leukocytoclastic or small vessel vasculitis, and secondary polyarteritis (systemic necrotizing vasculitis).

Neurologic Manifestations

Neurologic manifestations of rheumatoid arthritis include mild peripheral sensory neuropathy. Painful sensory-motor neuropathy (mononeuropathy) suggests vasculitis or nerve entrapment (e.g., carpal tunnel syndrome). Cervical vertebral subluxation can cause myelopathy. Erosive changes may promote basilar invagination of the odontoid process of C2 into the underside of the brain, causing spinal cord compression and death.

Pulmonary Manifestations

Pleural disease has been noted in more than 40% of autopsies in cases of rheumatoid arthritis, but clinically significant pleural disease is less frequent. Characteristically, rheumatoid pleural effusions are asymptomatic until they become large enough to interfere mechanically with respiration. The pleural fluid is an exudate with a concentration of glucose that is low (10-50 mg/dL) because of impaired transport of glucose into the pleural space. Pulmonary nodules appear singly or in clusters. Single nodules have the appearance of a coin lesion. Nodules typically are pleural-based and may cavitate and create a bronchopleural fistula. Pneumoconiosis complicating rheumatoid lung disease, or Caplan syndrome, results in a violent fibroblastic reaction and large nodules.

Acute interstitial pneumonitis is a rare complication that may begin as alveolitis and progress to respiratory insufficiency and death. Interstitial fibrosis is a chronic, slowly progressive process. It has physical findings of diffuse dry crackles on lung auscultation and a reticular nodular radiographic pattern affecting both lung fields, initially in the lung bases. A decrease in the diffusing capacity for carbon dioxide and a restrictive pattern are characteristic pulmonary function test findings. Interstitial disease is highly associated with smoking. Bronchiolitis obliterans with or without organizing pneumonia may occur with rheumatoid arthritis or its treatment. It produces an obstructive picture on pulmonary function testing and typically responds to corticosteroid treatment. High-resolution computed tomography is useful for distinguishing these different interstitial rheumatoid lung syndromes and predicting treatment response. Methotrexate treatment causes a hypersensitivity lung reaction in 1% to 3% of patients. It can present insidiously with a dry cough or with life-threatening pneumonitis.

- Rheumatoid pleural disease is common but asymptomatic until pleural effusions interfere with respiration.
- The exudative pleural fluid is remarkable for low levels of glucose.
- High-resolution computed tomography helps to distinguish among rheumatoid-associated interstitial lung diseases, including interstitial pneumonitis, interstitial fibrosis, and bronchiolitis obliterans with or without organizing pneumonia.
- Methotrexate hypersensitivity pneumonitis may be a life-threatening complication of therapy.

Cardiac Complications

Pericarditis has been noted in 50% of autopsies in cases of rheumatoid arthritis. However, patients rarely present with acute pericardial symptoms or cardiac tamponade. Recurrent effusive pericarditis without symptoms may evolve to chronic constrictive pericarditis. Signs of unexplained edema or ascites may be the presenting manifestations. Untreated constrictive pericarditis has a very high1-year mortality of 70%. It will not respond to medical therapies. Surgical pericardiectomy is necessary.

- Patients rarely present with acute pericardial symptoms despite frequent serous pericarditis.
- Rheumatoid pericardial disease frequently presents with edema or ascites due to occult constrictive disease.
- Chronic constrictive pericarditis necessitates surgical treatment.

Liver Abnormalities

Patients with rheumatoid arthritis can have increased levels of liver enzymes, particularly alkaline phosphatase. Increased levels of aspartate aminotransferase, γ-glutamyltransferase, and acute-phase proteins and hypoalbuminemia also occur in active rheumatoid arthritis. Liver biopsy shows nonspecific changes of inflammation. Nodular regenerative hyperplasia is rare and causes portal hypertension and

hypersplenism. Many medications used to treat rheumatoid arthritis may cause increased levels of the transaminases.

- Increased levels of liver enzymes, particularly alkaline phosphatase, may occur in rheumatoid arthritis.
- Nodular hyperplasia of the liver can complicate rheumatoid arthritis and lead to portal hypertension and hypersplenism.
- Many medications used to treat rheumatoid arthritis increase the levels of transaminases.

Ophthalmic Abnormalities

Keratoconjunctivitis sicca, or secondary Sjögren syndrome, is the most common ophthalmic complication in rheumatoid arthritis. Episcleritis and scleritis also occur independently of the joint inflammation and are usually treated topically. Severe scleritis progressing to scleromalacia perforans causes blindness. Infrequent ocular complications of rheumatoid arthritis include episcleral nodules, palsy of the superior oblique muscle caused by tenosynovitis of its tendon sheath (Brown syndrome), and uveitis. Retinopathy is an infrequent complication of antimalarial drug treatment.

- Keratoconjunctivitis sicca, or secondary Sjögren syndrome, is the most common ophthalmic complication in rheumatoid arthritis.
- Severe scleritis progressing to scleromalacia perforans causes blindness.

Laboratory Findings of Rheumatoid Arthritis

Nonspecific alterations in many laboratory values are common. In very active disease, normocytic anemia (hemoglobin value about 10 g/dL), leukocytosis, thrombocytosis, hypoalbuminemia, and hypergammaglobulinemia are common. Rheumatoid factor (IgM) occurs in 90% of patients, but its presence may not be detected for months after the initial joint symptoms occur. A positive rheumatoid factor is not specific for rheumatoid arthritis. Diseases in boldface type in Table 23-2 are most likely to have high titers of rheumatoid factor. Five percent of the general population has a low titer of rheumatoid factor. Anti-CCP antibodies are more specific for rheumatoid arthritis and may be present when rheumatoid factor is absent. Antinuclear antibodies are common in seropositive rheumatoid disease. C-reactive protein correlates with disease activity, but it is not more helpful than the erythrocyte sedimentation rate. Active rheumatoid arthritis is associated with low iron-binding capacity, low plasma levels of iron, and an increased ferritin value, unless they are iron-deficient.

- Normocytic anemia, leukocytosis, thrombocytosis, and hypoalbuminemia are common in active rheumatoid arthritis.
- Rheumatoid factor is not specific for the diagnosis of rheumatoid arthritis.
- Anti-CCP antibodies may be present when rheumatoid factor is absent. They are not present in the other diseases associated with a factor.

Synovial fluid is cloudy and light yellow, has poor viscosity, and typically contains 10,000 to 75,000 leukocytes/μL, predominantly neutrophils.

Radiographic Findings of Rheumatoid Arthritis

The radiographic findings in early rheumatoid arthritis are normal or show soft tissue swelling and periarticular osteopenia. Later, the characteristic changes of periarticular osteoporosis, symmetric narrowing of the joint space, and marginal bony erosions become obvious. These signs are most common in radiographs of the hands and forefeet. Radiographic changes at end-stage rheumatoid arthritis include subluxation and other deformities, joint destruction, fibrous ankylosis, and, rarely, bony ankylosis.

- The characteristic radiologic changes in rheumatoid arthritis include periarticular osteoporosis, symmetric narrowing of the joint space, and bony erosions of the joint margin. These occur earliest in the hands and metatarsal phalangeal joints.

Diagnosis of Rheumatoid Arthritis

Adult rheumatoid arthritis should be considered in a person older than 16 years with inflammatory joint symptoms lasting for more than 6 weeks. The time criterion is important because there are viral arthropathies, such as parvovirus B19 infection, that mimic acute rheumatoid arthritis. Morning stiffness lasting for more than 30 minutes, small joint involvement in the metatarsophalangeal joints (morning metatarsalgia), metacarpophalangeal joints with tenderness

Table 23-2 Diseases That May Have Positive Rheumatoid Factor*

Rheumatoid arthritis
Sjögren syndrome
Systemic lupus erythematosus
Scleroderma
Sarcoidosis
Idiopathic pulmonary fibrosis
Mixed cryoglobulinemia
Hypergammaglobulinemic purpura
Asbestosis
Malignancies
Infectious mononucleosis
Influenza
Chronic active hepatitis
Vaccinations
Tuberculosis
Syphilis
Subacute bacterial endocarditis
Brucellosis
Leprosy
Salmonellosis
Malaria
Kala-azar
Schistosomiasis
Filariasis
Trypanosomiasis

*Diseases in boldface type are the most likely to have high-titer rheumatoid factor.

and swelling, and more than three joints affected are clues to an early rheumatoid arthritis presentation. Four of the seven criteria of the American Rheumatism Association, listed in Table 23-3, are used to classify cases as definite rheumatoid arthritis for research studies, but the vast majority of patients with rheumatoid arthritis do not meet these criteria at early presentation.

Natural History of Rheumatoid Arthritis

The majority of patients have insidious onset of the joint disease, occurring over weeks to months. However, in a third of patients, the onset is rapid, occurring in days or weeks. Early in the course of the disease, most patients have oligoarthritis. Their disease becomes polyarticular with time. From 10% to 20% of patients have relentlessly progressive arthritis, and 70% to 90% have persistent, chronic, progressive arthritis. The course may be slow, fluctuating, or rapid, but the end point is the same: disabling, destructive arthritis. Seventy percent of patients experience polycyclic disease, with repeated flares interrupted by partial or complete remissions. Spontaneous remissions in the polycyclic or progressive group almost never occur after 2 years of disease. Patients who experience a persisting polyarthritis with increased acute-phase reactants and a positive rheumatoid factor or anti-CCP antibody are at high risk for early erosive disease within 1 to 2 years of symptom onset and early disability. The relationship between disease duration and inability to work is nearly linear. After 15 years of rheumatoid arthritis, 15% of patients are completely disabled. Life expectancy in seropositive rheumatoid arthritis is shortened, but it may be improving with more aggressive early intervention in the illness. Age, disease severity, comorbid cardiovascular disease, and functional status predict mortality. Educational level and socioeconomic factors also influence mortality.

- In a third of patients, the onset of rheumatoid arthritis is rapid (days or weeks).
- Among patients with rheumatoid arthritis, 70%-90% have persistent, chronic, progressive arthritis.
- The relationship between disease duration and inability to work is nearly linear.

Treatment of Rheumatoid Arthritis

The management of patients with rheumatoid arthritis requires making the correct diagnosis, determining the functional status of the patient, and selecting the goals of management with the patient. Goals of management include relieving inflammation and pain and maintaining function.

The principles emphasized by physical medicine include bed rest or rest periods, improving nonrestorative sleep, and joint protection (including modification of activities of daily life, range-of-motion exercises, orthotics, and splints, if they help the pain). Exercise should begin with range of motion and stretching to overcome contracture. Strengthening and conditioning exercises should be prescribed carefully, depending on the activity of the patient's disease.

Initial treatment includes but is not limited to a nonsteroidal anti-inflammatory drug given at anti-inflammatory doses. If the response is inadequate after 3 or 4 weeks, a trial of a second, chemically unrelated nonsteroidal anti-inflammatory drug is used. Low-dose prednisone (≤7.5 mg daily) may be necessary to reduce symptoms while disease-modifying therapies are initiated. Intra-articular corticosteroids are effective for symptomatic joints not responding to oral anti-inflammatory drugs. A disease-modifying agent of rheumatic disease (DMARD) is also known as a second-line agent, slow-acting antirheumatic drug, or remittive agent. The goal of DMARD therapy is to slow disease progression (erosive damage) and maintain joint function. A goal of disease remission will be possible as new therapies are introduced. Disease-modifying agents include the following:

- Methotrexate
- Hydroxychloroquine
- Sulfasalazine
- Minocycline
- Leflunomide
- Cyclosporine
- Azathioprine
- Anticytokine therapies, including anti-tumor necrosis factor and interleukin-1 inhibitors

DMARD therapy should be started early, once rheumatoid arthritis is diagnosed. The choice of first DMARD is empiric, but usually consists of methotrexate, sulfasalazine, hydroxychloroquine, or minocycline. Uninterrupted treatment with a disease-modifying agent for 3 to 6 months is usually necessary to assess its effect. Traditionally, DMARDs have been used sequentially, although recent studies have shown an enhanced benefit with combination DMARD treatments that include methotrexate. A second disease-modifying drug is substituted or added to the first one when a therapeutic or toxic roadblock is reached. Evidence supporting the pivotal pro-inflammatory role of tumor necrosis factor-α in rheumatoid arthritis has been exploited clinically with the development of several effective tumor necrosis factor-α antagonists. These generally are reserved for patients not responding to trials of more traditional and less expensive DMARDs.

Table 23-3 American Rheumatism Association Criteria for the Diagnosis of Rheumatoid Arthritis*

One or more hours of morning stiffness in and around the joints
Arthritis of three or more joint areas involved simultaneously
Arthritis of at least one area in the wrist, metacarpophalangeal or proximal interphalangeal joints
Symmetrical arthritis involving the same joint areas on both sides of the body
Rheumatoid nodules
Serum rheumatoid factor
Radiographic changes typical of rheumatoid arthritis, including periarticular osteoporosis, joint-space narrowing, and marginal erosions

*1987 revision.

- Goals of management include relieving inflammation and pain and maintaining function.
- A disease-modifying regimen is started when rheumatoid arthritis is diagnosed.
- Low-dose prednisone may be necessary to preserve function during initiation of DMARD therapy.
- With disease-modifying agents, uninterrupted treatment for 3 to 6 months is needed to assess efficacy. Combination DMARD therapy has become more common.

Surgery in the Treatment of Rheumatoid Arthritis

An orthopedic surgical procedure for resistant rheumatoid arthritis remains the most important therapeutic option for preserving or enhancing function. Synovectomy of the wrist and nearby tendon sheaths is beneficial when medication alone fails to control the synovitis. The operation preserves joint function and prevents the lysis of extensor tendons that can result in a loss of function. Synovectomy of the knee, either open or through an arthroscope, can delay the progression of rheumatoid arthritis from 6 months to 3 years. Removal of nodules and treatment for local nerve entrapment syndromes are also important surgical treatments for rheumatoid arthritis. Arthroplasty is reserved for patients in whom medical management has failed and in whom intractable pain or compromise in function developed because of a destroyed joint. Arthroplasty, arthrodesis (wrist), and synovectomy are important components of well-balanced rheumatology treatment programs. Total joint arthroplasty has a slightly poorer long-term outcome in rheumatoid arthritis than in osteoarthritis. Nevertheless, joint replacement has had a major impact on reducing patient disability.

- Orthopedic surgery is the most important advance in the treatment of medically resistant rheumatoid arthritis.
- Total joint arthroplasty has a slightly poorer long-term outcome in rheumatoid arthritis than in osteoarthritis.
- Typical clinical scenarios:
  Rheumatoid arthritis—A patient presents with bilateral inflammation of metacarpophalangeal and proximal interphalangeal joints and considerable morning stiffness. The joint involvement is symmetric. Laboratory tests are positive for rheumatoid factor.
  Baker cyst—A patient with a known history of rheumatoid arthritis who is receiving therapy presents with acute pain and swelling in the posterior aspect of the right knee. Mild fever and leukocytosis are present.

Conditions Related to Rheumatoid Arthritis

Seronegative Rheumatoid Arthritis

Rheumatoid factor-negative (seronegative) rheumatoid arthritis is not associated with extra-articular manifestations. However, the arthritis usually is destructive, deforming, and otherwise indistinguishable from seropositive rheumatoid arthritis.

- Seronegative rheumatoid arthritis is not associated with extra-articular manifestations.

Seronegative Rheumatoid Arthritis of the Elderly

A subgroup of patients older than 60 years with seronegative rheumatoid arthritis may have milder arthritis. In this subgroup, polyarticular inflammation suddenly develops and is controlled best with low doses of prednisone. The presence of anti-CCP antibodies may help to distinguish this condition from polymyalgia rheumatica. Minimal destructive changes and deformity occur. Some elderly patients with seronegative arthritis (men in their 70s) present with acute polyarthritis and pitting edema of the hands and feet, so-called RS3PE (remitting symmetric seronegative synovitis with pitting edema). They have a prompt and gratifying response to low doses of prednisone.

- Typical clinical scenario: In a patient older than 60 years, rheumatoid factor-negative polyarticular arthritis suddenly develops. It is best controlled initially with low doses of prednisone.

Adult-Onset Still Disease

Systemic *juvenile* rheumatoid arthritis is known as Still disease. It has quotidian (fever spike with return to normal all in 1 day) high-spiking fevers, arthralgia, arthritis, seronegativity (negative rheumatoid factor and antinuclear antibody), leukocytosis, macular evanescent rash, serositis, lymphadenopathy, splenomegaly, and hepatomegaly. Fever, rash, and arthritis are the classic triad of Still disease.

Adult-onset Still disease has a slight female predominance. Its onset commonly occurs between ages 16 and 35 years. Temperature more than 39°C occurs in a quotidian or double quotidian pattern in 96% of patients. The rash has a typical appearance: a macular salmon-colored eruption on the trunk and extremities. The transient rash is usually noticed at the time of increased temperature. Arthritis occurs in 95% of these patients, and in about a third the joint disease is progressive and destructive. Adult-onset Still disease has a predilection for the wrists, shoulders, hips, and knees. Sixty percent of patients complain of sore throat, which can confuse the diagnosis with rheumatic fever; however, the course is much more prolonged than that of acute rheumatic fever. Weight loss is common. Lymphadenopathy occurs in two-thirds of patients and hepatosplenomegaly in about half. Pleurisy, pneumonitis, and abdominal pain occur in less than a third of patients. The serum ferritin level is markedly increased.

Treatment of adult-onset Still disease includes high doses of aspirin or indomethacin. Corticosteroids may be needed to control the systemic symptoms. Half of patients require methotrexate to control the systemic and articular features.

- Typical clinical scenario: A patient presents with the classic triad of fever, rash, and arthritis.
- Rheumatoid factor and antinuclear antibodies are absent in Still disease.
- There is a predilection for the wrists, shoulders, hips, and knees.
- Sore throat occurs in 60% of patients.

Felty Syndrome

Felty syndrome has the classic triad of rheumatoid arthritis, leukopenia, and splenomegaly. (Classic Felty syndrome usually occurs after

12 years or more of rheumatoid arthritis.) It occurs in less than 1% of patients with seropositive rheumatoid arthritis. Splenomegaly either may not be clinically apparent or may manifest only after the arthritis and leukopenia have been present for some time. Other features of Felty syndrome are listed in Table 23-4. Patients with this syndrome frequently have bacterial infections, particularly of the skin and lungs. Infection related to the cytopenia is the major cause of mortality. High titers of rheumatoid factor are the rule, and a positive antinuclear antibody occurs in two-thirds of patients. Hypocomplementemia often occurs with active vasculitis. Patients often die of sepsis despite vigorous antibacterial treatment. Treatment can include corticosteroids, methotrexate, granulocyte colony-stimulating factor, and splenectomy.

- Felty syndrome occurs in <1% of patients with seropositive rheumatoid arthritis.
- Felty syndrome has the classic triad of rheumatoid arthritis, leukopenia, and splenomegaly.
- High titers of rheumatoid factor are the rule.
- Patients with Felty syndrome frequently die of infection.

Sjögren Syndrome

Sjögren syndrome has a triad of clinical features: keratoconjunctivitis sicca (with or without lacrimal gland enlargement), xerostomia (with or without salivary gland enlargement), and connective tissue disease (usually rheumatoid arthritis). Histologically, CD4 lymphocytic infiltration and destruction of lacrimal salivary glands characterize it. Clinically, it manifests with dry eyes and dry mouth. Primary Sjögren syndrome is diagnosed predominantly in middle-aged women. Additional features of primary Sjögren syndrome are listed in Table 23-5. Most patients have a polyclonal hypergammaglobulinemia. Autoantibodies typically are present, including rheumatoid factor, antinuclear antibodies, and antibodies to extractable nuclear antigens (SS-A and SS-B).

Patients can present with primary Sjögren syndrome without any additional connective tissue disease. The primary syndrome typically has episodic and nondeforming arthritis. More commonly, rheumatoid arthritis, systemic lupus erythematosus, scleroderma, polyarteritis nodosa, or polymyositis accompanies Sjögren syndrome. There is no perfect definition for Sjögren syndrome, and no test is completely diagnostic. Simple dry eyes of the elderly, benign sicca syndrome, is distinguished from Sjögren syndrome by the absence of SSA antibodies. Patients with Sjögren syndrome, but not the seronegative sicca syndrome, have an increased risk for development of non-Hodgkin lymphoma.

Treatment of primary Sjögren syndrome is mainly symptomatic. Pilocarpine, 5 mg orally 4 times daily, improves salivary and lacrimal gland function in the majority of the patients. Side effects, including flushing and sweating, limit its usefulness. In addition to hydration, systemic therapy is indicated if there is evidence of systemic inflammation. A Sjögren-like syndrome has been described in patients with human immunodeficiency virus (HIV) infection.

- Typical clinical scenario: A patient presents with dry eyes, dry mouth, and a connective tissue disorder (usually rheumatoid arthritis).
- Sjögren syndrome can exist by itself or with another formal connective tissue disease such as rheumatoid arthritis, systemic lupus erythematosus, scleroderma, or myositis.
- Treatment focuses on control of inflammation and symptoms of dryness.
- A Sjögren-like syndrome has been described in patients with HIV infection.

Osteoarthritis

Osteoarthritis is the failure of articular cartilage and subsequent degenerative changes in subchondral bone, bony joint margins,

synovium, and para-articular fibrous and muscular structures. Osteoarthritis is the most common rheumatic disease; 80% of patients have some limitation of their activities, and 25% are unable to perform major activities of daily living. More than 10% of the population older than 60 years has osteoarthritis. Annually, symptomatic hip or knee osteoarthritis develops in half a million new patients.

- Osteoarthritis is the most common rheumatic disease.
- More than 10% of the population older than 60 years has osteoarthritis.

Pathogenesis of Osteoarthritis

Two principal changes associated with osteoarthritis are the progressive focal degeneration of articular cartilage and the formation of new bone in the floor of the cartilage lesion at the joint margins (osteophytes). Not all the mechanisms causing osteoarthritis have been identified. Current theories include 1) mechanical process: cartilage injury, particularly after impact loading, and 2) biochemical process: failure of cartilage repair processes to adequately compensate for injury. A combination of mechanical and biochemical processes likely contributes in most cases of osteoarthritis. It must be emphasized that osteoarthritis is not just the consequence of "wear and tear."

- Osteoarthritis: progressive focal degeneration of articular cartilage, with subsequent degeneration of surrounding soft tissues and proliferation (osteophytosis) of bone.
- Osteoarthritis is not the consequence of normal use ("wear and tear").

Clinical Features of Osteoarthritis

The pain of an osteoarthritic joint is usually described as a deep ache. Subchondral bone edema may contribute to the pain. The pain occurs with use of the joint and is relieved with rest and cessation of weight bearing. As the disease progresses, the involved joint may be symptomatic with minimal activity or even at rest. The pain originates in the structures around the disintegrating cartilage (there are no nerves in cartilage). There may be stiffness in the joint with initial use, but this initial stiffness is not prolonged as it is in inflammatory arthritis, such as rheumatoid arthritis. Although the symptoms are related predominantly to mechanical failure and motion limits, joint debris and the associated repair process promote mild inflammation, accumulation of synovial fluid, and mild hypertrophy of the synovial membrane. Acute inflammation can transiently occur at Heberden nodes (distal interphalangeal joints with prominent osteophytes as a consequence of osteoarthritis) or at the knee with tearing of a degenerative meniscal cartilage.

- Osteoarthritic pain is usually described as a deep ache with joint use and is improved with rest.
- The stiffness with initial use of the joint is not prolonged in osteoarthritis as it is in inflammatory arthritis (rheumatoid arthritis).

Physical examination documents joint margin tenderness, fine crepitance, limits to motion, and enlargement of the joint. The enlargement is usually bony (proliferation of cartilage and bone to form osteophytes), but it can include effusions and mild synovial thickening. Deformity is a late consequence of the osteoarthritis and is associated with atrophy or derangement of the local soft tissues, ligaments, and muscles. Radiographic or physical examination evidence of the severity of osteoarthritis does not reliably predict a patient's symptoms.

Clinical Subsets of Osteoarthritis

Primary Osteoarthritis

Primary osteoarthritis is cartilage failure without a known cause that would predispose to osteoarthritis. It almost never affects the shoulders, elbows, ankles, metacarpophalangeal joints, or ulnar side of the wrist. It is divided into several clinical patterns, as described below.

Generalized osteoarthritis involves the distal interphalangeal joints, proximal interphalangeal joints, first carpometacarpal joints, hips, knees, and spine (Fig. 23-2). It occurs most frequently in middle-aged postmenopausal women.

Isolated nodal osteoarthritis is primary osteoarthritis that affects only the distal interphalangeal joints. It occurs predominantly in women and has a familial predisposition.

Isolated hip osteoarthritis is more common in men than in women. It has no clear association with obesity or activity.

Erosive osteoarthritis affects only the distal and proximal interphalangeal joints. Patients with erosive osteoarthritis have episodes of local inflammation. Mucous cyst formation at the distal interphalangeal joint is common. Painful flare-up of the disease recurs for years. Symptoms usually begin about the time of menopause. Bony erosions and collapse of the subchondral plate—features not usually seen in primary osteoarthritis—with osteophytes are markers of erosive osteoarthritis. Joint deformity can be severe. In many cases, bony

Fig. 23-2. Generalized osteoarthritis. Note prominent bony swelling at the proximal (Bouchard nodes) and distal (Heberden nodes) interphalangeal joints. The metacarpophalangeal joints are spared. Early hypertrophic changes are seen on profile at the first carpometacarpal joint, giving a slight squaring of the hand deformity, appreciated best on the left.

ankylosis develops. Ankylosis is usually associated with relief of pain. The synovium is intensely infiltrated with mononuclear cells. This condition may be confused with rheumatoid arthritis.

Diffuse idiopathic skeletal hyperostosis is a variant of primary osteoarthritis. It occurs chiefly in men older than 50 years. It is also known as Forestier disease. The diagnosis requires finding characteristic exuberant, flowing osteophytosis that connects four or more vertebrae with preservation of the disk space. Diffuse idiopathic skeletal hyperostosis must be distinguished from typical osteoarthritis of the spine with degenerative disk disease and from ankylosing spondylitis. Extraspinal sites of disease involvement include calcification of the pelvic ligaments, exuberant osteophytosis at the site of peripheral osteoarthritis, well-calcified bony spurs at the calcaneus, and heterotopic bone formation after total joint arthroplasty. Patients with diffuse idiopathic skeletal hyperostosis are often obese, and 60% have diabetes mellitus or glucose intolerance. Symptoms include mild back stiffness and, occasionally, back pain. Pathologically and radiologically, diffuse idiopathic skeletal hyperostosis is distinct from other forms of primary osteoarthritis.

- Primary osteoarthritis almost never affects the shoulders, elbows, ankles, metacarpophalangeal joints, or the ulnar side of the wrist.
- Generalized osteoarthritis involves the distal interphalangeal joints, proximal interphalangeal joints, first carpometacarpal joints, hips, knees, and spine.
- Isolated nodal osteoarthritis is primary osteoarthritis affecting only the distal interphalangeal joints.
- Isolated hip osteoarthritis is more common in men than in women.
- Erosive osteoarthritis affects only the distal and proximal interphalangeal joints.
- Diffuse idiopathic skeletal hyperostosis is a variant of primary osteoarthritis and should be distinguished from ankylosing spondylitis.

Secondary Osteoarthritis

Secondary osteoarthritis is cartilage failure caused by some known disorder, trauma, or abnormality. Any patient with an unusual distribution of osteoarthritis or widespread chondrocalcinosis should be considered to have secondary osteoarthritis. Secondary osteoarthritis frequently complicates trauma and the damage caused by inflammatory arthritis. Inherited disorders of connective tissue and several metabolic abnormalities, including ochronosis, hemochromatosis, Wilson disease, and acromegaly, are complicated by secondary osteoarthritis. Paget disease of bone, involving the femur or pelvis about the hip joint, can predispose to osteoarthritis.

- Osteoarthritis involving the shoulder, metacarpophalangeal joints, or isolated large joints or with chondrocalcinosis should prompt physicians to consider secondary causes of osteoarthritis.

Trauma or injury to a joint and supporting periarticular tissues predisposes persons to the most common type of secondary osteoarthritis. Stress from repeated impact loading could weaken subchondral bone. Internal joint derangement with ligamentous laxity or meniscal damage alters the normal mechanical alignment of the joint. Isolated large joint involvement is a clue to posttraumatic osteoarthritis. Chronic rotator cuff tear with subsequent loss of shoulder joint cartilage (cuff arthropathy) and knee osteoarthritis that develops years after meniscal cartilage damage are examples of secondary osteoarthritis.

Congenital malformations of joints, such as congenital hip dysplasia and epiphyseal dysplasia, lead to premature osteoarthritis. Other developmental abnormalities, including slipped capital femoral epiphysis and Legg-Calvé-Perthes disease (idiopathic avascular necrosis of the femoral head), may first present as premature osteoarthritis years after they occur. Inherited disorders of connective tissue frequently predispose the afflicted person to premature osteoarthritis. Table 23-6 describes several inherited disorders, including their gene defects and characteristics.

- Injury to a joint or supporting periarticular tissues can predispose to osteoarthritis.
- Posttraumatic osteoarthritis is the most common form of secondary osteoarthritis.
- Isolated large joint involvement is a clue to posttraumatic osteoarthritis.

Alkaptonuria/ochronosis is a rare autosomal recessive disorder of tyrosine metabolism. Deficiency of the enzyme homogentisic acid oxidase leads to excretion of large amounts of homogentisic acid in the urine. Black, oxidized, polymerized homogentisic acid pigment collects in connective tissues (ochronosis). The diagnosis may go unrecognized until middle life. The first manifestation can be secondary osteoarthritis. The patient's urine darkens when allowed to stand or with the addition of sodium hydroxide. Ochronotic arthritis affects the large joints (e.g., the hips, knees, and shoulders) and is associated with calcium pyrophosphate crystals in the synovial fluid. The radiographic finding of calcified intervertebral disks at multiple levels is characteristic of ochronosis. Other manifestations include grayish brown scleral pigment and generalized darkening of the ear pinnae.

- Alkaptonuria/ochronosis is a rare autosomal recessive disorder of tyrosine metabolism.
- Ochronosis: black, oxidized, polymerized homogentisic acid pigment collects in connective tissues.
- Ochronotic arthritis affects the large joints: the hips, knees, and shoulders.

Hemochromatosis was formerly considered an unusual autosomal recessive disorder of white males. It is now considered the commonest inherited disease. The full clinical spectrum of hemochromatosis includes hepatomegaly, bronze skin pigmentation, diabetes mellitus, the consequences of pituitary insufficiency, and degenerative arthritis. The arthropathy affects up to 50% of patients with hemochromatosis and generally resembles osteoarthritis; however, it involves the metacarpophalangeal joints and shoulders, joints not typically affected by generalized primary osteoarthritis. Attacks of acute pseudogout arthritis may occur in relation to deposition of calcium pyrophosphate dihydrate crystals. Chondrocalcinosis is commonly superimposed on chronic osteoarthritic change in

Table 23-6 Inherited Disorders of Connective Tissue

Condition	Gene defect	Characteristics
Marfan syndrome (autosomal dominant)	Fibrillin gene	Hypermobile joints: osteoarthritis, arachnodactyly, kyphoscoliosis Lax skin, striae, ectopic ocular lens Aortic root dilatation (aortic insufficiency), mitral valve prolapse, aneurysms, and aortic dissection
Ehlers-Danlos syndrome (10 subtypes)	Type I and type III collagen gene defects	Joint hypermobility, friable skin, osteoarthritis Type III collagen defects associated with vascular aneurysms
Osteogenesis imperfecta (autosomal dominant and recessive variations; the most common heritable disorder of connective tissue: 1:20,000; 4 subtypes)	Type I collagen gene defects	Brittle bones, blue sclerae, otosclerosis and deafness, joint hypermobility, and tooth malformation
Type II collagenopathies: Achondrogenesis type II Hypochondrogenesis Spondyloepiphyseal dysplasia Spondyloepimetaphyseal dysplasia Kniest dysplasia Stickler syndrome Familial precocious osteoarthropathy	Type II collagen gene defects	Spectrum from lethal (achondrogenesis) to premature osteoarthritis (Stickler syndrome)
Achondroplasia (autosomal dominant)	Fibroblast growth factor III receptor gene defect	Dwarfism, premature osteoarthritis
Pseudoachondroplasia	Cartilage oligomeric matrix protein (COMP) gene defect	Short stature, premature osteoarthritis
Multiple epiphyseal dysplasia (autosomal dominant)		

hemochromatosis. The pathogenesis of joint degeneration in hemochromatosis is not clear.

- Arthropathy affects up to 50% of patients with hemochromatosis.
- It involves the metacarpophalangeal joints and shoulders.

Wilson disease is a rare autosomal recessive disorder. Arthropathy occurs in 50% of adults with Wilson disease. This disease is suspected in anyone younger than 40 years with unexplained hepatitis, cirrhosis, or movement disorder. The diagnosis is suggested when the serum level of ceruloplasmin is less than 200 mg/L. Arthropathy is unusual in children with the disease. The radiologic appearance varies somewhat from that of primary osteoarthritis; there are more subchondral cysts, sclerosis, cortical irregularities, and radiodense lesions, which occur centrally and at the joint margins. Focal areas of bone fragmentation occur, but they are not related to neuropathy. Although chondrocalcinosis occurs, calcium pyrophosphate dihydrate crystals have not been observed in the synovial fluid.

- Arthropathy occurs in 50% of adults with Wilson disease.
- Arthropathy is unusual in children with Wilson disease.

Apatite microcrystals are associated with degenerative arthritis and are found in patients with hypothyroidism, hyperparathyroidism, and acromegaly. They occur without an associated endocrinopathy. The role of microcrystalline disease in the progression of osteoarthritis is unclear, especially in the absence of acute recurrent flares of pseudogout.

Neuroarthropathy (Charcot joint) commonly affects patients with diabetes mellitus. Men and women are equally affected. Patients with diabetic neuroarthropathy have had diabetes an average of 16 years. Frequently, the diabetes is poorly controlled. Diabetic peripheral neuropathy causes blunted pain perception and poor proprioception. Repeated microtrauma, overt trauma, small vessel occlusive disease (diabetes), and neuropathic dystrophic effects on bone contribute to neuroarthropathy.

Patients can present with an acute arthritic condition that includes swelling, erythema, and warmth. The foot, particularly the

tarsometatarsal joint, is involved most commonly in patients with diabetes. Patients usually describe milder pain than suggested by the clinical condition and radiographic appearances. They walk with an antalgic limp. Callus formation occurs over the weight-bearing site of bony damage, and the callus subsequently blisters and ulcerates. Infection can spread from skin ulcers to the bone. Osteomyelitis frequently complicates diabetic neuroarthropathy. Radiography shows disorganized normal joint architecture. Bone and cartilage fragments later coalesce to form characteristic sclerotic loose bodies. There is an attempt at reconstruction with new bone formation. This periosteal new bone is inhibited by small vessel ischemic change in some patients with diabetes. Diabetic osteopathy is a second form of neuroarthropathy. Osteopenia of para-articular areas, particularly the distal metacarpals and proximal phalanges, results in rapidly progressive osteolysis and juxta-articular cortical defects. This can be associated with osteomyelitis.

Initial treatment in patients with diabetes includes good local foot care, treatment of infection, and protected weight bearing. Involvement of the knee, lumbar spine, and upper extremity is uncommon. Classically, hip and spinal neuroarthropathy is caused by tertiary syphilis, and shoulder neuroarthropathy is associated with cervical syringomyelia.

- Neuroarthropathy (Charcot joint) most commonly affects the feet and ankles of patients with diabetes mellitus.
- Neuroarthropathy is a consequence of peripheral neuropathy and local injury.
- Osteomyelitis is caused by skin ulcers extending to the bone and should be suspected when an affected diabetic has sudden worsening of his or her glucose control.

Aseptic necrosis of the bone, also known as avascular necrosis of bone, may lead to collapse of the articular surface and subsequent osteoarthritis. It usually occurs in the hip after femoral neck fracture. Systemic corticosteroid therapy increases the risk of aseptic necrosis. Aseptic necrosis of the bone has other causes, including alcoholism, sickle cell disease, and systemic lupus erythematosus (Table 23-7). No underlying cause can be identified in 10% to 25% of patients.

Aseptic necrosis of bone usually affects the hips, shoulders, knees, or ankles. Treatment is conservative, including reduced weight bearing and analgesics. Some investigators have treated patients successfully with vascularized bone grafts in the bed of necrotic trabecular bone, although controlled studies are not available. Core decompression may help with pain but does not influence progression to gonarthritis. When there is evidence of cortical bone collapse, progression to advanced osteoarthritis is inevitable. The most sensitive test for aseptic necrosis is magnetic resonance imaging. Plain radiography is insensitive to early aseptic necrosis.

- Aseptic necrosis usually occurs in the hip after femoral neck fracture and may lead to osteoarthritis.
- Alcoholism and corticosteroid use are other common causes of avascular necrosis.

Hypertrophic osteoarthropathy is characterized by clubbing of the fingernails and painful distal long bone periostitis. The patient may have a noninflammatory arthritis at the ankles, knees, or wrists. This condition complicates primary and metastatic pulmonary malignancies, chronic pulmonary infections, cystic fibrosis, and hypoxic congenital heart disease. Treatment is usually symptomatic.

Hemophilic arthropathy, a type of progressive degenerative arthropathy, is more destructive than primary osteoarthritis. Patients with hemophilia and recurrent hemarthroses are at risk for hemophilic arthropathy. Widening of the intercondylar notch of the knees is an early radiographic feature suggesting the diagnosis of this condition.

Radiographic Features of Osteoarthritis

The radiographic features of osteoarthritis do not always predict the extent of symptoms. With aging, radiographic osteoarthritis is far more prevalent than the clinical illness. Common radiographic features include osteophyte formation, asymmetric joint-space narrowing, subchondral bony sclerosis, subchondral cysts, and buttressing of angle joints. Later bony changes include malalignment and deformity (Fig. 23-3). In the spine, the radiographic finding called spondylosis includes anterolateral spinous osteophytes, degenerative disk disease with disk-space narrowing, and facet sclerosis. A defect in the bony structure of the posterior neural arch produces spondylolysis. With bilateral spondylolysis, subluxation of one vertebra on another may occur, a condition called spondylolisthesis. The causes of spondylolisthesis are trauma, osteoarthritis, and congenital. No laboratory studies of blood are useful in the diagnosis of osteoarthritis.

- Common radiographic features of osteoarthritis include osteophyte formation, asymmetric joint-space narrowing, subchondral bony sclerosis, subchondral cysts, and buttressing of angle joints.
- No laboratory studies of blood are useful in the diagnosis of osteoarthritis.

Therapy for Osteoarthritis

Therapeutic goals include relieving pain, preserving joint motion and function, and preventing further injury and wear of cartilage. Weight loss (especially in knee osteoarthritis), use of canes or crutches, correction of postural abnormalities, and proper shoe support are helpful measures. Isometric or isotonic range-of-motion exercises

Table 23-7 Mnemonic Device for Causes of Aseptic Necrosis of Bone

A	Alcohol, atherosclerotic vascular disease
S	Steroids, sickle cell anemia, storage disease (Gaucher disease)
E	Emboli (fat, cholesterol)
P	Postradiation necrosis
T	Trauma
I	Idiopathic
C	Connective tissue disease (especially SLE), caisson disease

SLE, systemic lupus erythematosus.

Fig. 23-3. Severe osteoarthritis. Hypertrophic changes, asymmetric joint-space narrowing, and subchondral sclerosis are prominent at the interphalangeal joints and at the first carpometacarpal joint. Note that the metacarpophalangeal joints are completely spared, distinguishing this arthritis from rheumatoid arthritis. Also, there is joint-space narrowing and sclerosis at the base of the thumb at the first carpometacarpal joint and between the trapezium and the scaphoid. Osteoarthritis does not affect the entire wrist compartment equally. The involvement seen here is the most common. An additional interesting feature seen here is central erosions at the second and third proximal interphalangeal joints. This variant occasionally has been called erosive osteoarthritis.

and muscle strengthening provide para-articular structures with extra support and help reduce symptoms. Relief of muscle spasm with local application of heat or cold to decrease pain can help. Addressing the patient's ability to cope with the illness may be more helpful than medication therapy alone.

Initial drug therapy should be analgesics, such as acetaminophen (1 g 4 times daily as needed). Nonsteroidal anti-inflammatory drugs are beneficial for inflammatory flares of osteoarthritis and usually do not need to be taken in anti-inflammatory doses every day. Selective use of opioid analgesics can be considered for disabling pain, especially in persons who are not surgical candidates. Intra-articular corticosteroids offer some temporary relief but should be used only if there is a symptomatic effusion or synovitis. Injections of hyaluronic acid into the knee joint may provide short-term improvement in symptomatic osteoarthritis in selected patients.

Joint arthroplasty may relieve pain, stabilize joints, and improve function. Total joint arthroplasty is very successful at the knee or hip. Table 23-8 describes the indications for total joint arthroplasty in radiographically advanced osteoarthritis. Surgical treatment for osteoarthritis of the shoulder is usually reserved for patients with intractable pain. Tibial osteotomy redistributes knee-joint forces. Arthroscopy removes loose bodies and trims torn menisci to correct lockup or giving way of the joint. Herniated disks or spinal stenosis with radicular symptoms may require decompression.

- Simple analgesics such as acetaminophen are the first choice for treating osteoarthritis.

Arthritis in Chronic Renal Failure

Up to 75% of patients undergoing chronic renal dialysis have musculoskeletal complaints after 4 years of dialysis. Renal failure arthritis affects the interphalangeal joints, metacarpophalangeal joints, wrists, shoulders, and knees. Symmetric joint-space narrowing and para-articular osteoporosis, subchondral cysts, and erosions have been described. There is no osteophytosis to confuse this condition with osteoarthritis. The synovial fluid is noninflammatory, and the synovitis on biopsy is nonspecific. Possible causes of this arthritis include apatite microcrystal deposition, hyperparathyroidism, and renal failure amyloidosis. Aseptic necrosis occasionally affects large joints.

After 10 years of hemodialysis, 65% of patients have pathologic or radiologic evidence of amyloid deposition (renal failure amyloid arthropathy). The amyloid is composed of β_2-microglobulin, is arthrotropic, and results in complete joint-space loss that occurs over a 3- to 12-month period. Shoulder pain and stiffness syndrome and carpal tunnel syndrome are strongly related to this amyloid deposition. Currently, treatment is aimed at relieving the symptoms.

- Up to 75% of patients undergoing chronic renal dialysis have musculoskeletal complaints after 4 years of dialysis.
- Destructive arthritis, shoulder pain and stiffness syndrome, and carpal tunnel syndrome are strongly related to amyloid deposition.

Nonarticular Rheumatism

Fibromyalgia

Fibromyalgia is a condition characterized by chronic widespread musculoskeletal pain. Older synonyms include fibrositis, tension myalgias, generalized nonarticular rheumatism, and psychogenic rheumatism. For the diagnosis, the pain should be present for at least 3 months and should involve areas on both sides of the body above

Table 23-8 **Indications for Total Joint Arthroplasty**

Radiographically advanced osteoarthritis
Night pain that cannot be modified by changing position
Lockup or giving way of the weight-bearing joint associated with falls or near falls
Joint symptoms compromise activities of daily living

and below the waist and some part of the axial skeleton. Symptoms should not be explainable on the basis of other coexisting diseases or conditions. "A high" tender point count is an additional obligatory criterion for classification of fibromyalgia. Fibromyalgia affects 2% to 10% of all populations studied and 15% of all general medical patients seen by internists; 75% to 95% of all patients are women. It is unusual for the diagnosis to be made in a person younger than 12 years or after age 65. Of the patients (or their parents), 60% recall childhood growing pains (leg pains). Fibromyalgia is associated with psychosocial stress.

- Fibromyalgia is characterized by chronic widespread musculoskeletal pain.
- Fibromyalgia affects 2%-10% of all populations studied; 75%-95% of patients are women.

Symptoms

Patients typically describe pain all over the body and use qualitatively different descriptions of the pain and discomfort than used by patients with rheumatoid arthritis. Patients localize the pain poorly, referring it to muscle attachment sites or muscles. The discomfort may be worse late in the day after activity. Some patients report morning stiffness, but it is usually not as long or as severe as in patients with inflammatory arthritis. Physical activity or changes in the weather typically aggravate the symptoms. Most patients describe nonrestorative, nonrestful sleep. Psychosocial stress, anxiety, and depression frequently are present. Other patient complaints can include subjective joint swelling (without objective synovitis on examination), arthralgias, headaches, and paresthesias. About a third of patients have multiple somatic visceral symptoms, including urinary irritability, pelvic pain, temporomandibular joint symptoms, and irritable bowel syndrome.

- Patients with fibromyalgia typically describe pain all over the body.
- Physical activity or weather changes typically aggravate the symptoms.
- Multiple somatic symptoms, including headaches, paresthesias, numbness, and irritable bowel symptoms, are common.
- Widespread chronic musculoskeletal pain is associated with psychosocial stress.

Diagnosis

A detailed history and physical examination exclude most rheumatologic and neurologic diseases. The finding of painful points at muscle attachment sites supports the diagnosis of fibromyalgia. Laboratory evaluation should include a complete blood count, erythrocyte sedimentation rate, thyroid function studies, and baseline chemistry studies of electrolytes, creatinine, calcium, and liver function. In selected cases, if liver transaminase values are increased, then creatine kinase and hepatitis serologic tests may be indicated. Radiographs are sometimes helpful for excluding other diseases. There is no diagnostic test for fibromyalgia. If sleep disturbance is prominent, sometimes sleep studies are helpful as some patients with sleep apnea have fibromyalgia symptoms.

- Chronic widespread musculoskeletal pain not explained by physical findings of a rheumatic disease supports the diagnosis of fibromyalgia.
- No laboratory test confirms the diagnosis of fibromyalgia.

Natural History

Fibromyalgia is a chronic waxing and waning condition. Patients have periods of pain and dysfunction alternating with variable periods of feeling reasonably well. Over a period of years, a patient's symptoms and concerns can shift considerably from musculoskeletal concerns to fatigue or other associated symptoms. There is no increased physical disability in patients who have had fibromyalgia for longer periods in comparison with those for whom the diagnosis is recent. Treatment includes reassurance and education, addressing sleep problems, and establishing an exercise program. Nonsteroidal anti-inflammatory drugs, simple analgesics, and medications to help with sleep (such as tricyclic antidepressants) have a role in some patients. Chronic pain management techniques may be helpful for patients with impaired life skills.

- In fibromyalgia, symptoms wax and wane.
- There is no progressive physical disability; however, patients may feel that they are unable to function normally.

Low Back Pain

One-third of all people older than 50 years have episodes of acute low back pain. Chronic low back pain is the number one compensable work-related injury. The many causes of low back pain include mechanical, neurologic, inflammatory, infectious, neoplastic, and metabolic and referred pain from the viscera. The vast majority of episodes of acute low back pain cannot be explained on a structural basis. Only 3% of patients presenting with acute low back pain have a cause that is not apparent after the initial interview and physical examination. Clinical suspicion of acute spinal cord compromise, spinal infection, or neoplasm requires immediate evaluation and prompt therapy. More than 90% find relief on their own or with the help of a medical practitioner within the first 6 weeks after symptoms occur.

- Only 3% of patients presenting with acute low back pain have a cause that is not apparent after the initial interview and physical examination.

Diagnosis

The most important consideration during the initial evaluation of acute low back pain is the possibility of severe compromise of the spinal cord or cauda equina. In the absence of evidence for acute spinal cord compromise, spinal infection, or neoplastic involvement, immediate pursuit of a cause for the acute back pain is often not helpful. Objective leg weakness or bladder or bowel dysfunction is an indication for more extensive examination and possible surgical decompression. Substantial weight loss or pain that increases with recumbency suggests a neoplastic or infectious process. Pain that worsens with coughing, straining, or sneezing suggests irritation of the dura mater. Radiating pain, weakness, or numbness in an extremity

implicates irritation of a spinal nerve root. Exertional calf or thigh cramping but normal peripheral pulses suggest pseudoclaudication (spinal stenosis). Pseudoclaudication symptoms improve with leaning forward on a shopping cart while walking or with sitting (not standing still). Referred pain from an abdominal, pelvic, or hip area suggests an extra-axial cause. An insidious onset with prominent morning stiffness suggests an inflammatory axial arthropathy.

- Objective leg weakness or bladder or bowel dysfunction is an indication for more extensive examination.
- Substantial weight loss or pain that interferes with sleep suggests a neoplastic or infectious process.
- Exertional calf or thigh cramping but normal peripheral pulses suggest pseudoclaudication.
- An insidious onset with prominent morning stiffness suggests an inflammatory axial arthropathy.

Clinical suspicion of acute spinal cord compromise, spinal infection, or neoplasm requires immediate evaluation and prompt therapy. In the absence of specific historical or physical examination findings, laboratory or plain radiographic findings often are unrevealing. The radiographic findings of spondylosis, disk degeneration, facet osteoarthritis, transitional lumbosacral segments, Schmorl nodes, spina bifida occulta, or mild scoliosis are often incidental findings not relevant to a patient's complaints of acute back pain. The routine use of bone scanning, electromyography, computed tomography, or magnetic resonance imaging is usually not necessary to evaluate acute low back pain. More than 20% of asymptomatic adults older than 65 years may have evidence of spinal stenosis on magnetic resonance imaging. The indications for spinal radiography in patients with acute low back pain are listed in Table 23-9.

Treatment

The treatment of acute nonspecific low back pain begins with reassuring the patient, because 90% of all patients with acute low back pain have considerable improvement in 6 weeks. Temporary modification of activities by empowering the patient to adjust lifestyle and demands works best. Bed rest should never be prescribed for more than 3 days to treat acute nonspecific low back pain, because longer bed rest has not been shown to be more beneficial. Short-term use of narcotic analgesics or tramadol can supplement the use of acetaminophen, nonsteroidal anti-inflammatory drugs, and muscle relaxants such as cyclobenzaprine. Physical therapy measures include local heat and ice massage. Pelvic traction and transcutaneous electrical nerve stimulation add little to the management of acute nonspecific low back pain. Epidural glucocorticosteroid injections are best suited to acute disk herniation, although their role is controversial. Injections into the facets are helpful occasionally, particularly if the patient describes a locking or catching as part of the pain syndrome.

Table 23-9 Indications for Spinal Radiography in Patients With Acute Low Back Pain

First episode of acute back pain is after age 50 years
History of back disease
History of back surgery
History of neoplasm
Acute history of direct trauma to the back
Fever
Weight loss
Severe pain unrelieved in any position
Neurologic symptoms or signs

- Clinical suspicion of acute spinal cord compromise, spinal infection, or neoplasm requires immediate evaluation and prompt therapy.
- In 90% of patients, acute low back pain (local or sciatic presentations) remits within 6 weeks.
- Pelvic traction and transcutaneous electrical nerve stimulation add little to the management of acute nonspecific low back pain.

Bursitis

A bursa is a closed sac containing a small amount of synovial fluid and lined with a membrane similar to that surrounding a diarthrodial joint. Bursae are present in the areas where tendons and muscles move over bony prominences. Additional bursae form in response to irritative stimuli. Trauma or overuse, microcrystalline disease, chronic inflammatory arthritis, and infection cause bursitis. Treatment of aseptic bursitis involves strict immobilization, ice compresses, nonsteroidal anti-inflammatory drugs, bursal aspiration, corticosteroid injections, and, occasionally, physical therapy. Glucocorticosteroids should not be given if there is a clinical suggestion of sepsis.

- Always consider infection or microcrystalline disease in the differential diagnosis of acute bursitis.

Septic bursitis may result from puncture wounds or cellulitis or occur after a local injection. In half of the cases, there is no portal of entry for infection in septic superficial bursitis (olecranon and prepatellar bursae). The organisms frequently responsible for infection are staphylococci and streptococci. Patients with septic superficial bursitis present with localized pain and swelling. Warmth about the area of the superficial bursa should raise the possibility of a septic bursa. If there is doubt, the bursa should be aspirated with strict aseptic technique. The needle should enter from the side through uninvolved skin—not at the point of maximal fluctuance—to avoid creating a chronic draining fistula.

When infection is suspected, patients should be treated empirically with antistaphylococcal and antistreptococcal oral antibiotics, pending the microbiologic results. Gram stains are positive in only 40% to 60% of patients. The number of leukocytes in infected bursal fluid can be low compared with that in infected joint fluid. This may be due to the modest blood supply of the bursae compared with that of joints. Patients with more severe infections or with associated cellulitis frequently do not respond to outpatient management. They should be hospitalized and given antibiotics intravenously, and

the affected part should be immobilized for 3 or 4 days. Repeated aspirations or percutaneous suction drainage may be necessary until the fluid stops accumulating. In chronic cases, surgical bursectomy may be indicated.

- Septic bursitis frequently occurs without evidence of a portal of entry.
- Bursal warmth is the best predictor of infection.
- Gram stains are positive in only 40%-60% of patients.
- The number of leukocytes in infected bursal fluid can be low.
- Patients with more severe infections should be hospitalized.

Polymyalgia Rheumatica

Polymyalgia rheumatica is a clinical syndrome usually characterized by the onset of aching and morning stiffness in the proximal musculature (hip and shoulder girdles). It is more common in females than males and usually occurs in patients older than 60 years. Radionuclide joint scanning in patients with active polymyalgia rheumatica confirms hip and shoulder synovitis, a finding supporting synovitis as the cause of the symptoms. Patients usually have an increased erythrocyte sedimentation rate; autoantibody results, including rheumatoid factor, CCP antibodies, and antinuclear antibody, are usually negative or normal. A small number of patients may have a normal sedimentation rate at presentation. The C-reactive protein value is usually increased in these cases. The presence of other specific diseases such as rheumatoid arthritis, chronic infection, inflammatory myositis, or malignancy should be excluded. Patients with polymyalgia rheumatica have prompt (within 24-72 hours) response to small doses of prednisone (10-20 mg daily).

- Typical clinical scenario: An elderly patient presents with aching and morning stiffness in the proximal musculature and increased erythrocyte sedimentation rate.

Features and Differential Diagnosis

Patients with polymyalgia rheumatica complain of stiffness and pain. This stiffness is most prominent in the mornings and after prolonged sitting. They also have problems getting comfortable at night to sleep. They occasionally have mild constitutional symptoms, including sweats, fevers, anorexia, and weight loss. Very prominent constitutional features and markedly increased erythrocyte sedimentation rate could suggest associated giant cell arteritis. Extremity edema or oligoarticular synovitis can occur, particularly at the knees, wrists, and shoulders. Polyarticular small joint arthritis is not a feature. Table 23-10 summarizes the rheumatic syndromes and other diseases that occasionally present with a polymyalgia rheumatica-like syndrome. Clinical evaluation and screening laboratory tests usually distinguish polymyalgia rheumatica from these other conditions. A variant known as the RS3PE syndrome (remitting symmetric seronegative synovitis with pitting edema) can occur, primarily in older men. Patients with this present with symptoms of polymyalgia rheumatica but also synovitis and edema in the hands or feet.

- In polymyalgia rheumatica, stiffness is more prolonged in the mornings and after prolonged sitting.

Table 23-10 Systemic Illnesses Presenting With a Polymyalgia-like Syndrome

Rheumatic syndromes	Other systemic illnesses
Systemic vasculitis	Paraneoplastic syndromes
Myositis	Systemic amyloidosis
Systemic lupus erythematosus	Infectious endocarditis
Seronegative rheumatoid arthritis	Hyperthyroidism
Polyarticular osteoarthritis	Hypothyroidism
Fibromyalgia	Hyperparathyroidism
Remitting seronegative, symmetric synovitis and peripheral edema	Osteomalacia
	Depression

- Prominent constitutional features and markedly increased erythrocyte sedimentation rate could suggest associated giant cell arteritis.
- Extremity edema or oligoarticular synovitis can occur.

Pathogenesis and Relationship to Giant Cell Arteritis

Polymyalgia rheumatica can begin before, appear simultaneously with, or develop after the symptoms of giant cell arteritis. The pathogenesis of polymyalgia rheumatica is unknown. Clinicians appreciate the close relationship between giant cell arteritis and polymyalgia rheumatica. Up to 15% of patients with polymyalgia rheumatica also have giant cell arteritis. Familial aggregation and increased incidence in patients of northern European background suggest a genetic predisposition. HLA-DR4 is associated with these conditions more commonly than would be expected by chance. Among patients with giant cell arteritis, 40% have symptoms of polymyalgia rheumatica during the course of their disease.

- Up to 15% of patients with polymyalgia rheumatica also have giant cell arteritis.
- Among patients with active giant cell arteritis, 40% have symptoms of polymyalgia rheumatica.
- Polymyalgia rheumatica can begin before, appear simultaneously with, or develop after the symptoms of giant cell arteritis.

Treatment

All patients with polymyalgia rheumatica should respond completely after 3 to 5 days of treatment with prednisone, 10 to 20 mg/day. Sometimes, split-dose (5 mg 3 times daily) prednisone is more effective than a single daily dose of 15 mg. Patients should be followed clinically, and usually the erythrocyte sedimentation rate should be measured monthly to confirm the disease flare. Polymyalgia rheumatica is thought to be a self-limited disease, although relapses occur. Prednisone treatment is discontinued in more than half of patients within 2 years. A minority of patients may be at risk of later appearance of giant cell arteritis.

- All patients with polymyalgia rheumatica should respond completely after 3-5 days of treatment with prednisone.
- Polymyalgia rheumatica is thought to be a self-limited disease, although relapses occur and a small risk of late appearance of giant cell arteritis exists.

Vasculitic Syndromes

Vasculitis, or angiitis, is an inflammatory disease of blood vessels. Damage to the vessel wall and stenosis or occlusion of the vessel lumen by thrombosis and progressive intimal proliferation of the vessel result in the clinical manifestations of the illness. The distribution of the vascular lesions and the size of the blood vessels involved vary considerably in different vasculitic syndromes and in different patients with the same syndrome. Vasculitis can be transient, chronic, self-limited, or progressive. It can be the primary abnormality or due to another systemic process. Histopathologic classification does not distinguish local from systemic illness or secondary from primary insult. The key clinical features suggestive of vasculitis are listed in Table 23-11. Vasculitis "look-alikes," or simulators, are listed in Table 23-12. These diseases and conditions should be considered whenever a patient's condition suggests vasculitis. A scheme for diagnosing vasculitis is outlined in Table 23-13. The ability to recognize characteristic clinical patterns of involvement is very helpful in making the diagnosis of systemic necrotizing vasculitis (Fig. 23-4).

Table 23-11 Clinical Features That Suggest Vasculitis

Constitutional features
Fatigue, fever, weight loss, and anorexia
Skin lesions
Palpable purpura, necrotic ulcers, livedo reticularis, urticaria, nodules, and digital infarcts
Arthralgia or arthritis
Myalgia or prominent fibrositis
Polymyalgia rheumatica symptoms
Claudication or phlebitis
Headache
Cerebrovascular accident
Neuropathy
Mononeuritis multiplex
Hypertension
Abnormal renal sediment
Pulmonary abnormalities
Pulmonary hemorrhage, pulmonary nodules with cavities
Abdominal pain or intestinal hemorrhage
Nonspecific indicators of inflammation
Anemia, thrombocytosis, low levels of albumin, elevated erythrocyte sedimentation rate, increased levels of liver enzymes, or eosinophilia

- Vasculitic symptoms reflect the nonspecific systemic features of inflammation (constitutional features) and the ischemic consequences of vascular occlusion.

Specific Vasculitic Syndromes

Giant Cell Arteritis

Giant cell arteritis, also known as temporal arteritis, predominantly affects persons older than 50 years. The prevalence exceeds 223 cases per 100,000 persons older than 50. It is most common in persons of northern European ancestry. Females outnumber males by 3:1. Polymyalgia rheumatica symptoms may develop in 40% to 50% of all patients with giant cell arteritis. Up to 15% of patients with polymyalgia rheumatica have temporal artery biopsy findings positive for giant cell arteritis. There is considerable morbidity with this disease; however, the rate of blindness is declining. Affected patients are at higher subsequent risk of aortic aneurysms. The mortality rate for patients with giant cell arteritis is similar to that for the general population.

- Giant cell arteritis is most common in persons of northern European ancestry.
- Polymyalgia rheumatica develops in 40% to 50% of patients with giant cell arteritis.
- Up to 15% of patients with polymyalgia rheumatica have temporal artery biopsy findings positive for giant cell arteritis.

Pathology

Giant cell arteritis involves the primary and secondary branches of the aorta in a segmental or patchy fashion. However, any artery, and occasionally veins, can be affected. It is unusual for intracranial arteries to be involved. Histopathologically, all layers of the vessel wall are extensively disrupted, with intimal thickening and a prominent mononuclear and histiocytic infiltrate. Multinucleated giant cells infiltrate the vessel wall in 50% of cases. Fragmentation and disintegration of the internal elastic membrane, the other characteristic features, are closely associated with the accumulation of giant cells and vascular occlusive symptoms.

- Giant cell arteritis affects primary and secondary branches of the aorta in a segmental or patchy fashion.

Clinical Features

Early clinical features of giant cell arteritis include temporal headache, polymyalgia rheumatica symptoms, fatigue, and fever. The classic features of this disease are included in Table 23-14. Arteritis of the branches of the ophthalmic or posterior ciliary arteries causes ischemia of the optic nerve (ischemic optic neuritis) and blindness. Less often, retinal arterioles are occluded. Blindness occurs in fewer than 15% of untreated patients. Large peripheral artery involvement in giant cell arteritis occurs in about 10% of patients. Extremity claudication, Raynaud phenomenon, aortic dissection, decreased pulses, and vascular bruits suggest large peripheral artery involvement. Patients with large peripheral artery involvement do not differ from those with more classic giant cell arteritis, either histologically or with regard to laboratory findings. Late features include a markedly increased risk of thoracic aortic aneurysm.

Table 23-12 Syndromes That Mimic Vasculitis

Cardiac myxoma with embolization
Infective endocarditis
Thrombotic thrombocytopenic purpura
Atheroembolism: cholesterol or calcium emboli
Ergotism
Pseudoxanthoma elasticum
Ehlers-Danlos type 4
Neurovasculopathy secondary to antiphospholipid syndrome
Arterial coarctation or dysplasia
Infectious angiitis
Lyme disease
Rickettsial infection
HIV infection

HIV, human immunodeficiency virus.

- Typical clinical scenario: A 60-year-old patient presents with temporal headache, polymyalgia rheumatica-like symptoms, fatigue, and fever. The sedimentation rate is markedly increased. Physical examination shows scalp tenderness.
- Blindness occurs in <15% of untreated patients.

Diagnosis

The temporal artery biopsy specimen should be at least 3 cm long to compensate for patchy involvement. In 15% of patients, the biopsy is positive on the opposite side if that on the initial side is negative. Typical laboratory abnormalities in acute active giant cell arteritis include a markedly increased erythrocyte sedimentation rate, moderate normochromic anemia, and thrombocytosis. A mild increase in liver enzyme values, most typically alkaline phosphatase, occurs in one-third of patients because of granulomatous hepatitis. The erythrocyte sedimentation rate is rarely normal in patients with active giant cell arteritis. The diagnostic criteria for giant cell arteritis are given in Table 23-15.

- The temporal artery biopsy specimen should be at least 3 cm long to compensate for patchy involvement.
- In 15% of patients, the biopsy is positive on the opposite side if that on the initial side is negative.
- Typical laboratory abnormalities in giant cell arteritis are markedly increased erythrocyte sedimentation rate, moderate normochromic anemia, and thrombocytosis.

Treatment

Treatment is initiated with corticosteroids when the diagnosis of giant cell arteritis is considered and the biopsy is requested. A temporal artery biopsy specimen remains positive for disease even after several weeks of corticosteroid treatment. Initial treatment includes prednisone, typically 40 to 60 mg/day. A higher dose of corticosteroids can be given parenterally in cases of visual or life-threatening symptoms. A recent study suggested parenteral corticosteroids initially may lessen the total duration and cumulative dose needed.

Table 23-13 The Diagnostic Approach to Vasculitis

Proper clinical suspicion for vasculitis*

Therapeutics

*Table 23-11.

Most symptoms of giant cell arteritis begin to respond within 24 hours after corticosteroid therapy is initiated. Visual changes that are present for more than a few hours are often irreversible. Alternate-day administration of corticosteroids does not control symptoms in at least half of patients.

- Treatment is initiated with corticosteroids when the diagnosis of giant cell arteritis is considered and the biopsy is requested.
- Initial treatment of giant cell arteritis includes prednisone, typically 40-60 mg/day.
- Alternate-day administration of corticosteroids does not initially control symptoms in at least half of patients.

Outcome

Giant cell arteritis typically has a self-limited course. In 24 months, half of patients are able to discontinue treatment with corticosteroids. An effective steroid-sparing agent has not been identified, but methotrexate or azathioprine has been used in some patients. The diagnosis of giant cell arteritis does not influence mortality rates. Relapse may occur in a third of patients, and a thoracic or abdominal aneurysm develops in a third.

- Giant cell arteritis typically has a self-limited course over about 2 years, although relapses and late consequences, including aortic aneurysms, occur.

Takayasu Arteritis

Takayasu arteritis is also known as aortic arch syndrome or pulseless disease. Each year, about 2.6 new cases per 1,000,000 population occur. Most patients are between the ages of 15 and 40 years. At least 80% of them are female. This disease is more common in the Orient, Latin America, and Eastern Europe. Its pathologic features cannot be distinguished from those of giant cell arteritis. Takayasu arteritis affects the aorta and its primary branches. The arterial wall is irregularly thickened, with luminal narrowing, dilatations, aneurysms, and distortions. The aortic valve and coronary ostia can be involved.

- Among patients with Takayasu arteritis, most are female and between the ages of 15 and 40 years.
- The aorta and its primary branches are affected.

Clinical and Laboratory Features

The constitutional features of fever, weight loss, fatigue, and arthralgia can precede symptoms of ischemia to the brain or claudication of the extremities. Renovascular hypertension, pulmonary hypertension, and coronary artery insufficiency can complicate Takayasu arteritis. Cutaneous vasculitis, erythema nodosum, and synovitis occasionally occur in cases of active Takayasu arteritis. Compromise of the cerebral vasculature can lead to dizziness, blurry or fading vision, syncope, and, occasionally, stroke. Physical examination findings confirm vascular bruits, absence of peripheral pulses, and, occasionally, fever. When the disease is active, results of laboratory studies usually show increased erythrocyte sedimentation rate, normochromic anemia, and thrombocytosis. However, in some cases of active disease, the erythrocyte sedimentation rate is normal. The diagnosis can be confirmed with conventional angiography, although magnetic resonance angiography may become the imaging method of choice.

- Renovascular hypertension, pulmonary hypertension, and coronary artery insufficiency can complicate Takayasu arteritis.
- Typical clinical scenario: A young patient presents with fever, weight loss, fatigue, and arthralgia. Physical examination shows carotid bruits and absence of peripheral pulses. On laboratory testing, the erythrocyte sedimentation rate is increased.

Treatment and Outcome

Corticosteroid therapy alone is usually adequate for controlling the inflammation. Methotrexate or cyclophosphamide treatment is indicated in resistant cases. On average, patients receive corticosteroids for about 2 years. Late stenotic complications are amenable to vascular operation and bypass grafting. Survival is more than 90% at 10 years. Congestive heart failure from previous coronary artery involvement and cerebrovascular accidents are major causes of mortality.

- Survival in patients with Takayasu arteritis is >90% at 10 years.

Systemic Vasculitis

Systemic necrotizing vasculitis occurs alone or in association with several diseases (secondary). When it occurs as a primary vasculitis, it is most commonly a small vessel antineutrophil cytoplasmic antibody (ANCA)-associated disease of Wegener granulomatosis or microscopic polyangiitis. Medium vessel polyarteritis nodosa, frequently associated with hepatitis B, is far less common. A secondary necrotizing vasculitis can occur in association with rheumatoid arthritis, systemic lupus erythematosus, other connective tissue diseases, cryoglobulinemia, hepatitis C infection, hairy cell leukemia, and other malignant conditions.

- Systemic necrotizing vasculitis occurs alone or in association with several diseases.

Pathology

These diseases are characterized by transmural inflammation and necrosis of blood vessels. Classic polyarteritis nodosa affects medium-sized muscular arteries. ANCA-associated vasculitis affects arterioles, venules, and capillaries. The size of the affected vessels plays a large part in determining the clinical manifestations of the syndromes.

- Systemic vasculitis may affect a spectrum of vessel sizes.

Clinical Features

Systemic vasculitis usually is associated with prominent constitutional features, including fever, fatigue, weight loss, and, occasionally, myalgia or arthralgia, along with manifestations of multisystem organ

Table 23-15 Diagnostic Criteria for Giant Cell Arteritis

Temporal artery biopsy findings positive for classic giant cell arteritis
or

Rapid response to corticosteroids

involvement. Virtually any organ can be affected eventually. Other features are listed in Table 23-16. Occasionally, vasculitis is limited to a single organ or found incidentally associated with cancer at the time of operation and cured by surgical removal. Other cases are limited to isolated involvement of the skin or peripheral nerves.

Classic polyarteritis nodosa is a necrotizing vasculitis of small and medium-sized arteries and is associated with vascular nephropathy (usually without glomerulonephritis), causing multiple renal infarctions, hypertension, and renal failure. Hypertension develops as a result of angiographically demonstrable renal artery compromise or, less commonly, glomerular involvement. Lung involvement is very uncommon.

Microscopic polyangiitis is distinguished from polyarteritis nodosa as a necrotizing vasculitis that affects capillaries, venules, and arterioles and most frequently presents with pauci-immune and sometimes rapidly progressive necrotizing glomerulonephritis. Proteinuria is common, and, rarely, a nephritic syndrome may develop. There is an active urinary sediment, with red blood cells and red cell casts characteristic of glomerular involvement. Renal insufficiency is frequently noted at presentation, and glomerulonephritis causes oliguric renal failure in one-third of all patients. Renal angiography in microscopic polyangiitis is usually normal. Hypertension is uncommon. Lung involvement, including pulmonary capillaritis and hemorrhage, eventually may affect up to a third of patients with microscopic polyangiitis.

Systemic vasculitis may be a manifestation or complication of other diseases. This secondary vasculitis complicates hepatitis C infection, rheumatoid arthritis, Sjögren syndrome, mixed cryoglobulinemia, hairy cell leukemia, myelodysplastic syndrome, and other hematologic malignancies. Some forms of secondary vasculitis have more favorable clinical presentations. For example, systemic rheumatoid vasculitis most commonly manifests with constitutional symptoms, skin lesions, and neuropathy. It rarely causes a necrotizing glomerulonephritis or pulmonary hemorrhage.

- Systemic vasculitis is associated with prominent constitutional features, including fever, fatigue, weight loss, and, occasionally, myalgia or arthralgia, along with manifestations of multisystem organ involvement.
- ANCA-associated vasculitis disorders of Wegener granulomatosis and microscopic polyangiitis are more common than classic polyarteritis nodosa.
- Secondary vasculitis may be a complication of other diseases.

Diagnosis

Abnormal laboratory findings include normocytic anemia, increased erythrocyte sedimentation rate, and thrombocytosis. Microscopic polyangiitis presents with a myeloperoxidase-specific perinuclear (p-) ANCA in 90% of cases. Complement consumption is not part of primary systemic vasculitis. Low complement may be evident if immune complexes such as cryoglobulins are part of the pathogenesis of secondary vasculitis. Hepatitis B infection occurs in a small proportion of patients with ANCA-negative (classic) polyarteritis nodosa and should always be sought, because treatment is directed against the infection. Hepatitis C is associated with the secondary vasculitis that is the cause of some cases of mixed cryoglobulinemia.

Table 23-16 Clinical Features of Systemic Vasculitis

Common features	Uncommon features
Fever, fatigue, weight loss	Coronary arteritis
Arthralgia, arthritis	Myocardial infarction
Myalgia	Congestive heart failure
Mononeuritis multiplex	Central nervous system abnormalities
Focal necrotizing glomerulonephritis	Seizures
Abnormal renal sediment	Cerebrovascular accident
Hypertension	Lung (interstitial pneumonitis)
Skin abnormalities	Eye (retinal hemorrhage)
Palpable purpura	Testicular pain
Livedo reticularis	
Cutaneous infarctions	
Abdominal pain/ischemic bowel	
Liver enzyme abnormalities	

Evaluation should document the extent and severity of the condition. The confirmatory test typically is angiography or biopsy of involved tissue showing vasculitis. The biopsy should be of accessible symptomatic tissue. If medium-sized vessel polyarteritis nodosa is suspected, visceral angiography, including views of the renal and mesenteric arteries, shows saccular or fusiform aneurysm formation coupled with smooth, tapered stenosis alternating with normal or dilated blood vessels (Fig. 23-5).

- Microscopic polyangiitis often presents with positive myeloperoxidase-specific p-ANCA.
- Hepatitis B infection occurs in a small proportion of patients with ANCA-negative (classic) polyarteritis nodosa and should always be sought, because treatment is directed against the infection.
- Hepatitis C is associated with some cases of mixed cryoglobulinemia.
- Confirmatory diagnostic tests include angiography or biopsy of involved tissue showing vasculitis.
- Visceral angiography shows saccular or fusiform aneurysm formation coupled with smooth, tapered stenosis.
- Consider visceral angiography for diagnosis when the patient has significant gastrointestinal symptoms or markedly increased liver enzyme values and no tissue or organ system (nerve, skin) is affected or easily sampled by biopsy.

Treatment

The cornerstone of treatment is early diagnosis and corticosteroid therapy. Cytotoxic or antimetabolite drugs such as cyclophosphamide, methotrexate, and azathioprine are used in combination with corticosteroids. The choice of the second agent is usually determined according to the severity of organ involvement. When a patient's

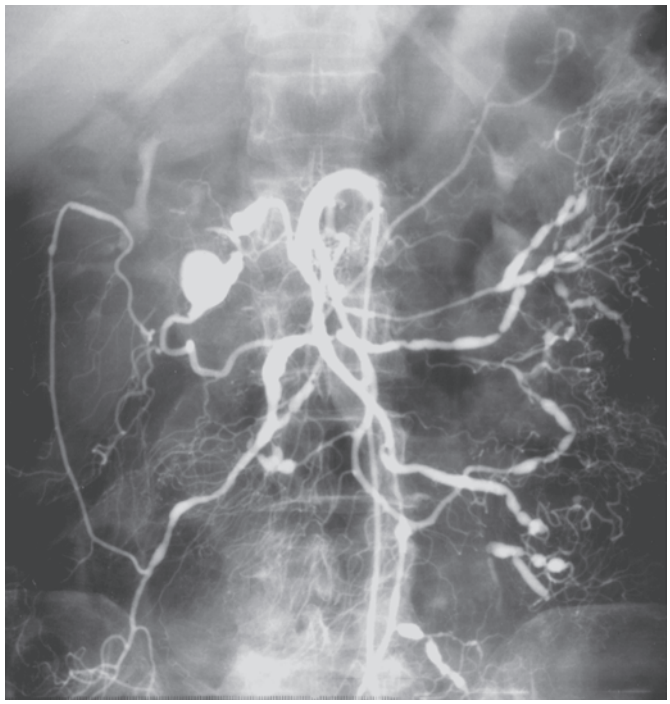

Fig. 23-5. Visceral polyarteritis nodosa. Angiography shows the classic features of smooth tapers followed by normal or dilated vessels. Note the large saccular aneurysm in the hepatic artery. (From Audiovisual Aids Subcommittee of the Education Committee of the American College of Rheumatology. Syllabus: revised clinical slide collection on the rheumatic diseases and 1985, 1988, and 1989 slide supplements. Atlanta [GA]: American College of Rheumatology. Used with permission.)

condition deteriorates in the face of potent treatment, consider possible progression of disease, superimposed infection, or noninflammatory, proliferative, occlusive vasculopathy. Hepatitis-associated vasculitis is treated best with antiviral drugs after a short course of systemic corticosteroids.

- Cyclophosphamide, methotrexate, and azathioprine are often used in conjuction with corticosteroids.

Outcome

In the first year after diagnosis of systemic vasculitis, deaths are related to the extent of disease activity, particularly gastrointestinal tract ischemia and renal insufficiency. Distinguishing classic polyarteritis nodosa from microscopic polyangiitis and type of organ involvement may influence treatment, complications, relapse rate, and mortality. After 1 year, complications of treatment, including infections in the immunocompromised patient, contribute most to mortality rates. With treatment, survival at 5 years is between 55% and 60% for microscopic polyangiitis and between 75% and 90% for classic polyarteritis nodosa.

- In the first year after diagnosis, deaths are related to the extent of disease activity, particularly gastrointestinal tract ischemia and renal insufficiency.
- Complications from treatment affect long-term mortality.
- Typical clinical scenario: A patient presents with fever, fatigue, weight loss, arthralgia, mononeuritis multiplex, and renal failure. Renal angiography shows saccular and fusiform aneurysm formation with smooth, tapered stenosis of the vessels. Laboratory testing shows increased sedimentation rate and negative antimyeloperoxidase antibodies. Chest radiography is normal.

Churg-Strauss Vasculitis

Churg-Strauss vasculitis, or Churg-Strauss syndrome, is similar to microscopic angiitis and Wegener granulomatosis in that it involves small vessels and may be associated with ANCA antibodies. The median age at onset is about 38 years (range, 15-69 years). Churg-Strauss vasculitis is defined by 1) a history of, or current symptoms of, asthma, 2) peripheral eosinophilia (>1.5 × 10^9 eosinophils/L), and 3) systemic vasculitis of at least two extrapulmonary organs. There is a slight male predominance. The histopathologic features of the disease include eosinophilic extravascular granulomas and granulomatous or nongranulomatous small vessel necrotizing vasculitis. It typically involves the small arteries, veins, arterioles, and venules.

- Churg-Strauss vasculitis: history of, or current symptoms of, asthma, peripheral eosinophilia (>1.5 × 10^9 eosinophils/L), and systemic vasculitis of at least two extrapulmonary organs.
- It involves small arteries, veins, arterioles, and venules.

Clinical Features

Churg-Strauss syndrome has three clinical stages. Patients need not progress in an orderly manner from one stage to another. There usually is a prodrome of allergic rhinitis, nasal polyposis, or asthma. In the second stage, peripheral blood and tissue eosinophilia develops, suggesting Löffler syndrome. Chronic eosinophilic pneumonia and gastroenteritis may remit or recur over years. The third stage is life-threatening vasculitis. Transient, patchy pulmonary infiltrates or nodules, pleural effusions, pulmonary angiitis and cardiomegaly, eosinophilic gastroenteritis, extravascular necrotizing granulomata of the skin, mononeuritis multiplex, and polyarthritis can complicate Churg-Strauss syndrome. A Churg-Strauss–like syndrome has been reported in some patients treated with the asthma medication zafirlukast.

- Churg-Strauss syndrome: prodrome of allergic rhinitis, nasal polyposis, or asthma.
- Peripheral blood and tissue eosinophilia develops.
- Transient, patchy pulmonary infiltrates, extravascular necrotizing granulomata of the skin, and mononeuritis multiplex can complicate Churg-Strauss syndrome.

Treatment and Outcome

The 1-year survival with treated Churg-Strauss syndrome is similar to that with microscopic polyangiitis. There is more cardiac involvement but fewer renal deaths than in polyarteritis nodosa. Treatment includes corticosteroids with or without the addition of cytotoxic agents. The eosinophilia resolves with treatment.

- In Churg-Strauss syndrome, there is more cardiac involvement but fewer renal deaths than in polyarteritis nodosa.
- Typical clinical scenario: A patient presents with a history of bronchial asthma with recent worsening of pulmonary symptoms and development of mononeuritis multiplex. There is a history of nasal polyposis. Physical evaluation reveals palpable purpura. On laboratory testing, the eosinophil count is markedly increased.

Buerger Disease

Buerger disease, or thromboangiitis obliterans, occurs almost exclusively in young adult smokers, who typically present with claudication of the instep and loss of digits from ischemic injury. Buerger disease affects the small and medium-sized arteries and veins of the extremities. Acute vasculitis in Buerger disease is accompanied by characteristic intraluminal thrombus that contains microabscesses. Usually, the disease is arrested when smoking is stopped. In contrast to other forms of vasculitis, Buerger disease is best thought of as a vasculopathy.

- Buerger disease occurs almost exclusively in young adult smokers.
- Patients present with loss of digits from ischemic injury.
- The disease is arrested when smoking is stopped.

Isolated (Primary) Angiitis of the Central Nervous System

Clinical Features

Isolated, or primary, angiitis of the central nervous system, once thought to be rare, has a chronic fluctuating and progressive course. The average age of patients presenting with this disease is 45 years. Forty percent of patients have had symptoms for less than 4 weeks at presentation, and another 40% present with symptoms that have been noted for more than 3 months. The most common symptom is headache (mild or severe), often associated with nausea or vomiting. Nonfocal neurologic abnormalities (including confusion, dementia, drowsiness, or coma) may interrupt prolonged periods of apparent remission. Acute stroke-like focal neurologic presentations are increasingly described. Cerebral hemorrhage occurs in fewer than 4% of patients. Focal and nonfocal neurologic abnormalities coexist in half of patients. Systemic features—fever, weight loss, arthralgia, and myalgia—are uncommon and occur in fewer than 20% of patients; seizures occur in about 25%.

- Isolated angiitis of the central nervous system has a chronic fluctuating and progressive course, most commonly without evidence of systemic inflammation.
- Most common symptom is headache.
- Complications include acute strokes, with or without nonfocal neurologic abnormalities (decreased consciousness or cognition).
- Cerebral hemorrhage occurs in <4% of patients.

Diagnosis

There are no reliable noninvasive tests for making the diagnosis. The mainstays of diagnosis are cerebral angiography and biopsy of central nervous system tissues, including the leptomeninges. The cerebrospinal fluid is abnormal in most patients with pathologically documented primary angiitis of the central nervous system. Computed tomography of the head is not specific or sensitive for the condition. Magnetic resonance imaging may be sensitive but does not distinguish this primary angiitis from other vasculopathic or demyelinating lesions of the brain, and it is not useful for following the condition. Patients with a chronic progressive course are more likely to have the diagnosis made pathologically and have abnormal results on examination of the cerebrospinal fluid.

- The mainstays of diagnosis of isolated angiitis are cerebral angiography and biopsy of central nervous system tissues, including the leptomeninges.

Rheumatologic syndromes that may produce a clinical picture similar to that of primary angiitis of the central nervous system include Cogan syndrome (nonsyphilitic keratitis and vestibular dysfunction), Behçet syndrome (uveitis, oral and genital ulcers, meningitis, and vasculitis), systemic lupus erythematosus, and polyarteritis. Drug-induced vasculopathy (particularly cocaine), demyelinating disease, human immunodeficiency virus (HIV) infection, Lyme disease, syphilis, carcinomatous meningitis, angiocentric immunoproliferative lesions, and antiphospholipid antibody syndrome are also part of the differential diagnosis in patients presenting with a syndrome suggesting primary angiitis of the central nervous system.

Treatment

The treatment for primary angiitis of the central nervous system may be influenced by the clinical subset. Younger patients with acute disease in whom the diagnosis was made with angiography may have a benign course and typically respond well to a short course of treatment with corticosteroids and calcium channel blockers to prevent vasospasm. Patients with a protracted course, abnormal cerebrospinal fluid, and diagnosis made with brain and leptomeningeal biopsy are best treated with combination therapy, including corticosteroids and cytotoxic agents. If untreated, this clinical subset has a high mortality rate.

- The mortality rate is high among patients with histopathologically confirmed or recurrent symptoms treated without cytotoxic agents.

Wegener Granulomatosis

Clinical Features

Wegener granulomatosis is a well-recognized pathologic triad of upper and lower respiratory tract necrotizing granulomatous inflammation and focal segmental necrotizing glomerulonephritis. Wegener granulomatosis occurs in less than 1 person annually per 100,000 population. The peak incidence of the disease occurs in the fourth and fifth decades of life. There is a slight male predominance. Eighty-five percent of the patients have generalized disease, including glomerulonephritis; 15% can present with local inflammation involving only the upper respiratory tract or kidneys. The clinical features of this disease are summarized by the mnemonic ELKS: involvement of *e*ar/nose/throat, *l*ung, *k*idney, and *s*kin. Lung involvement most

commonly includes thick-walled, centrally cavitating pulmonary nodules. Alveolitis and pulmonary hemorrhage occur in up to 20% of patients. Biopsy in patients with renal involvement shows focal segmental necrotizing glomerulonephritis and, occasionally, granulomatous vasculitis. Skin involvement may include urticaria, petechiae, papules, vesicles, ulcers, pyoderma, and livedo reticularis. Inflammatory arthritis is usually oligoarticular and transient, occurring early in the clinical presentation. Central nervous system involvement includes distal sensory neuropathy, mononeuritis multiplex, and cranial nerve palsies. Conjunctivitis, uveitis, and proptosis are not unusual. Neurosensory hearing loss has been described together with serous otitis and inner ear vasculitis. Wegener granulomatosis-associated subglottic tracheal stenosis due to chondritis should be distinguished from primary polychondritis. Laboratory testing shows a positive cytoplasmic (c-) ANCA test.

- Typical clinical scenario: A 50-year-old patient presents with the triad of upper and lower respiratory tract necrotizing granulomatous inflammation and focal segmental necrotizing glomerulonephritis. Laboratory testing shows a positive c-ANCA test.
- ELKS: involvement of *e*ar/nose/throat, *l*ung, *k*idney, and *s*kin.
- Alveolitis and pulmonary hemorrhage occur in up to 20% of patients.
- Central nervous system involvement includes distal sensory neuropathy, mononeuritis multiplex, and cranial nerve palsies.

Pathologic Diagnosis

The diagnosis of Wegener granulomatosis may require finding characteristic pathologic features in biopsy specimens. Biopsy of the upper respiratory tract suggests the diagnosis in 55% of patients, but only 20% have granulomata or vasculitis associated with necrosis. An open lung biopsy has a higher diagnostic yield than transbronchial biopsy. Renal biopsies usually show only a focal segmental necrotizing glomerulonephritis. Infrequently, renal biopsy shows vasculitis. Relevant laboratory findings in active Wegener granulomatosis include nonspecific increases in the erythrocyte sedimentation rate and platelet count, normocytic anemia, and low levels of albumin. A positive proteinase 3 antibody, c-ANCA test in a patient with the clinical features of Wegener granulomatosis may be sufficient for diagnosis, especially if tissue is not easily obtained.

- Laboratory findings in Wegener granulomatosis include nonspecific increases in erythrocyte sedimentation rate and platelet count and normocytic anemia.
- Diagnosis: positive proteinase 3, c-ANCA test and granulomatous inflammation on biopsy.

ANCA

c-ANCA is directed against proteinase 3, a serine protease from azurophilic granules. c-ANCA occurs in more than 90% of active cases of generalized Wegener granulomatosis. Occasionally, it is found in idiopathic crescentic glomerulonephritis, microscopic polyarteritis nodosa, and Churg-Strauss syndrome. The antibody titer tends to correlate with disease activity.

p-ANCA is directed against myeloperoxidase and other neutrophil cytoplasmic constituents. p-ANCA (anti-myeloperoxidase-specific) is found in idiopathic crescentic glomerulonephritis, microscopic polyarteritis nodosa, Churg-Strauss syndrome, Wegener granulomatosis, and other connective tissue diseases. p-ANCA directed against other antigens can occur in patients with inflammatory bowel disease, autoimmune liver disease, other connective tissue diseases, malignancies, and even drug-induced syndromes.

- Proteinase 3, c-ANCA occurs in >90% of active cases of Wegener granulomatosis.
- Non-myeloperoxidase p-ANCA is found in many different conditions.

Treatment and Outcome

If untreated, generalized Wegener granulomatosis is associated with a mean survival of 5 months and 95% mortality in 1 year. More than 95% of patients eventually have clinical remission with oral cyclophosphamide treatment. Corticosteroids are useful initially, and the dose can be tapered quickly after the disease is controlled. Mortality in the first year of disease is related primarily to the inflammatory process, with pulmonary hemorrhage or renal failure. In subsequent years, drug toxicity may dominate, with opportunistic infection and increasing risk of neoplasm and hemorrhagic cystitis related to the use of cyclophosphamide. Relapses even years after treatment are not uncommon.

- If untreated, generalized Wegener granulomatosis is associated with a mean survival of 5 months.
- Cyclophosphamide has revolutionized the treatment of Wegener granulomatosis and dramatically altered the natural history.
- Corticosteroids are useful initially, and the dose can be tapered quickly after the disease is controlled.

Small Vessel Vasculitis and Cutaneous Vasculitis

Clinical Features

Small vessel vasculitis occurs by itself or complicates many infectious, neoplastic, and connective tissue diseases. The most common cause of isolated cutaneous vasculitis is drugs. It manifests with urticaria, palpable purpura, livedo reticularis, or skin ulceration. Small vessel vasculitis occurs with many illnesses; a partial listing is given in Table 23-17.

- The most common cause of isolated cutaneous vasculitis is drugs.
- Isolated cutaneous vasculitis manifests with urticaria, palpable purpura, livedo reticularis, or skin ulceration.
- It can complicate most types of primary and secondary systemic vasculitis.

Histopathology

A neutrophilic- or (uncommonly) lymphocytic-predominant infiltrate surrounds small arteries, veins, arterioles, or venules. The histopathologic picture called "leukocytoclastic vasculitis" includes immune complexes deposited in vessel walls, along with fibrin

Table 23-17 Conditions With Small Vessel Vasculitis

Systemic small vessel vasculitis
Systemic vasculitis
Wegener granulomatosis
Polyarteritis (primary and secondary)
Churg-Strauss vasculitis
Takayasu arteritis
Schönlein-Henoch purpura/vasculitis
Serum sickness
Goodpasture syndrome
Nonsystemic small vessel vasculitis
Hypocomplementemic vasculitis
Leukocytoclastic vasculitis related to:
Rheumatoid arthritis
Sjögren syndrome
Systemic lupus erythematosus
Other connective tissue diseases
Drug-induced and postinfectious angiitis
Mixed cryoglobulinemia
Malignancy-associated vasculitis
Inflammatory bowel disease
Organ transplant-associated vasculitis
Hypergammaglobulinemic purpura of Waldenström

deposition, endothelial cell swelling and necrosis, and a polymorphonuclear leukocytoclasis with scattering of nuclear fragment or nuclear dust. A classic clinical correlate of leukocytoclastic vasculitis is palpable purpura. This is a pathologic diagnosis and not a specific clinical condition.

- A classic clinical correlate of leukocytoclastic vasculitis is palpable purpura.

Diagnosis

The clinician must interpret small vessel or cutaneous vasculitis as a clinical finding and not a diagnosis. These various conditions are distinguished clinically and pathologically. For instance, Schönlein-Henoch vasculitis is suggested by the clinical features of abdominal pain or gastrointestinal hemorrhage in addition to the classic picture of lower extremity purpura, arthritis, and hematuria. Schönlein-Henoch vasculitis has IgA deposition in vessel walls and normal complement levels. Mixed cryoglobulinemia has circulating cryoglobulins and evidence of complement consumption. Complement levels, especially C4, may be low transiently in hypersensitivity vasculitis. Hypersensitivity vasculitis is almost always a nonsystemic small vessel vasculitis temporally related to infection, ingestion of drugs, or, less commonly, malignancy. The results of other laboratory studies are nonspecific. The leukocyte count and platelet count may be increased. Eosinophilia may be present. The erythrocyte sedimentation rate usually is increased.

- Complement levels may be low in mixed cryoglobulinemia and hypersensitivity vasculitis.
- Schönlein-Henoch vasculitis has four classic clinical features: lower extremity purpura, arthritis, gastrointestinal hemorrhage, and nephritis. IgA is noted on biopsy.

Treatment and Outcome

The outcome of nonsystemic small vessel vasculitis depends on the underlying condition. Control of the infection or discontinuation of the offending drug may be all that is required. In other cases, corticosteroids or nonsteroidal anti-inflammatory drugs are beneficial. Hypersensitivity vasculitis is usually self-limited, but it may recur with repeated exposure to the antigen or drug.

- Nonsystemic small vessel vasculitis: the outcome is good.
- Hypersensitivity vasculitis may recur with repeated exposure to the antigen or drug.

Cryoglobulinemia

Cryoglobulins are immunoglobulins that reversibly precipitate at reduced temperatures. They are grouped into two major categories. *Type I cryoglobulins* are aggregates of a single monoclonal immunoglobulin and generally are associated with multiple myeloma, Waldenström macroglobulinemia, and lymphomas. They usually are found in high concentrations (1-5 g/dL). Patients with type I cryoglobulins are often asymptomatic. Symptoms of type I cryoglobulinemia are usually related to increased viscosity and include headaches, visual disturbances, nosebleeds, Raynaud phenomenon, and ischemic ulceration from occlusion of arterioles and venules by precipitated immune complexes. Vasculitis is rare.

- Type I cryoglobulins are aggregates of a single monoclonal immunoglobulin.
- Patients with type I cryoglobulins are often asymptomatic.
- Symptoms are usually related to increased viscosity.
- Vasculitis is rare.

Type II and *type III cryoglobulins* consist of more than one class of immunoglobulin (mixed cryoglobulinemia) and can occur alone (essential, primary) or be due to another disease. Type II cryoglobulinemia involves a monoclonal immunoglobulin (usually IgM) with anti-immunoglobulin specificity (rheumatoid factor). Type III cryoglobulinemia involves polyclonal immunoglobulins (usually IgM) directed against other polyclonal immunoglobulins (usually IgG). Not all rheumatoid factors are cryoglobulins. Other components of the immune complexes formed in mixed cryoglobulinemia include hepatitis C antigen, other infectious agents, cellular/nuclear antigens, and complement. These immune complexes precipitate slowly and are present in smaller quantities (50-500 mg/dL) than type I cryoglobulins.

Type II cryoglobulins frequently are associated with chronic infections (most commonly hepatitis C), autoimmune disorders, and, occasionally, lymphoma. The immune complexes that form precipitate on endothelial cells in peripheral blood vessels and fix complement, promoting vasculitic inflammation. The size of immune

complexes, ability to fix complement, persistent IgM production, and many other factors may influence the clinical presentation of mixed cryoglobulinemia. The typical presentation is that of nonsystemic small vessel vasculitis with palpable purpura, urticaria, and cutaneous ulceration. Peripheral neuropathy, arthralgia, and arthritis are common. Less commonly, mixed cryoglobulinemia is complicated by hepatosplenomegaly, pneumonitis or pulmonary hemorrhage, focal segmental necrotizing glomerulonephritis, serositis (pleurisy, pericarditis), and thyroiditis.

- Type II cryoglobulins frequently are associated with chronic infections (most often hepatitis C) and immune disorders.
- Typical presentation: nonsystemic small vessel vasculitis with palpable purpura, urticaria, and cutaneous ulceration.
- Peripheral neuropathy, arthralgia, and arthritis are common.

Laboratory Studies

Patients with type II cryoglobulinemia and small vessel vasculitis usually have an increased erythrocyte sedimentation rate, increased immunoglobulin levels, positive rheumatoid factor, and low levels of complement. Evidence of chronic hepatitis infection (particularly hepatitis C) frequently is identified. For cryoglobulin testing, it is important to draw blood into a warmed syringe and to keep it warm until transferred to a cryocrit tube. Cooled specimens must be kept for up to 3 days to identify type II cryoglobulins. Serum protein electrophoresis, immunoelectrophoresis, and quantitative immunoglobulin determinations can be helpful in some cases.

- Immunoglobulin levels and the erythrocyte sedimentation rate are increased, rheumatoid factor is positive, and complement levels are low.
- Evidence of chronic hepatitis infection (particularly hepatitis C) frequently is identified.

Outcome

The clinical course depends on the underlying associated conditions and on the organs involved. Progressive renal disease is the most common systemic complication. Pulmonary hemorrhage can be life-threatening.

- Outcome depends on associated conditions and organs involved.
- Progressive renal disease is the most common systemic complication.

Vasculitis Associated With Connective Tissue Diseases

Obliterative Endarteropathy

Vascular involvement in rheumatoid arthritis can have various presentations. Vasculitis in patients with rheumatoid arthritis usually occurs only in seropositive (rheumatoid factor-positive) patients. Digital nail fold and nodule infarcts occur in some patients with active rheumatoid arthritis. Histopathologically, this is a bland, obliterative endarteropathy with intimal proliferation. Managing the rheumatoid arthritis itself is all that is needed, because these vasculopathic changes require no other therapy. A process similar to that of obliterative endarteropathy occurs in scleroderma and systemic lupus erythematosus. A renal arcuate artery vasculopathy is responsible for scleroderma renal crisis.

- Rheumatoid factor is invariably present in patients with rheumatoid arthritis who have vasculitis.

Small and Medium-Sized Vessel Vasculitis

Small vessel vasculitis or leukocytoclastic vasculitis with palpable purpura and systemic vasculitis (polyarteritis) can occur with seropositive nodular rheumatoid arthritis. A systemic necrotizing vasculitis, histopathologically indistinguishable from polyarteritis nodosa, complicates some cases of seropositive rheumatoid arthritis. Systemic lupus erythematosus can present with leukocytoclastic vasculitis or a polyarteritis-like picture. Sjögren syndrome uncommonly includes small vessel vasculitis, with either a polymorphonuclear leukocyte or a lymphocyte predominance. Type II cryoglobulins and vasculitis may complicate many different connective tissue diseases. Cryoglobulins should be assayed in any patient with an autoimmune disease in whom vasculitis develops.

- Rheumatoid arthritis, Sjögren syndrome, and systemic lupus erythematosus can present with skin-limited vasculitis or a polyarteritis-like picture.
- Cryoglobulins should be assayed in any patient with an autoimmune disease in whom vasculitis develops.

Large Vessel Vasculitis

Aortitis, an inflammation of the aortic root with dilatation and aortic insufficiency, occurs in a minority of patients with HLA-B27–associated spondyloarthropathies. Patients present with aortic valve insufficiency.

Atypical Vasculitic Syndromes: Differential Diagnosis

Patients may present with the classic features of one of the vasculitic syndromes described above. When they do not, a diagnostic approach to determine what type of vasculitis is present may prove difficult. Some patterns suggesting vasculitic disease and their differential diagnoses are listed in Tables 23-18 and 23-19 and Figure 23-6.

Skin Lesions Associated With Vasculitis

Palpable purpura suggests leukocytoclastic vasculitis, but this pathologic diagnosis does not define the clinical syndrome. Table 23-19 outlines the differential diagnosis of palpable purpura. Nodules or papules diagnosed as necrotizing granuloma on biopsy occur in Churg-Strauss syndrome, Wegener granulomatosis, rheumatoid arthritis, and, occasionally, systemic lupus erythematosus. Other nodules or papules without necrotizing granulomata can be the sign of angiocentric lymphoproliferative disorders or sarcoidosis or they may be related to inflammatory bowel disease. Urticarial or pustular lesions complicate hypocomplementemic vasculitis, inflammatory bowel arthritis syndrome, and Behçet syndrome. Livedo reticularis, which is associated with proliferative endarteropathy, occurs in connective tissue diseases and antiphospholipid antibody

Table 23-18 Acute Pulmonary-Renal Syndrome: Differential Diagnosis

Common
Wegener granulomatosis
Churg-Strauss syndrome
Goodpasture syndrome
Systemic small vessel vasculitis
Systemic lupus erythematosus (SLE)
Cryoglobulinemic vasculitis
Uncommon
Schönlein-Henoch purpura/vasculitis
Connective tissue disease (other than SLE)-associated vasculitis
Rheumatoid arthritis
Mixed connective tissue disease
Polychondritis
Behçet syndrome
Thrombotic thrombocytopenic purpura
Thromboembolic disease
Infectious pneumonia-associated hypersensitivity vasculitis
Streptococcus
Mycoplasma
Legionella

Table 23-19 Palpable Purpura: Differential Diagnosis

Polyarteritis
Churg-Strauss syndrome
Wegener granulomatosis
Schönlein-Henoch purpura/vasculitis
Cryoglobulinemic vasculitis
Connective tissue disease-associated vasculitis (rheumatoid arthritis, Sjögren syndrome, systemic lupus erythematosus)
Hypersensitivity vasculitis
Drugs, infection, malignancy

syndrome and in association with cholesterol emboli and many systemic necrotizing vasculitides.

- Urticarial or pustular lesions complicate hypocomplementemic vasculitis, inflammatory bowel arthritis syndrome, and Behçet syndrome.
- Livedo reticularis occurs in connective tissue diseases and antiphospholipid antibody syndrome.

Sinusitis and Vasculitis

Included in the differential diagnosis of sinusitis and presumed vasculitis are Wegener granulomatosis, Churg-Strauss syndrome, relapsing polychondritis, angiocentric lymphoproliferative disorders, sarcoidosis, nasopharyngeal carcinoma, and, occasionally, systemic bacterial or fungal infection.

Antirheumatic Drug Therapies

Colchicine and allopurinol treatments are considered in the section on gout.

Nonsteroidal Anti-Inflammatory Drugs (NSAIDs)

NSAIDs are among the most commonly prescribed medications in the world. There are no clear guidelines for selecting a particular NSAID on the basis of toxicity or efficacy. Patients vary in their responsiveness to different drugs. The various NSAIDs available permit individualization of therapy. All of them are equivalent to aspirin with regard to efficacy. They are all potent cyclooxygenase (COX) inhibitors or prodrugs of COX inhibitors. Clinical studies have not consistently found greater efficacy or tolerance for any one of these medications. NSAIDs are used to treat all types of arthritis and many types of soft tissue rheumatism.

- Patients vary in their responsiveness to different drugs.
- NSAIDs are all potent COX inhibitors or prodrugs of COX inhibitors.

Mechanisms of Action of NSAIDs

The mechanism of action of NSAIDs is incompletely understood. They decrease prostaglandin synthesis by inhibiting COX conversion of arachidonic acid to prostaglandin precursors. Prostaglandins cause vasodilatation, mediate pain, and potentiate the inflammatory effects of histamines and bradykinin. Furthermore, prostaglandins act as immunomodulators, influencing cellular and humoral immune responses. NSAIDs have potent analgesic effects that are related to their suppression of prostaglandin synthesis. Decreased levels of prostaglandin decrease the sensitivity of peripheral nerve receptors and may affect pain transmission. Acetaminophen is not a potent prostaglandin inhibitor in peripheral tissue. However, it does affect prostaglandin concentrations in neural tissue. This may explain the analgesic effect of acetaminophen. Acetaminophen, salicylates, and other NSAIDs are potent antipyretic medications.

- NSAIDs decrease prostaglandin synthesis by inhibiting COX conversion of arachidonic acid to prostaglandin precursors, explaining most of their therapeutic effects.
- Prostaglandins cause vasodilatation, mediate extravasation and pain sensation, potentiate inflammatory mediators, and influence cellular and humoral immunity.
- Acetaminophen is not a potent prostaglandin inhibitor in peripheral tissue.

Mechanisms of Toxicity of NSAIDs

Toxic reactions are due primarily to inhibition of COX-1 and prostaglandin production. Recent investigation has uncovered two forms of COX: COX-1 and COX-2. COX-1 is constitutively expressed in most tissues and produces the prostaglandin precursors needed for "housekeeping function." Prostaglandins protect the gastric mucosal barrier from autodigestion. Patients with renal

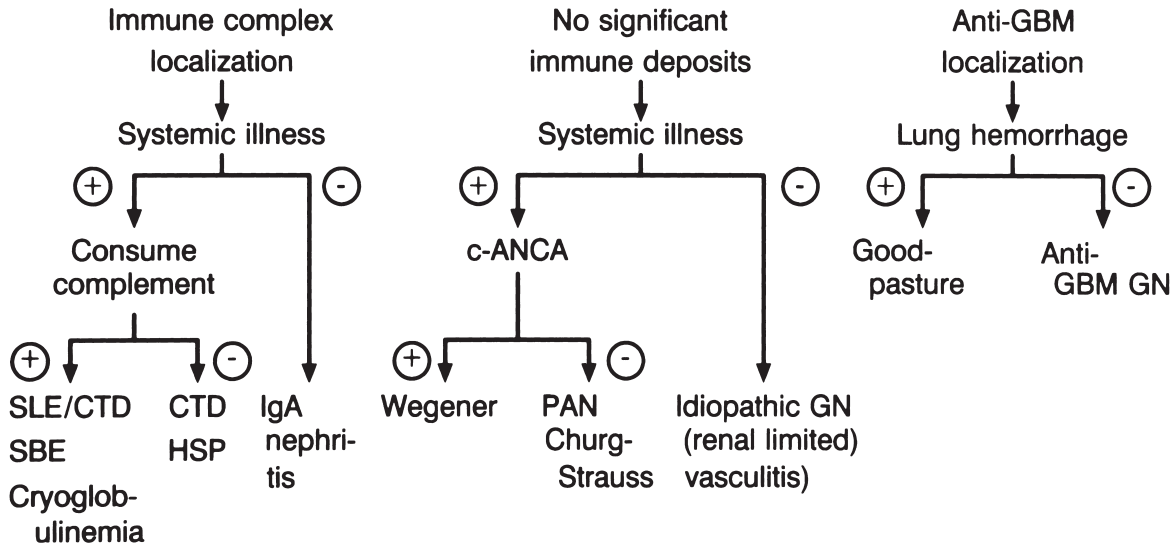

Fig. 23-6. Diagnostic approach to vasculitis. Disease pattern recognition. Focal segmental necrotizing glomerulonephritis (kidney biopsy). c-ANCA, antineutrophil cytoplasmic antibody with cytoplasmic staining; CTD, connective tissue disease; GBM, glomerular basement membrane; GN, glomerulonephritis; HSP, Henoch-Schönlein purpura; PAN, polyarteritis nodosa; SBE, subacute bacterial endocarditis; SLE, systemic lupus erythematosus. (Modified from Rosen S, Falk RJ, Jennette JC. Polyarteritis nodosa, including microscopic form and renal vasculitis. In: Churg A, Churg J, editors. Systemic vasculitides. New York: Igaku-Shoin Medical Publishers; 1991, p. 57-77. Used with permission.)

insufficiency or liver or cardiac disease may have prostaglandin-dependent renal blood flow. NSAIDs interfere with the synthesis of thromboxane via COX-1, which influences vascular tone, platelet aggregation, and hemostasis. COX-2 is not found in resting cells but is rapidly induced in activated fibroblasts, endothelial cells, and smooth muscle cells by cytokines, growth factors, and lipopolysaccharide. Simply viewed, the acute anti-inflammatory effects of NSAIDs relate to their ability to inhibit COX-2. The side effects of NSAIDs reside mostly with their ability to inhibit COX-1 and the "housekeeping function" associated with the prostaglandins synthesized by COX-1. Selective COX-2 inhibitors were developed to reduce the risk of gastrointestinal toxicity.

Blocking COX with currently available NSAIDs augments conversion of arachidonic acid to leukotrienes. Leukotrienes (previously known as "slow-reacting substance of anaphylaxis") aggravate asthma, rhinitis, hives, and nasal polyps.

- The acute anti-inflammatory action of NSAIDs is mediated by COX-2 inhibition.
- Toxic reactions are due primarily to inhibition of COX-1.
- Selective COX-2 inhibitors are available to reduce the risk of gastrointestinal toxicity.
- NSAIDs interfere with the synthesis of thromboxane and influence platelet function.
- Leukotrienes aggravate asthma, rhinitis, hives, and nasal polyps. NSAIDs may increase the production of leukotrienes.

NSAIDs are bound extensively to plasma proteins. Protein binding has obvious implications for other medications that are also protein-bound. Indomethacin, diclofenac, and piroxicam decrease lithium excretion. NSAIDs also can influence methotrexate toxicity at high doses (>50 mg/week) by interfering with the renal clearance of methotrexate. At the dose range of methotrexate used in rheumatic diseases, this is not a concern.

Most NSAIDs attenuate the effects of antihypertensive medications. Diuretics, β-adrenergic blockers, and angiotensin-converting enzyme inhibitors are the drugs affected most by the influence of NSAIDs on renal prostaglandins. Aspirin irreversibly inhibits COX-1. The effect of all the other NSAIDs on COX-1 is reversible. These drugs prolong bleeding time. Aspirin therapy needs to be discontinued for up to 10 days before the bleeding time returns to normal. NSAID therapy should be discontinued at least four drug half-lives before invasive procedures in which bleeding is a concern. NSAIDs with a short half-life are best when an acute effect (e.g., treatment of acute gout) is required. The half-life is proportional to the onset of maximal clinical benefit. The common side effects of NSAIDs are listed in Table 23-20.

- Diuretics, β-blockers, and angiotensin-converting enzyme inhibitors are the drugs affected most by the influence of NSAIDs on renal prostaglandins.
- Aspirin irreversibly inhibits COX-1.
- NSAIDs usually prolong the bleeding time.

Gastrointestinal Side Effects of NSAIDs

Twenty percent of chronic users of NSAIDs have gastric ulcer noted on endoscopy, and 15% to 35% report dyspepsia, but this complaint does not appear to be related to abnormal findings on endoscopy. Nausea and abdominal pain are described in up to 40% of users of NSAIDs. Stomach upset or pain forces discontinuation

of therapy with these drugs in more than 10% of patients. Gastrointestinal blood loss related to these drugs is most often occult and can result in iron deficiency anemia. The true incidence of significant gastrointestinal bleeding requiring hospitalization or operation or resulting in death is unknown. However, the elderly, persons with considerable cardiovascular morbidity, and persons with a previous history of NSAID-associated ulcer are at greatest risk for significant gastrointestinal toxicity related to NSAIDs. These patients are the most likely candidates to benefit from the risk reduction of selective COX-2 inhibitors. Alcohol, corticosteroid, or tobacco use also predisposes to the development of gastrointestinal toxicity.

- Of chronic users of NSAIDs, 20% have gastric ulcer and 15%-35% have dyspepsia.
- Stomach upset or pain forces discontinuation of therapy with these drugs in >10% of patients.
- Gastrointestinal blood loss related to these drugs is most often occult.
- A small number of NSAID users are at risk of increased gastrointestinal toxicity and may be candidates for a selective COX-2 inhibitor.

Other Toxic Effects of NSAIDs

Central nervous system symptoms such as headaches, dizziness, mood alterations, blurred vision, and confusion are reported most frequently with the use of indomethacin. Ibuprofen, tolmetin, and sulindac have been associated with aseptic meningitis in patients with systemic lupus erythematosus. All the central nervous system effects resolve when the use of NSAIDs is discontinued. Rashes, urticaria, exfoliative dermatitis, erythema multiforme, and scalded skin syndrome or toxic epidermal necrolysis all occur, albeit rarely, with the use of NSAIDs. Easy bruisability is a common complaint of chronic users of these drugs. Dependent petechiae may develop if platelet function is already compromised. Pulmonary infiltrates, bronchospasm, and anaphylaxis may occur with all NSAIDs, including aspirin. Although it is not IgE-mediated, anaphylaxis occurs most commonly in patients who have the classic triad of asthma, nasal polyps, and aspirin sensitivity. Combination therapy with NSAIDs should be avoided. Whereas toxicity is additive, there is no evidence that the therapeutic effect is additive. Recently, selective COX-2 inhibitors have been associated with increased cardiovascular complications. As a result, some agents have been removed from the market.

- Combination therapy with two different NSAIDs should be avoided.

Nonacetylated Salicylates

Careful studies have not identified significant differences in efficacy of nonacetylated salicylates compared with NSAIDs. Nonacetylated salicylates (e.g., salsalate) minimally inhibit COX-1 and are about half as potent as aspirin for inhibiting COX-2. Although their use decreases the incidence of gastrointestinal bleeding, they can cause many of the gastrointestinal symptoms that influence patient compliance. Tinnitus remains a potential problem. Nonacetylated

Table 23-20 Common Side Effects of Nonsteroidal Anti-inflammatory Drugs

Gastrointestinal
Nausea
Abdominal pain
Constipation or diarrhea
Occult blood loss and iron deficiency anemia
Peptic ulcer disease
Colitis and colonic hemorrhage
Renal
Reduced renal blood flow
Reduced glomerular filtration rate
Increased creatinine clearance
Pyuria
Interstitial nephritis
Papillary necrosis
Nephrotic syndrome
Hyperkalemia and type IV renal tubular acidosis
Fluid retention
Hematologic
Bone marrow suppression
Agranulocytosis
Aplastic anemia
Iron deficiency anemia
Platelet-aggregating defect
Neurologic
Delirium/confusion
Headache
Dizziness
Blurred vision
Mood swings
Aseptic meningitis
Dermatologic
Urticaria
Erythema multiforme
Exfoliative syndromes (toxic epidermal necrolysis)
Oral ulcers
Dermatitis
Pulmonary
Pulmonary infiltrates
Noncardiac pulmonary edema (aspirin toxicity)
Anaphylaxis and bronchospasm
Nasal polyps
Drug interactions
Augment hemostatic effect of warfarin
Attenuate antihypertensive effect of diuretics, β-blockers, angiotensin-converting enzyme inhibitors
Influence drug metabolism
Methotrexate (high doses only)
Lithium
Oral hypoglycemic agents

salicylates do not interfere with renal blood flow, and they do not inhibit platelet function. They usually can be safely prescribed for patients with aspirin allergy.

- Nonacetylated salicylates minimally inhibit COX-1.
- Nonacetylated salicylates do not interfere with renal blood flow, and they do not inhibit platelet function.
- Nonacetylated salicylates can cause stomach upset or tinnitus.

Disease-Modifying Antirheumatic Drugs

Antimalarial Compounds (Hydroxychloroquine)

Open and randomized placebo-controlled studies have confirmed the benefit of hydroxychloroquine in the management of rheumatoid arthritis and systemic lupus erythematosus. The dose typically does not exceed 4.5 mg/kg daily. Retinopathy is the major toxic effect associated with the use of hydroxychloroquine. The risk of irreversible retinopathy is small (<3%) in patients taking less than 4.5 mg/kg daily. The elderly may be at somewhat increased risk. Regular eye examinations can identify the premaculopathy stage of the toxic reaction, which is reversible. Permanent symptomatic retinopathy is preventable when patients have eye examinations every 6 to 12 months.

- Retinopathy is the major toxic effect associated with the use of hydroxychloroquine.
- The risk of irreversible retinopathy is small (<3%) in patients taking <4.5 mg/kg daily.

The clinical response to hydroxychloroquine does not appear before 8 weeks. Improvement may not occur until 6 months of continuous therapy. Approximately 40% to 60% of patients with rheumatoid arthritis may respond (based on established criteria for response). It is used most commonly in combination with NSAIDs or low doses of corticosteroids in patients with early or mild polyarthritis.

- The clinical response to hydroxychloroquine does not appear before 8 weeks and may not occur until 6 months of continuous therapy.

Sulfasalazine

Enteric-coated tablets of sulfasalazine have reduced some of the immediate gastrointestinal upset associated with this drug. The metabolites of sulfasalazine include 5-aminosalicylic acid and sulfapyridine. The results of short-term randomized trials indicate significant efficacy in mild-to-moderate rheumatoid arthritis. Rheumatologists also recommend treatment with sulfasalazine for seronegative spondyloarthropathies and psoriatic arthritis; however, peripheral arthritis responds more effectively than axial or spinal inflammation. The benefit of this drug in rheumatoid arthritis is equal to that of intramuscular injections of gold but with fewer toxic effects. Sulfasalazine treatment is usually reserved for early or milder cases of inflammatory polyarthritis. Although the onset of efficacy occurs as early as 8 weeks, the effect may not be documented for as long as 6 months. The toxic effects include nausea, vomiting, gastric ulcers, and, more rarely, hepatitis or cholestasis. Ten percent of patients complain of headache or sense of fatigue. Recently, a combination of sulfasalazine, hydroxychloroquine, and methotrexate was found to be superior to single-drug therapy for patients with rheumatoid arthritis in whom treatment with at least one DMARD had failed.

- Sulfasalazine treatment is usually reserved for early or milder cases of inflammatory polyarthritis.
- Sulfasalazine is used in combination with methotrexate and hydroxychloroquine for refractory rheumatoid arthritis.

Methotrexate

Methotrexate is a structural analogue of folic acid and is considered an antimetabolite rather than a cytotoxic agent. It is used extensively in rheumatoid arthritis and also has a place in the treatment of psoriatic arthritis and peripheral arthritis of seronegative spondyloarthropathies. Methotrexate may have a role in the treatment of arthritis in systemic lupus erythematosus and scleroderma. Its mechanism of action includes inhibition of folate metabolism (critical in nucleotide production), inhibition of leukotriene B_4, and increasing intracellular adenosine. It has both immunomodulatory and anti-inflammatory effects. Its strongest effect is on rapidly dividing cells, particularly those in the S phase of the cell cycle. Methotrexate is unique among the first-line disease-modifying antirheumatic drugs because its antirheumatic effect occurs within 4 to 6 weeks. Oral, subcutaneous, intramuscular, and intravenous routes are equally effective for low dosages.

- Methotrexate is used extensively in rheumatoid arthritis and has a place in the treatment of psoriatic arthritis, peripheral arthritis of seronegative spondyloarthropathies, and the arthritis in systemic lupus erythematosus and scleroderma.
- The antirheumatic effect occurs within 4-6 weeks.

In patients with rheumatoid arthritis receiving methotrexate, 80% have substantial improvement within the first year of therapy. At 5 years, it is estimated that at least 35% of patients treated with methotrexate still take it. No other DMARD has this combination of efficacy and tolerability. Most patients with rheumatoid arthritis have a severe flare of their disease within 3 weeks after discontinuation of methotrexate therapy. This drug should not be used in patients with significant renal dysfunction (creatinine >2.0 mg/dL). Coadministration of trimethoprim-sulfamethoxazole and methotrexate increases the risk of hematologic toxicity.

- 80% of rheumatoid arthritis patients taking methotrexate have substantial improvement within the first year of treatment.
- Most patients with rheumatoid arthritis have a severe flare of their disease within 3 weeks after discontinuation of methotrexate therapy.

Gastrointestinal toxic reactions are common side effects of methotrexate. Nausea and vomiting may persist for 24 to 48 hours after ingestion. Stomatitis and diarrhea are insurmountable problems for some patients. Methotrexate treatment should be withheld from patients

with significant gastric ulceration until their ulcers have healed. Methotrexate should not be used in patients with significant liver disease. Increased liver enzyme levels suggest a subclinical hepatic toxic effect due to methotrexate. Persistent increase in aspartate aminotransferase levels or decreasing albumin levels are markers for developing hepatic fibrosis and, potentially, cirrhosis. Cryptic cirrhosis may develop without liver enzyme abnormalities being detected. Stomatitis and the less common hematologic abnormalities such as leukopenia, thrombocytopenia, and pancytopenia may respond to folic acid supplementation. Pulmonary toxic side effects include chemical pneumonitis and insidious pulmonary fibrosis, beginning with a dry cough. Acute pneumonitis due to methotrexate may be associated with eosinophilia. Neurologic features such as headache and seizure are uncommon. Methotrexate is teratogenic and should be withheld for 3 months before the patient attempts to conceive.

Supplemental folic acid, 1 mg daily, is provided to patients taking methotrexate. This strategy often reduces mild side effects and may help to prevent cytopenia and liver toxicity.

- Gastrointestinal toxic reactions are common side effects of methotrexate.
- Methotrexate should not be used in patients with significant liver disease.
- Stomatitis and diarrhea are insurmountable problems for some patients.

Leflunomide

Leflunomide is an immunoregulatory agent that interferes with pyrimidine synthesis and is approved for the treatment of rheumatoid arthritis. Its efficacy may be comparable to that of methotrexate and is noted within 12 weeks after initiation of therapy. Toxic effects are also comparable to those of methotrexate, although no pulmonary complications have been reported. The most common side effects include gastrointestinal distress, rashes, and alopecia. The monitoring of side effects, including cytopenias and liver toxicity, that is recommended currently is the same as that recommended for methotrexate. This drug is a teratogen and must be avoided in pregnancy. A protocol with cholestyramine is used to accelerate the clearance of leflunomide.

Azathioprine

Azathioprine and its metabolites are purine analogues. It is considered a cytotoxic agent. Azathioprine is metabolized by xanthine oxidase and thiopurine methyltransferase. Allopurinol, an inhibitor of xanthine oxidase, delays the metabolism of azathioprine and can lead to toxic reactions if the dose of azathioprine is not decreased by 50% to 66%. Thiopurine methyltransferase can be assayed; low levels of this enzyme predict the 1 in 300 patients in whom a severe hematologic reaction to azathioprine will develop. Controlled studies have documented the efficacy of azathioprine in the treatment of rheumatoid arthritis and systemic lupus erythematosus.

The most common toxic effects of azathioprine are gastrointestinal effects and cytopenias. An idiosyncratic, acute pancreatitis-like attack is an absolute contraindication to further treatment with this drug. Cholestatic hepatitis is rare, but if it occurs, it generally does so within the first several weeks after drug administration. If tolerated initially, hematologic toxic effects become the most significant concern. In patients who have undergone organ transplant, azathioprine treatment increases the risk of neoplasia, particularly lymphomas, leukemias, and skin and cervical malignancies. Azathioprine does not alter fertility, but it may have some teratogenic potential. For pregnant women, azathioprine should be reserved for those with severe or life-threatening rheumatic diseases.

- Azathioprine is a cytotoxic agent.
- The most common toxic effects of azathioprine are gastrointestinal effects and cytopenias.
- Allopurinol should be avoided in patients taking azathioprine.

Cyclophosphamide

Cyclophosphamide is a potent alkylating agent. It acts on dividing and nondividing cells, interfering with cellular DNA function. It depletes T cells and B cells, causing considerable immunosuppression. Oral cyclophosphamide is well absorbed and completely metabolized within 24 hours, and most of its metabolites are excreted in the urine. Allopurinol increases the risk of leukopenia in patients taking cyclophosphamide. Short-term studies document significant efficacy of this drug in the treatment of rheumatoid arthritis at doses of 1 to 2 mg/kg per day. Unequivocal healing and arrest of erosive change occur. The considerable toxicity associated with chronic administration of cyclophosphamide limits its use in rheumatoid arthritis to very severe cases, often with complicating vasculitis. It is the drug of choice in the treatment of generalized Wegener granulomatosis. Intravenous administration of cyclophosphamide is efficacious in managing systemic necrotizing vasculitis and severe systemic lupus erythematosus, including proliferative glomerulonephritis. Short-term advantages of intravenous pulse of cyclophosphamide may include fewer toxic effects on the bladder and perhaps a lower risk of infection.

- Cyclophosphamide depletes T cells and B cells, causing considerable immunosuppression.
- Cyclophosphamide is efficacious in managing systemic necrotizing vasculitis and severe systemic lupus erythematosus.

Dose-related bone marrow suppression is common in patients receiving cyclophosphamide and requires close laboratory monitoring. Immunosuppression from treatment with cyclophosphamide increases the risk of infection. Herpes zoster infection occurs in most patients receiving the drug orally. Cyclophosphamide directly affects ovarian and testicular function. Premature ovarian failure frequently occurs in premenopausal lupus patients taking the drug. Spermatogenesis also can be affected by this drug, which causes atrophy of seminiferous tubules. Cyclophosphamide has teratogenic potential. Alopecia, stomatitis, cardiomyopathy (with drug doses used to treat cancer), and pulmonary fibrosis may complicate cyclophosphamide therapy. The metabolites of this drug, including acrolein, accumulate in the bladder. Acrolein has direct mucosal toxic effects and causes hemorrhagic cystitis. This complication is potentially life-threatening. The chronic use of cyclophosphamide taken orally is associated with

an increased risk of neoplasia, including hematologic and bladder malignancies. The risk of malignancy with intravenous pulse therapy has not been established. All patients who have had cyclophosphamide therapy should have urinalysis and urine cytology performed at regular intervals for life.

- Dose-related bone marrow suppression is common in patients receiving cyclophosphamide.
- Cyclophosphamide directly affects ovarian and testicular function.
- The chronic use of cyclophosphamide is associated with an increased risk of neoplasia.

Glucocorticosteroids

Glucocorticosteroids modify the inflammatory response dramatically. They are potent inhibitors of neutrophil function. Glucocorticosteroids suppress cellular immune activity and, to a lesser extent, inhibit the humoral response. Low doses of glucocorticosteroids (<10 mg of prednisone per day) are frequently used in the day-to-day management of the articular manifestations of rheumatoid arthritis. At least one-third of all patients with rheumatoid arthritis take glucocorticosteroids chronically. High doses of glucocorticosteroids (1-2 mg of prednisone per kilogram of body weight) may be required for life-threatening or serious inflammatory disorders, including systemic vasculitis and complications of systemic lupus erythematosus. Prednisone doses of more than 30 mg/day are associated with a higher risk of infection, including *Pneumocystis carinii*. This is particularly the case if prednisone is given in addition to cyclophosphamide, azathioprine, or methotrexate. Many clinicians add one double-strength trimethoprim-sulfamethoxazole tablet twice a week to these immunosuppressive regimens as prophylaxis against *Pneumocystis* infection.

- Glucocorticosteroids are potent inhibitors of neutrophil function.
- They suppress cellular immune activity and, to a lesser extent, inhibit the humoral response.
- One-third of all patients with rheumatoid arthritis take glucocorticosteroids chronically.

These drugs have many side effects; these are not idiosyncratic but actually unwanted effects of the medication. The duration of treatment and the dose used determine how fast an unwanted effect appears. Many patients with rheumatoid arthritis tolerate prednisone doses of 1 to 5 mg/day for years without having serious side effects. Patient concerns about glucocorticosteroids include weight gain from increased appetite, water retention, and hirsutism. Longer-term concerns include thinning of the skin, easy bruising, progressive osteoporosis (unclear if this happens with physiologic doses of prednisone) and compression fractures, high blood pressure, glucose intolerance, cataract formation, and aggravation of glaucoma. Glucocorticosteroids interfere with wound healing and increase the risk of opportunistic infection. Steroid-induced osteoporosis should be anticipated, and patients should be treated with calcium, vitamin D supplementation, and oral bisphosphonates. The psychoactive potential of high doses of glucocorticosteroids is an additional factor in treating older patients. Glucocorticosteroid psychosis can complicate the diagnosis of neuropsychiatric lupus.

- Many patients with rheumatoid arthritis tolerate prednisone doses in the 1-5 mg/day range for years without having serious side effects.
- Long-term concerns: thinning of the skin, progressive osteoporosis and compression fractures, high blood pressure, glucose intolerance, cataract formation, and aggravation of glaucoma.
- Glucocorticosteroid psychosis can complicate the diagnosis of neuropsychiatric lupus.
- Glucocorticosteroids interfere with wound healing and increase the risk of opportunistic infection.
- Bisphosphonates, calcium, and vitamin D are used to reduce the risk of glucocorticoid osteoporosis.

Anticytokine Therapies

Appreciation of the role of tumor necrosis factor-α and interleukin-1 in the inflammatory process in rheumatoid arthritis has led to the development of specific inhibitors of these cytokines. Tumor necrosis factor antagonists include neutralizing antibodies (infliximab and adalimunab) and soluble receptor recombinant fusion protein (etanercept). Anakinra is a recombinant interleukin-1 receptor antagonist. Anti-cytokine therapies are very expensive. Their roles in the management of rheumatoid arthritis are still being defined. Because of evidence that they delay radiographic progression, they are usually added to other therapies such as methotrexate when the disease has not been adequately controlled. The primary risk of these agents, especially the tumor necrosis factor inhibitors, is infection. Reactivation of latent tuberculosis is a major concern, and potential candidates for tumor necrosis factor inhibitors must be evaluated with tuberculin testing before treatment.

Part II

William W. Ginsburg, MD

Crystalline Arthropathies

Hyperuricemia and Gout

Hyperuricemia has been described in 2% to 18% of normal populations. Hyperuricemia is associated with hypertension, renal insufficiency, obesity, and arteriosclerotic heart disease. The prevalence of clinical gouty arthritis ranges from 0.1% to 0.4%. There is a family history of gout in 20% of patients with gouty arthritis. Genetic studies suggest a multifactorial inheritance pattern. Of patients with hyperuricemia whose uric acid level is more than 9 mg/dL, gout develops in 5 years in approximately 20%.

- Hyperuricemia is associated with hypertension, renal insufficiency, obesity, and arteriosclerotic heart disease.
- The prevalence of gouty arthritis is 0.1%-0.4%.
- 20% of patients with gouty arthritis have a family history of gout.
- In patients with a uric acid level more than 9 mg/dL, gout develops in 20% in 5 years.

Ninety percent of patients with gout have underexcretion of uric acid. They have reduced filtration of uric acid, enhanced tubular reabsorption, or decreased tubular secretion. Overproduction of uric acid is the cause of hyperuricemia in approximately 10% of patients with primary gout. Of these 10%, about 15% have one of the two X-linked inborn errors of purine metabolism: 1) hypoxanthine-guanine phosphoribosyltransferase deficiency (Lesch-Nyhan syndrome) and 2) 5-phosphoribosyl-1-pyrophosphate synthetase overactivity. Of the remaining 85% of patients who have overproduction, most are obese, but the cause of overproduction and the relationship between obesity and overproduction of uric acid remain unknown.

- 10% or less of patients with gout have overproduction of uric acid.

Events leading to initial crystallization of monosodium urate in a joint after many years of asymptomatic hyperuricemia are unknown. Trauma with disruption of microtophi in cartilage may lead to release of urate crystals into synovial fluid. The urate crystals become coated with immunoglobulin and then complement. They are then phagocytosed by leukocytes with subsequent release of chemotactic protein, activation of the kallikrein system, and disruption of the leukocytes, which release lysosomal enzymes into synovial fluid.

Important Enzyme Abnormalities in the Uric Acid Pathway (Fig. 23-7)

Lesch-Nyhan syndrome is a complete deficiency of hypoxanthine-guanine phosphoribosyltransferase. It is characterized by an X-linked disorder in young boys, hyperuricemia, self-mutilation, choreoathetosis, spasticity, growth retardation, and severe gouty arthritis.

Overactivity of 5-phosphoribosyl-1-pyrophosphate synthetase is associated with hyperuricemia, X-linked genetic inheritance, and gouty arthritis.

Adenosine deaminase deficiency is inherited in an autosomal recessive pattern. It causes a combined immunodeficiency state with

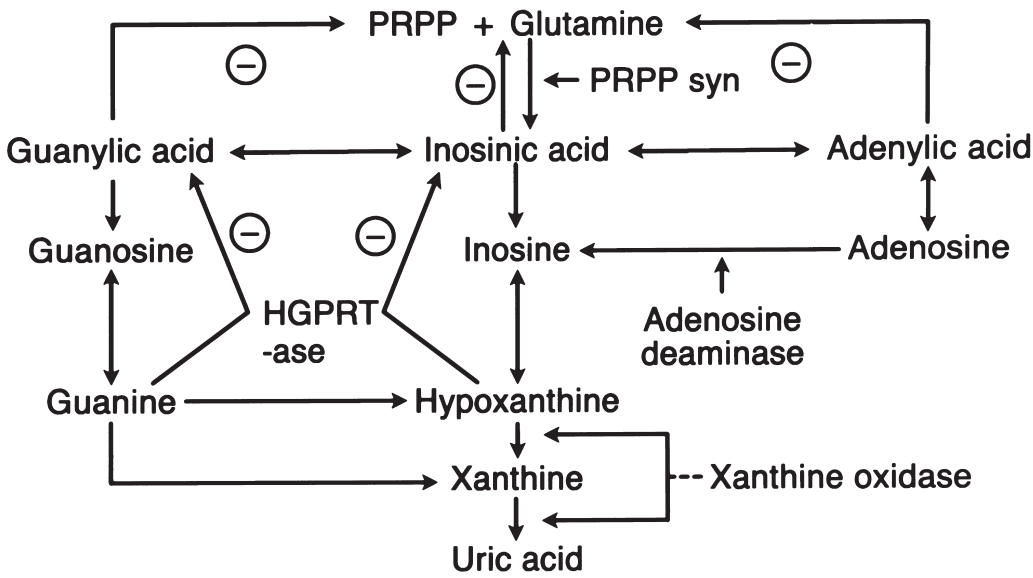

Fig. 23-7. Purine metabolism. HGPRTase, hypoxanthine-guanine phosphoribosyltransferase; PRPP, phosphoribosylpyrophosphate; PRPP syn, phosphoribosylpyrophosphate synthetase; ⊖, feedback inhibition.

severe T-cell and mild B-cell dysfunction. There is a buildup of deoxyadenosine triphosphate in lymphocytes, which is toxic to immature lymphocytes. Features of the disorder are hypouricemia, recurrent infection, chondro-osseous dysplasia, and an increased deoxyadenosine level in plasma and urine. Treatment for the disorder is with irradiated frozen red blood cells or marrow transplantation.

Xanthine oxidase deficiency is also inherited in an autosomal recessive pattern. It is characterized by hypouricemia, xanthinuria with xanthine stones, and myopathy associated with deposits of xanthine and hypoxanthine.

Causes of Secondary Hyperuricemia

Secondary hyperuricemia can be attributed to overproduction or underexcretion of uric acid (Table 23-21).

- Important causes of overproduction of uric acid include cancer, psoriasis, and sickle cell anemia.
- Important causes of underexcretion of uric acid include chronic renal insufficiency, lead nephropathy, alcohol, diabetic ketoacidosis, and drugs, notably thiazide diuretics, nicotinic acid, and cyclosporine.

Causes of Hypouricemia

Increased urinary excretion of uric acid contributes to hypouricemia. It can develop in healthy persons with an isolated defect in tubular reabsorption of uric acid. It also can be related to diminished reabsorption of urate, such as in Fanconi syndrome, Fanconi syndrome associated with Wilson disease, carcinoma of the lung, acute myelogenous leukemia, light-chain diseases, and use of outdated tetracycline. Malignant neoplasms, such as carcinoma, Hodgkin disease, and sarcoma, also are associated with increased excretion of uric acid. Hypervolemia caused by inappropriate secretion of antidiuretic hormone also can be a factor. Drugs involved in increased excretion of uric acid are high-dose aspirin, probenecid and other uricosuric agents, and glyceryl guaiacolate. Radiographic contrast agents that can cause hypouricemia are iopanoic acid (Telopaque), iodipamide meglumine (Cholografin), and diatrizoate sodium (Hypaque). It also can occur in severe liver disease.

Decreased synthesis of uric acid also can cause hypouricemia. The drug allopurinol inhibits the enzyme xanthine oxidase, causing hypouricemia. The decrease also can be caused by congenital deficiencies in enzymes involved in purine biosynthesis: 5-phosphoribosyl-1-pyrophosphate synthetase deficiency, adenosine deaminase deficiency, purine nucleoside phosphorylase deficiency, and xanthine oxidase deficiency (xanthinuria). Acquired deficiency in xanthine oxidase activity (metastatic adenocarcinoma of lung) also can cause decreased synthesis of uric acid, as can acute intermittent porphyria.

Factors Predisposing to Gout and Pseudogout

The following can predispose to an attack of gout or pseudogout: trauma, operation (3 days after), major medical illness (myocardial infarction, cerebrovascular accident, pulmonary embolus), fasting, alcohol use, infection, and acidosis. The attacks are precipitated by changes in the urate equilibrium between the blood and joints.

Table 23-21 Causes of Secondary Hyperuricemia

Overproduction of uric acid
Myeloproliferative disorders
Polycythemia, primary or secondary
Myeloid metaplasia
Chronic myelocytic leukemia
Lymphoproliferative disorders
Chronic lymphocytic leukemia
Plasma cell proliferative disorders
Multiple myeloma
Disseminated carcinoma and sarcoma
Sickle cell anemia, thalassemia, and other forms of chronic hemolytic anemia
Psoriasis
Cytotoxic drugs
Infectious mononucleosis
Obesity
Increased purine ingestion
Underexcretion of uric acid
Intrinsic renal disease
Chronic renal insufficiency of diverse cause
Saturine gout (lead nephropathy)
Drug-induced
Thiazide diuretics, furosemide, ethacrynic acid, ethambutol, pyrazinamide, low-dose aspirin, cyclosporine, nicotinic acid, laxative abuse, levodopa
Endocrine conditions
Adrenal insufficiency, nephrogenic diabetes insipidus, hyperparathyroidism, hypoparathyroidism, pseudohypoparathyroidism, hypothyroidism
Metabolic conditions
Diabetic ketoacidosis, lactic acidosis, starvation, ethanolism, glycogen storage disease type I, Bartter syndrome
Other
Sarcoidosis
Down syndrome
Beryllium disease

- Factors that precipitate gout and pseudogout include trauma, operation, alcohol use, and acidosis.

Clinical Manifestations of Acute Gout

In 50% of patients with gout, the metatarsophalangeal joint of the great toe is involved initially (podagra), and this joint is eventually involved in more than 75% of patients. Rapid joint swelling is associated with extreme tenderness. Uric acid crystals, which are needle-shaped and strongly negatively birefringent under polarized light, are always found in the joint during an acute attack. The diagnosis of gout is established by the demonstration of uric acid crystals in the joint aspirate. The joint fluid is usually inflammatory, and the polymorphonuclear neutrophil count is between 5 and 75 $\times 10^9$/L.

Gout occurs most commonly in middle-aged men, but, after menopause, the incidence of gout in women increases. Although gout is usually monarticular and usually involves the joints in the lower extremity, attacks may become polyarticular over time in some patients.

- Podagra is the initial presentation of gout in 50% of cases.
- Uric acid crystals are negatively birefringent under polarized light microscopy.
- Gout is usually monarticular and most often involves the joints in the lower extremities.
- Typical clinical scenario: Pain, swelling, redness, and tenderness develop over the right metatarsophalangeal joint of the great toe 3 days after myocardial infarction in an elderly patient. Aspiration of the joint shows needle-like crystals, which are strongly negatively birefringent under polarized light. Joint fluid has a polymorphonuclear neutrophil value of 50×10^9/L.

Treatment of Acute Gouty Arthritis

Indomethacin or other nonsteroidal anti-inflammatory drugs (NSAIDs) are the drugs of choice for the treatment of acute gouty arthritis and should be used for a 7- to 10-day course. These drugs are relatively contraindicated in patients with congestive heart failure, active peptic ulcer disease, or renal insufficiency. NSAIDs should not be used in patients with nasal polyps and aspirin sensitivity because they may cause bronchospasm.

- NSAIDs are the initial drugs of choice for an acute attack of gouty arthritis.
- NSAIDs should be avoided in patients with congestive heart failure, peptic ulcer disease, and renal insufficiency.

Intra-articular or oral corticosteroids and subcutaneous adrenocorticotropic hormone are other treatments, especially in patients who have contraindications to colchicine and NSAIDs. Oral corticosteroids may need to be given for 10 days to avoid relapses. Allopurinol or probenecid should not be administered until the acute attack completely subsides. Because of severe gastrointestinal side effects, high-dose oral colchicine is rarely used for an acute attack. Intravenously administered colchicine in a single dose (1-2 mg) has no gastrointestinal side effects. It has increased toxicity in patients with renal insufficiency, bone marrow depression, sepsis, and immediate prior use of oral colchicine. Repeat dosages should be avoided. It can cause severe skin necrosis if it infiltrates into subcutaneous tissues.

- Colchicine has the potential for gastrointestinal side effects with the oral form, but there are no gastrointestinal side effects with single-dose intravenous administration.
- Avoid intravenous colchicine in patients with renal insufficiency, bone marrow depression, sepsis, or immediate prior use of oral colchicine.

Treatment During Intercritical Period

Oral colchicine, 0.6 mg twice a day, should be given prophylactically with probenecid or allopurinol for 6 to 12 months to prevent exacerbation of acute gout.

Probenecid inhibits tubular reabsorption of filtered and secreted urate, thereby increasing urinary excretion of uric acid. It should not be used if the patient has a history of kidney stones or if the 24-hour urine uric acid value is more than 1,000 mg (normal, less than 600 mg/day). Probenecid delays the renal excretion of indomethacin and thereby increases its blood level. Probenecid delays the renal excretion of acetylsalicylic acid (ASA), and ASA completely blocks the uricosuric effect of probenecid. ASA also blocks tubular secretion of urates. Probenecid should not be used with methotrexate because probenecid increases methotrexate blood levels, increasing toxicity.

- Probenecid inhibits tubular reabsorption of filtered and secreted urate.
- Probenecid should not be used if the patient has a history of kidney stones or if 24-hour uric acid value is more than 1,000 mg.
- Probenecid delays renal excretion of indomethacin and ASA.

Allopurinol is a xanthine oxidase inhibitor. It is the drug of choice to prevent gouty attacks if the patient has a history of renal stones, tophi, or renal insufficiency. Allopurinol also can precipitate gout. Allopurinol and probenecid usually are not used simultaneously unless the patient has extensive tophaceous gout with good renal function. Allopurinol can cause a rash and a severe toxicity syndrome consisting of eosinophilia, fever, hepatitis, decreased renal function, and an erythematous desquamative rash. This syndrome usually occurs in patients with decreased renal function. Allopurinol should be given in the lowest dose possible to keep the uric acid value less than 6 mg/dL. If allopurinol is used in conjunction with 6-mercaptopurine or azathioprine, the dose of 6-mercaptopurine or azathioprine needs to be reduced at least 25% or bone marrow toxicity can occur. Both of these drugs are metabolized by xanthine oxidase, which allopurinol inhibits. Patients who have had transplantation frequently receive both medications.

- Allopurinol is a xanthine oxidase inhibitor.
- Allopurinol can precipitate gout.
- It is the drug of choice if patient has a history of renal stones, tophi, or renal insufficiency.
- Allopurinol can cause a severe toxicity syndrome: eosinophilia, fever, hepatitis, decreased renal function, and erythematous desquamative rash.

The indications for use of allopurinol rather than probenecid for lowering the uric acid level are tophaceous gout, gout complicated by renal insufficiency, uric acid excretion more than 1,000 mg/day, history of uric acid calculi, use of cytotoxic drugs, and allergy to uricosuric agents. Allopurinol should be used before treatment of rapidly proliferating tumors. The nucleic acid liberated with cytolysis is converted to uric acid and can cause renal failure due to precipitation of uric acid in collecting ducts and ureters (acute tumor lysis syndrome). Patients also should have adequate hydration and alkalinization of the urine before chemotherapy.

- Indications for allopurinol include tophaceous gout, gout complicated by renal insufficiency, history of uric acid calculi, and use of cytotoxic drugs.

Renal Disease and Uric Acid

Renal function is not necessarily adversely affected by an increased serum urate concentration. The incidence of interstitial renal disease and renal insufficiency is no greater than that in patients of comparable age with similar degrees of hypertension, arteriosclerotic heart disease, diabetes, and primary renal disease. Correction of hyperuricemia (to 10 mg/dL or less) has no apparent effect on renal function.

Most rheumatologists do not treat asymptomatic hyperuricemia if the uric acid level is less than 10.0 mg/dL (normal, to 8.0). When hyperuricemia is associated with a urinary uric acid of more than 1,000 mg/24 hours, which increases the risk of uric acid stones, renal function should be monitored closely. Excessive exposure to lead may contribute to the renal disease found in some patients with gout.

- Renal function is not necessarily adversely affected by an increased serum urate concentration.
- Correction of hyperuricemia (to 10 mg/dL or less) has no apparent effect on renal function.

Miscellaneous Points of Importance

- Positive diagnosis of a crystalline arthritis requires identification of crystal by polarization microscopy.
- Allopurinol therapy should not be started during an acute attack of gout.
- 30% of patients with chronic tophaceous gout are positive for rheumatoid factor (usually weakly positive).
- 10% of patients with acute gout are positive for rheumatoid factor (usually weakly positive).
- 5%-10% of patients will have a gout and a pseudogout attack simultaneously.
- 50% of synovial fluids aspirated from first metatarsophalangeal joints of asymptomatic patients with gout have crystals of monosodium urate.
- Up to 20% of patients with acute gout have a normal level of serum uric acid at the time of the acute attack.
- Gout in a premenopausal female is very unusual.
- Sulfinpyrazone is also uricosuric and potentially therapeutic.
- There have been many recent reports of superimposed gout occurring in Heberden and Bouchard nodes in older women taking thiazide diuretics.
- A septic joint can trigger a gout or pseudogout attack in a predisposed person. Synovial fluid should always be analyzed for crystals, Gram stain, and culture.
- The frequency of gout in patients who have had cardiac transplantation is high (25%). (Both cyclosporine and diuretics cause hyperuricemia.)

Calcium Pyrophosphate Deposition Disease

Etiologic Classification

Calcium pyrophosphate deposition (CPPD) is classified as idiopathic, hereditary, or associated with metabolic disease. The associated diseases include hyperparathyroidism, hemochromatosis-hemosiderosis, hypothyroidism, gout, hypomagnesemia, hypophosphatasia, Wilson disease, and ochronosis.

- CPPD associations include hyperparathyroidism, hemochromatosis-hemosiderosis, hypothyroidism, and hypomagnesemia.

Pseudogout

When CPPD causes an acute inflammatory arthritis, the term *pseudogout* is applied. CPPD crystals are weakly positively birefringent and are rhomboid. Pseudogout rarely involves the first metatarsophalangeal joint. It most commonly affects the knees, but the wrists, elbows, ankles, and intervertebral disks may be involved. It usually occurs in older individuals. Most patients with pseudogout have chondrocalcinosis on radiography. The presence of chondrocalcinosis does not necessarily mean that a patient will have pseudogout or even CPPD.

- Pseudogout is an acute inflammatory arthritis caused by CPPD.
- CPPD crystals are weakly positively birefringent under polarized light microscopy.
- Pseudogout most commonly affects the knees, but the wrists, elbows, ankles, and intervertebral disks can be affected.
- Chondrocalcinosis is found on radiographs in most patients with pseudogout.
- Chondrocalcinosis does not mean that patients will have pseudogout or even CPPD.

Treatment of Pseudogout

For treatment of acute attacks, NSAIDs or injection of a steroid preparation can be used. Intravenously administered colchicine is effective for acute attacks, but oral administration is not consistently effective. Prophylactic oral colchicine (0.6 mg 2-3 times daily) can lead to a decrease in the frequency and severity of pseudogout attacks. In patients with underlying metabolic disease, the frequency of acute attacks of pseudogout does not necessarily decrease with treatment of the underlying disease (such as hypothyroidism or hyperparathyroidism).

- Treatment of acute attacks of pseudogout: NSAIDs, injection of steroid preparation, or colchicine given intravenously.
- Prophylactic oral colchicine can lead to a decrease in the frequency and severity of attacks.
- Typical clinical scenario: An elderly patient presents with acute pain, swelling, and redness over the right knee joint. Radiographic examination shows chondrocalcinosis. Aspiration of joint fluid shows rhomboid crystals that are weakly positively birefringent on polarized light examination.

Hydroxyapatite Deposition Disease (Basic Calcium Phosphate Disease)

Presentation

Clinical presentations of hydroxyapatite deposition disease include 1) acute inflammation, including calcific tendinitis, osteoarthritis with inflammatory episodes, periarthritis or arthritis dialysis syndrome, and

calcinotic deposits in scleroderma and 2) chronic inflammation, including severe osteoarthritis and Milwaukee shoulder or knee: advanced glenohumeral and knee osteoarthritis, rotator cuff tear, noninflammatory paste-like joint fluid containing hydroxyapatite.

- Hydroxyapatite deposition disease can present as acute or chronic inflammation.

Diagnosis and Treatment

Individual crystals cannot be seen on routine polarization microscopy (Table 23-22). Small, round (shiny coin) bodies 0.5 to 100 μm are seen. On electron microscopy, these represent lumps of needle-shaped crystals. Positive identification requires transmission electron microscopy or elemental analysis. Alizarin red stain showing calcium staining provides a presumptive diagnosis (if CPPD is excluded). Treatment involves NSAIDs and intra-articular steroids.

- In hydroxyapatite deposition disease, individual crystals are not seen on polarization microscopy.
- Positive identification requires transmission electron microscopy.

Calcium Oxalate Arthropathy

Calcium oxalate arthropathy occurs in patients with primary oxalosis and in patients undergoing chronic hemodialysis. It can cause acute inflammatory arthritis. Crystals are large, bipyramidal, and birefringent. Calcium oxalate can cause chondrocalcinosis or large soft tissue calcifications.

- Calcium oxalate arthropathy occurs in patients with primary oxalosis and patients undergoing chronic hemodialysis.

Other Crystals Implicated in Joint Disease

Cholesterol crystals are a nonspecific finding and have been found in the synovial fluid of patients with various types of chronic inflammatory arthritis. Cryoglobulin crystals are found in essential cryoglobulinemia and paraproteinemia. Corticosteroid crystals are found in an arthritis flare after a corticosteroid injection, and Charcot-Leyden crystals have been found in hypereosinophilic syndromes. In patients undergoing hemodialysis, aluminum phosphate crystals can develop.

Spondyloarthropathies

Conditions that form the spondyloarthropathies include ankylosing spondylitis, reactive arthritis, enteropathic spondylitis, and psoriatic arthritis.

Spondyloarthropathies are characterized by involvement of the sacroiliac joints (uncommon in rheumatoid arthritis), peripheral arthritis that is usually asymmetric and oligoarticular, absence of rheumatoid factor, and an association with HLA-B27 in more than 90% of cases. They are enthesopathic disorders.

The HLA region of chromosome 6 contains genes of the human histocompatibility complex. Every person has two of chromosome 6, one inherited from each parent. On each of these there is an HLA-A and HLA-B allele. Therefore, everyone has two HLA-A types and two HLA-B types. With regard to inheritance, an offspring has a 50% chance of acquiring a specific HLA-A or HLA-B antigen from a parent (Fig. 23-8). Siblings have a 25% chance of being identical for all four HLA-A and HLA-B alleles.

The frequency of HLA-B27 in control populations is as follows: whites (United States), 8%; African blacks, 0%; Asians, 1%; Haida (North American Indian), 50%.

The rheumatic diseases associated with HLA-B27 are ankylosing spondylitis (HLA-B27 in more than 90%), reactive arthritis (more than 80%), enteropathic spondylitis (approximately 75%), and psoriatic spondylitis (approximately 50%).

- Ankylosing spondylitis is associated with HLA-B27 in more than 90% of cases.

Many theories have been proposed to explain the association between HLA-B27 and the spondyloarthropathies: B27 may act as a receptor site for an infective agent, may be a marker for an immune response gene that determines susceptibility to an environmental trigger, and may induce tolerance to foreign antigens with which it cross-reacts.

An offspring of a person with HLA-B27 has a 50% chance of carrying the antigen. In randomly selected persons with HLA-B27, the chance of the disease developing is 2%. In B27-positive relatives of B27-positive patients with ankylosing spondylitis, the risk of the disease developing is 20%.

Table 23-22 **Differential Diagnosis According to Results of Synovial Fluid Analysis**

Diagnosis	Leukocyte count, ×10⁹/L	Differential	Polarization microscopy
Degenerative joint disease	<1	Mononuclear cells	Negative
Rheumatoid arthritis	5-50	PMNs	Negative
Gout	5-100	PMNs	Monosodium urate
Pseudogout	5-100	PMNs	CPPD
Hydroxyapatite	5-100	PMNs	Negative
Septic arthritis	≥100	PMNs	Negative

CPPD, calcium pyrophosphate deposition disease; PMN, polymorphonuclear leukocytes.

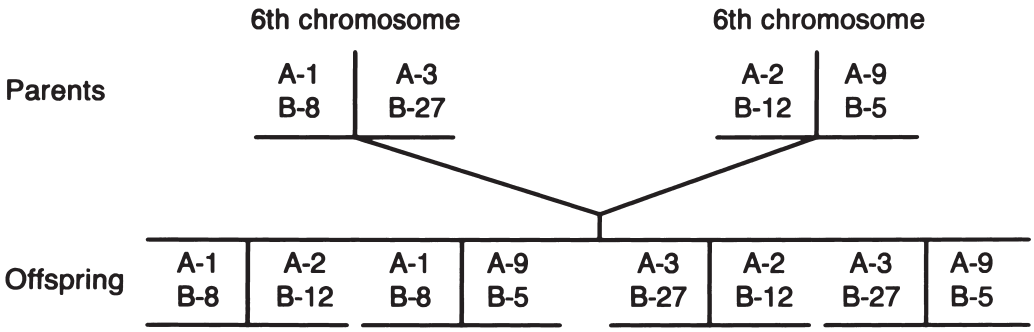

Fig. 23-8. Inheritance of HLA antigens.

Ankylosing Spondylitis

Ankylosing spondylitis is a chronic systemic inflammatory disease that affects the sacroiliac joints, the spine, and the peripheral joints. Sacroiliac joint involvement defines this disease, and back pain, decreased spinal motion, and reduced chest expansion also are often found.

- Sacroiliac joint involvement defines ankylosing spondylitis, and back pain, decreased spinal motion, and reduced chest expansion also are often found.

Features

Characteristic features of low back pain in ankylosing spondylitis are age at onset usually between 15 and 40 years, insidious onset, duration of more than 3 months, morning stiffness, improvement with exercise, family history, involvement of other systems, and diffuse radiation of back pain.

- Typical clinical scenario: A 20-year-old man has a history of low back pain of insidious onset that improves with exercise. He has diminished chest expansion, iritis, and tenderness over the sacroiliac joints. Laboratory testing shows an increased sedimentation rate. Rheumatoid factor is negative. Radiographic examination shows sclerosis and erosions of the sacroiliac joints and squaring of the vertebral bodies with the presence of syndesmophytes.

Findings of ankylosing spondylitis on physical examination are listed in Table 23-23. Other physical findings in ankylosing spondylitis are listed in Table 23-24.

The radiographic findings in ankylosing spondylitis are 1) sacroiliac involvement with erosions, "pseudo widening" of joint space, sclerosis (both sides of sacroiliac joint; this finding is needed for diagnosis), and fusion and 2) spine involvement with squaring of superior and inferior margins of vertebral body, syndesmophytes, and bamboo spine.

- Radiographic findings in ankylosing spondylitis include sacroiliac sclerosis and possible erosions, spine involvement with squaring of the vertebral bodies, syndesmophytes, and bamboo spine.

Laboratory Findings

The erythrocyte sedimentation rate may be increased, there may be an anemia of chronic disease, rheumatoid factor is absent, and 95% of white patients are positive for HLA-B27.

Extraspinal Involvement

Enthesopathic involvement distinguishes spondyloarthropathies from rheumatoid arthritis and consists of plantar fasciitis, Achilles tendinitis, and costochondritis. Hip and shoulder involvement are common (up to 50%), but peripheral joints can be affected, usually with asymmetric involvement of the lower extremities. Some patients in whom juvenile rheumatoid arthritis is diagnosed, especially male adolescents, may have juvenile ankylosing spondylitis in which peripheral arthritis preceded the axial involvement.

- Enthesopathic involvement is characteristic of ankylosing spondylitis and the other spondyloarthropathies and consists of plantar fasciitis, Achilles tendinitis, and costochondritis.
- Hip and shoulder involvement are common (up to 50%).

Extraskeletal Involvement

Other findings in active disease include 1) fatigue, 2) weight loss, 3) low-grade fever, and 4) iritis (25% of patients). Iritis is an important clinical clue in the diagnosis of spondyloarthropathies. It is not found in adults with rheumatoid arthritis.

Table 23-23 **Findings in Ankylosing Spondylitis**

Characteristic	
Scoliosis	Absent
Decreased range of movement	Symmetric
Tenderness	Diffuse
Hip flexion with straight-leg raising	Normal
Pain with sciatic nerve stretch	Absent
Hip involvement	Frequently present
Neurodeficit	Absent

Table 23-24 Results of Testing in Ankylosing Spondylitis

Test	Method	Results
Schober	Make a mark on the spine at level of L5 and one at 10 cm directly above with the patient standing erect. Patient then bends forward maximally and the distance between the two marks is measured	An increase of <5 cm indicates early lumbar involvement
Chest expansion	Measure maximal chest expansion at nipple line	Chest expansion of <5 cm is clue to early costovertebral involvement
Sacroiliac compression	Exert direct compression over sacroiliac joints	Tenderness or pain suggests sacroiliac involvement

- Iritis is an important clue to the diagnosis of spondyloarthropathies and is not found in adults with rheumatoid arthritis.

Late complications can include 1) traumatic spinal fracture leading to cord compression, 2) cauda equina syndrome (symptoms include neurogenic bladder, fecal incontinence, radicular leg pain), 3) fibrotic changes in upper lung fields, 4) aortic insufficiency in 3% to 5% of patients, 5) complete heart block, and 6) secondary amyloidosis.

- Late complications of ankylosing spondylitis include traumatic spinal fractures leading to cord compression, cauda equina syndrome, fibrotic changes in upper lung fields, and aortic insufficiency.

Ankylosing Spondylitis in Men and Women

Ankylosing spondylitis has been thought to be a disease primarily of men, but it is now recognized that the incidence in women is higher than originally thought, although women have less tendency for spinal ankylosis. The ratio of men to women is approximately 3:1. Women more frequently have osteitis pubis and peripheral joint involvement.

Differential Diagnosis

The differential diagnosis includes diffuse hypertrophic skeletal hyperostosis, osteitis condensans ilii, fusion of sacroiliac joint seen in paraplegia, osteitis pubis, infection, and degenerative joint disease. The clinical symptoms of diffuse hypertrophic skeletal hyperostosis are "stiffness" of spine and relatively good preservation of spine motion. It generally affects middle-aged and elderly men. Patients with diffuse hypertrophic skeletal hyperostosis can have dysphagia related to cervical osteophytes. Criteria for the condition are "flowing" ossification along the anterolateral aspect of at least four contiguous vertebral bodies, preservation of disk height, absence of apophyseal joint involvement, absence of sacroiliac joint involvement, and extraspinal ossifications, including ligamentous calcifications.

Osteitis condensans ilii usually affects young to middle-aged females with normal sacroiliac joints. Radiography shows sclerosis on the iliac side of the sacroiliac joint only.

The sacroiliac joint also can be involved with 1) tuberculosis, 2) metastatic disease, 3) gout, 4) Paget disease, or 5) other infections (*Brucella*, *Serratia*, *Staphylococcus*).

- Osteitis condensans ilii usually affects young to middle-aged females; radiography shows sclerosis on the iliac side of the sacroiliac joint only.
- The sacroiliac joint can be involved with metastatic disease, gout, Paget disease, or infection (*Brucella*, *Serratia*, *Staphylococcus*).

Treatment

Treatment involves physical therapy (upright posture is very important), exercise (swimming), cessation of smoking, genetic counseling, and drug therapy with NSAIDs such as indomethacin. Sulfasalazine and methotrexate therapy also may provide benefit, especially in patients with peripheral joint involvement. Tumor necrosis factor inhibitors etanercept and infliximab recently were approved, and both can provide benefit for spinal and peripheral joint symptoms.

Reactive Arthritis

This is an aseptic arthritis induced by a host response to an infectious agent rather than direct infection. HLA-B27 is associated in 80% of cases. The condition develops after infections with *Salmonella* organisms, *Shigella flexneri*, *Yersinia enterocolitica*, and *Campylobacter jejuni*, which cause diarrhea, and *Chlamydia* and *Ureaplasma urealyticum*, which cause nonspecific urethritis. Inflammatory eye disease (conjunctivitis or iritis) and mucocutaneous disease (balanitis, oral ulcerations, or keratoderma) also can occur. Keratoderma blennorrhagicum is a characteristic skin disease on the palms and soles which is indistinguishable histologically from psoriasis. Joint predilection is for the toes and asymmetric large joints in the lower extremities. It can cause "sausage" toe, as can psoriatic arthritis. The distal interphalangeal joints in the hands can be affected also. Cardiac conduction disturbances and aortitis can develop. Sacroiliitis (sometimes unilateral) can occur. Long-term studies indicate that the disease remains episodically active in 75% of patients and that disability is a frequent outcome.

- Reactive arthritis is an aseptic arthritis induced by a host response to an infectious agent rather than direct infection.
- HLA-B27 is associated in 80% of cases.
- Reactive arthritis develops after infections with *Salmonella*, *Shigella flexneri*, *Yersinia enterocolitica*, *Campylobacter jejuni*, *Chlamydia*, *Ureaplasma urealyticum*.

Treatment is with NSAIDs (indomethacin). Sulfasalazine and methotrexate are used in patients with chronic disease. Treatment with tetracycline or erythromycin-type antibiotics may decrease the duration and severity of illness in some cases of *Chlamydia*-triggered reactive arthritis.

Arthritis Associated With Inflammatory Bowel Disease

Two distinct types of arthritis are associated with chronic inflammatory bowel disease: 1) a nondestructive oligoarthritis of the peripheral joints tending to correlate with the activity of the bowel disease and 2) ankylosing spondylitis (enteropathic spondylitis). The spondylitis is not a complication of the bowel disease. It may be diagnosed many years before the onset of bowel symptoms, and its subsequent progress bears little relationship to the bowel disease. Approximately 75% of patients with enteropathic spondylitis and inflammatory bowel disease are HLA-B27–positive. Patients with inflammatory bowel disease alone do not have an increased frequency of HLA-B27 and are not at increased risk for development of spondylitis.

- Patients with inflammatory bowel disease may have a nondestructive oligoarthritis of the peripheral joints which tends to correlate with the activity of the bowel disease.

Psoriatic Arthritis

Psoriatic arthritis develops in 7% or less of patients with psoriasis. Pitting of nails is strongly associated with joint disease. Patients with more severe skin disease are at higher risk for the development of arthritis. A "sausage" finger or toe is characteristic of psoriatic arthritis and is very uncommon in rheumatoid arthritis. Radiographic evidence of involvement of the distal interphalangeal joint with erosions is common in psoriasis and uncommon in rheumatoid arthritis. Psoriatic arthritis also can, in severe cases, cause a characteristic "pencil-in-cup" deformity of the distal interphalangeal and proximal interphalangeal joints on radiography.

- Psoriatic arthritis develops in 7% or less of patients with psoriasis.
- Pitting of nails is strongly associated with joint disease.
- "Sausage" finger or toe is characteristic.
- "Pencil-in-cup" deformity of the distal and proximal interphalangeal joints is found on radiography.

There are five clinical groups of psoriatic arthritis: 1) predominantly distal interphalangeal joint involvement, 2) asymmetric oligoarthritis, 3) symmetric polyarthritis-like rheumatoid arthritis but negative for rheumatoid factor, 4) arthritis mutilans, and 5) psoriatic spondylitis (HLA-B27–positive in 50%-75% of cases). Treatment is with NSAIDs, methotrexate, and tumor necrosis factor inhibitors.

Iritis and Rheumatologic Diseases

Various rheumatologic diseases are associated with iritis, particularly the seronegative spondyloarthropathies. Iritis is uncommon in rheumatoid arthritis and systemic lupus erythematosus. Nongranulomatous iritis without any other associated symptoms may be associated with HLA-B27 in almost 50% of patients.

Behçet Syndrome

Behçet syndrome is most common in Middle Eastern countries and Japan. HLA-B51 is associated with the syndrome. In addition to oral and genital ulcerations, uveitis, synovitis, cutaneous vasculitis, and meningoencephalitis may be present. The pathergy reaction (hyperreactivity of the skin in response to superficial trauma) also occurs. Migratory, superficial thrombophlebitis and erythema nodosum also have been associated with this syndrome. The combination of recurrent aphthous dermatitis, similar ulcerations in the genital area, and uveitis is most common. Treatment is with corticosteroids, although more aggressive immunosuppression often is required.

Osteoid Osteoma

Osteoid osteoma is a benign bone tumor. It usually occurs in males and females between the ages of 5 and 30 years. The classic symptom is bone pain at night, which is relieved completely with aspirin or another NSAID. The diagnosis may be made with routine radiography, but often this is negative and bone scanning may be helpful for localizing the tumor. Tomography or computed tomography then can be done for better visualization. Radiography shows a small nidus, usually less than 1 cm, varying from radiolucent to radiopaque, depending on the age of the lesion. There is usually a lucent ring around the nidus and adjacent bone sclerosis. Definitive treatment includes excision, which is curative.

- Osteoid osteoma is a benign bone tumor.
- Bone pain at night is relieved by aspirin or another NSAID.
- Treatment includes excision, which is curative.

Bypass Arthritis

Bypass arthritis occurs in patients who have undergone intestinal bypass operations, including jejunocolic or jejunoileal. The arthritis may be acute or subacute, is usually intermittent, and can last occasionally for short periods, only to recur. The most commonly affected joints are the metacarpophalangeal, proximal interphalangeal, wrists, knees, and ankles. It commonly is associated with a dermatitis, which can be pustular. Circulating immune complexes composed of bacterial antigens have been found in both the circulation and the synovial fluid and are thought to be the cause of this disorder. Treatment consists of NSAIDs and antibiotics such as tetracycline, but reanastomosis may be necessary for complete resolution of symptoms.

- Bypass arthritis occurs in patients who have had intestinal bypass operations.

- Most commonly affected joints are metacarpophalangeal, proximal interphalangeal, wrists, knees, and ankles.
- Bypass arthritis is commonly associated with a dermatitis.

Systemic Lupus Erythematosus

Systemic lupus erythematosus (SLE) is a chronic inflammatory disease of unknown cause with a wide spectrum of clinical manifestations and variable course characterized by exacerbations and remissions. Antibodies that react with nuclear antigens commonly are found in patients with the disease. Genetic, hormonal, and environmental factors seem to be important in the cause.

- SLE is characterized by exacerbations and remissions.

Diagnosis

At least four of the following findings are needed for the diagnosis of SLE: malar rash; discoid lupus; photosensitivity; oral ulcers; nonerosive arthritis; proteinuria (protein >0.5 g/day) or cellular casts; seizures or psychosis; pleuritis or pericarditis; hemolytic anemia, leukopenia, lymphopenia, or thrombocytopenia; antibody to nuclear DNA (nDNA), antibody to Sm (Smith), IgG or IgM antiphospholipid antibodies, positive test for lupus anticoagulant, or false-positive results of VDRL test; and positive results of fluorescent antinuclear antibody test.

Epidemiology

The female:male ratio is 8:1 during the reproductive years. The first symptoms usually occur between the second and fourth decades of life. The disease seems to be less severe in the elderly. In SLE with onset at an older age, the female:male ratio is equal. The frequency of SLE is increased in American blacks, Native Americans, and Asians.

- Female:male ratio in SLE is 8:1 during the reproductive years.
- The frequency of SLE is increased in American blacks, Native Americans, and Asians.

Etiology

In human disease, viral-like particles in glomeruli of patients with SLE have been reported; however, attempts to isolate viruses have been unsuccessful. A direct causal relationship between virus and SLE has not yet been established. Patients with SLE have increased antibody titers to a wide range of antigens without much sign of specificity for a particular viral agent.

- In SLE, there are increased antibody titers to a wide range of antigens without much sign of specificity for a particular viral agent.

Genetics

Among relatives of patients with SLE, 20% have a different immunologic disease. Another 25% have antinuclear antibodies, circulating immune complexes, antilymphocyte antibodies, or a false-positive result on VDRL test without clinical disease. Concordance for SLE among monozygotic twins is much greater than among dizygotic twins. Multiple genetic and environmental factors are important in the development of SLE. Immune complex levels are much higher in persons with close contact to SLE patients than in unexposed consanguineous relatives. The frequency of HLA-B8, HLA-DR2, and HLA-DR3 is increased.

- 20% of relatives of patients with SLE have a different immunologic disease.
- In SLE, the frequency of HLA-B8, HLA-DR2, and HLA-DR3 is increased.

Pathogenesis

There is a change in the activity of the cellular immune system with an absolute decrease in T-suppressor cells. There is an increase in the activity of the humoral immune system with B-cell hyperactivity resulting in polyclonal activation and antibody production.

Circulating immune complexes (anti-nDNA) may contribute to glomerulonephritis and skin disease, among other manifestations. Immune complexes bind complement, which initiates the inflammatory process. Organ-specific autoantibodies also contribute to the pathophysiology of the disease and include antibodies that are 1) antierythrocyte, 2) antiplatelet, 3) antileukocyte, 4) antineuronal, and 5) antithyroid.

- Circulating immune complexes (anti-nDNA) are responsible for glomerulonephritis and certain skin manifestations.
- Organ-specific autoantibodies also may contribute to the pathophysiology.

Late complications of SLE are related to vascular damage, sometimes in the relative absence of active immunologic disease. Damage to the intima during active disease ultimately may result in various thrombotic, ischemic, and hypertensive manifestations.

Clinical Manifestations

Fever in SLE usually is caused by the disease, but infection must be ruled out. Shaking chills and leukocytosis strongly suggest infection.

Articular

The arthritis is characteristically inflammatory but nondeforming and nonerosive. Avascular necrosis of bone occurs, and not only in patients taking steroids. The femoral head, navicular bone, and tibial plateau are most commonly affected.

Dermatologic

Discoid lupus involves the face, scalp, and extremities. There is follicular plugging with atrophy leading to scarring. Subacute cutaneous LE is a subset of SLE that primarily has skin involvement with psoriasiform or annular erythematous lesions. Patients may be negative for antinuclear antibodies but frequently are positive for antibodies to the extractable nuclear antigen SS-A (Ro).

Cardiopulmonary

Cardiac involvement in SLE is manifested by pericarditis, myocarditis, valvular involvement, accelerated coronary atherosclerosis, and coronary vasculitis.

Pulmonary involvement in SLE is manifested by any of the following: pleurisy, pleural effusions, pneumonitis, pulmonary hypertension, hemorrhage, and diaphragmatic dysfunction.

Neuropsychiatric

Central nervous system lupus is a most variable and unpredictable phenomenon. Manifestations such as impaired cognitive function, seizures, long tract signs, cranial neuropathies, psychosis, and migraine-like attacks occur with little apparent relationship to each other or to other systemic manifestations. Immune complexes in the choroid plexus are *not* specific for central nervous system disease because they also occur in patients without central nervous system disease. Patients may have increased cerebrospinal fluid protein (IgG), pleocytosis, and antineuronal antibodies.

Results of electroencephalography can be abnormal. Magnetic resonance imaging usually shows areas of increased signal in the periventricular white matter, similar to those found in multiple sclerosis. Magnetic resonance imaging findings are often nonspecific and sometimes can be seen in patients who have SLE without central nervous system manifestations. Pathologic examinations of autopsy specimens usually reveal microinfarcts, nerve cell loss, rarely vasculitis, or no detectable abnormalities.

Proposed pathogenetic mechanisms causing neuropsychiatric manifestations include autoneuronal antibodies, vasculitis, leukoagglutination, antiphospholipid-associated hypercoagulability, and cytokine effect.

Psychosis caused by steroid therapy is probably rarer than previously thought. When there is doubt about the cause of the psychosis in patients with SLE, the steroid dose can be increased and the patient observed. Patients rarely can have isolated central nervous system involvement and normal results of cerebrospinal fluid examination and no other organ involvement.

Particularly with neuropsychiatric symptoms or respiratory symptoms, secondary causes must be considered, especially infection, hypertension, anemia, hypoxia, and fever. Fever should be considered due to infection until proved otherwise.

- Central nervous system lupus is a most variable and unpredictable phenomenon.
- Immune complexes in the choroid plexus are not specific for central nervous system disease.
- Magnetic resonance imaging findings are nonspecific.
- Particularly with neuropsychiatric symptoms or respiratory symptoms, secondary causes must be considered, especially infection, hypertension, anemia, hypoxia, and fever.
- Fever should be considered due to infection until proved otherwise.

Pregnancy and SLE

Women with SLE who become pregnant have a high prevalence of spontaneous abortion. Because abortion itself may lead to a flare of the disease, therapeutic abortion ordinarily is not recommended after the first trimester. Flares of disease should be treated with steroids, particularly during the postpartum period.

In infants of mothers with SLE, thrombocytopenia and leukopenia can develop from passive transfer of antibodies. They also can have transient cutaneous lesions and transient complete heart block. Mothers usually have anti-SS-A (Ro), which crosses the placenta and is transiently present in the infant. Mothers usually are HLA-B8/DR3-positive, but there is no HLA association in the child.

Renal Involvement

The types of renal disease in SLE are 1) mesangial, 2) focal glomerulonephritis, 3) membranous glomerulonephritis, 4) diffuse proliferative glomerulonephritis, 5) interstitial nephritis with defects in the renal tubular handling of K^+, and 6) renal vein thrombosis with nephrotic syndrome.

Treatment of renal disease depends in part on the results of renal biopsy. Patients with high activity indices on biopsy such as active inflammation, proliferation, necrosis, and crescent formation are considered for aggressive therapy. Patients with high chronicity indices such as tubular atrophy, scarring, and glomerulosclerosis are less likely to respond to aggressive therapy. Patients with mesangial changes alone do not require aggressive therapy. Active diffuse proliferative glomerulonephritis is treated with high-dose steroids and cyclophosphamide. Recently, mycophenolate mofetil has shown efficacy equivalent to cyclophosphamide with fewer side effects and can be considered an alternative to induction and maintenance therapy in lupus nephritis. Immunosuppressive agents lower the incidence of renal failure in patients with diffuse proliferative glomerulonephritis and may improve overall survival. Appropriate treatment for focal proliferative glomerulonephritis and membranous glomerulonephritis is controversial because the prognosis is more favorable.

- Renal biopsies are helpful for directing therapy in renal disease associated with SLE.
- Patients with mesangial changes alone do not require aggressive therapy.
- Active diffuse proliferative glomerulonephritis is treated with high-dose steroids and immunosuppressive agents.

Laboratory Findings

Anemia of chronic disease and hemolytic anemia (Coombs positive) can occur. Leukopenia usually does not predispose to infection. Antilymphocyte antibodies cause lymphopenia in SLE. Idiopathic thrombocytopenic purpura with the presence of platelet antibodies can be the initial manifestation of SLE. Polyclonal gammopathy due to hyperactivity of the humoral immune system is common. The erythrocyte sedimentation rate usually correlates with disease activity.

Hypocomplementemia (CH_{50}, C3, C4) usually correlates with active disease. Hypocomplementemia with increased anti-nDNA antibodies usually implies renal disease (or skin disease). Complement split products (such as C3a, C5a, Ba/BB) are increased in active disease. A total complement value too low to measure with normal C3 and C4 values suggests a hereditary complement deficiency. Familial C2 deficiency is the most common complement deficiency in SLE, but C1r, C1s, C1q, C4, C5, C7, and C8 deficiencies also have been reported.

Patients with SLE may have false-positive results of the VDRL test as a result of antibody to phospholipid, which cross-reacts with

VDRL. Patients with SLE also can have false-positive results of the fluorescent treponemal antibody test, but they usually have the "beaded pattern" of fluorescence. LE cells are present in approximately 70% of patients with SLE and are caused by antibody to deoxyribonucleoprotein (DNP). This test is not specific and is no longer performed in many centers. Anti-DNP also is detected by the fluorescent antinuclear antibody test in a homogeneous pattern.

Anti-nDNA levels fluctuate with disease activity, whereas levels of other autoantibodies (ribonucleoprotein, Sm, antinuclear antibody) show *no* consistent relationship to levels of anti-nDNA or disease activity. Methods used to measure anti-nDNA are 1) an immunofluorescent method using *Crithidia lucilia*, an organism with a kinetoplast that contains helical native DNA free of other nuclear antigens—therefore, there is no single-stranded DNA contamination, and 2) radioimmunoassay and enzyme-linked immunosorbent assay, which suffer from the difficulty of maintaining DNA in its native double-stranded state and so are contaminated with single-stranded DNA.

Although all patients with lupus should have positive results of antinuclear antibody tests, a positive result is by no means specific for lupus. Antinuclear antibody patterns are outlined in Table 23-25. Other autoantibodies and disease associations are outlined in Table 23-26.

- Hemolytic anemia (Coombs positive) can occur in SLE.
- Idiopathic thrombocytopenic purpura can be the initial manifestation of SLE.
- Hypocomplementemia (CH50, C3, C4) usually correlates with active disease.
- Hypocomplementemia with increased anti-nDNA antibodies usually implies renal disease (or skin disease).
- Anti-nDNA levels fluctuate with disease activity, but other associated antibodies do not.
- A positive result of an antinuclear antibody test is by no means specific for lupus.

Treatment

Treatment should match the activity of SLE in the individual patient. Serial monitoring of organ function and appropriate laboratory evaluation (anti-nDNA, C3, erythrocyte sedimentation rate) allow rapid

Table 23-25 Antinuclear Antibody Patterns

Fluorescent pattern	Antigen	Disease association
Rim, peripheral, shaggy	nDNA	SLE
Homogeneous	DNP	SLE, others
Speckled	ENA	MCTD, SLE, others
Nucleolar	RNA	Scleroderma

DNP, deoxyribonucleoprotein; ENA, extractable nuclear antigen; MCTD, mixed connective tissue disease; SLE, systemic lupus erythematosus.

Table 23-26 Autoantibodies in Rheumatic Diseases

Antibody	Disease association
Anti-nDNA	SLE, 50%-60%
Anti-Sm (Smith)	SLE, 30%
Anti-RNP (ribonucleoprotein)	MCTD, 100% high titer
	SLE, 30% titer
	Scleroderma, low frequency, low titer
Anti-SS-A	Sjögren, 70%
	SLE, 35%
	Scleroderma + MCTD, low frequency, low titer
Anti-SS-B	Sjögren, 60%
	SLE, 15%
Antihistone	Drug-induced SLE, 95%
	SLE, 60%
	RA, 20%
Anti-Sc1-70 (antitopoisomerase I)	Scleroderma, 25%
Anticentromere	CREST, 70%-90%
	Scleroderma, 10%-15%
Anti-PM1	PM, 50%
Anti-Jo1 (histidyl-tRNA synthetase)	PM/interstitial lung disease, 30%

CREST, syndrome of *c*alcinosis cutis, *R*aynaud phenomenon, *e*sophageal dysmotility, *s*clerodactyly, *t*elangiectasia; MCTD, mixed connective tissue disease; PM, polymyositis; RA, rheumatoid arthritis; SLE, systemic lupus erythematosus.

recognition and treatment of flares and appropriate tapering of steroid dose during periods of disease quiescence. Table 23-27 provides guidelines for treatment, and Table 23-28 outlines the complications of treatment.

Outcome

The 10-year survival rate is 90% in newly diagnosed SLE. Prognosis is worse in blacks and Hispanics than in whites. Prognosis is worse in patients with creatinine values more than 3.0 mg/dL. The major causes of death are 1) renal disease, 2) infection, 3) central nervous system involvement, and 4) vascular disease (such as myocardial infarction).

- The 10-year survival rate is 90% in newly diagnosed SLE.
- The prognosis is worse in blacks and Hispanics.
- Typical clinical scenario: A young woman presents with malar rash and photosensitivity. She has a history of oral ulcers and arthralgias. Laboratory results are significant proteinuria and red blood cell casts in the urine. There is a normochromic normocytic anemia with a positive Coombs test. Antibody to nDNA is present. Results of the VDRL test are positive.

Drug-Induced Lupus

Many drugs have been implicated in drug-induced lupus. The most common drugs are listed in Table 23-29. One must differentiate between the clinical syndrome of drug-induced lupus and only a positive antinuclear antibody result without clinical symptoms. Many drugs can cause a positive antinuclear antibody result without ever causing the clinical syndrome of drug-induced lupus. Only hydralazine and procainamide have been strongly implicated in drug-induced lupus. A drug-induced lupus syndrome develops in approximately 5% of persons taking hydralazine and in 15% to 25% of those who take procainamide. Virtually all patients taking procainamide for 1 year will have a positive result of the antinuclear antibody test.

- Only hydralazine and procainamide are strongly implicated in drug-induced lupus.
- Virtually all patients taking procainamide for 1 year have a positive result of the antinuclear antibody test.

Clinical Features

The clinical manifestations of drug-induced lupus include arthralgias and polyarthritis, which occur in approximately 80% of cases. Malaise is common, and fever has been reported in up to 40% of cases. Cardiopulmonary involvement is also common, and approximately 30% of patients have pleural-pulmonary manifestations as their presenting symptoms. Pericarditis has been reported in approximately 20% of cases. Diffuse interstitial pneumonitis has been noted. Asymptomatic pleural effusions may be found on routine chest radiography. A few cases of pericardial tamponade have been reported. In contrast to SLE, the incidence of renal and central nervous system

Table 23-27 Treatment of Manifestations of Systemic Lupus Erythematosus

Manifestation	Treatment
Arthritis, fever, mild systemic symptoms	ASA, NSAID
Photosensitivity, rash	Avoidance of sun, use of sunscreens
Rash, arthritis	Hydroxychloroquine (Plaquenil)
Significant thrombocytopenia, hemolytic anemia	Steroids
Renal disease, CNS disease, pericarditis, other significant organ involvement	Steroids
Rapidly deteriorating renal function	Cyclophosphamide, mycophenolate mofetil

ASA, acetylsalicylic acid; CNS, central nervous system; NSAID, nonsteroidal anti-inflammatory drug.

Table 23-28 Complications of Treatment for Systemic Lupus Erythematosus

Treatment	Complication
Ibuprofen	Aseptic meningitis (headache, fever, stiff neck, CSF pleocytosis)
NSAID	Decreased renal blood flow
ASA	Salicylate hepatitis (common), benign
Cyclophosphamide	Hemorrhagic cystitis, alopecia, opportunistic lymphomas, infection, increased incidence of lymphomas (CNS)
Hydroxychloroquine (Plaquenil)	Retinal toxicity

ASA, acetylsalicylic acid; CNS, central nervous system; CSF, cerebrospinal fluid; NSAID, nonsteroidal anti-inflammatory drug.

Table 23-29 Implicated Agents in Drug-Induced Lupus

Definite	Probable
Common	Phenytoin
Procainamide	Carbamazepine
Hydralazine	Ethosuximide
Uncommon	Propylthiouracil
Isoniazid	Penicillamine
Methyldopa	Sulfasalazine
Chlorpromazine	Lithium carbonate
Quinidine	Acebutolol
Minocycline	Lovastatin

involvement is low in drug-induced lupus. Therefore, it is regarded as more benign than SLE. Other clinical differences include a lower incidence of skin manifestations, lymphadenopathy, and myalgias in drug-induced disease.

- In drug-induced lupus, arthralgias and polyarthritis occur in about 80% of cases.
- Malaise is common, and fever occurs in up to 40% of cases.
- About 30% of patients have pleural-pulmonary manifestations on presentation.
- Pericarditis is reported in about 20% of cases.
- The incidence of renal and central nervous system involvement is low.

SLE is predominantly a disease of premenopausal females, whereas drug-induced disease has an almost equal sex distribution and occurs in an older population. This disparity in age reflects the use of hydralazine and procainamide primarily in an older population.

Laboratory Abnormalities

Virtually all patients with SLE and drug-induced lupus have antinuclear antibodies. Although patients with SLE and drug-induced lupus are serologically similar in many respects, there are notable differences. Antibodies to nDNA are found in only a small percentage of cases of drug-induced lupus but in approximately 60% of cases of SLE. Serum total hemolytic complement, C3, and C4 are usually normal in drug-induced disease, in contrast to SLE. Antibodies such as anti-Sm, SS-A, SS-B, and RNP are also unusual in drug-induced lupus. The frequency of antihistone antibodies in drug-induced lupus is high (>95% of cases), but these also occur in approximately 60% of cases of SLE. Other, less frequent laboratory abnormalities in drug-induced lupus can include a positive LE preparation, positive Coombs test, positive rheumatoid factor, false-positive result of serologic test for syphilis, circulating anticoagulants, and cryoglobulins.

Metabolism

Drugs involved in drug-induced lupus have different chemical structures, but three of them—isoniazid, procainamide, and hydralazine—contain a primary amine that is acetylated by the hepatic *N*-acetyltransferase system. Persons who are taking one of these drugs and who are *slow* acetylators have a much higher incidence of serologic abnormalities and clinical disease than rapid acetylators. These manifestations also occur over a shorter period in slow acetylators than in rapid acetylators.

- Slow acetylators have a much higher incidence of serologic abnormalities and clinical disease.

Treatment

When possible, patients with drug-induced lupus should stop using the offending drug. Symptoms usually subside within several weeks, although the duration for complete resolution varies depending on the drug. Serologic abnormalities can remain for years after resolution of clinical symptoms. Patients taking procainamide are most likely to have a rapid remission once use of the drug is stopped, but patients taking hydralazine might have prolonged clinical manifestations. Treatment depends on the clinical manifestations and could include NSAIDs or possibly low-dose prednisone if needed.

- Typical clinical scenario: A patient presents with a history of fever, arthralgias, fatigue, and a rash. The patient is taking procainamide for suppression of a ventricular arrhythmia. Laboratory results are a positive antinuclear antibody test and negative anti-nDNA antibody.

Overlap Syndromes

An overlap syndrome is a disease characterized by features of more than one connective tissue disease. Secondary Sjögren syndrome accompanying another connective tissue disease is not classified as an overlap syndrome.

Mixed Connective Tissue Disease

This is a distinct disease with variable features of SLE, polymyositis, systemic sclerosis, and rheumatoid arthritis. The incidence of renal disease is low. It is serologically characterized by a positive antinuclear antibody and by a high titer of the autoantibody anti-RNP. Anti-nDNA antibodies usually are not present. Raynaud phenomenon is common.

Undifferentiated Connective Tissue Disease

This category includes patients with symptoms that do not fulfill the diagnostic criteria for a definite or specific connective tissue disease. Common symptoms include Raynaud phenomenon, arthralgias, fatigue, and variable joint or soft tissue swelling. The antinuclear antibody may be positive, but other autoantibodies are not present. Patients need to be observed to determine whether progression to a distinct connective tissue disease occurs.

Antiphospholipid Antibody Syndrome

The lupus anticoagulant and various phospholipid antibodies have been associated with recurrent arterial and venous thromboses.

Antiphospholipid antibodies may be either the IgG or the IgM class. The hallmark of the antiphospholipid antibody syndrome is prolongation on all phospholipid-dependent coagulation tests. The antibodies prolong the partial thromboplastin time at the level of the prothrombin activator complex of the clotting cascade. The antiphospholipid antibodies are thought to interact with the β_2-glycoprotein-1 that binds to phospholipid, interfering with the calcium-dependent binding of prothrombin factor Xa to the phospholipid. The failure of normal plasma to correct the prolonged clotting time distinguishes the lupus anticoagulant and antiphospholipid antibody clotting factors from clotting factor deficiencies. In the usual coagulation screening tests, the lupus anticoagulant results in prolongation of the activated partial thromboplastin time without prolongation of the prothrombin time (Table 23-30).

- Antiphospholipid antibodies are of either the IgG or the IgM class.
- Prolongation on all phospholipid-dependent coagulation tests is the laboratory hallmark of the antiphospholipid antibody syndrome.
- Activated partial thromboplastin time is prolonged and not corrected by adding normal plasma, but it is corrected with the addition of platelet-rich plasma, and this is the laboratory hallmark of a lupus anticoagulant.

Various other tests are reported to be sensitive for detection of lupus anticoagulants, including the plasma clotting time, kaolin clotting time, a platelet neutralization procedure, and modified Russell viper venom time.

Many, but not all, patients with the lupus anticoagulant also have increased IgG or IgM antiphospholipid antibody levels.

The lupus anticoagulant and antiphospholipid antibodies are associated with SLE, but they also have been reported in various other autoimmune, malignant, infectious, and drug-induced diseases. Other associated diseases include Sjögren syndrome, rheumatoid arthritis, idiopathic thrombocytopenic purpura, Behçet syndrome, myasthenia gravis, and mixed connective tissue disease. The antibodies are also found in persons with no apparent disease but in whom recurrent thrombosis develops. This is the primary antiphospholipid antibody syndrome, which represents approximately 50% of cases.

- Lupus anticoagulant and antiphospholipid antibodies also have been reported in various other autoimmune, malignant, infectious, and drug-induced diseases.
- The primary antiphospholipid antibody syndrome represents 50% of cases.

Clinical Features

There is an association between the presence of the lupus anticoagulant and antiphospholipid antibodies and recurrent venous or arterial thrombosis. Thrombotic events described have included stroke, transient ischemic attacks, myocardial infarctions, brachial artery thrombosis, deep venous thrombophlebitis, retinal vein thrombosis, hepatic vein thrombosis resulting in Budd-Chiari syndrome, and pulmonary hypertension. Other manifestations include recurrent fetal loss, thrombocytopenia, positive results of Coombs test, migraines, chorea, epilepsy, chronic leg ulcers, livedo reticularis, and progressive dementia resulting from cerebrovascular accidents. Recently, acquired valvular heart disease, especially aortic insufficiency, has been described. The mechanism or mechanisms by which antiphospholipid antibodies are associated with thromboembolic manifestations remain unclear. Blocking the production of prostacyclin from vascular endothelial cells, inhibition of the prekallikrein activity protein C pathway and fibrinolysis, and decreased plasminogen activator release have all been described.

Although many patients with lupus and other diseases can have a lupus anticoagulant or antiphospholipid antibodies, of either the IgG or the IgM class, thrombosis will not necessarily develop. In general, patients with the highest levels of antiphospholipid antibodies are more prone to thrombosis than those with lower levels. Also, the IgG antiphospholipid antibody is more strongly associated with recurrent thrombosis than is the IgM antiphospholipid antibody. If there is no history of thrombosis, most physicians are reluctant to treat the patient with a lupus anticoagulant or increased antiphospholipid antibodies alone without clinical manifestations.

- There is an association between the presence of the lupus anticoagulant and antiphospholipid antibodies and recurrent venous or arterial thrombosis.
- Other manifestations: recurrent fetal loss, thrombocytopenia, positive Coombs test, migraines, chorea, epilepsy, chronic leg ulcers, livedo reticularis, and progressive dementia from cerebrovascular accidents.
- Acquired valvular heart disease, especially aortic insufficiency, has been described.
- Patients with the highest levels of antiphospholipid antibodies are more prone to thrombosis.
- IgG antiphospholipid antibody is more strongly associated with recurrent thrombosis.

Treatment

For most patients who have recurrent thrombosis and high-titer anticardiolipin antibody, warfarin is prescribed in doses sufficient to yield international normalized ratio values close to 3 and will need to be taken for life. Low-dose aspirin and subcutaneous heparin have been used in pregnant women to prevent fetal loss. Corticosteroids have not been clearly shown to be efficacious for preventing thrombosis.

Table 23-30 Coagulation Tests Characterizing the Lupus Anticoagulant

Screening tests
Prothrombin time normal
PTT prolonged
Plasma clot time prolonged
Tests identifying the lupus anticoagulant
Prolonged PTT not corrected by adding normal plasma

PTT, partial thromboplastin time.

- Typical clinical scenario: A young patient presents with recurrent deep venous thrombosis. In the absence of anticoagulant therapy, the activated partial thromboplastin time is prolonged. Laboratory tests show that this prolongation is not corrected by the addition of normal plasma.

Raynaud Phenomenon

This is biphasic or triphasic color changes (pallor, cyanosis, erythema) accompanied by pain and numbness in the hands or feet. Cold is a common precipitating agent. Associated factors are listed in Table 23-31.

- Cold is a common precipitating agent for Raynaud phenomenon.

Raynaud phenomenon is related to an abnormality of the microvasculature associated with intimal fibrosis. In male patients with Raynaud phenomenon, a rare occurrence, a connective tissue disease may develop. Although Raynaud phenomenon is common in females, it usually is not associated with a connective tissue disease unless the patient has positive results for antinuclear antibody, which suggest that a connective tissue disease may develop in the future.

Skin capillary microscopy reveals tortuous, dilated capillary loops in systemic sclerosis, mixed connective tissue disease, and polymyositis. They also may be present in patients with Raynaud phenomenon who will go on to have systemic sclerosis, polymyositis, or mixed connective tissue disease.

Treatment involves smoking cessation, wearing gloves, biofeedback, 2% nitrol paste, and antihypertensive agents (prazosin or the calcium channel blockers amlodipine besylate or nifedipine). A stellate ganglion block, digital nerve block, or surgical digital sympathectomy is used if ischemia is severe. β-Adrenergic blockers increase spasm and should be avoided.

To differentiate primary Raynaud phenomenon from the secondary form (resulting from a connective tissue disease), clinical features are considered. In primary Raynaud disease, females are usually affected, the onset is at menarche, usually all digits are involved, and attacks are very frequent. The severity of symptoms is mild to moderate, and they can be precipitated by emotional stress. Digital ulceration and finger edema are rare, as is periungual erythema. Livedo reticularis is frequent.

In persons with Raynaud phenomenon due to a connective tissue disease, both males and females are affected. The onset of Raynaud phenomenon is in the mid-20s or later. It often begins in a single digit, and attacks are usually infrequent (zero to five a day). It is moderate to severe, and the disorder is not precipitated by emotional stress. Digital ulceration, finger edema, and periungual erythema are frequent. Livedo reticularis is uncommon.

Systemic Sclerosis (Scleroderma)

For the diagnosis of systemic sclerosis, one major criterion or two or more minor criteria need to be present. The major criterion is symmetric induration of the skin of the fingers and the skin proximal to metacarpophalangeal or metatarsophalangeal joints. The minor criteria are sclerodactyly, digital pitting scars or loss of substance from the finger pad, and bibasilar pulmonary fibrosis.

- Systemic sclerosis is characterized by symmetric induration of the skin of the fingers and the skin proximal to metacarpophalangeal or metatarsophalangeal joints, sclerodactyly, fingertip pitting or scarring, and bibasilar pulmonary fibrosis.

Clinical Manifestations

Skin

Patients are at risk for the development of rapidly progressive acral and trunk skin thickening and early visceral abnormalities. Skin and visceral changes tend to parallel each other in severity, but not always. Some patients have rapid progression for 2 to 3 years and then arrest of the disorder, allowing for some improvement of the disorder.

Raynaud Phenomenon

Raynaud phenomenon occurs in almost all patients. It usually occurs more than 2 years before skin changes. The vasospasm in the hands can be associated with reduced perfusion to the heart, lungs, kidneys, and gastrointestinal tract. If Raynaud phenomenon is not present but skin findings are suggestive of scleroderma, another disease such as eosinophilic fasciitis should be considered.

Articular

Nondeforming symmetric polyarthritis similar to rheumatoid arthritis may precede cutaneous manifestations by 12 months. Patients

Table 23-31 Causes of Secondary Raynaud Phenomenon

Chemotherapeutic agents
Bleomycin
Vinblastine
Toxins
Vinyl chloride
Vibration-induced injuries
Jackhammer use
Vascular occlusive disorders
Thoracic outlet obstruction
Atherosclerosis
Vasculitis
Connective tissue diseases
Scleroderma, 90%-100%
Mixed connective tissue disease, 90%-100%
Systemic lupus erythematosus, 15%
Rheumatoid arthritis, <10%
Polymyositis
Miscellaneous
Cryoglobulinemia
Cold agglutinins
Increased blood viscosity

can have both articular erosions and nonarticular bony resorptive changes of ribs, mandible, radius, ulna, and distal phalangeal tufts which are unique to systemic sclerosis. Up to 60% of patients have "leathery" crepitation of the tendons of the wrist.

Pulmonary

A considerable decrease in diffusing capacity can be present with a normal chest radiograph. Diffuse interstitial fibrosis occurs in approximately 70% of patients and is the most common pulmonary abnormality. Patients who have active alveolitis demonstrated by 1) bronchopulmonary lavage, 2) high-resolution computed tomography showing ground-glass appearance without honeycombing, or 3) lung biopsy are most likely to respond to prednisone and cyclophosphamide therapy with improvement of pulmonary function. Pleuritis (with effusion) is very rare. Pulmonary hypertension is more common in patients with CREST (*c*alcinosis cutis, *R*aynaud phenomenon, *e*sophageal dysmotility, *s*clerodactyly, *t*elangiectasias) variant.

- A considerable decrease in diffusing capacity can be present with a normal chest radiograph.
- Diffuse interstitial fibrosis occurs in approximately 70% of patients and is the most common pulmonary abnormality.
- Pleuritis is very rare.
- Pulmonary hypertension is more common in patients with CREST variant.

Cardiac

Cardiac abnormalities occur in up to 70% of patients. Conduction defects and supraventricular arrhythmias are most common. Pulmonary hypertension with cor pulmonale is the most serious problem.

- Cardiac abnormalities occur in up to 70% of patients. Pulmonary hypertension with cor pulmonale is a serious potential problem.

Gastrointestinal

Esophageal dysfunction is the most frequent gastrointestinal abnormality. It occurs in 90% of patients and often is asymptomatic. Lower esophageal sphincter incompetence with acid reflux may produce esophageal strictures or ulcers. Medications to reduce acid production are important. Reduced esophageal motility may respond to therapy with metoclopramide, cisapride, or erythromycin. Small bowel hypomotility may be associated with pseudo-obstruction, bowel dilatation, bacterial overgrowth, and malabsorption. Treatment with tetracycline may be helpful, but promotility agents are less effective. Colonic dysmotility also occurs, and wide-mouthed diverticuli may be found.

Renal

Renal involvement may result in fulminant hypertension, renal failure, and death if not treated aggressively. Proteinuria, newly diagnosed *mild* hypertension, microangiopathic hemolytic anemia, vascular changes on renal biopsy, and rapid progression of skin thickening may precede overt clinical findings of renal crisis. Renal involvement with hyperreninemia necessitates the use of angiotensin-converting enzyme inhibitors. Aggressive early antihypertensive therapy can extend life expectancy.

Laboratory Findings

Antitopoisomerase I antibody (anti-Scl-70) is found in approximately 25% of patients with scleroderma, and anticentromere antibody occurs in 10% to 20%.

Treatment

No remissive or curative therapy is available. Retrospective studies suggest that D-penicillamine (62.5 mg daily) may decrease skin thickness, prevent or delay internal organ involvement, and perhaps prolong life expectancy, but enthusiasm for this treatment has faded. Aggressive nutritional support, including hyperalimentation, may be required for extensive gastrointestinal disease.

- No remissive or curative therapy is available for systemic sclerosis.

CREST Syndrome

This is characterized by *c*alcinosis cutis, *R*aynaud phenomenon, *e*sophageal dysmotility, *s*clerodactyly, and *t*elangiectasias. Skin involvement progresses slowly and is limited to the extremities. Development of internal organ involvement occurs but is delayed. Lung involvement occurs in 70% of patients. Diffusing capacity may be low, and pulmonary hypertension can develop. The latter is more common in CREST than in diffuse scleroderma. Bosentan was recently approved for severe pulmonary hypertension, scleroderma, and CREST syndrome. Onset of Raynaud phenomenon occurs less than 2 years before skin changes. Anticentromere antibody is found in 70% to 90% of patients and antiscleroderma-70 antibody in 10%. The incidence of primary biliary cirrhosis is increased.

- In CREST syndrome, 70% of patients have lung involvement.
- The diffusing capacity may be low, and pulmonary hypertension can develop.
- Anticentromere antibody is present in 70%-90% of patients.
- There is an increased incidence of primary biliary cirrhosis.

The clinical manifestations of limited and systemic scleroderma are listed in Table 23-32.

Scleroderma-Like Syndromes

Disorders Associated With Occupation or Environment

This group includes polyvinyl chloride disease, organic solvents, jackhammer disease, silicosis, and toxic oil syndrome.

Eosinophilic Fasciitis

Clinical features of this disorder include tight bound-down skin of the extremities, characteristically sparing the hands and feet. Peau d'orange skin changes can develop. Onset after vigorous exercise is common. Raynaud phenomenon does not occur, and there is no visceral involvement. Flexion contractures and carpal tunnel syndrome can develop.

Table 23-32 Clinical Findings in Limited and Diffuse Scleroderma

Clinical finding	Cutaneous disease	
	Limited	Diffuse
Raynaud phenomenon	Precedes other symptoms by years	Onset associated with other symptoms within 1 year
Nailfold capillaries	Dilated	Dilated with dropout
Skin changes	Distal to elbow	Proximal to elbow with involvement of trunk
Telangiectasia, digital ulcers, calcinosis	Frequent	Rare early, but frequent later in the course
Joint and tendon involvement	Uncommon	Frequent (tendon rubs)
Visceral disease	Pulmonary hypertension	Renal, intestinal, and cardiac disease; pulmonary interstitial fibrosis
Autoantibodies	Anticentromere (70%-90%)	Antitopoisomerase 1 (Scl-70) (25%)
10-year survival	>70%	<70%

Laboratory findings are peripheral eosinophilia, increased sedimentation rate, and hypergammaglobulinemia. The diagnosis is based on the findings of inflammation and thickening of the fascia on deep fascial biopsy. Treatment is with prednisone (40 mg daily). The response is usually good. Associated conditions are aplastic anemia and thrombocytopenia (both antibody-mediated) as well as leukemia and myeloproliferative diseases.

- Eosinophilic fasciitis is characterized by tight bound-down skin of the extremities, usually sparing the hands and feet.
- Raynaud phenomenon does not occur.
- There is no visceral involvement.
- Laboratory findings include peripheral eosinophilia.
- Treatment with prednisone provides good response.

Metabolic Causes of Scleroderma-Like Syndrome

This group includes porphyria, amyloidosis, carcinoid, and diabetes mellitus (flexion contractures of the tendons in the hands, cheiropathy, can develop).

Other Causes

As a manifestation of *graft-versus-host disease*, skin induration develops in up to 30% of patients who receive a bone marrow transplant. *Drug-induced disorders* are caused by carbidopa, bleomycin, and bromocriptine. *Eosinophilic myalgia syndrome* is associated with ingestion of contaminated L-tryptophan. Eosinophilia, myositis, skin induration, fasciitis, and peripheral neuropathy develop. Skin changes are similar to those of eosinophilic fasciitis. There is a poor response to steroids. *Scleredema* frequently occurs after streptococcal upper respiratory tract infection in children. It is usually self-limiting. Swelling of the head and neck is common. In adults, diabetes mellitus often is associated. *Scleromyxedema* is associated with IgG monoclonal protein. Cocaine use and appetite suppressants also cause scleroderma-like illness.

The Inflammatory Myopathies

Inflammatory myopathies can be classified into several categories, including polymyositis, dermatomyositis, myositis associated with malignancy, childhood-type, and overlap connective tissue disease. Polymyositis is an inflammatory myopathy characterized by proximal muscle weakness. Patients with dermatomyositis have an associated rash that includes a heliotrope hue of the eyelids, a rash on the metacarpophalangeal and proximal interphalangeal joints (Gottron papules), and photosensitivity dermatitis of the face. Most patients have an increased creatine kinase level, a characteristic electromyogram, and a characteristic muscle biopsy.

Electromyography is characteristic but not diagnostic of inflammatory myopathies. It shows decreased amplitude and increased spike frequency, it is polyphasic, and conduction speed is normal. Fibrillation is not specific for inflammatory myopathies, but when present it indicates active disease. Loss of fibrillation usually means the inflammatory myopathy is under control, but if the electromyographic result is still myopathic, it suggests an associated steroid myopathy caused by treatment. The muscle biopsy, which is mandatory in all patients with inflammatory myopathy, shows degeneration, necrosis, and regeneration of myofibrils with lymphocytic and monocytic infiltrate in a perivascular or interstitial distribution.

In patients older than 40 years, perhaps 10% of those with dermatomyositis and polymyositis have an associated malignancy. The antibody anti-Jo1 is associated with polymyositis and dermatomyositis in approximately 25% of cases. This antibody is associated with inflammatory arthritis, progressive interstitial lung disease, Raynaud phenomenon, and increased mortality primarily due to respiratory failure. The autoantibody anti-Mi-2 is associated with dermatomyositis in 2% to 20% of patients.

- Polymyositis is an inflammatory myopathy characterized by proximal muscle weakness.

- Dermatomyositis is an inflammatory myopathy plus a rash that includes heliotrope hue of eyelids.
- Electromyography is characteristic but not diagnostic of polymyositis.
- Perhaps 10% of patients older than 40 years with dermatomyositis and polymyositis have associated malignancy.
- Anti-Jo1 is associated with polymyositis and dermatomyositis, pulmonary disease, and increased mortality.
- Typical clinical scenario: A 50-year-old patient presents with bilateral progressive proximal muscle weakness. There is a history of arthralgias. On physical examination there is a rash over the eyelids bilaterally. Laboratory testing shows positive anti-Jo1 antibody and increased creatine kinase level.

Treatment of polymyositis includes prednisone (60 mg daily), usually for 1 to 2 months, until the muscle enzyme values normalize. The dosage is slowly reduced thereafter, and the clinical course and creatine kinase values are monitored. In severe or steroid-resistant cases, either azathioprine (1-2 mg/kg per day) or methotrexate can be used.

Aspiration pneumonia can occur as a result of pharyngeal weakness. If so, a liquid diet, feeding tube, or feeding gastrostomy is needed until there is clinical improvement.

Inclusion Body Myositis

Inclusion body myositis needs to be considered in the differential diagnosis of inflammatory myopathies. This usually occurs in the older age group. The onset of weakness is more insidious, occurring over many years. The creatine kinase value often is only minimally to several times increased, and distal and proximal weakness occur. The electromyogram, besides showing a myopathic picture, also has an associated neuropathic picture. The diagnosis of inclusion body myositis is made from biopsy. Histopathologic findings are indistinguishable from those of polymyositis except for the presence of eosinophilic inclusions and rimmed vacuoles with basophilic enhancement. Inclusion body myositis responds poorly to prednisone and immunosuppressive therapy, and the course is one of slow, progressive weakness.

- Inclusion body myositis usually occurs in the older age group.
- Diagnosis is made from biopsy.
- It responds poorly to prednisone.

Drug-Induced Myopathies

Muscle Disease

Drugs may cause an inflammatory myopathy. The myopathy associated with colchicine mimics polymyositis, and patients have muscle weakness and an increased creatine kinase level. This often occurs in the setting of a patient with gout and renal insufficiency receiving long-term therapy with colchicine. Lipid-lowering drugs such as the statins, other drugs including zidovudine, D-penicillamine, and hydroxychloroquine, and addictive drugs such as heroin or cocaine have all been associated with myopathy. Corticosteroids cause a steroid myopathy with proximal muscle weakness and a normal creatine kinase value.

Infectious Arthritis

An infectious cause should be ruled out immediately in a patient with acute monarticular arthritis. Approximately 5% to 10% of patients with septic arthritis present with multiple joint involvement.

Bacterial Arthritis

Nongonococcal bacterial arthritis is caused by hematogenous spread of bacteria, direct inoculation (which is usually traumatic), or extension of soft tissue infection with osteomyelitis into the joint space. Large joints are more commonly affected. Patients who are elderly or immunosuppressed are predisposed to septic arthropathy, including patients with cancer, diabetes mellitus, chronic renal failure, liver disease, or sickle cell anemia. Patients with chronic inflammatory and degenerative arthritis are also at increased risk for septic arthritis, and the possibility of septic arthritis should be considered in patients with a preexisting polyarthritis who have a single joint flare that is out of proportion to the rest of their joint symptoms. In any patient with a septic joint, the possibility of infectious endocarditis, other septic joints, or a disk space infection should be considered.

Septic arthritis is a medical emergency. A thorough search for a source of infection is important. Joint aspiration is required. Gram staining of centrifuged synovial fluid and appropriate cultures should be performed. Typically, patients with nongonococcal septic arthritis have a leukocyte value of more than 50,000/μL in the synovial fluid. Low glucose levels in synovial fluid and high levels of lactic acid are common but not specific for septic arthritis. Blood cultures should be performed when septic arthritis is considered. Radiographs of an involved joint may show an associated osteomyelitis or previous local trauma, but radiographic findings of infection usually lag considerably behind clinical symptoms.

Staphylococcus aureus is the most common pathogen in adult patients with nongonococcal bacterial arthritis. In sickle cell anemia, *Salmonella* is the organism commonly causing septic arthritis. *Pseudomonas* should be considered in the context of cat or dog bites, and an anaerobic infection should be considered in cases of human bites. Intravenous drug users may have bacteremia with unusual organisms, such as *Pseudomonas* or *Serratia*, and this may present with septic arthritis in unusual locations, such as the sternoclavicular or sacroiliac joints. The portal of entry may help predict the infecting organism; for example, gram-negative bacilli, such as *Escherichia coli* and *Klebsiella*, may cause septic arthritis in older patients with gastrointestinal or genitourinary infections or instrumentation.

Broad-spectrum antibiotics should be used until culture results are available. Daily aspiration and lavage of the affected joint should be performed until clinical improvement is obvious. Synovial fluid leukocytes and volume should decrease, or orthopedic arthroscopic or even open drainage should be considered. Such drainage usually is indicated in joints such as the hip, which are not readily accessible. The duration of treatment depends on the virulence of the organisms, but antibiotics usually are given intravenously for at least 2 weeks.

- Nongonococcal bacterial arthritis usually is caused by hematogenous spread of bacteria, direct inoculation (which is usually traumatic), or extension of soft tissue infection or osteomyelitis.

- Synovial fluid Gram stain and culture are essential.
- The portal of entry may predict the organism causing septic arthritis.
- Antibiotic therapy should be initiated even before culture results are available.
- If repeated aspiration and antibiotics do not lead to clinical improvement as well as a decrease in synovial fluid volume and leukocytosis, then arthroscopic or open drainage and debridement may be necessary.
- Typical clinical scenario: A patient presents with acute swelling of the right knee, fever, and constitutional symptoms. The joint is tender and painful.

Gonococcal Arthritis

Disseminated gonococcal infection develops in approximately 0.2% of patients with gonorrhea. The male:female ratio is 3:1. This is the most common form of septic arthritis in younger, sexually active persons who may be asymptomatic carriers of gonococci. When gonococcal infection is suspected, specimens from the pharynx, joints, rectum, blood, and genitourinary tract should be cultured. Females present with gonococcal arthritis commonly during pregnancy or within 1 week after onset of menses, possibly related to the pH of vaginal secretions. The most common form of gonococcal arthritis is the disseminated gonococcal arthritis syndrome with fever, dermatitis, and an inflammatory tenosynovitis. Approximately 50% of these patients present with an inflammatory arthritis, commonly of the knee, wrist, or ankle. Tenosynovitis is more common than large joint effusions. Rash, sometimes with pustules or hemorrhagic vesicles, is common. The second form of gonococcal arthritis commonly begins as a migratory polyarthralgia, which subsequently localizes to one or more joints.

Synovial fluid cultures are positive in only 30% of patients with known disseminated gonococcal infection. Culture of the skin lesion is positive for gonococcus in 40% to 60% of patients with disseminated gonococcal infection. The leukocyte count in the joint fluid may be lower than in the other types of septic arthritis. Joint effusions in patients with disseminated gonococcal infection may be related to a *reactive* postinfectious response rather than to bacterial invasion. Rare patients who have recurrent disseminated gonococcal infection may have an associated terminal complement component deficiency (C5-C9).

Most patients with disseminated gonococcal arthritis are treated as outpatients. Current treatment recommendations suggest a later third-generation cephalosporin, such as ceftriaxone, 1.0 g per day. Treatment involves a minimal 7-day course. Treatment should include an antichlamydial antibiotic.

- Gonococcal arthritis develops in 0.2% of patients with gonorrhea.
- In the disseminated gonococcal arthritis syndrome, fever, dermatitis, and tenosynovitis are common.
- In the nonbacteremic form of gonococcal arthritis, migratory polyarthralgias are followed by inflammation localizing to one or more joints.
- Synovial fluid cultures are positive in 30% of patients with known disseminated gonococcal infection.
- Joint fluid leukocyte counts may be lower than in other types of septic arthritis.
- Joint effusions may be related to a reactive or postinfectious arthritis.
- Treatment recommendations are the use of a later third-generation cephalosporin (e.g., ceftriaxone).
- Treatment should include an antichlamydial antibiotic.

Mycobacterial and Fungal Joint Infections

These types of organisms usually cause chronic bone and joint infections. Months are required for radiographic changes to be obvious. A synovial biopsy and culture may be required to document these infections. Tuberculous arthritis is often otherwise asymptomatic and usually is caused by direct extension from adjacent bony infection. Atypical mycobacterial infection may cause an inflammatory arthritis and tenosynovitis frequently involving the hand and wrist. Surgical excision and prolonged treatment with multiple drug regimens are often required. Sporotrichosis and blastomycosis are the fungi most likely to have osteoarticular manifestations.

- Tuberculous arthritis is often otherwise asymptomatic and is caused by direct extension from adjacent bony infection.
- Atypical mycobacterial infection may cause an inflammatory arthritis and tenosynovitis most commonly affecting the hand and wrist.
- Sporotrichosis and blastomycosis are the fungi most likely to have osteoarticular manifestations.

Spinal Septic Arthritis

This condition should be suspected in patients with acute or chronic, unrelenting back pain associated with fever and marked local tenderness. The thoracolumbar region is most commonly affected. An antecedent infection or procedure predisposing to bacteremia may help suggest this diagnosis. Imaging studies usually have evidence for infection crossing the disk space. In tuberculous spinal septic arthritis (Pott disease), the site of involvement is most commonly T10-L2, and there is usually an associated paraspinal abscess.

Intravertebral disk infection is often a difficult diagnosis to establish because pain patterns may be unusual and localizing signs may be absent. Bone scanning may be helpful, but magnetic resonance imaging may be very helpful, particularly because of the ability to show extension of infection into surrounding tissues.

Infected Joint Prostheses

Infection in joint prostheses occurs in 1% to 5% of all joint replacements. Symptoms and signs of infection may be difficult to detect during the postoperative period. Fever may not be present, and laboratory findings are often unhelpful, although the erythrocyte sedimentation rate may be increased. There may or may not be evidence of loosening of the cement holding the new joint in place, and radiographs may reveal lytic changes around the prosthesis. A negative bone scan is reassuring. Aspiration of fluid from the prosthetic joint is necessary to confirm infection. Prosthetic joint arthritis usually is caused by gram-positive organisms, particularly *Staphylococcus aureus* and *Staphylococcus epidermidis*, in the first 6 months after the

replacement operation and by gram-negative and fungal organisms after 6 months. In long-standing prosthetic joints, return of pain and evidence of prosthetic loosening may be the only signs and symptoms. Patients with prosthetic joints do not require antibiotic prophylaxis before invasive dental, gastrointestinal, or genitourinary procedures according to the recent guidelines, unless obvious immunosuppression is present.

- Prosthetic joint arthritis usually is caused by a gram-positive organism within the first 6 months after joint replacement.
- Prosthetic joint infections usually are caused by gram-negative or fungal organisms beyond the initial 6 months after joint replacement.

Lyme Disease

Lyme disease is a tick-borne spirochetal illness with acute and chronic manifestations primarily affecting the skin, heart, joints, and nervous system. Diagnosis is important because treatment with appropriate antibiotics at an early stage of disease can prevent chronic sequelae. Even some chronic symptoms are treatable. Endemic areas in the United States include Connecticut, Delaware, Maryland, Massachusetts, New Jersey, New York, Pennsylvania, Rhode Island, Minnesota, Wisconsin, California, Nevada, Oregon, and Utah.

- Lyme disease is a tick-borne spirochetal illness.
- Acute and chronic manifestations affect skin, heart, joints, and nervous system.

The Tick

Ticks that transmit Lyme disease include *Ixodes dammini* in the northeastern and midwestern United States and *Ixodes pacificus* in the western United States. *Amblyomma americanum* ("lone star" tick) is a possible vector in the eastern, southern, and western United States. *Ixodes scapularis* is the common deer tick. It has a wide distribution. Humans are accidental hosts.

The Spirochete

Borrelia burgdorferi was an unknown organism until isolated initially from ticks by Burgdorfer in 1983. It is similar to an organism causing relapsing fever. It apparently exists only in the digestive tract of tick vectors.

Clinical Stages

Signs and symptoms occur in stages that may overlap. Later stages may occur without evidence of previous disease.

Stage I

About 50% to 67% of patients experience erythema chronicum migrans. Flu-like symptoms, including fever, headache, malaise, and adenopathy, can occur. They usually occur several days to a month after the tick bite.

- In stage I Lyme disease, 50%-67% of patients experience erythema chronicum migrans.

Stage II

Symptoms begin weeks to months after the initial symptoms in stage I. Disseminated infection develops and can include symptoms of the skin, musculoskeletal system, heart, and nervous system. In approximately 15% of untreated patients, neurologic symptoms develop, including Bell palsy, meningoencephalitis, and sensory and motor radiculoneuritis. Approximately 5% of untreated patients have cardiac abnormalities, including heart block. About 30% to 50% of untreated patients have arthritis. This usually affects large joints, primarily the knees, and joint fluid analysis shows a leukocytosis similar to that in rheumatoid arthritis. Baker cysts may form early and are prone to rupture in patients who have arthritis of the knees.

- In stage II Lyme disease, symptoms begin weeks to months after initial symptoms of stage I.
- Disseminated infection develops.
- 15% of untreated patients have neurologic symptoms.
- 5% of untreated patients have cardiac abnormalities.
- 30%-50% of untreated patients have arthritis.

Stage III

This usually occurs several years after the initial onset of illness. Episodes of arthritis can develop and become chronic. Histologically, the synovium resembles that in rheumatoid arthritis, although a unique feature of Lyme arthritis is the finding of an obliterative endarteritis. Spirochetes occasionally are seen in and around the blood vessels. Patients in whom chronic joint disease develops have increased frequency of HLA-DR4, often in combination with HLA-DR2. Patients with chronic arthritis have a poor response to antibiotics.

- Stage III Lyme disease occurs several years after initial onset of illness.
- Episodes of arthritis can be chronic.
- Synovium resembles that in rheumatoid arthritis.
- A unique feature of Lyme arthritis is obliterative endarteritis in the synovium.
- Patients with chronic joint disease have increased frequency of HLA-DR4, often in combination with HLA-DR2.

Diagnosis

Culturing the organism is difficult and of low yield. Antibody to spirochete can be measured by several techniques. The enzyme-linked immunosorbent assay (ELISA) is most commonly performed, but there is a substantial frequency of false-positive results. Patients with other autoimmune disease can have false-positive results. Also, such results may occur in syphilis, relapsing fever, and Rocky Mountain spotted fever. Up to 25% of patients with lupus and rheumatoid arthritis have false-positive results of Lyme test by ELISA. It is important to remember that test results remain negative for up to 4 to 6 weeks after infection. Also, if patients are treated early with tetracycline or another antibiotic, the results might never be positive, although symptoms of chronic Lyme disease can result. The Western blot assay for Lyme disease is now being used as a confirmatory test if the ELISA test result is positive.

- In Lyme disease, culturing the organism is difficult and of low yield.
- The ELISA assay is commonly performed but there is a substantial frequency of false-positive results.
- False-positive ELISA results may occur in syphilis, relapsing fever, and Rocky Mountain spotted fever.
- Up to 25% of patients with lupus and rheumatoid arthritis have false-positive results of Lyme test by ELISA.
- Patients treated early with tetracycline or other antibiotics may never have positive results.

Treatment

For early treatment of Lyme disease, either oral tetracycline or doxycycline, or amoxicillin in children, for 14 to 21 days can prevent later complications. The optimal treatment for patients with neurologic, cardiac, and arthritic symptoms of Lyme disease includes ceftriaxone, 2 g intravenously daily for 28 days. Patients with Lyme disease can experience worsening of symptoms analogous to the Jarisch-Herxheimer reaction and can be treated with acetaminophen.

- Early treatment of Lyme disease is either oral tetracycline or doxycycline (amoxicillin in children) for 14-21 days.
- Treatment for neurologic, cardiac, and arthritic symptoms of Lyme disease includes ceftriaxone for 28 days.

Rheumatic Fever and Poststreptococcal Reactive Arthritis

Arthritis affects two-thirds of all patients with rheumatic fever. One-third of patients with acute rheumatic fever have no obvious antecedent pharyngitis. In adults, arthritis may be the only clinical feature of acute rheumatic fever and often occurs early. The arthritis usually involves the large joints, particularly the knees, ankles, elbows, and wrists. The arthritis may be migratory, with each joint remaining inflamed for approximately 1 week. The arthritis of rheumatic fever is nonerosive; however, repeated attacks may result in a Jaccoud deformity, in which the metacarpophalangeal joints are in ulnar deviation as a result of tendon laxity rather than bony damage.

Patients with joint symptoms without carditis may be treated with high-dose salicylates (3-6 g per day). Corticosteroids may be required if patients do not respond to salicylates. Joint symptoms may rebound when anti-inflammatory therapy is discontinued.

- The arthritis in rheumatic fever may be migratory and usually involves the large joints, particularly the knees, ankles, elbows, and wrists.
- Repeated attacks of rheumatic fever may result in Jaccoud deformity.
- The mainstay treatment for the arthritis of rheumatic fever is high-dose salicylates (3-6 g per day).

Viral Arthritis

Viruses associated with arthralgia and arthritis include human immunodeficiency virus (HIV), hepatitis B, rubella, parvovirus, and, less commonly, mumps, adenovirus, herpesvirus, and enterovirus. Most viral-related arthritides have joint symptoms with a semiacute onset, but fortunately they are usually of brief duration. The arthritis is nondestructive.

Although *parvovirus* infection in children is usually mild, in adults associated arthralgias and arthritis are common, and the distribution of involved joints is symmetric and may mimic rheumatoid arthritis. Joint symptoms in adults are usually self-limited, but chronic disease develops in some patients. The diagnosis of parvovirus infection is made by demonstrating the presence of anti-B19 IgM antibodies, but these may be increased in patients for only 2 months after acute infection. Because the joint symptoms usually occur approximately 1 to 3 weeks after the initial infection, the antibodies are usually present at the time of onset of rash or joint symptoms. Treatment is usually conservative and includes anti-inflammatory medications, but in more chronic infections more aggressive treatment such as low-dose corticosteroids may be warranted. Parvovirus infection also has been associated rarely with significant hematologic abnormalities.

Hepatitis B virus infection has been associated with an immune complex-mediated arthritis, which can be dramatic. The arthritis is usually limited to the pre-icteric prodrome, although patients with chronic types of hepatitis may have recurrent arthralgias or arthritis. Polyarteritis nodosa has been associated with chronic hepatitis. *Hepatitis B* and more commonly *hepatitis C* are associated with mixed cryoglobulinemia. *Rubella* virus infection is frequently associated with joint complaints in young adults. In a few patients, the symptoms have persisted for months to years. Joint symptoms may occur just before or after the appearance of the characteristic rash.

- Parvovirus infection in adults may cause a symmetric polyarthritis mimicking rheumatoid arthritis.
- Parvovirus infection can be documented by demonstrating the presence of anti-B19 IgM antibodies.
- Hepatitis B virus infection has been associated with an arthritis limited to the pre-icteric prodrome.
- Hepatitis B and C viremia have been associated with cryoglobulinemia and vasculitis.
- Rubella virus infection frequently is associated with joint complaints in young adults.

Rheumatologic Manifestations of HIV Infection (Table 23-33)

Musculoskeletal complaints can be among the first manifestations of HIV infection. Articular manifestations can be extremely debilitating. Epidemiologic studies have not concluded whether HIV infection predisposes to arthritis or whether other viral or new mechanisms associated with HIV infection have a role in the pathogenesis of arthritis.

Reactive Arthritis and Undifferentiated Spondyloarthropathy

Signs and symptoms of reactive arthritis, psoriatic arthritis, or a nonspecific enthesopathy and related destructive arthritis may occur before or simultaneously with the onset of HIV infection. The

Serologic abnormalities

prevalence of these conditions in HIV-infected patients varies from 0.5% to 10% in reports. These HIV-associated spondyloarthropathies have a predisposition for patients who are HLA-B27–positive and frequently are associated with severe enthesopathy and dactylitis. Progressive axial involvement is less common in HIV-associated arthritides. The foot and ankle are common sites of enthesopathy in reactive arthritis, which may be severe. Symptoms may be episodic. Most HIV-infected patients with reactive arthritis have skin and mucocutaneous manifestations, including urethritis, keratoderma blennorrhagicum, circinate balanitis, or painless oral ulcers, but conjunctivitis is unusual. In approximately one-third of patients, the onset of HIV-associated reactive arthritis has been linked to a documented infection with specific enteric organisms known to precipitate reactive arthritis. Genitourinary tract infection with *Ureaplasma* or *Chlamydia* is less common.

- Enthesopathy and dactylitis may be severe in HIV-infected patients.
- Mucocutaneous features are common, but conjunctivitis is unusual.

Lupus-Like Illnesses in HIV Infection

Some of the features of systemic lupus erythematosus are similar to those in HIV infection. Fever, lymphadenopathy, mucous membrane lesions, rashes, arthritis, and hematologic abnormalities are common to both lupus and HIV infection. HIV infection also may be associated with polyclonal B-cell activation resulting in autoantibody production, including antinuclear and antiphospholipid antibodies. HIV infection should be considered in the differential diagnosis of systemic lupus erythematosus in any patient who is at risk for HIV. Antinuclear antibodies in high titer have not been found in HIV infection, and antibodies to double-stranded DNA are absent.

- Although some features of HIV infection may resemble lupus, antinuclear antibodies are present in low titer only, and antibodies to double-stranded DNA are absent.

HIV-Associated Vasculitis

Different types of vasculitic syndromes have been described in association with HIV infection. Primary angiitis of the central nervous system, angiocentric lymphoproliferative lesions related to lymphomatoid granulomatosis, and polyarteritis nodosa have been reported. It has not been established whether the association of vasculitis and HIV infection is coincidental, related to comorbidities such as drugs or other infections, or represents a direct pathogenetic role for the HIV. All patients with primary angiitis of the central nervous system and lymphoproliferative angiocentric vasculopathies should be tested for HIV. Any person with known HIV infection who presents with new mononeuritis should be evaluated for vasculitis.

Other HIV-Associated Rheumatic Syndromes

The diffuse, infiltrative lymphocytosis syndrome is manifested by xerostomia, xerophthalmia, and salivary gland swelling mimicking Sjögren syndrome. The glands are infiltrated with CD8 lymphocytes. In contrast to Sjögren syndrome, HIV-positive patients usually do not have antibodies to SS-A or SS-B and are usually rheumatoid factor-negative.

There is an inflammatory articular syndrome associated with HIV infection which is distinct from any resemblance to spondyloarthropathy. Usually this is an oligoarthritis affecting joints of the lower extremities and is short-lived.

There is an acquired immunodeficiency syndrome-associated myopathy that may be viral. There is also a myopathy due to zidovudine therapy. Fibromyalgia also has been reported in up to 25% of HIV-infected patients.

Other Types of Infectious Arthritis

Whipple disease is a rare cause of arthropathy and usually is associated with constitutional symptoms, fever, neurologic symptoms, malabsorption, lymphadenopathy, and hyperpigmentation. There may be a slow, progressive dementia. The arthritic symptoms may precede the gastrointestinal manifestations. The infectious agent is *Tropheryma whippelii*. Small bowel or synovial biopsy may be necessary to establish the diagnosis. Treatment is usually with doxycycline or trimethoprim-sulfamethoxazole, often required for a year.

Vascular Diseases

Peter C. Spittell, MD

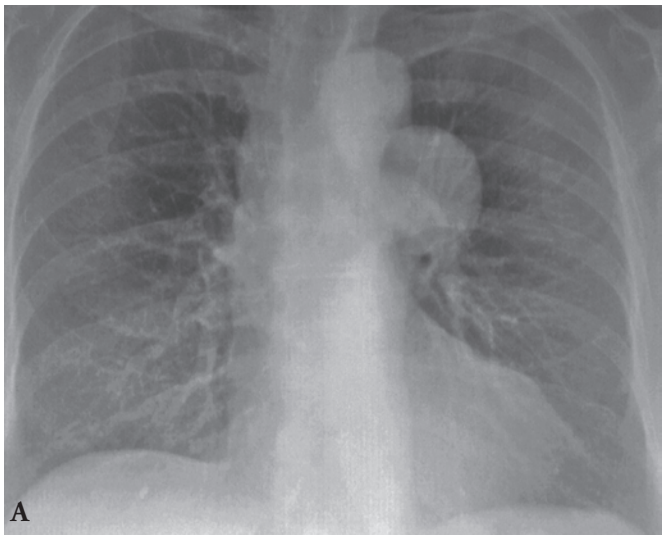
Peripheral vascular diseases are prevalent in current medical practice. Characteristic clinical features, accurate diagnostic techniques, and improved treatment of peripheral vascular disease further emphasize the need for increased awareness of this group of disorders.

Disease of the Aorta

Aneurysmal Disease

Thoracic Aortic Aneurysm

Thoracic aortic aneurysms are caused most commonly by atherosclerosis, but they also occur in patients with systemic hypertension, inherited disorders of connective tissue (e.g., Marfan syndrome), giant cell arteritis (cranial and Takayasu disease), and infection and as a result of trauma. There is also a familial tendency. Most thoracic aortic aneurysms are asymptomatic and are discovered incidentally on chest radiography (Fig. 24-1). Symptoms, when present, may include chest or back pain, vocal hoarseness, cough, dyspnea, stridor,



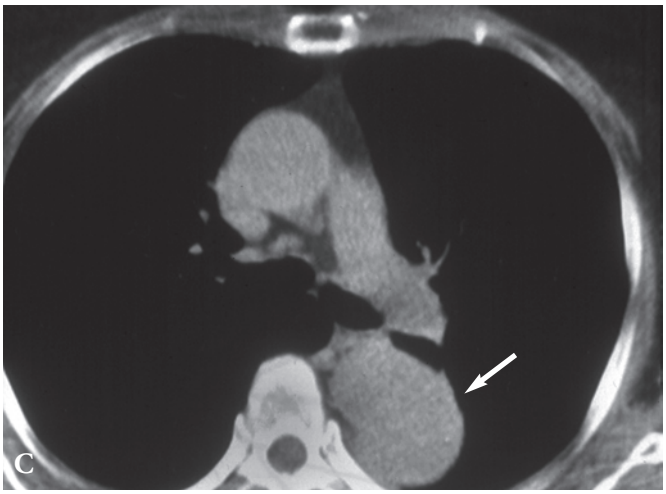


Fig. 24-1. *A* and *B*, Chest radiographs (*A*, anteroposterior; *B*, lateral) show a large mass in the left posterior chest. *C*, Computed tomogram shows a saccular aneurysm in the mid-descending thoracic aorta.

and dysphagia. Findings on physical examination may include systemic hypertension, fixed distention of a neck vein(s), aortic regurgitation, a fixed vocal cord, signs of cerebral or systemic embolism, and other aneurysmal disease (i.e., abdominal aortic aneurysm). Complications of thoracic aortic aneurysm include rupture, dissection, embolism, pressure on surrounding structures, infection, and, rarely, thrombosis. Factors that seem to worsen the prognosis include diastolic hypertension, aneurysm size (critical hinge point for rupture >6 cm ascending aorta and >7 cm descending thoracic aorta), traumatic aneurysm, and associated coronary and carotid artery disease. The overall cumulative risk of rupture after 5 years is 20%, but rupture risk is a function of aneurysm size at recognition (0% for aneurysms <4 cm in diameter, 16% for aneurysms 4.0-5.9 cm, and 31% for aneurysms ≥6.0 cm). Computed tomography (CT), magnetic resonance imaging (MRI) (Fig. 24-2), and transesophageal echocardiography (TEE) are all accurate in the diagnosis of thoracic aortic aneurysm. Medical management of thoracic aortic aneurysm includes control of systemic hypertension (preferably with a β-adrenergic blocking agent), discontinuation of tobacco use, diagnosis and treatment of associated coronary and carotid artery disease, and follow-up combining clinical assessment and noninvasive imaging tests. Indications for surgical resection include the presence of symptoms attributable to the aneurysm, an aneurysm rapidly enlarging under observation (particularly if the patient has poorly controlled hypertension), traumatic aneurysm, pseudoaneurysm, mycotic aneurysm, and an aneurysm 6 cm or more in diameter (5.5-6 cm in low-risk patients). In patients with Marfan syndrome, operation is indicated when the ascending aortic diameter exceeds 4.5 to 5 cm.

Fig. 24-2. Magnetic resonance angiograph (longitudinal view) shows a large ascending aortic aneurysm and moderate aortic regurgitation.

Abdominal Aortic Aneurysm

Approximately three-fourths of all atherosclerotic aneurysms involve the abdominal aorta. Most abdominal aortic aneurysms (AAAs) are infrarenal, and 2% to 5% are suprarenal, usually the result of distal extension of a thoracic aneurysm (thoracoabdominal aneurysm). Men are affected more frequently than women (9:1), and the majority of patients are older than 50 years. There is a familial tendency for development of AAA, and both sex-linked and autosomal patterns of inheritance are involved. There is a strong association with current or prior chronic tobacco exposure. Infection and trauma are additional causes of AAA.

The majority of patients with AAA are asymptomatic. The most common physical examination finding is the presence of a pulsatile abdominal mass. The sensitivity of abdominal palpation for the detection of AAA is 43% overall (57% for aneurysms ≥4.0 cm in diameter, 29% for aneurysms <4.0 cm in diameter). A tortuous abdominal aorta, transmitted pulsation from an abdominal mass, or a horseshoe kidney anteriorly displacing the abdominal aorta are conditions that can mimic AAA on physical examination. Because physical examination for the detection of AAA lacks sensitivity, screening tests are indicated in high-risk subsets of patients. Early detection of AAA can reduce mortality. Furthermore, single screening ultrasonography for men older than 65 years can identify the majority of AAAs. The United States Preventive Services Task Force recommends a one-time screening ultrasonography in men ages 65 to 75 years who have ever smoked. Screening of siblings and first-degree relatives of patients with aneurysm generally begins at age 50 years.

When AAAs are symptomatic without rupture, the most common complaint is abdominal pain. New low back pain can occur and may be due to dissection within the aneurysm or retroperitoneal hematoma. Abdominal pain radiating to the flank, groin, or testes also may occur. Livedo reticularis, blue toes with palpable pulses, hypertension, renal insufficiency, increased erythrocyte sedimentation rate, and transient eosinophilia characterize atheroembolism in association with AAA (Fig. 24-3). Atheroembolism can occur spontaneously or as a result of anticoagulants (warfarin or thrombolytic therapy) or angiographic or surgical procedures. Treatment of choice is surgical resection of the symptomatic AAA if feasible.

The most frequent complication of AAA is rupture, which is related to aneurysm size: 1-year incidence of rupture for AAA diameter 5.5 to 5.9 cm is 9.4%; diameter 6.0 to 6.9 cm, 10.2%; diameter 7.0 cm or more, 32.5%. The triad of severe abdominal pain, hypotension, and a tender abdominal mass characterizes rupture of an AAA. The pain is acute in onset, constant, and severe, most commonly located in the lumbar area or diffusely throughout the abdomen, with radiation into the flanks, genitals, or legs. The abdominal aorta is usually tender, and there may be peritoneal signs if free rupture into the peritoneal cavity has occurred. Less common presentations of AAA include obstructive uropathy due to ureteral compression, gastrointestinal hemorrhage when the aneurysm ruptures into the intestinal tract, high-output congestive heart failure due to an aortocaval fistula, and disseminated intravascular coagulation.

AAA can be diagnosed reliably with ultrasonography, CT, or MRI (Fig. 24-4). Angiography is not required unless the renal or

Fig. 24-3. *A* and *B*, Patient with atheroembolism, characterized by livedo reticularis (upper thighs, plantar surface of feet) and multiple blue toes.

peripheral arterial circulation needs to be visualized to plan treatment.

Medical management of AAA includes control of systemic hypertension (preferably with a β-adrenergic blocking agent), discontinuation of tobacco use, treatment of associated coronary and carotid artery disease, and serial noninvasive imaging tests. Noninvasive imaging should be used to assess both absolute aneurysm size and growth rate. The frequency of surveillance is based on aneurysm size at initial detection (Table 24-1).

In a good-risk patient, selective surgical treatment of AAA should be considered for aneurysms 5.0 to 5.5 cm in diameter. When the patient has considerable comorbid conditions (pulmonary, cardiac, renal, or liver disease), surgical therapy is individualized. Endovascular repair of AAA with stent grafts that are delivered intraluminally by catheters is an alternative to open surgical repair, and early results are comparable to those of open repair. At tertiary care centers, more than 30% of AAA repairs are accomplished with an endovascular approach. With extended follow-up, however, postoperative complications and graft failures have been reported in some patients, resulting in reintervention, conversion to open repair, or death. The high incidence of secondary interventions brings into question the durability of endograft repair and emphasizes the need for detailed long-term follow-up care.

Inflammatory AAA accounts for approximately 2% to 4% of all AAAs. An inflammatory AAA is suggested by the triad of abdominal or back pain, weight loss, and increased erythrocyte sedimentation rate. Obstructive uropathy may occur with ureteral involvement. The findings on CT are diagnostic. The treatment is surgical resection regardless of aneurysm size. The role of corticosteroids is not well defined.

Operation is also indicated for AAAs that are symptomatic, traumatic, infectious in origin, or rapidly expanding (>0.5 cm a year).

- Elective surgical repair is definitely indicated when the AAA diameter is more than 5.0 cm in good-risk patients.
- Surgical treatment is also indicated for AAAs that are symptomatic, traumatic, infectious in origin, or are rapidly expanding (>0.5 cm a year).
- The triad of back pain, weight loss, and increased erythrocyte sedimentation rate suggests an inflammatory AAA. The findings on CT are diagnostic. Treatment is surgical resection regardless of aneurysm size.

Aortic Dissection

Etiology

The most common predisposing factors for aortic dissection are advanced age, male sex, hypertension, Marfan syndrome, and congenital abnormalities of the aortic valve (bicuspid or unicuspid valve). When aortic dissection complicates pregnancy, it usually occurs in the third trimester. Iatrogenic aortic dissection, as a result of cardiac operation or invasive angiographic procedures, also can occur.

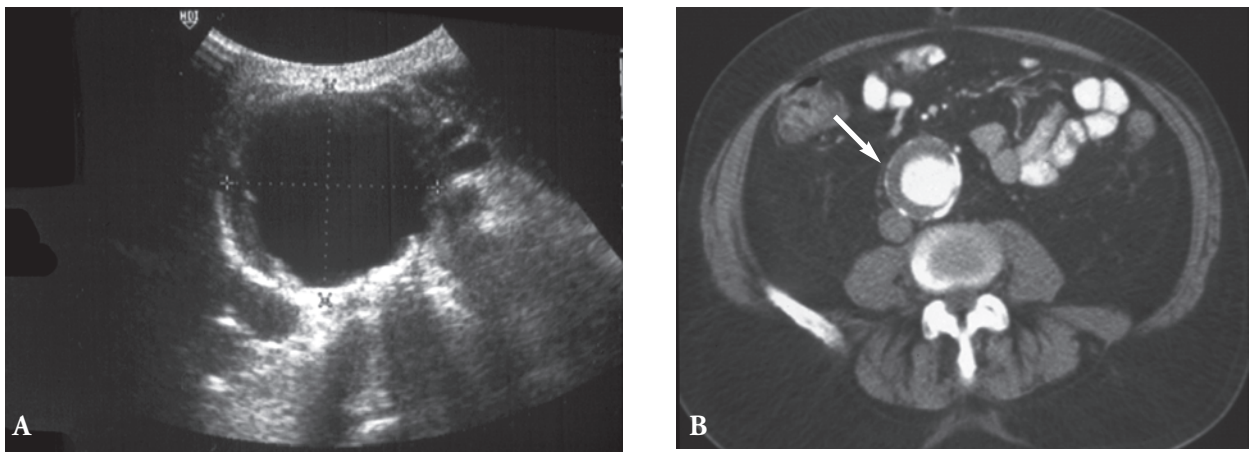

Fig. 24-4. *A*, Ultrasonogram (transverse view) shows a 4.7-cm abdominal aortic aneurysm. *B*, Computed tomogram (contrast-enhanced) shows an abdominal aortic aneurysm with moderate mural thrombus.

Table 24-1 Surveillance of Abdominal Aortic Aneurysm

Size at initial detection, cm	Surveillance interval
3.0-3.4	3 y
3.5-3.9	1 y
4.0-4.9	6 mo
≥5.0	3 mo*

*If surveillance is ongoing (vs. surgery).

Data from McCarthy RJ, Shaw E, Whyman MR, Earnshaw JJ, Poskitt KR, Heather BP. Recommendations for screening intervals for small aortic aneurysms. Br J Surg. 2003;90:821-6.

Classification

Aortic dissection involving the ascending aorta is designated as type I or II (proximal, type A), and dissection confined to the descending thoracic aorta is designated as type III (distal, type B) (Fig. 24-5).

Clinical Features

The acute onset of severe pain (often migratory) in the anterior aspect of the chest, back, or abdomen occurs in 70% to 80% of patients, and hypertension is present in 60% to 80%. Additional findings include aortic diastolic murmur (15%-20%), pulse deficits (10%-40%), and neurologic changes (10%-30%). Syncope in association with aortic dissection occurs when there is rupture into the pericardial space, producing cardiac tamponade. Congestive heart failure is most commonly due to severe aortic regurgitation. Acute myocardial infarction (most commonly inferior infarction due to right coronary artery ostial involvement), pericarditis, and complete heart block are additional cardiac presentations.

Clues to type I aortic dissection include substernal pain, aortic valve incompetence, decreased pulse or blood pressure in the right arm, decreased right carotid pulse, pericardial friction rub, syncope, ischemic electrocardiographic changes, and Marfan syndrome.

Clues to type III aortic dissection include interscapular pain, hypertension, and left pleural effusion.

- In a patient with a catastrophic presentation, systemic hypertension, and unexplained physical findings of vascular origin, especially in the presence of chest pain and an aortic murmur, aortic dissection should always be included in the differential diagnosis and an appropriate screening test performed on an emergency basis.

Laboratory Tests

Chest radiography may show widening of the superior mediastinum and supracardiac aortic shadow, deviation of the trachea from the midline, a discrepancy in diameter between the ascending and descending aorta, and pleural effusion (Fig. 24-6). Normal findings on chest radiography do not exclude aortic dissection.

Electrocardiography most commonly reveals left ventricular hypertrophy, but ST-segment depression, ST-segment elevation, T-wave changes, and the changes of acute pericarditis and complete heart block can occur.

Diagnosis

Aortic dissection can be definitively diagnosed with any of the following imaging methods: echocardiography, CT, MRI, and aortography (Fig. 24-7).

Combined transthoracic and transesophageal echocardiography (TTE/TEE) can be used to identify an intimal flap, entry and reentry sites, a dilated aortic root (>4 cm), thrombus formation, widening of the aortic walls, aortic regurgitation, pericardial effusion or cardiac tamponade, pleural effusion, involvement of the left common carotid or left subclavian arteries, and proximal abdominal aortic involvement. Multiplane transducers have markedly improved the accuracy of TEE. Advantages of TEE include portability, safety, accuracy, rapid diagnosis, use in patients with hemodynamic instability, and intraoperative applications.

CT can accurately detect the intimal flap, identify two lumina, and show displaced intimal calcification, a disparate size between the ascending and descending aortic lumina, hemopericardium, pleural effusion, and abdominal aortic involvement. Disadvantages of CT include nonportability (limiting use in patients with hemodynamic instability) and the need for intravenous contrast agents.

MRI is highly accurate for the diagnosis of aortic dissection. Demonstration of the intimal flap, entry or exit sites, thrombus formation, aortic regurgitation, pericardial effusion, pleural effusion, and abdominal aortic involvement is possible. MRI is also able to delineate involvement of aortic arch vessels. Disadvantages of MRI include cost, nonportability, and other standard MRI contraindications.

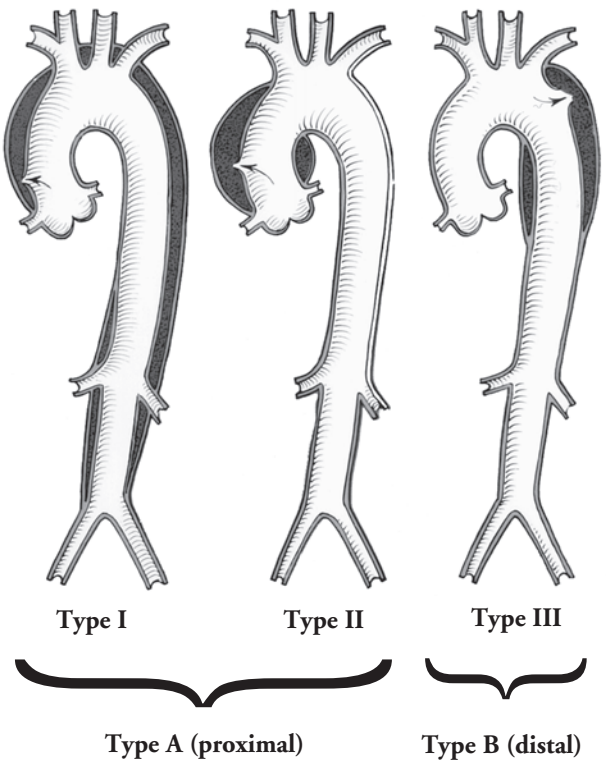

Fig. 24-5. Classification system for aortic dissection.

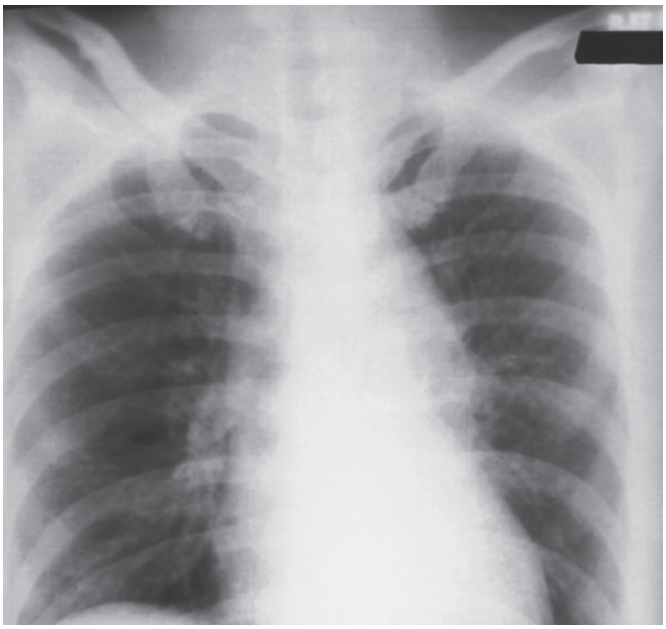

Fig. 24-6. Chest radiograph in a patient with aortic dissection shows widening of the superior mediastinum.

Aortography can accurately diagnose aortic dissection by showing the intimal flap, opacification of the false lumen, and deformity of the true lumen. Also, associated aortic regurgitation and coronary artery anatomy can be visualized, in addition to branch vessel involvement. The disadvantages include invasive risks, exposure to intravenous contrast agents, and nonportability.

The choice of test (TTE/TEE, CT, MRI, or aortography) in a patient with suspected acute aortic dissection depends on which is most readily available and the hemodynamic stability of the patient.

The initial management of suspected acute aortic dissection is shown in Figure 24-8.

The most common cause of death is rupture into the pericardial space, with subsequent cardiac tamponade. Cardiac tamponade due to aortic dissection is a surgical emergency, and pericardial fluid should be removed only in the operating room after cardiopulmonary bypass has been instituted. Echocardiographically guided pericardiocentesis in a patient with cardiac tamponade complicating aortic dissection is associated with an increased risk of aortic rupture and death. Other causes of death in aortic dissection include acute congestive heart failure due to severe aortic regurgitation, rupture through the aortic adventitia, rupture into the left pleural space, and occlusion of vital arteries.

- Aortic dissection can be diagnosed with TTE/TEE, CT, MRI, or aortography.

Treatment

Pharmacologic therapy should be instituted as soon as the diagnosis of aortic dissection is suspected (Table 24-2). Emergency operation is indicated in types I and II (proximal, type A) aortic dissection. Continued pharmacologic therapy in the coronary care unit is the preferred initial management in type III (distal, type B) aortic dissection, and surgical therapy is delayed (2-3 weeks) for selected patients whose general medical condition permits operation. When long-term pharmacologic therapy for type III aortic dissection is used, indications for operation include development of saccular aneurysm, increasing aortic diameter, or symptoms related to chronic dissection.

- Emergency operation is indicated in types I and II aortic dissection.
- Pharmacologic treatment is the preferred initial management in type III aortic dissection.

Penetrating Aortic Ulcer

Penetrating aortic ulcer occurs when an atherosclerotic plaque undergoes ulceration and penetrates the internal elastic lamina. It results in one of four possible consequences: 1) formation of an intramural hematoma, 2) formation of a saccular aneurysm, 3) formation of a pseudoaneurysm, or 4) transmural aortic rupture. Penetrating aortic ulcer most commonly involves the mid or distal descending thoracic aorta, less often the ascending or abdominal aorta. The clinical

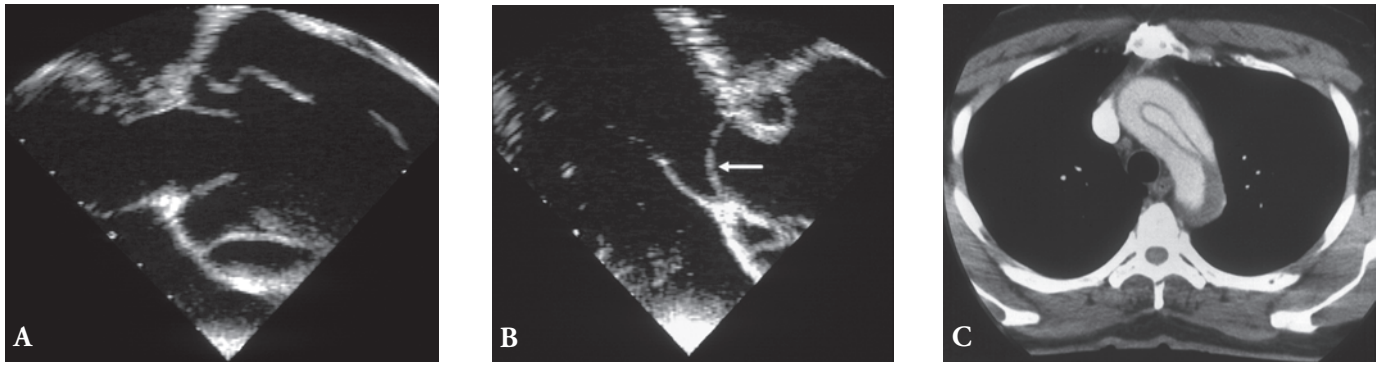

Fig. 24-7. *A*, Multiplane transesophageal echocardiogram (longitudinal view) shows an intimal flap in the ascending aorta. *B*, In diastole, the intimal flap prolapses through the aortic valve (*arrow*). *C*, Computed tomogram (contrast-enhanced) shows a spiraling intimal flap in the transverse aortic arch.

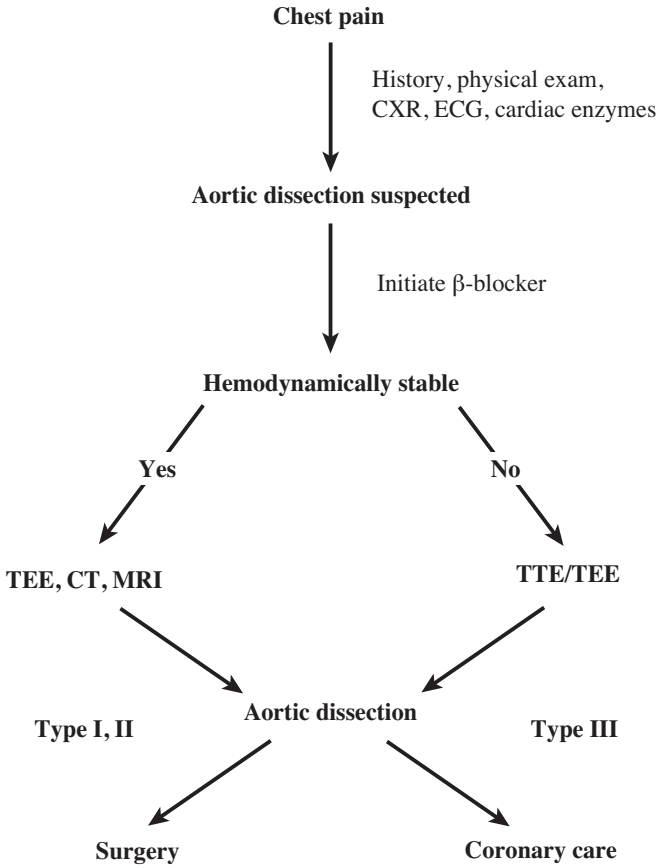

Fig. 24-8. Algorithm for initial management of suspected acute aortic dissection. CT, computed tomography; CXR, chest radiography; ECG, electrocardiography; MRI, magnetic resonance imaging; TEE, transesophageal echocardiography; TTE, transthoracic echocardiography.

features of penetrating aortic ulcer are similar to those of aortic dissection and include acute onset of pain in the anterior or posterior chest (or both) and hypertension. Pulse deficits, neurologic signs, and acute cardiac disease (aortic regurgitation, myocardial infarction, pericardial effusion) do not occur in penetrating aortic ulcer, as they do in classic aortic dissection.

The treatment of penetrating aortic ulcer is usually nonoperative if only an intramural hematoma is present. With control of hypertension, the intramural hematoma tends to resolve spontaneously over time. Surgical therapy is indicated for patients who have ascending aortic involvement, patients in whom a saccular aneurysm or pseudoaneurysm develops, or patients with intramural hematoma who have persistent symptoms, increasing aortic diameter, or poorly controlled hypertension. The most common serious complication of surgical therapy for penetrating aortic ulcer is paraplegia.

Aortic Intramural Hematoma

Aortic intramural hematoma is characterized by the absence of an intimal tear and also is associated with cystic medial necrosis. Aortic intramural hematoma is increasingly recognized, largely due to advances in noninvasive imaging techniques. The exact cause of aortic intramural hematoma is not well defined. Aortic intramural hematoma is diagnosed in the same manner as aortic dissection. The classification schemes are also identical, and traditionally the management has been similar—operation for type A intramural hematoma and medical treatment for type B lesions.

Incomplete Aortic Rupture

Incomplete rupture of the thoracic aorta (in the region of the aortic isthmus) results from a sudden deceleration injury. It occurs most often in victims of motor vehicle accidents and should be suspected when there is evidence of chest wall trauma, decreased or absent leg pulses, left-sided hemothorax, or widening of the superior mediastinum on chest radiography. Affected patients are usually hypertensive at initial presentation. TEE, CT, MRI, or angiography can confirm the diagnosis (Fig. 24-9). Treatment is emergency surgical repair in patients who are suitable surgical candidates. At initial presentation, the condition of 40% to 50% of patients is unstable. No clinical or imaging criteria accurately predict future complete rupture, so even if a patient presents with a chronic incomplete rupture, operation is still indicated. Most patients are young, and the risk of elective surgical repair is low, with an otherwise good prognosis for long-term survival if aortic repair is successful.

- Incomplete rupture of the thoracic aorta (in the region of the aortic isthmus) results from a sudden deceleration injury, frequently a motor vehicle accident.

Thoracic Aortic Atherosclerosis

Atherosclerosis of the thoracic aorta usually involves the origin of the brachiocephalic arteries, principally the left subclavian and occasionally the innominate artery. Although atherosclerotic disease of the aortic arch branches is usually asymptomatic, stenosis of the origin of the left or right subclavian artery may cause intermittent claudication of the arm of sufficient degree to warrant surgical treatment. With complete occlusion of the origin of either subclavian artery, collateral blood flow to the arm may be derived principally from the cerebral circulation via reversed flow through the ipsilateral vertebral artery, so-called subclavian steal. This may result in episodes of transient cerebral ischemia, especially when the ipsilateral arm is exercised. A similar situation may occur on the right side if the obstruction occurs at the origin of the innominate artery, in which case flow in the right vertebral artery can "reverse" to enter the right subclavian artery. In addition to the symptoms of transient cerebral ischemia, physical signs of this condition include reduced arm and wrist pulses and reduced blood pressure on the affected side. The astute examiner, when palpating both radial pulses simultaneously, also may detect a delay in pulsation on the affected side.

Furthermore, a coronary-subclavian steal phenomenon may occur in patients who have undergone prior coronary artery bypass grafting in which the internal mammary artery is used. When a hemodynamically significant subclavian artery stenosis is present ipsilateral to the internal mammary artery graft, flow through the internal mammary artery may reverse or "steal" during upper extremity exercise.

Table 24-2 Initial Pharmacologic Therapy for Acute Aortic Dissection

Hypertensive patients
Sodium nitroprusside intravenously (2.5-5.0 μg/kg per minute)
with
Propranolol intravenously (1 mg every 4-6 h)
• Goal: Systolic blood pressure in the range of 110 mm Hg (or the lowest level maintaining a urine output of 25-30 mL/h) until oral medication is started
Or Esmolol, metoprolol, or atenolol intravenously (in place of propranolol)
Or Labetolol intravenously (in place of sodium nitroprusside and a β-blocker)
Normotensive patients
Propranolol 1 mg intravenously every 4-6 h or 20-40 mg orally every 6 h (metoprolol, atenolol, esmolol, or labetolol may be used in place of propranolol)

Acquired coarctation of the thoracic aorta due to focally obstructive calcific atherosclerotic disease is rare. Symptomatic patients present with upper extremity hypertension and reduced blood pressure in the lower extremities, with or without intermittent claudication.

Microemboli or macroemboli from atherosclerotic plaque and thrombus in the thoracic aorta are important causes of cerebral and systemic embolism. Aortic atheroma occurs in approximately 27% of patients with previous embolic events and is also a strong predictor of coronary artery disease. Thoracic aortic atherosclerotic plaque is most accurately assessed with TEE. Plaque thickness more than 4 mm or mobile thrombus (of any size) is associated with an increased risk of embolism. Embolism can occur spontaneously, in relation to invasive angiographic procedures, as a result of warfarin or thrombolytic therapy, and from cardiac surgical procedures requiring cardiopulmonary bypass. Treatment is surgical resection if a focal source of embolism is present and the patient's general medical condition permits. Antiplatelet agents and a statin medication should be used for the management of all patients unless an absolute contraindication is present. Warfarin therapy may be beneficial for reducing subsequent embolic events, but further randomized trials are required.

- Emboli from atherosclerotic plaque and thrombus in the thoracic aorta are important causes of cerebral and systemic embolism.

Peripheral Arterial Occlusive Disease

Intermittent Claudication

Clinical Features

Lower extremity arterial occlusive disease affects 8 to 12 million Americans, but 75% have no significant symptoms. Despite an overall incidence of 30% in high-risk groups (age >70 years, diabetes, tobacco use), the condition is frequently not diagnosed (>30%). Furthermore, peripheral arterial disease can provide an important clue to systemic atherosclerosis and identify persons at increased risk for left ventricular systolic dysfunction, myocardial infarction, and cerebrovascular accident. Variable presentations occur with lower extremity arterial occlusive disease, including no symptoms (or atypical symptoms), intermittent claudication, and critical limb ischemia (rest pain, ulceration, gangrene). The degree of functional limitation varies depending on the degree of arterial stenosis, collateral circulation, exercise capacity, and comorbid conditions. Intermittent claudication (aching, cramping, or tightness) is always exercise-induced and may involve one or both legs, and symptoms occur at

Fig. 24-9. Aortogram in a patient involved in a severe motor vehicle accident shows a contained rupture of the proximal descending thoracic aorta just distal to the origin of the left subclavian artery.

a fairly constant walking distance. Relief is obtained by standing still. Supine ankle:brachial systolic pressure indices before and after exercise testing (treadmill walking or active pedal plantar flexion) can confirm the diagnosis (Table 24-3). Furthermore, a low ankle:brachial systolic pressure index (<0.9) is associated with an increased risk of stroke, cardiovascular death, and all-cause mortality.

- The discomfort of intermittent claudication is always exercise-induced; standing still provides relief.

Pseudoclaudication

Pseudoclaudication, due to lumbar spinal stenosis, is the condition most commonly confused with intermittent claudication. Pseudoclaudication is usually described as a "paresthetic" discomfort that occurs with standing or walking (variable distances). Symptoms are almost always bilateral and are relieved by sitting or leaning forward. The patient often has a prior history of chronic back pain or lumbosacral spinal operation. The diagnosis of lumbar spinal stenosis can be confirmed with normal or minimally abnormal ankle:brachial systolic pressure indices before and after exercise, in combination with characteristic findings on electromyography and CT or MRI of the lumbar spine (Table 24-4).

- Pseudoclaudication occurs with standing or walking.

Natural History

Peripheral arterial occlusive disease is associated with considerable mortality because of its association with coronary and carotid atherosclerosis. The 5-year mortality rate in patients with intermittent claudication is 29%, and the overall amputation rate over 5 years is 4%. More than half of patients have stable or improved symptoms over this same period. Continued use of tobacco results in a 10-fold increase in the risk for major amputation and a more than 2-fold increase in mortality. The effect of diabetes mellitus on patients with intermittent claudication deserves special mention; it accounts for the majority of amputations in a community (12-fold increased risk of below-knee amputation and a cumulative risk of major amputation exceeding 11% over 25 years). Other clinical features that predict an increased risk of limb loss in lower extremity arterial occlusive disease include ischemic rest pain, ischemic ulceration, and gangrene.

- The 5-year mortality rate in patients with intermittent claudication is 29%, predominantly due to associated coronary atherosclerosis.
- Tobacco use, diabetes mellitus, ischemic rest pain, ulceration, and gangrene are associated with an increased risk of limb loss in patients with intermittent claudication.

Diagnosis

Peripheral angiography is rarely needed to diagnose intermittent claudication. Semi-quantification of the severity of peripheral arterial disease can readily be obtained with noninvasive testing (determination of ankle:brachial systolic pressure indices before and after exercise or duplex ultrasonography). Angiography is indicated to define arterial anatomy before operation or endovascular therapy. Angiography also is indicated when an "uncommon" type of arterial disease is suspected. Magnetic resonance angiography is an accurate alternative to standard angiography and is especially useful for preoperative planning in patients with contraindications to invasive angiography (i.e., renal insufficiency or severe allergy to contrast media).

- Peripheral angiography is rarely needed to diagnose intermittent claudication.

Treatment

Medical management of lower extremity arterial occlusive disease involves three areas: risk factor reduction, exercise training, and pharmacologic therapy. In addition, weight reduction (if obese), foot care and protection, and avoidance of vasoconstrictive drugs are of benefit. Foot care and protection are of paramount importance in patients with diabetes who have peripheral arterial disease. The combination of peripheral neuropathy, small vessel disease, or peripheral arterial disease in patients with diabetes makes foot trauma more likely to be associated with a nonhealing wound or ulcer.

All patients with peripheral arterial disease should be prescribed an antiplatelet agent. Aspirin (81-325 mg a day) is effective, resulting

Table 24-3 Grading System for Lower Extremity Arterial Occlusive Disease*

Grade	ABI	
	Supine resting	Post-exercise
Normal	≥1.0	No change or increase
Mild disease	0.8-0.9	>0.5
Moderate disease	0.5-0.8	>0.2
Severe disease	<0.5	<0.2

ABI, ankle:brachial systolic pressure index.

*After treadmill exercise, 1-2 mph, 10% grade, 5 minutes or symptom-limited or active pedal plantar flexion, 50 repetitions or symptom-limited.

Table 24-4 Differential Diagnosis of Intermittent Claudication and Pseudoclaudication

	Claudication	Pseudoclaudication
Onset	Walking	Standing and walking
Character	Cramp, ache	"Paresthetic"
Bilateral	+/-	+
Walking distance	Fairly constant	More variable
Cause	Atherosclerosis	Spinal stenosis
Relief	Standing still	Sitting down, leaning forward

in a decreased risk of limb loss, reduced need for vascular surgery, and a decreased incidence of major coronary and cerebrovascular events. Clopidogrel (75 mg a day) has been shown to be more effective than aspirin for preventing major atherosclerotic vascular events.

Exercise training is of significant benefit in intermittent claudication. A regular walking program (level ground, walking the distance to claudication, stopping to rest for relief, repeatedly for 45-60 minutes per session, 4 or more days a week, continued for 6 months) can result in a significant (often more than 180%) improvement in initial distance to claudication in many patients. For patients who do not adequately respond to a walking program, cilostazol may be useful. Cilostazol, a phosphodiesterase III inhibitor, results in a significant improvement in walking ability (an approximate doubling of initial and absolute distance to claudication) compared with placebo and pentoxifylline. Cilostazol seems to be more effective than pentoxifylline, but it is contraindicated in patients with congestive heart failure of any severity. The dose is 100 mg orally daily (50 mg orally twice daily in patients taking diltiazem, ketoconazole, or other inhibitors of cytochrome P-450 3A4). Propionyl-L-carnitine seems to improve alterations in carnitine metabolism in patients with a severe functional impairment from intermittent claudication, resulting in improvement in maximal walking distance and quality of life. The dose is 1 g orally twice daily.

Statins should be considered in patients with peripheral arterial disease and have been shown to improve the symptoms of intermittent claudication and to reduce the incidence of adverse cardiovascular and cerebrovascular events. In hypercholesterolemic patients with symptomatic peripheral arterial occlusive disease, simvastatin in high doses (40 mg a day) may improve walking performance and the symptoms of intermittent claudication. Angiotensin-converting enzyme inhibitors also reduce the risk of ischemic cardiovascular events in patients with peripheral arterial disease and have nephroprotective effects in patients with diabetes.

Indications for endovascular or surgical revascularization in a patient with peripheral arterial occlusive disease are "disabling" (lifestyle-limiting) symptoms despite optimal medical therapy, diabetes mellitus with symptoms, or critical limb ischemia (ischemic rest pain, ischemic ulceration, or gangrene).

Revascularization is *elective* in nondiabetic patients with intermittent claudication because 1) it does not improve coronary or cerebrovascular disease, the major cause of mortality, and consequently does not affect overall long-term survival; 2) the incidence of severe limb-threatening ischemia is relatively low because runoff is usually adequate; 3) perioperative complications of peripheral vascular operation, although infrequent, do occur; and 4) reocclusion may occur.

Revascularization in patients with ischemic rest pain or ischemic ulceration or in those with diabetes mellitus and progressive symptoms of intermittent claudication is *indicated* because 1) the incidence of limb loss is increased without revascularization, 2) operation may permit a lower anatomical level of amputation, and 3) the risks of the procedure are generally less than the risk of amputation.

Percutaneous intervention (balloon angioplasty and stents) is an effective alternative to surgical therapy in patients with proximal disease, short, partial occlusions, and good distal runoff. The ideal lesion for angioplasty is an iliac stenosis less than 5 cm. Advantages of angioplasty over operation include less morbidity, shorter convalescence, lower cost, and preservation of the saphenous vein for future use. Percutaneous transluminal angioplasty in aortic or iliac disease also may allow for an infrainguinal surgical procedure to be performed at reduced perioperative risk (compared with intra-abdominal aortic operation).

- For intermittent claudication, medical management is important as initial therapy, including antiplatelet agents, cessation of tobacco use, lipid reduction, foot care and protection, a walking program, and, in selected cases, cilostazol.
- Diabetes mellitus with progressive claudication symptoms and critical limb ischemia (ischemic rest pain, ischemic ulceration, and gangrene) are associated with an increased risk of limb loss in patients with lower extremity arterial occlusive disease. The presence of these features warrants an invasive approach (angiography followed by endovascular or surgical revascularization).

Cardiac Risk and Vascular Surgery

Patients with peripheral arterial disease (AAA, lower extremity arterial occlusive disease, and cerebrovascular disease) have an approximate 60% incidence of significant coronary artery disease (>70% stenosis of one or more epicardial coronary arteries). Up to 30% of patients have severe correctable three-vessel coronary artery disease with reduced left ventricular function, the group most likely to benefit from coronary artery bypass grafting. Clinical markers that identify patients who are at increased risk for a perioperative "cardiac event" when undergoing vascular operation include age older than 70 years, angina, diabetes mellitus, ventricular ectopy, Q waves on electrocardiography, and a carotid bruit. If the preoperative clinical evaluation indicates that further noninvasive cardiac testing is indicated, pharmacologic stress (i.e., dobutamine, dipyridamole, or adenosine) is usually performed because patients with intermittent claudication often cannot achieve an adequate double product during standard treadmill exercise. The presence of reversible defects (thallium-201 or sestamibi scintigraphy) or new regional wall motion abnormalities on stress echocardiography predicts an increased perioperative cardiac risk (30% and 53%, respectively). In contrast, the absence of perfusion abnormalities or stress-induced regional wall motion abnormalities predicts a perioperative cardiac risk of 3% and less than 1%, respectively. An assessment of resting left ventricular function alone, by either radionuclide angiography or echocardiography, is not predictive of perioperative cardiac risk during vascular operation.

- Clinical markers that identify patients who are at increased risk for a perioperative cardiac event when undergoing vascular operation include age older than 70 years, angina, diabetes mellitus, ventricular ectopy, pathologic Q waves on electrocardiography, and carotid bruit.
- An assessment of resting left ventricular function alone is not predictive of perioperative cardiac risk during vascular operation.

Acute Arterial Occlusion

The symptoms of acute arterial occlusion are sudden in onset (<5 hours) and include the "5 Ps": pain, pallor, paresthesia (numbness),

poikilothermy (coldness), and absent pulse(s).

Features that suggest a *thrombotic* cause of acute arterial occlusion include previous occlusive disease in the involved limb, occlusive disease involving other extremities, acute aortic dissection, hematologic disease, arteritis, inflammatory bowel disease, neoplasm, and ergotism.

An *embolic* cause of acute arterial occlusion is suggested by the presence of cardiac disease (valvular, ischemic), atrial fibrillation, proximal aneurysm, or proximal atherosclerotic disease.

After confirmation by angiography, the initial therapeutic options for acute arterial occlusion include intra-arterial thrombolysis and surgical therapy (thromboembolectomy). If thrombolysis is the initial treatment, percutaneous treatment or surgical therapy is usually indicated to treat the underlying stenosis (if present) to improve long-term patency rates.

- The "5 Ps" suggestive of acute arterial occlusion include pain, pallor, paresthesia, poikilothermy (coldness), and absent pulse(s).

Peripheral Arterial Aneurysms

Because aneurysms are most commonly caused by atherosclerosis, they are more common in men 60 years or older. Coronary and carotid occlusive disease are frequent comorbid conditions. Other predisposing factors for aneurysmal disease include hypertension, familial tendency, connective tissue disease, trauma, infection, and inflammatory disease.

Most aneurysms are asymptomatic. Complications of aneurysms include embolization, pressure on surrounding structures, infection, and rupture. Aneurysms of certain arteries develop specific complications more often than other complications. For example, the most common complication of aortic aneurysms is rupture, whereas embolism is a more common complication of femoral and popliteal artery aneurysms.

An iliac artery aneurysm usually occurs in association with an AAA, but it may occur as an isolated finding. Iliac artery aneurysms may cause atheroembolism, obstructive urologic symptoms, unexplained groin or perineal pain, or iliac vein obstruction. CT with intravenous contrast agent and MRI are the preferred diagnostic procedures. Surgical resection is indicated when the aneurysm is symptomatic or larger than 3 cm in diameter.

Thrombosis, venous obstruction, embolization, popliteal neuropathy, popliteal thrombophlebitis, rupture, and infection can complicate popliteal artery aneurysm. Popliteal artery aneurysms are bilateral in 50% of patients, and 40% of patients have one or more aneurysms at other sites, usually the abdominal aorta. The diagnosis is readily made with ultrasonography, but angiography is necessary before surgical treatment to evaluate the proximal and distal arterial circulation. When a popliteal aneurysm is diagnosed, operation is the treatment of choice to prevent serious thromboembolic complications.

- An iliac artery aneurysm usually occurs in association with an AAA, but it may occur as an isolated finding.
- Popliteal artery aneurysms are bilateral in 50% of patients, and 40% of patients have one or more aneurysms at other sites.

Uncommon Types of Arterial Occlusive Disease

The clinical features that suggest an uncommon type of peripheral arterial occlusive disease include young age, acute ischemia without a history of arterial occlusive disease, and involvement of the upper extremity or digits (Fig. 24-10). Uncommon types of arterial occlusive disease include thromboangiitis obliterans, arteritis associated with connective tissue disease, giant cell arteritis (cranial and Takayasu disease), and arterial occlusive disease due to blunt trauma or arterial entrapment.

Thromboangiitis Obliterans (Buerger Disease)

The diagnostic clinical criteria for thromboangiitis obliterans (Buerger disease) are listed in Table 24-5. More definitive diagnosis of thromboangiitis obliterans requires angiography, which usually shows multiple, bilateral focal segments of stenosis or occlusion with normal proximal vessels. Treatment of thromboangiitis obliterans is the same as for other types of occlusive peripheral arterial disease, but particular emphasis is placed on the need for permanent abstinence from all forms of tobacco. Smoking cessation ameliorates the course of the disease but does not invariably stop further exacerbations. Abstinence from tobacco also substantially reduces the risk of ulcer formation and amputation, thus improving quality of life in patients with thromboangiitis obliterans. Because the arteries involved are small, arterial reconstruction for ischemia in patients with Buerger disease is technically challenging. Distal arterial reconstruction, if necessary, is indicated to prevent ischemic limb loss. Collateral artery bypass is an option when the main arteries are affected by the disease. A patent but diseased artery should be avoided as a target for reconstruction. Sympathectomy may be useful in severe digital ischemia with ulceration to control pain and to improve cutaneous blood flow. Therapeutic angiogenesis with phVEGF$_{165}$ gene transfer may be beneficial in patients with advanced Buerger disease that is unresponsive to standard medical or surgical treatment methods.

- Treatment of thromboangiitis obliterans is the same as for other

Fig. 24-10. Patient with thromboangiitis obliterans has gangrene of the tips of multiple upper extremity digits.

Table 24-5 Clinical Criteria for Thromboangiitis Obliterans

Age	<40 years (often <30 years)
Sex	Males most often
Habits	Tobacco, cannabis use
History	Superficial phlebitis
	Claudication, arch or calf
	Raynaud phenomenon
	Absence of atherosclerotic risk factors other than smoking
Examination	Small arteries involved
	Upper extremity involved (positive Allen test)
	Infrapopliteal artery disease
Laboratory	Normal glucose, blood counts, sedimentation rate, lipids, and screening tests for connective tissue disease and hypercoagulable disorders
Radiography	No arterial calcification

types of occlusive peripheral arterial disease, but particular emphasis is placed on the need for permanent abstinence from all forms of tobacco.

Popliteal Artery Entrapment

Popliteal artery entrapment (PAE) is an uncommon congenital abnormality that is often overlooked clinically. PAE is important because repeated compression of the popliteal artery can lead to localized atherosclerosis, poststenotic dilatation, or thrombosis resulting in serious ischemia in the distal leg or foot. PAE occurs most often in young men, who may present with a complaint of intermittent claudication in the arch of the foot or calf. If the popliteal artery is not already occluded, the finding of reduced pedal pulses with sustained active plantar flexion should increase suspicion of the disorder.

PAE can occur by several mechanisms. The artery can be compressed because of its anomalous relationship to the medial head of the gastrocnemius muscle (looping around and under or through the muscle), by its displacement by an anomalous insertion of the plantaris muscle, or by passing beneath rather than behind the popliteal muscle.

The diagnosis of PAE can be made noninvasively with duplex ultrasonography, CT, and MRI. MRI is superior to ultrasonography and CT for defining the exact abnormality in PAE, with results similar to those with digital subtraction angiography. The combined morphologic and functional evaluation of the popliteal fossa makes MRI the investigation of choice in the management of young adults with intermittent claudication. MRI is particularly useful when the popliteal artery is occluded, in which situation ultrasonography and angiography are of limited value.

Angiographic findings in PAE include irregularity of the wall of the popliteal artery in an otherwise normal arterial tree, often associated with prestenotic or poststenotic dilatation. If the artery is still patent, medial displacement of the popliteal artery from its normal position in the popliteal space and popliteal artery compression with extension of the knee and dorsiflexion of the foot are diagnostic angiographic findings. If the mechanism of compression is by the plantaris or popliteal muscle, the position of the artery may appear normal on angiography. If PAE has been diagnosed in one limb, the contralateral limb should be screened because bilateral disease occurs in more than 25% of patients.

The management of PAE depends on the clinical presentation and anatomical findings. Although the natural history of PAE is not well defined, surgery has been advocated to prevent progression of the disease from repetitive arterial trauma. Detection and treatment of PAE at an early stage appear to permit better long-term results.

Thoracic Outlet Compression Syndrome

Compression of the subclavian artery in the thoracic outlet (thoracic outlet compression syndrome) can occur at several points, but the most common site of compression is in the costoclavicular space between the uppermost rib (cervical rib, or first rib) and the clavicle. If the patient is symptomatic, the presentation may be any one of the following: Raynaud phenomenon in one or more fingers of the ipsilateral hand, digital cyanosis or ulceration, and "claudication" of the arm or forearm. Occlusive arterial disease in the affected arm or hand is readily detected on examination of the arterial pulses and with the Allen test. Compression of the subclavian artery in the thoracic outlet can be determined by noting a decreased or absent pulse in the ipsilateral radial artery during performance of thoracic outlet maneuvers. Venous compression resulting in edema and deep venous thrombosis, and neurologic compression resulting in paresthesias or pain, also can occur. The diagnosis is confirmed with duplex ultrasonography, magnetic resonance angiography, or angiography, with the involved arm in the neutral and hyperabducted position.

The optimal therapy for thoracic outlet compression is controversial. In general, treatment depends on the severity of symptoms. In minimally symptomatic patients, physical therapy and education regarding the relationship of arm and body position to arterial compression may be sufficient treatment. In patients who have more severe symptoms, aneurysm formation, distal embolization, or digital ischemia, surgical treatment is indicated. Surgical resection of the first thoracic or cervical rib is the most effective way to relieve the arterial compression. In some cases, thrombectomy and reconstruction of the subclavian artery in patients with subclavian artery stenosis, thrombosis, or occlusion are also indicated. Sympathectomy may be used as an adjunctive surgical procedure when there is extensive digital or hand ischemia. Stent placement in residual subclavian artery stenoses has been successful but needs to be performed after surgical decompression of the costoclavicular space to decrease the likelihood of recurrent symptoms or damage to the stent.

It is important to remember that all of the connective tissue disorders and giant cell arteritides can involve peripheral arteries and that symptoms of peripheral arterial involvement may dominate the clinical picture. Other than the medical measures already discussed for ischemic limbs, therapy is directed mainly at the underlying disease. Only after the inflammatory process is controlled should

surgical revascularization of chronically ischemic extremities be performed.

Heparin-Induced Thrombocytopenia

Heparin-induced thrombocytopenia (HIT) affects between 5% and 10% of patients who receive heparin therapy, but the incidence of arterial or venous thrombosis is less than 1% to 2%. HIT (type II) typically occurs 5 to 14 days after heparin exposure and is associated with arterial thrombosis (arterial occlusion, ischemic strokes, myocardial infarction) and venous thrombosis (pulmonary embolism, phlegmasia cerulea dolens [venous gangrene], and sagittal sinus thrombosis) (Fig. 24-11). The diagnosis of HIT is primarily clinical (occurrence of thrombocytopenia during heparin therapy, resolution of thrombocytopenia when heparin therapy is discontinued, and exclusion of other causes of thrombocytopenia) and can be confirmed by demonstration in vitro of a heparin-dependent platelet antibody. Treatment of HIT includes discontinuation of all forms of heparin exposure (subcutaneous, intravenous, or heparin flushes and heparin-coated catheters), including low-molecular-weight heparins. The current anticoagulant of choice for HIT is a direct thrombin inhibitor, that is, lepirudin or argatroban.

Vasospastic Disorders

Vasospastic disorders are characterized by episodic color changes of the skin resulting from intermittent spasm of the small arteries and arterioles of the skin and digits. Vasospastic disorders are important because they frequently are a clue to another underlying disorder such as arterial occlusive disease, connective tissue disorders, neurologic disorders, or endocrine disease. Vasospastic disorders also can appear as side effects of drug therapy, specifically of ergot preparations, estrogen replacement therapy, and certain β-blockers.

Raynaud Phenomenon

When Raynaud phenomenon is present, several clinical features can help to differentiate primary Raynaud disease from secondary Raynaud phenomenon (Table 24-6).

Fig. 24-11. Multiple gangrenous upper extremity digits in a patient with heparin-induced thrombocytopenia.

Primary Raynaud disease is more common in women than men and usually has its onset before age 40 years. Episodes are characterized by triphasic color changes (white, blue, then red). Symptoms are usually bilateral and often symmetric and precipitated by cold exposure or emotion. Ischemic or gangrenous changes are not present. The absence of any causal condition and the presence of symptoms for at least 2 years are also required for diagnosis. Raynaud disease is generally a benign condition; treatment emphasizes protection from cold exposure and other vasoconstrictive influences. Patients with severe symptoms not controlled by local measures may benefit from a trial of a calcium-channel blocker or an α_1-adrenergic receptor antagonist.

Secondary Raynaud phenomenon affects men more often than women, and in most patients the onset is after age 40 years. It is usually unilateral or asymmetric at onset. Associated pulse deficits, ischemic changes, and systemic signs and symptoms are often present. Identification of the underlying cause is basic to appropriate treatment for secondary Raynaud phenomenon.

The initial laboratory evaluation in a patient with Raynaud phenomenon includes a complete blood count, determination of the erythrocyte sedimentation rate, urinalysis, serum protein electrophoresis, antinuclear antibody test, tests for cryoglobulin, cryofibrinogen, and cold agglutinins, and chest radiography to detect disorders not identified by the medical history and physical examination.

- Primary Raynaud disease is a benign condition more common in women than men, and its onset is usually before age 40 years.
- Secondary Raynaud phenomenon affects men more often than women, and in most patients the onset is after age 40 years.

Livedo Reticularis

Spasm or occlusion of dermal arterioles causes livedo reticularis, the bluish mottling of the skin in a lacy, reticular pattern. Primary livedo reticularis is idiopathic and not associated with an identifiable underlying disorder. Secondary livedo reticularis is suggested by an abrupt, severe onset of symptoms, ischemic changes, and systemic symptoms. Most commonly, it is the result of embolism of atheromatous debris from thrombus within a proximal aneurysm or from proximal atheromatous plaques. The appearance of livedo reticularis in a patient older than 50 years should suggest the possibility

Table 24-6 Characteristic Clinical Features of Primary and Secondary Raynaud Phenomenon

	Primary	Secondary
Age at onset, y	<40	>40
Sex	Women	Men
?Bilateral	+	+/-
?Symmetric	+	+/-
?Toes involved	+	-
Ischemic changes	-	+
Systemic manifestations	-	+

of atheroembolism. Other causes of secondary livedo reticularis include connective tissue disease, vasculitis, myeloproliferative disorders, dysproteinemias, reflex sympathetic dystrophy, cold injury, and as a side effect of amantadine hydrochloride therapy.

- The appearance of livedo reticularis in a patient older than 50 years should suggest the possibility of atheroembolism.

Chronic Pernio

Chronic pernio is a vasospastic disorder characterized by sensitivity to cold in patients (usually women) with a past history of cold injury. Chronic pernio presents with symmetric blueness of the toes in the autumn and resolution of the discoloration in the spring (Fig. 24-12). Without treatment, the cyanosis may be accompanied by blistering of the skin of the affected toes. The cyanosis can often be relieved in a few days after instituting treatment with an α_1-adrenergic receptor antagonist, which can then be used to prevent recurrence.

Erythromelalgia

Erythromelalgia is the occurrence of red, hot, painful, burning extremity digits on exposure to warm temperatures or after exercise. It is not a vasospastic disorder but is associated with color change of the skin. It may be primary (idiopathic) or be due to an underlying disorder, most commonly myeloproliferative disorders (polycythemia rubra vera), diabetes mellitus, or small fiber neuropathy. Treatment of the primary form includes avoidance of exposure to warm temperatures, aspirin, and a nonselective β-blocker, which is helpful in some patients. In persons with secondary erythromelalgia, treatment of the underlying disorder usually relieves the symptoms.

Edema

Lower extremity edema is commonly encountered in clinical practice. Aside from edema due to underlying cardiac disease, other causes of regional edema usually can be identified from characteristic clinical features (Table 24-7).

Fig. 24-12. Characteristic lesions of chronic pernio.

Lymphedema

Lymphedema can be primary (idiopathic) or due to an underlying disorder. Primary lymphedema (lymphedema praecox) usually affects young women (nine times more frequently than men) and begins before the age of 40 years (often before age 20 years). In women, the symptoms often first appear at the time of menarche or with the first pregnancy. Edema is bilateral in about half the cases. The initial evaluation in a young woman with lymphedema should include a complete history and physical examination (including pelvic examination and Papanicolaou smear) and CT of the abdomen and pelvis to exclude a neoplastic cause of lymphatic obstruction.

- In a healthy young woman with painless progressive swelling of one or both lower extremities in a pattern consistent with lymphedema, lymphedema praecox is the most likely diagnosis.

Secondary lymphedema is broadly classified into obstructive (postsurgical, postradiation, neoplastic) and inflammatory (infectious) types. Obstructive lymphedema due to neoplasm typically begins after the age of 40 years and is due to pelvic neoplasm or non-Hodgkin lymphoma. The most frequent cause in men is prostate cancer.

- In a man older than 60 years with painless progressive swelling of one leg, the diagnosis is prostate cancer until proved otherwise.

Inflammatory (infectious) lymphedema occurs as a result of chronic or recurring lymphangitis or cellulitis (or both). The portal of entry for infection is usually dermatophytosis (tinea pedis), which is often overlooked. The diagnosis of lymphedema can be confirmed noninvasively with lymphoscintigraphy.

Medical management of lymphedema includes edema reduction therapy, followed by daily use of custom-fitted graduated compression (usually 40-50 mm Hg compression) elastic support. Manual lymphatic drainage is a type of massage used in combination with skin care, support and compression therapy, and exercise in the management of lymphedema. A combined multimethod approach may substantially reduce excess limb volume and improve quality of life. Antifungal treatment is essential if dermatophytosis is present. Weight reduction in obese patients is also beneficial. Surgical treatment of lymphedema (lymphaticovenous anastomosis, lymphedema reduction) is indicated in highly selected patients.

Table 24-7 Differential Diagnosis of Regional Types of Edema

Feature	Venous	Lymphedema	Lipedema
Bilateral	Occasional	+/-	Always
Foot involved	+	+	0
Toes involved	0	+	0
Thickened skin	0	+	0
Stasis changes	+	0	0

Venous Disease

Deep venous thrombosis (DVT) is the third most common cardiovascular disease, after acute coronary syndromes and stroke. Approximately 1 in 1,000 individuals is affected by venous thromboembolism each year, and more than 200,000 new cases occur in the United States annually. Of these, 30% of patients die within 30 days; one-fifth suffer sudden death due to pulmonary embolism. The Virchow triad of stasis, hypercoagulability, and vascular endothelial damage contributes in varying degrees to the development of DVT. Independent risk factors for venous thromboembolism include increasing age, male sex, surgery, trauma, hospital or nursing home confinement, malignancy, neurologic disease with extremity paresis, central venous catheter or transvenous pacemaker, prior superficial vein thrombosis, varicose veins, and liver disease; among women, additional risk factors include pregnancy, oral contraceptive use, and hormone replacement therapy. A major clinical risk factor (immobility, trauma, or recent operation) is present in approximately half of patients with confirmed DVT. A family history of thrombophilia is important, because there are several identifiable and treatable inherited disorders of coagulation.

Causes of recurrent DVT are listed in Table 24-8.

Protein C Deficiency

Protein C deficiency is characterized by recurrent venous thrombosis and is inherited as an autosomal dominant trait. Episodes of thrombosis are generally spontaneous and usually begin before the age of 30 years. Protein C levels are about 50% of normal. Treatment is lifelong oral anticoagulation, and there is a potential risk of warfarin necrosis. Acquired protein C deficiency can develop in patients with liver disease or disseminated intravascular coagulation, or it can occur postoperatively. Purpura fulminans occurs in persons homozygous for this condition.

Protein S Deficiency

Protein S deficiency also causes recurrent venous thrombosis and is inherited as an autosomal dominant trait. Onset of episodes usually begins before the age of 35 years, and the episodes are generally spontaneous. Protein S levels are about 50% of normal. Treatment is lifelong oral anticoagulation, and there is no risk of warfarin necrosis. Acquired protein S deficiency can occur in association with the nephrotic syndrome, warfarin therapy, pregnancy, antiphospholipid antibody syndrome, and disseminated intravascular coagulation.

Antithrombin III Deficiency

Antithrombin III deficiency, characterized by recurrent venous and arterial thrombosis, is also inherited as an autosomal dominant trait. The first thrombotic episode is usually after age 20 years and is usually provoked by infection, trauma, operation, or pregnancy. Antithrombin III levels are usually 40% to 60% of normal. Treatment is lifelong oral anticoagulation. An acquired form of antithrombin III deficiency can occur in patients with nephrotic syndrome or severe liver disease and in those receiving estrogen therapy.

Factor V (Leiden) Mutation

Factor V Leiden mutation, the genetic defect underlying resistance to activated protein C, is the most common risk factor for venous thrombosis. Heterozygous carriers of a mutation in factor V (factor V Leiden) are at increased risk for venous thrombosis (i.e., activated protein C resistance). This mutation may occur in 5% to 10% of the general population and may account for as many as 50% of patients with recurrent venous thromboembolism. Heterozygous carriers of factor V mutation have an 8-fold increased risk of venous thromboembolism, whereas homozygous carriers have an 80-fold increased risk. Of interest, in patients who have had myocardial infarction without significant coronary artery stenosis, the prevalence of factor V Leiden is considerably higher than in controls, suggesting that factor V Leiden mutation is an independent risk factor for myocardial infarction. Factor V Leiden mutation also increases the risk of cerebrovascular accident and paradoxic embolism (in patients with a patent foramen ovale).

Prothrombin 20210 G-A Mutation

A mutation in the prothrombin gene has been identified in some patients with venous thromboembolism. The mechanism whereby this abnormality might cause thrombosis has been assumed to be an increase in prothrombin levels. Available data indicate that this mutation may be associated with an increased risk of venous thrombosis but not arterial thrombosis (with a possible exception for myocardial infarction).

Hyperhomocysteinemia

Hyperhomocysteinemia, a disorder of methionine metabolism, is a risk factor for premature atherosclerosis and recurrent DVT. Inherited forms (disorders of transsulfuration and remethylation) and acquired forms (chronic renal failure, organ transplantation, acute lymphoblastic leukemia, psoriasis, vitamin deficiencies [vitamins

B_6 and B_{12} and folate], and medications [phenytoin, carbamazepine, theophylline]) occur. Hyperhomocysteinemia is an independent risk factor for stroke, coronary artery disease, peripheral arterial disease, and DVT. A normal plasma homocysteine level is 5 to 15 µmol/L. Folic acid at a dosage of 0.4 mg per day reduces homocysteine levels, but higher doses of folate are required in patients with chronic renal failure. Prospective treatment trials are lacking. Screening for hyperhomocysteinemia should be considered in patients with premature atherosclerotic disease, a strong family history of premature atherosclerosis, idiopathic DVT, chronic renal failure, systemic lupus erythematosus, or severe psoriasis and in organ transplant recipients.

Clinical Evaluation of DVT

Symptoms of DVT include extremity pain, redness, and swelling, although many patients may be asymptomatic. Signs of DVT include pitting edema, warmth, erythema, tenderness, and a dilated superficial venous pattern in the involved extremity. Although leg veins are the most common location of DVT, upper extremity DVT may occur, especially in patients with a central venous line or transvenous permanent pacemaker. Extensive DVT involving an entire extremity may lead to venous gangrene (phlegmasia cerulea dolens), most commonly in association with an underlying malignancy. The clinical diagnosis of DVT is neither sensitive (60%-80%) nor specific (30%-72%), and three-fourths of patients who present with suspected acute DVT have other causes of leg pain such as cellulitis, leg trauma, muscular tear or rupture, postphlebitic syndrome, or Baker cysts. Therefore, objective noninvasive tests are required to establish a diagnosis of DVT.

Important historical features in a patient with DVT which should increase suspicion of a hypercoagulable disorder include spontaneous event, unusual site (mesenteric or cerebral), young age, positive family history, and recurrent events.

Although venography is the reference standard for the diagnosis of DVT and is highly accurate for both proximal and calf DVT, it is invasive, expensive, and technically inadequate in about 10% of patients, and it may precipitate a DVT in approximately 3% of patients. Noninvasive tests (duplex ultrasonography, magnetic resonance venography) for diagnosing DVT are accurate for proximal DVT but not calf vein thrombosis. If the results of noninvasive testing are nondiagnostic or are discordant with the clinical assessment, venography is indicated.

- Noninvasive tests for diagnosing DVT are accurate for proximal DVT but not calf vein thrombosis.
- If the results of noninvasive testing are nondiagnostic or are discordant with the clinical assessment, venography is indicated.

Continuous-Wave Doppler

Doppler assessment at the bedside, which evaluates each limb systematically for spontaneous venous flow, phasic flow with respiration, augmentation with distal compression, and venous competence with the Valsalva maneuver and proximal compression, is useful in the diagnosis of proximal DVT. Continuous-wave Doppler is relatively insensitive to calf vein thrombosis.

Impedance Plethysmography and Strain-Gauge Outflow Plethysmography

Impedance plethysmography and strain-gauge outflow plethysmography both reliably detect occlusive thrombi in the proximal veins (popliteal, femoral, and iliac veins) but are less reliable for detecting nonocclusive thrombi and are insensitive for calf DVT. False-positive results do occur (extrinsic venous obstruction, increased central venous pressure). The reported sensitivity of impedance plethysmography for proximal DVT ranges from 70% to 90%.

Compression Ultrasonography

Compression ultrasonography (venous noncompressibility is diagnostic of DVT; venous compressibility excludes DVT) is highly sensitive and specific for detecting proximal DVT. It is currently the most accurate noninvasive test for the diagnosis of a first symptomatic proximal DVT. Compression ultrasonography is less accurate for symptomatic patients with isolated calf vein thrombosis. It should be noted that both impedance plethysmography and compression ultrasonography have decreased sensitivity when used to evaluate asymptomatic patients (22% and 58%, respectively). Withholding anticoagulant therapy in symptomatic patients with suspected DVT who have normal results on serial compression ultrasonography or impedance plethysmography is safe.

D-Dimer

Plasma levels of D-dimer, a product of fibrin degradation, are increased in patients with acute DVT. D-Dimer functions as an exclusionary test in patients with suspected DVT. For example, in a patient with both a negative objective test (compression ultrasonography or impedance plethysmography) and normal results of D-dimer test, a diagnosis of DVT becomes highly unlikely. D-Dimer is also useful to exclude DVT in patients with a low clinical suspicion of DVT.

Evaluation of Idiopathic DVT

In a patient with idiopathic DVT, a clinical evaluation that includes a complete history and physical examination, routine laboratory testing (hematology group with differential count, chemistry profile, urinalysis, fecal hemoglobin test), and chest radiography seems to be appropriate for detecting cancer. Mammography, pelvic examination, and Papanicolaou smear should be included in a woman with idiopathic DVT. Additional testing should be guided by any abnormalities detected by the initial clinical evaluation.

Treatment of DVT

Treatment options for acute DVT include anticoagulant therapy (heparin, warfarin), thrombolytic therapy, vena cava filter, and surgical thrombectomy.

Anticoagulant therapy is initiated with intravenous heparin, followed within 24 hours by institution of warfarin therapy. Low-molecular-weight heparin (subcutaneously) is an alternative to intravenous unfractionated heparin for the treatment of inpatient DVT and pulmonary embolism and outpatient uncomplicated DVT. Heparin is discontinued when the INR is greater than 2.0. The optimal duration of warfarin anticoagulation for a first episode of DVT is controversial. Available data suggest that it is necessary to tailor the duration

of anticoagulation individually according to the topography of DVT and the presence of continuing risk factors. For proximal DVT, a short course seems sufficient in patients with temporary risk factors (6 months), and a longer course (more than 6 months) is recommended for patients with continuing risk factors or idiopathic DVT.

The inherited or acquired hypercoagulable states can be divided into those that are common and associated with a modest risk of recurrent DVT (i.e., isolated factor V Leiden or 20210 G-A prothrombin gene mutation) and those that are uncommon but associated with a high risk of recurrence (i.e., antithrombin III, protein C or S deficiencies, and antiphospholipid antibodies). The presence of one of the latter abnormalities favors more prolonged anticoagulant therapy. For patients with a high risk of recurrent DVT, there is a paucity of evidence, particularly for patients with thrombophilia, and randomized controlled trials in this population are required. An assessment of low- or fixed-dose oral anticoagulation is also needed to reduce hemorrhagic complications.

When problems with anticoagulation (i.e., contraindications, complications, failed effect, or unacceptable risk) are present, insertion of a vena cava filter may be indicated. Vena cava filters are also indicated for prophylactic use in patients at high risk of pulmonary embolism and as an adjunct to an urgent surgical procedure in the patient with acute DVT. Complications of vena cava filters include pulmonary embolism (1%-4%), caval thrombus (19%-24%), penetration of the cava (9%), filter migration (6%), fracture (2%), and lower extremity edema (25%).

Thrombolytic therapy may be indicated when DVT is extensive, with thrombosis extending into the iliac veins or inferior vena cava, or in upper extremity DVT. Thrombolytic therapy has the best results when initiated less than 7 days after the onset of DVT, and it may decrease the incidence of the postphlebitic syndrome by salvaging venous valve function. Catheter-directed delivery of the thrombolytic agent directly into the thrombus is used. Surgical thrombectomy is reserved for patients with limb-threatening DVT (i.e., phlegmasia cerulea dolens).

Reduction of limb edema, initially by leg elevation and woven elastic (Ace) wrapping, is an integral part of the initial therapy of acute DVT. When edema has been reduced, a graduated compression elastic support stocking is required to both control edema and prevent development of the postphlebitic (postthrombotic) syndrome. A 30- to 40-mm Hg graduated elastic support garment is usually sufficient. Customized, graduated compression stockings significantly reduce the occurrence of the postphlebitic syndrome in patients with a first episode of proximal DVT.

Postphlebitic Syndrome

Chronic venous insufficiency (postphlebitic syndrome) is a common disorder that results in significant morbidity. In approximately 30% of patients with DVT, postphlebitic syndrome develops within 20 years after the initial DVT. Chronic venous insufficiency most commonly results in swelling, pain, fatigue, and heaviness in the involved extremity. Secondary varicose vein formation, venous stasis changes, and cutaneous ulceration can occur in untreated cases (Fig. 24-13). Venous claudication in the setting of prior iliofemoral or vena cava thrombosis causes discomfort, fullness, tiredness, and aching of the extremity during exercise. In contrast to patients with intermittent claudication, patients with venous claudication must sit down and elevate the extremity for relief. Postphlebitic syndrome due to chronic deep venous incompetence is frequently misdiagnosed as recurrent DVT. The correct diagnosis is suggested by the clinical findings of chronic venous insufficiency (edema, venous stasis changes, secondary varicose vein formation) and confirmed by exclusion of new thrombus formation by objective testing (e.g., compression ultrasonography). "Side-by-side" comparison of current ultrasonographic studies with previous ultrasonographic or venographic studies is invaluable for documenting new venous thrombosis.

Treatment of postphlebitic syndrome includes initial aggressive efforts at edema reduction with woven elastic (Ace) wrapping and pumping devices until edema is reduced, followed by fitting with a graduated compression elastic support stocking (30-40 mm Hg). Periodic leg elevation during the day and weight reduction in obese patients are also beneficial.

- The treatment of postphlebitic syndrome includes initial aggressive efforts at edema reduction with woven elastic (Ace) wrapping and pumping devices until edema is reduced, followed by fitting with a graduated compression elastic support stocking (30-40 mm Hg).
- Periodic leg elevation during the day and weight reduction in obese patients are also beneficial.

Leg Ulcer

The cause of lower extremity ulceration usually can be determined with clinical examination. Clinical features of the four most common types of leg ulcer are summarized in Table 24-9.

Fig. 24-13. A patient with severe deep venous incompetence and perforator vein incompetence with severe venous stasis changes and indurated cellulitis.

Table 24-9 Clinical Features of the Four Most Common Types of Leg Ulcer

Feature	Type of ulcer			
	Venous	Arterial	Arteriolar	Neurotrophic
Onset	Trauma +/-	Trauma	Spontaneous	Trauma
Course	Chronic	Progressive	Progressive	Progressive
Pain	No (unless infected)	Yes	Yes	No
Location	Medial aspect of leg	Toe, heel, foot	Lateral, posterior aspect of leg	Plantar
Surrounding skin	Stasis changes	Atrophic	Normal	Callous
Ulcer edges	Shaggy	Discrete	Serpiginous	Discrete
Ulcer base	Healthy	Eschar, pale	Eschar, pale	Healthy or pale

Vascular Diseases Pharmacy Review

Kevin W. Odell, PharmD

Drug	Dosage	Toxic/adverse effects	Comments
Warfarin	Patient-specific	Bleeding, skin necrosis in patients who have protein C deficiency, purple toe syndrome, osteoporosis, alopecia, rash	Anticoagulant effect reversible with vitamin K 2.5-5 mg orally or fresh frozen plasma Lab monitor: PT, INR Pregnancy category X
Aspirin	81-325 mg once daily	Bleeding, hypoglycemia (high doses), dyspepsia, gastric ulcers, dysgeusia, hepatotoxicity (rare), urticaria, rash	Lab monitor: bleeding time Use with caution in children and teens with viral infections (risk of Reye syndrome) Use with caution in patients with asthma (risk of bronchospasm)
Clopidogrel	75 mg once daily	Bleeding, rash, urticaria, edema, hypertension, gastrointestinal upset, increased liver function values, rare decrease in platelets, leukocytes, and hemoglobin	Lab monitor: platelet aggregation if suspected adverse effects Rare cases of thrombotic thrombocytopenic purpura have been reported with use
Pentoxifylline	400 mg three times a day with meals	Bleeding, dizziness, headache, dyspepsia, GI bleed, nausea and vomiting, rash, brittle fingernails, leukopenia (rare)	Decrease dose to twice daily if GI or CNS side effects Consider discontinuing if GI or CNS side effects persist
Cilostazol	100 mg twice a day	Palpitations, tachycardia, dizziness, vertigo, headache, diarrhea, rash	No effect on PT, INR, or bleeding time
Heparin	Dose usually based on weight	Bleeding, thrombocytopenia, skin necrosis, disseminated intravascular coagulation, erythematous plaques, alopecia, osteoporosis	Lab monitor: aPTT, platelet counts Anticoagulant effect reversible with protamine
Low-molecular-weight heparins Dalteparin Enoxaparin Tinzaparin	Once or twice a day subcutaneously based on weight or condition	Bleeding, pain or bruising at injection site, osteoporosis, rash	Lab monitor: antifactor Xa activity Anticoagulant effect partially reversible with protamine Use with caution in patients with history of heparin-induced thrombocytopenia
Fondaparinux	Once a day subcutaneously based on weight or condition	Bleeding, pain or bruising, rash, pruritus at injection site, fever, anemia	Lab monitor: antifactor Xa activity Recombinant factor VIIa reverses anticoagulant effect

aPTT, activated partial thromboplastin time; CNS, central nervous system; GI, gastrointestinal; INR, international normalized ratio; PT, prothrombin time.

Women's Health

Lynne T. Shuster, MD
Deborah J. Rhodes, MD

The science and practice of women's health have evolved considerably during the past 10 years. Increasingly, internal medicine physicians will be expected to manage diseases or conditions unique to women, more prevalent or more serious in women, or for which risk factors or interventions are different in women than in men.

Menstruation and Menopause

Menstruation

The normal menstrual cycle is comprised of three phases: follicular (proliferative), periovulatory, and luteal (secretory). Menses start at the onset of the follicular cycle, when circulating levels of estrogen and progesterone are low and signal the hypothalamus and pituitary to release follicle-stimulating hormone (FSH). FSH initiates maturation of the follicle, which then increases estrogen production and new endometrial growth. At periovulation, the mature follicle triggers a surge in luteinizing hormone, causing release of an ovum. Luteinizing hormone then stimulates the residual ovarian follicle to transform into a corpus luteum. During the luteal phase, progesterone secretion from the corpus luteum leads to a thickened, enriched endometrium. The corpus luteum then regresses if fertilization does not occur, estrogen and progesterone levels decline, and menses occurs. Menstrual cycle length is determined by the rate and quality of follicular growth and development, and it is most variable in the early teenage years and the years preceding menopause. Most women have cycles lasting from 24 to 35 days, but about 20% of women have irregular cycles on an ongoing basis. Women at the extremes of body mass index tend to have longer mean cycle lengths. Women within 5 to 7 years after menarche and 10 years before menopause have greater cycle variability.

Premenstrual Syndrome

Premenstrual syndrome (PMS) is defined as the cyclic occurrence of symptoms that are of sufficient severity to interfere with some aspects of life and that appear with consistent and predictable relationship to the luteal phase. Typical symptoms include mood irritability, abdominal bloating, breast tenderness, appetite changes, fatigue, or decreased concentration. Up to 85% of menstruating women report one or more premenstrual symptoms, but only 5% to 10% have symptoms of sufficient severity to interfere with life, meeting the diagnostic criteria for PMS.

Premenstrual dysphoric disorder differs from PMS in the severity of the emotional symptoms. Typically, emotional symptoms predominate over physical symptoms in premenstrual dysphoric disorder and may include markedly depressed mood, marked anxiety, persistent anger or emotional lability, lethargy, difficulty concentrating, insomnia or hypersomnia, and feeling out of control. These symptoms occur during the last week of the luteal phase and remit within a few days of the onset of menses. They must markedly interfere with work, school, or usual social activities and relationships with others. Other disorders that could cause the symptoms must be considered before making the diagnosis, and prospective daily rating during at least two consecutive cycles should be completed to confirm the diagnosis.

Reducing the intake of caffeine, salt, and alcohol and increasing complex carbohydrates during the luteal phase may be helpful for some women with mild to moderate PMS symptoms. Calcium carbonate (1,200-1,600 mg daily in divided doses) has been found to reduce the severity of PMS symptoms. Some studies have found vitamin B_6 (50-100 mg daily) or magnesium (200-400 mg daily) to be helpful for PMS symptoms, but the evidence is less strong than for calcium.

For women with more severe premenstrual symptoms or premenstrual dysphoric disorder, selective serotonin reuptake inhibitors are the treatment of choice. They may be prescribed continuously or only during the luteal phase when symptoms occur. Oral contraceptives, used to suppress ovulation, may improve physical symptoms of PMS but have not been proved to help with mood.

- 5% to 10% of patients have symptoms severe enough to meet diagnostic criteria for PMS.
- Selective serotonin reuptake inhibitors are the treatment of choice for severe PMS.
- Oral contraceptives may improve physical symptoms but do not help mood.

Abnormal Vaginal Bleeding

Bleeding that is excessive in amount or outside the normal cyclic bleeding pattern is considered abnormal uterine tract bleeding (Table 25-1). Following are some commonly used terms: *amenorrhea*, absence of bleeding for three usual cycles; *oligomenorrhea*, bleeding at intervals more than 35 days apart; *menorrhagia*, excessive or prolonged bleeding at regular intervals; *metrorrhagia*, bleeding occurring at irregular intervals, normal or reduced in amount; and *menometrorrhagia*, prolonged or excessive bleeding occurring at irregular intervals.

Evaluation of vaginal bleeding includes meticulous history taking with emphasis on the age of the patient; date of last menstrual period; timing, duration, and amount of bleeding; pattern of bleeding; pain associated with the bleeding; evidence of ovulatory cycling (regular menses; cyclic symptoms such as breast tenderness, fluid retention, menstrual cramps, mood changes; midcycle cervical mucus); contraceptive history; medical conditions such as thyroid disease or blood dyscrasias; and current medications.

Physical examination, in addition to breast and pelvic examination, includes assessing the body habitus and hair distribution and thyroid and skin examination. Obese women can have irregular, anovulatory bleeding because of increased circulating levels of estrogen from androgen conversion in adipose tissue. Patients under the 10th percentile in body weight may have oligomenorrhea due to hypothalamic dysfunction. Hirsutism can suggest polycystic ovary syndrome, a cause of oligomenorrhea. Petechiae can suggest abnormal clotting disorders. Vaginal atrophy and cervical lesions can cause postcoital spotting or bleeding. Blood coming from the cervical os suggests a higher source of bleeding from the uterus or fallopian tubes, directing further evaluation to these sites. Rectal examination may identify hemorrhoids that may have bled and been mistaken by the patient as vaginal bleeding.

In women of reproductive age, pregnancy always needs to be considered first. In reproductive women with vaginal bleeding along with unilateral pelvic pain, particularly after an episode of amenorrhea, ectopic pregnancy needs to be considered. In postmenopausal women with vaginal bleeding, endometrial cancer needs to be ruled out.

Table 25-1 Possible Causes of Abnormal Bleeding

Pregnancy	Endometrial carcinoma
Anovulation or oligo-ovulation	Coagulation disorders
Fibroids	Hyperprolactinemia
Polyps, endometrial or endocervical	Liver disease
	Thyroid dysfunction
Adenomyosis	Obesity
Endometriosis	Anorexia
Infection, including pelvic inflammatory disease, vaginal or cervical infection	Rapid fluctuations in weight
	Corticosteroids
	Hormonal contraceptives
Endometrial hyperplasia	Tamoxifen

When history, physical examination, and pregnancy testing do not reveal the cause of abnormal uterine bleeding, further evaluation is needed:

1. Tests to determine the following are needed: complete blood count, thyroid function, liver function, FSH, and estradiol levels, and dehydroepiandrosterone and testosterone if there are signs of hyperandrogenism.
2. Endometrial biopsy is a relatively simple in-office procedure that does not require anesthesia and is highly accurate for diagnosing endometrial abnormalities.
3. Transvaginal ultrasonography measurement of endometrial thickness is a good test for excluding endometrial cancer in a woman with postmenopausal bleeding.The sensitivity for detection of endometrial cancer in postmenopausal women with bleeding and an endometrial thickness more than 4 to 5 mm is around 96%. The likelihood of endometrial cancer increases with increasing endometrial thickness. Endometrial biopsy is required if the endometrial lining is thicker than 4 to 5 mm, if diffuse or focal increased echogenicity of the endometrium is noted, if there is persistent bleeding, or if the endometrium is not adequately visualized.
4. Hysteroscopy provides direct visualization of the endometrial cavity and is particularly useful for diagnosis and treatment of focal lesions that may be missed on endometrial sampling.
5. Magnetic resonance imaging can be helpful when ultrasonography is not definitive for determining the presence of fibroids or adenomyosis.

- Patients under the 10th percentile in body weight may have oligomenorrhea due to hypothalamic dysfunction.
- Transvaginal ultrasonography is a good test for excluding endometrial cancer; it has a sensitivity of about 96% at a thickness of more than 4 to 5 mm.

Dysfunctional Uterine Bleeding

Abnormal, excessive uterine bleeding not due to a specific identifiable cause is considered dysfunctional uterine bleeding. It is a term frequently used to refer to noncyclic, anovulatory bleeding. Dysfunctional uterine bleeding is most commonly observed at the extremes of reproductive age (i.e., at perimenarche and perimenopause). Useful therapies include hormonal contraception (most commonly with combination oral contraceptive pills), cyclic oral progestins (mostly commonly medroxyprogesterone acetate 10 mg daily for 10-13 days), and nonsteroidal anti-inflammatory drugs (which may reduce menorrhagia blood loss up to 50%).

Menopause

Menopause is a natural biologic process that occurs when the supply of ovarian follicles is depleted, resulting in permanent cessation of menses. Menopause is a clinical diagnosis, confirmed when a woman has had no menstrual periods for 12 months. It occurs naturally between the ages of 42 and 58 (average age, 51), or it may be induced by surgery, chemotherapy, or pelvic radiation. It tends to occur earlier in women who smoke and women who are nulliparous.

Hot flashes, characterized by the abrupt onset of warmth and

red skin blotching typically involving the chest, face, and neck, often associated with transient anxiety, palpitations, and profuse sweating, are considered the hallmark of menopause. Most menopausal women experience hot flashes, but only 10% to 15% report that they are frequent or severe. Hot flashes usually begin 2 or more years before menopause, tend to peak within 2 to 3 years after menopause, but may continue in some women for many years. The frequency, duration, and intensity of hot flashes vary for each woman, and they may interfere with sleep, concentration, and mood. Hot flashes coincide with declining estrogen levels, but they are not specifically due to hypoestrogenism. Their mechanism is attributed to dysfunction of the thermoregulatory center in the hypothalamus, likely due to complex neuroendocrine pathways involving norepinephrine, serotonin, estrogen, and testosterone.

Other postmenopausal symptoms include vaginal dryness and irritation, urinary urgency and frequency, discomfort with sex and other changes in sexual function, mood swings, and cognitive changes. Menopausal symptoms tend to be more intense after surgically induced menopause than natural menopause. Differential diagnosis of hot flashes includes thyroid dysfunction, infection, carcinoid syndrome, pheochromocytoma, autoimmune disorders, mast cell disorders, pancreatic tumors, and, rarely, seizure disorders. When hot flashes occur in a healthy woman of typical menopausal age, no diagnostic testing is necessary. If the clinical scenario is atypical, an increased FSH level may sometimes be helpful for confirming that the hot flashes are due to menopause, and thyroid function is commonly assessed.

- Menopause is a clinical diagnosis confirmed when a woman has had no menstrual periods for 12 months.
- Hot flashes are considered the hallmark of menopause and are confirmed with an increased FSH level in atypical cases.

After menopause, any vaginal bleeding (with the exception of predictable bleeding associated with hormone therapy) is abnormal and needs diagnostic evaluation.

Perimenopause

Perimenopause is the transitional period during which time reproductive hormone levels become more variable; symptoms such as hot flashes, vaginal dryness, and sleep disturbances may begin even while menses still occur. Anovulation is common during this interval and contributes to the irregular uterine bleeding patterns typical of perimenopause.

Menstrual changes during perimenopause may include lighter or heavier bleeding, bleeding that is shorter (less than 2 days) or longer (more than 4 days) in duration, or skipped menstrual periods. Certain patterns of bleeding warrant further evaluation: very heavy flow, especially with clots; menstrual bleeding lasting more than 7 days; intervals less than 21 days from the onset of one period to the next; spotting or bleeding between periods; or uterine bleeding after sexual intercourse. Despite a decline in fertility, pregnancy is still possible until menopause is reached.

Use of oral contraceptives may be continued or started during perimenopause. In addition to providing contraceptive benefits, they are helpful for restoring regular menses, decreasing dysmenorrhea, reducing menorrhagia, enhancing bone mineral density, and suppressing hot flashes in perimenopausal women. For treatment of hot flashes during perimenopause, oral contraceptives are preferred over menopausal regimens of estrogen-progestogen therapy, because postmenopausal hormone therapy does not suppress endogenous ovarian function and excess bleeding can result.

The decision about when to stop use of oral contraceptives or switch to postmenopausal hormone therapy is not straightforward. Clinical signs of menopause are masked by taking hormonal contraceptives. FSH levels are labile in perimenopause, and unless they are consistently increased to more than 30 mIU/mL, menopause is not confirmed. Additionally, hormonal contraceptives may lower FSH levels, confounding interpretation in women taking oral contraceptives. Even measuring the FSH level on the seventh pill-free day is not sensitive for confirming menopause. If certainty in establishing menopause is needed for a woman taking oral contraceptives, FSH testing after a pill-free interval of 1 to 2 months while using alternative contraception is appropriate.

Hormone Therapy

Estrogen is the most effective treatment for hot flashes and other troublesome menopausal symptoms, but recent studies have resulted in increased scrutiny of its use. The Women's Health Initiative found an increased risk for cardiovascular disease and stroke in women treated with a combination of estrogen and progesterone hormone. The U.S. Food and Drug Administration now advises that postmenopausal hormone therapy is appropriate only for women with moderate to severe symptoms of menopause, including vasomotor symptoms (hot flashes) and urogenital symptoms (e.g., vaginal dryness and discomfort, urinary frequency and burning). It should be prescribed at the lowest dose needed for symptom relief and for the shortest duration possible. There is great controversy about the applicability of these recommendations for women early in menopause or women receiving long-term estrogen therapy after surgical menopause.

The results from the Women's Health Initiative summarizing risks for selected outcomes in both the combination hormone and estrogen-alone arms of the study are described in Table 25-2.

Prescribing Menopausal Hormone Therapy

If clinical indications are appropriate for estrogen therapy, the following general guidelines are used: 1) combination estrogen plus progestogen is needed if the woman's uterus is intact, to provide adequate protection against endometrial hyperplasia or cancer; 2) unopposed estrogen therapy is prescribed if the woman's uterus has been removed; 3) transdermal estrogen is preferred over oral in the setting of hypertriglyceridemia, headaches, liver or gallbladder disease, or history of phlebitis, and vaginal estrogen therapy is preferred for treatment of urogenital atrophy; 4) the incidence of coronary heart disease, stroke, pulmonary embolism, breast cancer, and dementia is increased with combination estrogen and progesterone therapy; and 5) the risk of pulmonary embolus is increased with estrogen alone.

Table 25-2 Risks of Hormone Replacement Therapy

Outcome	Risk, by therapy	
	Combination E + P	Estrogen alone*
CHD events	Increased	Unchanged
Stroke	Increased	Increased
Pulmonary embolism	Increased	Increased
Breast cancer	Increased	Unchanged
Colon cancer	Decreased	Unchanged
Hip fracture	Decreased	Decreased
Dementia	Increased	Increased

CHD, coronary heart disease, including acute myocardial infarction, silent myocardial infarction, coronary death; E + P, conjugated equine estrogens + medroxyprogesterone acetate.
*Conjugated equine estrogens alone, in women without a uterus.

Contraception, Infertility, and Pregnancy

Contraception

A woman's life expectancy is inversely proportional to the number of pregnancies she has. At least 50% of pregnancies in the United States are unintended. Contraceptive methods include hormonal, intrauterine, barrier, chemical, or physiologic approaches. None are 100% effective, and all are associated with some degree of risk. However, nearly all contraceptive methods are safer than carrying a pregnancy to term.

Factors that should be considered in counseling women regarding choice of contraceptive methods include efficacy, convenience, duration of action, reversibility and time to return of fertility, effect on uterine bleeding, risk of adverse events, affordability, and protection against sexually transmitted diseases. Balancing the advantages and disadvantages of each method will guide each woman's individual decision (Table 25-3). Methods consistent with her values and lifestyle are most likely to be successful.

Effective contraceptive management requires education and counseling regarding appropriate use. It is particularly important, however, for internists to be familiar with the uses and potential risks of oral contraceptives.

Oral Contraceptives

The main types of oral contraceptives are fixed-dose estrogen-progestin pills, phasic estrogen-progestin pills, and daily progestin-only pills. Combination estrogen-progestin pills are most effective for preventing ovulation and are highly effective (97%-99%) for preventing pregnancy. All oral contraceptives act on cervical mucus and tubal motility to interfere with sperm transport. Progestins also alter the endometrium, thereby interfering with implantation of fertilized ovum.

Noncontraceptive benefits of oral contraceptives include a reduction in dysmenorrhea, menstrual flow, and development of functional ovarian cysts; an increase in bone mineral density; a reduced risk of ovarian cancer (by 40%-80% depending on duration of use) and endometrial cancer (by 50%); and reduced risk for pelvic inflammatory disease and ectopic pregnancy. Other uses of oral contraceptives include the treatment of acne, hirsutism, and perimenopausal symptoms.

The synthetic estrogens used in oral conceptives cause an increase in the hepatic production of proteins that affect thrombosis, including factors V, VIII, X, and fibrinogen, and an increase in angiotensinogen, which may affect blood pressure. Blood pressure should be monitored in all women taking oral contraceptives, particularly estrogen-containing oral contraceptives. Although there is an increased risk of venous thromboembolism with all estrogen-containing oral contraceptives, the absolute risk is low. The risk is reduced with lower-dose estrogen-containing oral contraceptives, and the excess risk is lower after the first year of use. Women with inherited coagulopathies are at further increased risk for venous thromboembolism from use of combination oral contraceptives, but screening for thrombophilias currently is not recommended unless the woman has a personal or strong family history of thrombotic events. Use of low-dose oral contraceptives by nonsmoking women without hypertension is not associated with a significantly increased risk for myocardial infarction or stroke. Women older than 35 years who smoke cigarettes have a relative contraindication to combination oral contraceptives, because of an increased risk for myocardial infarction and stroke (Table 25-4).

Progestins have adverse lipid effects, including a decrease in high-density lipoprotein and an increase in low-density lipoprotein, and these are related to the amount and potency of the progestin. Estrogens, however, increase high-density lipoprotein and decrease low-density lipoprotein. Newer combination oral contraceptives with lower-androgenic progestins have a less adverse effect on lipids. The net effect of newer combination oral contraceptives is little or no change in total cholesterol, high-density lipoprotein, or low-density lipoprotein levels, although there is a substantial increase in triglyceride levels from the synthetic estrogen component.

The relationship between use of oral contraceptives and breast

Table 25-3 Currently Available Contraceptive Methods

- Reversible methods
  - Intrauterine devices, contraceptive implants, and injectable contraceptives

    - Minimally influenced by compliance
  - Oral contraceptives
    - Very low pregnancy rate if taken consistently and correctly
    - Actual pregnancy rates are increased because of incorrect use
  - Other methods, including diaphragms, cervical caps, condoms, spermicides, withdrawal, and periodic abstinence
    - Actual pregnancy rates are much higher than perfect-use rates
- Permanent methods
  - Tubal ligation
  - Vasectomy

Table 25-4 Contraindications to Use of Estrogen-Containing Oral Contraceptives

Absolute contraindications
History of deep venous thrombosis or pulmonary embolism
History of arterial venous thrombosis
Active liver disease
Cardiovascular disease such as congestive heart failure, myocardial infarction or coronary artery disease, atrial fibrillation, mitral stenosis, mechanical heart valve
Systemic diseases that affect the vascular system (such as systemic lupus erythematosus, diabetes with retinopathy or nephropathy)
Cigarette smoking by women older than 35 years
Uncontrolled hypertension
History of breast cancer
Undiagnosed amenorrhea
Relative contraindications
Classic migraine
Hypertriglyceridemia
Depression

cancer risk remains controversial. There may be a slight increase in breast cancer risk that decreases after discontinuation of use. There has been concern that the large increase in the rate of breast cancer in the developed parts of the world may be due to hormonal contraception, but most studies have not confirmed a significant association.

Progestin-only pills are an option for women who request a contraceptive pill but need to avoid estrogen. They are associated with a slightly higher failure rate than combined oral contraceptives and there is a higher frequency of breakthrough bleeding. Conditions for which they are commonly considered include migraine headaches, age older than 35 years, smoking, hypertension, diabetes, history of thromboembolism, cardiac disease such as coronary artery disease or congestive heart failure, cerebrovascular disease, and hypertriglyceridemia.

- Combination estrogen-progestin pills prevent pregnancies at a rate of 97%-99%.
- Other benefits of oral contraceptives include an increase in bone mineral density, a 40%-80% reduced risk of ovarian carcinoma, and a 50% reduction in the risk of endometrial carcinoma.
- Women older than 35 years who are taking oral combination contraceptives and smoke cigarettes are at an increased risk for myocardial infarction and stroke.

Infertility

Infertility is defined as the inability to conceive after 1 year of intercourse without contraception. It may be due to male or female factors, or a combination of the two, but the cause is often difficult to elucidate. The most commonly identified causes of female infertility include ovulatory disorders (such as from polycystic ovary syndrome, hypothyroidism, hyperprolactinemia, eating disorders, extreme stress), endometriosis, pelvic adhesions, and tubal blockage or other tubal abnormalities. Decreasing oocyte quality with advanced age also has become a major cause of infertility as an increasing portion of women delay childbearing.

Initial evaluation of the woman commonly includes assessment of ovulation by basal body temperature charting for 1 month and mid-luteal progesterone level testing, assessment of ovarian reserve by measuring day 3 FSH level, assessment of fallopian tube patency with hysterosalpingography, and exclusion of endocrinologic causes by measurement of prolactin and thyroid-stimulating hormone levels.

Medical Issues of Pregnancy

Preconception Counseling

Good prenatal care is associated with improved pregnancy outcomes. In addition to recommending a healthful diet, exercise, and avoidance of smoking and illicit drugs, preconception counseling should address the following:

Supplementation with folic acid before conception decreases the risk of neural tube defects. For women with no history of neural tube defects in prior pregnancies, 0.4 mg is adequate and can be obtained in most over-the-counter multivitamins or in prenatal vitamins.

Alcohol abuse during pregnancy is the third leading cause of mental retardation and also is associated with early spontaneous abortion, placental abruption, and possibly attention deficit disorder in children of moderate drinkers. The greatest negative impact is at the time of conception through the first month of pregnancy. Avoiding alcohol prevents fetal alcohol syndrome. There is no agreement about the lowest safe level of alcohol consumption for pregnant women or women planning pregnancy.

Smoking is associated with low birth weight, perinatal mortality, infertility, spontaneous abortion, ectopic pregnancy, placenta previa and placental abruption, and subsequent sudden infant death syndrome.

Caffeine intake limited to 1 to 2 cups of coffee or caffeinated beverage daily is not associated with miscarriage or birth defects.

- Alcohol abuse during pregnancy is the third leading cause of mental retardation and is associated with early spontaneous abortion and placental abruption.
- Smoking is associated with low birth weight, perinatal mortality, infertility, spontaneous abortion, ectopic pregnancy, placenta previa and placental abruption, and sudden infant death syndrome.

Immunizations and Pregnancy

- Tetanus-diphtheria: Tetanus immunization is indicated routinely for pregnant women. All patients should be given a tetanus booster if they have not had one in 10 years.
- Measles, mumps, and rubella vaccine should not be given to pregnant women because of a theoretical risk to the fetus from live virus vaccine. For persons born before 1957 in the United States, immunity is usually established. Nonpregnant women of childbearing age should be given the combined measles,

mumps, and rubella vaccine if there is uncertainty about immunity. There is little risk to receiving the vaccine even if immunity already exists.
- Rubella: Measles, mumps, and rubella vaccine should not be given to pregnant women. All nonpregnant women of childbearing age should be vaccinated if no documentation exists of prior immunization or if rubella antibody testing is negative.
- Influenza: Women who will be pregnant during the influenza season should be vaccinated, regardless of trimester of pregnancy.
- Hepatitis B: Neither pregnancy nor lactation is a contraindication to vaccination of women at risk.
- Pneumococcal: Women at increased risk, such as those who are asplenic and those with cardiopulmonary, chronic kidney, or liver disease, should be vaccinated. It is preferable to wait until after the first trimester.
- Varicella: Pregnant women should not be vaccinated, because the effects on the fetus from this vaccine are unknown. For nonpregnant persons, having a pregnant household contact is not a contraindication to vaccination.

Hypertension and Pregnancy

Hypertension, complicating up to 15% of pregnancies, is the most common medical problem in pregnancy and an important cause of maternal and fetal morbidity and mortality worldwide. Hypertension may precede pregnancy or develop during pregnancy. Chronic hypertension predating pregnancy is associated with an increased risk for preeclampsia, placental abruption, fetal growth retardation, and prematurity, but 85% of women with chronic hypertension have an uncomplicated pregnancy. Hypertension originating during pregnancy is diagnosed when the blood pressure after 20 weeks of gestation increases more than 30 mm Hg systolic or 15 mm Hg diastolic, or when the blood pressure is persistently 140/90 mm Hg or more in a woman who was previously normotensive. Although treatment for mild gestational hypertension is not of proven benefit, monitoring for the development of preeclampsia and intervening before complications develop is very important for reducing serious maternal and perinatal complications.

During normal pregnancy, intravascular volume increases by 40% and cardiac output increases by 20%, but peripheral vascular resistance decreases. There is a net decrease in blood pressure in the second trimester, but in the third trimester blood pressure tends to increase to pre-pregnancy or first-trimester levels. With preeclampsia, which occurs after 20 weeks of gestation, both cardiac output and plasma volume are reduced, but systemic vascular resistance is increased, resulting in worsening hypertension, proteinuria, hyperuricemia, and sometimes coagulation abnormalities. Perfusion to the placenta, kidneys, liver, and brain is reduced. Risks include seizures, stroke, placental abruption with disseminated intravascular coagulation, pulmonary edema, renal failure, liver hemorrhage, and death.

Methyldopa, β-adrenergic blockers, and vasodilators are preferred medications when treatment is needed for hypertension during pregnancy. Diuretics should be used with caution because of their potential risk of volume depletion. Angiotensin-converting enzyme inhibitors and angiotensin-receptor blockers should be avoided for pregnant women or women likely to become pregnant because of associated risks for miscarriage, fetal death, fetal malformations, and neonatal renal failure. Risks from these agents primarily are associated with use in the second and third trimesters.

Thromboembolic Disease and Pregnancy

Pregnancy is associated with multiple changes that increase clot formation, yet thromboembolism is uncommon during pregnancy. However, women with hereditary thrombophilias are at high risk for thrombosis during pregnancy, with potentially serious complications. Women with antiphospholipid antibodies are prone to arterial or venous thromboemboli, placental infarction, recurrent pregnancy loss, preeclampsia, fetal growth retardation, or fetal death.

Low-molecular-weight heparin is usually the preferred treatment for thromboembolism during pregnancy or for prevention in high-risk women. Warfarin should be avoided during pregnancy because of its teratogenicity. Aspirin is recommended before conception for women with antiphospholipid antibodies. Once pregnancy is established, additional treatment with heparin, glucocorticoids, or other medications may be indicated.

- Low-molecular-weight heparin is the preferred treatment for thromboembolism during pregnancy or for prophylaxis.

Thyroid Disorders and Pregnancy

Maternal hypothyroidism is associated with infertility, miscarriage, stillbirth, placental abruption, preeclampsia, and motor and mental retardation in the infant. Thyroid-stimulating hormone should be measured early in pregnancy. Women taking thyroid hormone should be monitored each trimester; approximately 20% will require a dose increase during pregnancy. Thyroid-stimulating hormone levels are altered only slightly by pregnancy and remain useful for the detection of hypothyroidism or for monitoring thyroid hormone replacement.

Hyperthyroidism is the second most common endocrine disorder (after diabetes) during pregnancy and occurs in about 0.2% of pregnancies. Signs of hyperthyroidism such as tachycardia, a sensation of warmth, and fatigue can be a part of normal pregnancy, and an inappropriately low weight gain may be the only clue. Mild hyperthyroidism is generally well tolerated, but poorly controlled hyperthyroidism can be associated with spontaneous abortion, premature delivery, low birth weight, preeclampsia, and congestive heart failure. Propylthiouracil is the treatment of choice, given in the smallest doses necessary, in order to prevent fetal goiter and hypothyroidism. Radioiodine is absolutely contraindicated, and surgery is relatively contraindicated for gestational hyperthyroidism. In many women, the dose of propylthiouracil can be tapered or use can be discontinued in the last trimester.

Postpartum thyroid dysfunction occurs in up to 10% of women during the year after delivery, and it mostly occurs in women with goiters. Transient hyperthyroidism followed by hypothyroidism is typical. Hypothyroidism is often temporary, warranting thyroid hormone replacement for just several months.

Diseases of the Uterus and Adnexa

Endometriosis

Endometriosis is a common condition in which endometrial glands and stroma occur outside the endometrial cavity and uterine wall, commonly in the ovary or on the pelvic peritoneal surfaces such as the cul-de-sac and rectovaginal septum. Commonly associated symptoms include dysmenorrhea, dyspareunia, and premenstrual spotting. It is found in 20% to 40% of women with infertility and up to 65% of women with chronic pelvic pain. The amount of endometriosis does not correlate with the severity of symptoms.

Treatment depends primarily on the severity of symptoms and the desire for future fertility. Nonsteroidal anti-inflammatory drugs, by inhibiting prostaglandins, help reduce menstrual bleeding and pain. Oral contraceptive pills reduce menstrual bleeding and pain and also may slow disease progression. Oral progestogens such as medroxyprogesterone acetate, given cyclically, likewise can slow progression of endometriosis. When symptoms are more severe, treatment with gonadotropin-releasing hormone agonists (e.g., leuprolide) can provide relief from pain and involution of endometriosis implants by causing temporary castration. If fertility is desired and other treatments have failed, resection of endometriomas and lysis of tubal adhesions may be recommended. Even with minimal endometriosis, laparoscopic resection can improve fertility. For severe endometriosis, when fertility is desired, preoperative or postoperative treatment with danazol or a gonadotropin-releasing hormone agonist may be given to further improve the likelihood of subsequent fertility.

- 20% to 40% of women with infertility and up to 65% of women with chronic pelvic pain have endometriosis.

Uterine Fibroids

Leiomyomata uteri, also known as fibroids, are the most common pelvic tumors in women, occurring in approximately 25% of women of reproductive age. Fibroids are benign tumors that arise from smooth muscle cells and can be intramural, submucosal, or subserosal. Most fibroids cause no symptoms; only 25% of women with fibroids are symptomatic. Abnormal uterine bleeding is the most common symptom associated with fibroids, but fibroids also can cause pelvic pressure or pain. Reproductive dysfunction associated with fibroids is less common, but large fibroids do increase the risk of premature labor, and a fibroid under the placenta increases the risk of placental abruption.

Parity, oral contraceptive use, and smoking decrease the risk of fibroid formation. The relative risk of fibroids is twofold to threefold greater in black women than white women.

The diagnosis is usually suspected after finding an enlarged, mobile, irregular uterus in a nonpregnant patient. Pelvic ultrasonography typically is used to support the diagnosis and to exclude a malignant-appearing lesion. If ultrasonographic findings are inconclusive, magnetic resonance imaging may be helpful.

Treatment of fibroids is necessary only if they are symptomatic. Symptoms typically wane after menopause. Abnormal uterine bleeding is the most common symptom. Fibroids typically cause prolonged or excessively heavy menstruation but not intermenstrual bleeding. The bleeding pattern is influenced more by location of the fibroids than by size: submucosal fibroids are more likely to cause heavy bleeding. If treatment is needed (because of bleeding, anemia, or pain), a trial of medical therapy before surgical therapy is reasonable to determine whether symptoms can be controlled. Gonadotropin-releasing hormone agonists lead to amenorrhea and a reduction in uterine size in most cases. They usually are used only as a temporizing measure to reduce blood loss before definitive surgery or in women approaching menopause who are expected to require no more than 6 months of treatment. Adverse effects (including a reduction in bone density) often preclude long-term use. Pre-treatment patterns of bleeding and uterine size usually return rapidly after cessation of treatment. Danazol, an androgenic steroid, can be used to control anemia and decrease bleeding but does not reduce uterine volume. Low-dose oral contraceptives do not cause fibroids to grow and thus are not contraindicated in premenopausal women with fibroids. However, oral contraceptives and progestational agents have little efficacy in treating uterine fibroids.

Surgical treatment is indicated when significant symptoms persist despite medical treatment, when there is a suspicion of malignancy, or when infertility or recurrent pregnancy loss is thought to be related to fibroids. Surgical options include hysterectomy or myomectomy (removal of the myomas with uterine conservation). Myomectomy is a good option for women who want to preserve childbearing potential. One disadvantage is the high risk of new fibroid formation after myomectomy (approximately 50% at 5 years). Other, less invasive options in women who have completed childbearing include endometrial ablation, myolysis (laparoscopic thermal coagulation or cryoablation of fibroids), uterine artery embolization, and magnetic resonance-guided focused ultrasound ablation.

Endometrial Cancer

Endometrial cancer is the most common gynecologic malignancy in the United States and accounts for 6% of all cancers in women. It affects postmenopausal women; the average age at diagnosis is 60 years. The incidence increases with age; fewer than 5% of cases occur before the age of 40 years. Most cases are diagnosed at an early stage. Risk factors for endometrial cancer include increasing age, unopposed estrogen therapy, infertility or nulliparity, chronic anovulation (such as with polycystic ovary syndrome), late menopause (after age 52 years), obesity, diabetes mellitus, and tamoxifen therapy. Smoking does not seem to increase the risk of endometrial cancer. There are some familial associations with endometrial cancer, but the risk incurred by family history is not as strong as in some other cancers, such as breast cancer. An increased risk of uterine cancer has been found in families with hereditary nonpolyposis colorectal cancer (Lynch syndrome II) and *BRCA1* mutations. Screening for uterine cancer in asymptomatic women is not warranted, except in women with known or suspected mutations associated with hereditary nonpolyposis colorectal cancer.

The most common type of endometrial cancer is endometrioid adenocarcinoma. Clear cell and serous carcinomas are rarer and more aggressive. The classic symptom of endometrial carcinoma is abnormal uterine bleeding. The possibility of endometrial cancer needs to be excluded in any postmenopausal woman with bleeding

(with the exception of predictable bleeding related to hormone therapy). Atypical endometrial cells on Papanicolaou smear are twice as likely to be associated with endometrial carcinoma as benign-appearing endometrial cells. An endometrial biopsy is recommended for women 40 years or older with any endometrial cells noted on Papanicolaou smear unless the test was done during an episode of bleeding.

Transvaginal ultrasonography often is used to evaluate the endometrium in women with abnormal uterine bleeding. In postmenopausal women, an endometrial thickness of less than 4 to 5 mm is associated with a low risk of endometrial disease; a thicker lining should prompt further evaluation, such as endometrial biopsy or hysteroscopy with dilation and curettage. Endometrial biopsy also may be used as the initial diagnostic test to evaluate abnormal uterine bleeding.

Uterine sarcoma accounts for only 5% of uterine cancers, and the prognosis is poorer than for other types of uterine cancer. It can arise from the endometrium or myometrium. Risk factors include race (risk higher in blacks), pelvic irradiation, and tamoxifen.

- Endometrial cancer is the most common gynecologic malignancy in the United States and accounts for 6% of all cancers in women.
- Average age at diagnosis is 60 years.
- Risk factors include increasing age, unopposed estrogen therapy, infertility, nulliparity, chronic anovulation, late menopause, obesity, diabetes mellitus, and tamoxifen therapy.

Adnexal Masses

Adnexal masses occur in females of all ages, and 90% are benign. The differential diagnosis and management of an adnexal mass depend on the patient's age and menstrual status.

The differential diagnosis of an adnexal mass includes both ovarian and extraovarian masses. Examples of adnexal masses are listed in Table 25-5.

The most probable cause of an adnexal mass differs depending on the patient's age. The most common adnexal mass in a premenopausal woman is a physiologic ovarian cyst. Pregnancy should always be excluded in a premenopausal woman with an adnexal mass, because an ectopic pregnancy necessitates urgent treatment. In women of reproductive age, only 5% to 18% of adnexal masses are malignant. In women older than 50 years, 30% to 60% of adnexal masses are malignant. The median age at diagnosis of ovarian cancer is 63. In postmenopausal women, any solid enlargement of an ovary must be considered to be cancer until proved otherwise.

Many of the risk factors for epithelial ovarian cancer relate to the total number of ovulatory cycles. Thus, gravida 0, early age at menarche, and late age at menopause increase the risk of ovarian cancer. Other risk factors include Caucasian race, age older than 34 years at first birth, use of postmenopausal hormone therapy for more than 10 years, and family history of ovarian or endometrial cancer. Protective factors associated with a reduced risk of ovarian cancer include oral contraceptive therapy, multiparity, tubal ligation, and breastfeeding.

Several features of the history may assist in the diagnosis. Patients with ovarian cancer often present with vague complaints such as back pain, fatigue, bloating, constipation, abdominal pain, and urinary symptoms. The combination of bloating, increased abdominal size, and urinary symptoms was found in almost half of women with ovarian cancer. The onset of mid-cycle pain in premenopausal women suggests a follicular or corpus luteum cyst. Pain during or after intercourse may be related to a ruptured cyst. Chronic dysmenorrhea and dyspareunia often occur with endometriosis. The sudden onset of severe pain, often with fever, nausea, and vomiting, suggests ovarian torsion. Pelvic pain with fever suggests pelvic inflammatory disease, appendicitis, diverticulitis, or torsion. Renal colic also should be considered in the differential diagnosis of pelvic pain.

Pelvic ultrasonography is the best radiologic test to evaluate adnexal masses and can distinguish whether they are cystic or solid. Both transvaginal and transabdominal ultrasonography may be necessary. Transvaginal ultrasonography provides better resolution of pelvic structures, whereas transabdominal ultrasonography is better for visualizing abdominal structures. The normal ovary is typically 3.5 cm in greatest dimension in the premenopausal patient and 1.5 cm in greatest dimension after menopause. A palpable ovary in a postmenopausal woman should be considered suspicious, as should an ovary that on ultrasonography is twice the size of the contralateral ovary in a postmenopausal woman. Ultrasonographic features that increase the likelihood of malignancy include septations, mural or septal nodules, thickened or irregular walls, and partially solid or solid masses.

Follicular and corpus luteum cysts are typically solitary, thin-walled, unilocular, and less than 10 cm in diameter. Corpus luteum cysts may be associated with hemorrhage. In the premenopausal woman, a cyst with no solid component that is less than 10 cm in

Table 25-5 Differential Diagnosis of Adnexal Mass

Ovarian mass
Physiologic cyst, simple or hemorrhagic
Follicular
Corpus luteum
Polycystic ovary syndrome
Benign ovarian neoplasm
Leiomyoma (fibroid)
Endometrioma
Dermoid cyst (cystic teratoma); most common ovarian tumor in women in their second and third decades
Cystadenoma
Metastatic carcinoma (i.e., colon, endometrium, breast); non-Hodgkin lymphoma
Ovarian carcinoma
Extraovarian mass
Ectopic pregnancy
Tubo-ovarian abscess
Paraovarian cyst
Peritoneal inclusion cyst
Diverticular abscess
Cancer of the fallopian tube

size can be managed with follow-up ultrasonography after several cycles. Approximately 70% resolve spontaneously. If the cyst is unchanged or larger after an interval of observation, surgery is required. Prescribing oral contraceptives during the observation period helps to prevent formation of new cysts. Masses more than 10 cm require surgical exploration, as do masses that are solid, fixed, or bilateral. Surgical exploration also is needed in women who present with ascites, suspicion of metastatic disease, or a family history of breast or ovarian cancer in a first-degree relative.

Benign ovarian cysts also can occur in postmenopausal women, but the management differs because of the higher risk of ovarian cancer. A postmenopausal woman with a simple unilocular cyst on ultrasonography which is less than 5 cm can be followed with serial ultrasonography examinations and determination of CA 125 levels at 3-month intervals. Most cysts resolve spontaneously within 1 year. Postmenopausal women with complex cysts or cysts more than 5 cm should be referred for surgical consultation, as should women with a symptomatic adnexal mass. Other factors that should prompt surgical consultation in a postmenopausal woman with an adnexal mass are an increased CA 125 level, suspicion of metastatic disease, ascites, or a family history of breast or ovarian cancer in a first-degree relative. Surgical management of suspicious adnexal masses should be guided by the potential risk of tumor spill by rupture of the ovarian capsule during laparoscopic removal of the tumor. Thus, open laparotomy may be more prudent when neoplasm is suspected.

The CA 125 level may contribute to the diagnostic evaluation of an adnexal mass but is not sufficient to establish or exclude a diagnosis of ovarian cancer. Many conditions unrelated to ovarian cancer can increase the CA 125 level, including endometriomas, uterine fibroids, pelvic inflammatory disease, pancreatic and other malignancies, and cirrhosis. The specificity of CA 125 is low in premenopausal women, thus its usefulness as a diagnostic tool is limited. In contrast, the combination of a suspicious finding on pelvic ultrasonography and an increased CA 125 level is highly specific and sensitive for ovarian cancer in postmenopausal women. The CA 125 test should not be used as screening for ovarian cancer in the general population. However, screening with transvaginal ultrasonography and tests for CA 125 levels is appropriate in women with a family history of ovarian cancer or a known *BRCA1* or *BRCA2* mutation. Determining the CA 125 level is most useful as a surveillance test in women with an established diagnosis of ovarian cancer. When the CA 125 level is increased at the time of diagnosis, it can be followed to gauge response to chemotherapy and to monitor for recurrence.

- 30% to 60% of adnexal masses are malignant.
- In postmenopausal women, any enlargement of an ovary must be considered malignant until proved otherwise.
- Risk factors for ovarian carcinoma include gravida 0, early age at menarche, and late age at menopause.
- A suspicious result on pelvic ultrasonography and an increased CA 125 level are highly specific and sensitive for ovarian carcinoma.
- Typical clinical scenario of ovarian carcinoma: A 63-year-old woman has an adnexal mass and an increased CA 125 level.

Breast Conditions

Evaluation of the Palpable Breast Mass

Breast lumps are common and most are benign: in one study, 11% of women presenting with a palpable breast mass were found to have cancer. The challenge of distinguishing benign from malignant lumps should be guided by two principles: benign characteristics by history or on physical examination are not sufficient to exclude a cancer, and negative findings on mammography and ultrasonography do not definitively exclude a cancer if the clinical suspicion is high.

Elements of the history that are important in evaluating the palpable breast lump are precise location of the lump, when the patient first noted the lump, the association of any pain or skin or nipple changes (such as discharge), whether the lump has changed in size, and whether the size of the lump fluctuates with the menstrual cycle. The patient's risk factors for breast cancer also should be assessed, particularly in regard to prior history of breast cancer, prior history of atypia or lobular carcinoma in situ of the breast, or family history of breast cancer.

The physical examination should be done in both the sitting and the supine position and should begin with a visual inspection of the breasts for asymmetry, puckering, dimpling, nipple lesions or retraction, erythema, and peau d'orange. Palpation of the breast should include all tissue from the clavicle to the inframammary area and from the sternum to the mid-axillary line. Palpation of the axillary and supraclavicular areas also should be part of the clinical breast examination.

Diagnostic mammography is recommended as part of the evaluation in all women 30 to 35 years or older who have a palpable breast mass. Initial mammography in younger women is often difficult to interpret because the density of the breast tissue reduces the sensitivity of mammography. Although mammography may be useful in younger women when the suspicion of cancer is high on clinical examination, the negative predictive value of mammography is limited in this setting.

Ultrasonography is most useful as the initial imaging method in the evaluation of women younger than 30 years who have a palpable breast mass, as an adjunct to mammography in women 30 to 35 years or older with a palpable breast mass and normal mammography, and as an adjunct to mammography to clarify whether a nodule found on mammography is solid or cystic. A palpable mass or mammographic nodule that corresponds to a simple cyst on ultrasonography does not require further diagnostic evaluation. A complex cyst should be aspirated under ultrasonographic guidance to confirm complete resolution of the cyst.

There are three primary diagnostic methods for tissue evaluation of breast masses: fine-needle aspiration (FNA), core needle biopsy, and excisional biopsy. FNA is inexpensive to perform and can be done in an office setting, but the sensitivity and specificity vary according to the skill of the operator and cytopathologist. FNA should be distinguished from cyst aspiration, which has as its goal removal of cystic fluid that does not need to be sent for cytologic analysis provided that it is nonbloody. Bloody fluid or cells aspirated from a solid mass should be sent for cytologic analysis. A negative FNA result is not sufficient to exclude cancer if suspicion is high on the basis of clinical examination or imaging.

In a core needle biopsy, a larger needle is used, thereby providing adequate tissue for histologic diagnosis. This technique is often done in conjunction with imaging guidance and has a higher sensitivity and better specimen quality than FNA. Concordance between core needle biopsy and excisional biopsy exceeds 90%. Core needle biopsy is also used to confirm the diagnosis in women with locally advanced breast cancer before administration of neoadjuvant chemotherapy.

Excisional biopsy is reserved for cases in which FNA and core biopsy are technically unfeasible or when the findings on FNA or core biopsy are discordant with the findings on physical examination or imaging. Excisional biopsy also should be done when FNA shows atypical cells or a core biopsy shows atypical ductal or lobular hyperplasia or lobular carcinoma in situ. It also excludes the presence of ductal carcinoma in situ or invasive carcinoma in the surrounding tissues.

Evaluation of Nonpalpable Mammographic Abnormalities

Calcifications found on mammography generally are classified into three categories: benign, intermediate concern, or high suspicion for malignancy. Round and oval calcifications that are also uniform in size and shape are more likely to be benign, whereas pleomorphic calcifications are more likely to be malignant. Biopsy must be done for suspicious calcification, whereas intermediate calcification may be reassessed with mammography in 6 months or biopsy done.
For nodules found on mammography which are not palpable, biopsy can be done under stereotactic guidance, under ultrasonographic guidance (if visible on ultrasonography), or by wire localization excisional biopsy.

- Benign characteristics on history or physical examination do not exclude breast cancer.
- Negative findings on mammography and ultrasonography do not definitively exclude breast cancer.
- Pleomorphic calcifications are most likely malignant.

Breast Pain

Breast pain can be classified into three categories: cyclic, noncyclic, and extramammary. Cyclic mastalgia occurs in premenopausal women: pain generally begins in the luteal phase of the menstrual cycle (2 weeks before the onset of menstruation) and resolves with menstruation. This type of mastalgia is usually diffuse and bilateral, but it may be more severe in one breast and most concentrated in the upper outer aspect of the breast.

Noncyclic mastalgia is defined as constant or intermittent breast pain that is not associated with the menstrual cycle. It typically presents in women in their fourth or fifth decade of life. The cause of most cases of noncyclic breast pain is elusive, but some cases may be attributed to pregnancy, duct dilatation, cysts, fibroadenomas, injury, prior breast surgery, breast infections, and exogenous estrogen exposure. Fewer than 10% of women who present with breast pain have cancer. The risk of subsequent breast cancer after normal findings on clinical examination and mammography for breast pain is estimated to be only 0.5%; thus, patients can be reassured in this setting.

Extramammary pain has numerous possible causes; the most common are costochondritis and other chest wall syndromes. Therapy should be directed at the underlying cause of pain.

The evaluation of focal breast pain should include mammography; if the result is negative, ultrasonography is done in the area of the pain. Ultrasonography often is used alone to evaluate focal breast pain in younger women.

Reassurance that the pain is not due to cancer is often the only necessary treatment. For persistent breast pain, there is overlap in the initial treatment strategies for cyclic and noncyclic breast pain: a properly fitted brassiere, the application of heat or cold, gentle massage, dietary restrictions (caffeine, sodium, dietary fat), relaxation techniques, and exercise. Over-the-counter analgesics also may be effective. Eliminating or adjusting doses of exogenous estrogen may alleviate breast pain. Other hormonal agents may be effective in patients with severe cyclic breast pain. Danazol is the only medication approved by the U. S. Food and Drug Administration for treatment of mastalgia, but the incidence of adverse androgenic effects limits its use. Several studies have shown a reduction in mastalgia with tamoxifen and bromocriptine, but adverse effects also limit their use.

- Fewer than 10% of women who present with breast pain are found to have cancer.

Nipple Discharge

Nipple discharge is a common complaint in women of reproductive age. Nipple discharge most often is due to benign causes, but it must be evaluated to exclude two rare but serious causes: a pituitary tumor and breast cancer. It is helpful to classify nipple discharge into two categories: nipple discharge due to galactorrhea and nipple discharge due to ductal lesions.

Galactorrhea is defined as milk production more than 1 year after weaning or in any nulligravid or menopausal woman. Galactorrhea usually appears as a spontaneous, milky discharge from multiple ducts of both breasts. It results from a relative or absolute increase in serum prolactin. The evaluation and treatment of galactorrhea are discussed in the endocrinology chapter.

Nipple discharge not due to galactorrhea is caused by ductal lesions, either benign or malignant. Although the character of the discharge is not pathognomonic for any specific lesion, a discharge that is due to cancer is often spontaneous, unilateral, and emanating from a single duct. Discharge due to cancer is typically bloody, serosanguineous, or watery. Approximately 5% of all cases of nipple discharge are due to cancer. Most cancer-associated discharges are due to ductal carcinoma in situ or papillary carcinoma. Factors that are associated with an increased likelihood of cancer are age older than 55 years, bloody discharge, and the presence of a mass.

In the absence of a palpable mass or mammographic lesion, nipple discharge is rarely due to cancer. Benign conditions that can cause nipple discharge include ductal ectasia (ductal dilatation with or without inflammation), fibrocystic breast changes, and intraductal papilloma.

If the discharge can be reproduced on examination, it should be characterized as unilateral or bilateral, spontaneous or expressible, and emanating from a single or multiple ducts. The discharge should

be assessed for gross or occult blood (using Hemoccult testing). Discharge that is grossly bloody or Hemoccult-positive should be sent for cytologic analysis; this has a high positive predictive value but a low negative predictive value. The most common cause of bloody nipple discharge is an intraductal papilloma. Although benign, surgical duct excision is required to exclude the possibility of a papillary carcinoma.

Mammography should be done in all nonlactating women with nipple discharge, with the exception of women younger than 30 years in whom ultrasonography may be a reasonable substitute. If mammography shows a suspicious mass, then surgical consultation should be obtained. If mammography is negative, ultrasonography should be considered in the subareolar area to determine whether an intraductal lesion is visible. Galactography and ductoscopy are not routinely used in the evaluation of bloody nipple discharge.

Patients who have nipple discharge that is neither bloody nor galactorrhea and who have normal mammographic and ultrasonographic results can be reassured and followed. Patients with bloody or watery (clear) discharge that can be localized to one duct require surgical duct excision even if the mammographic and ultrasonographic results are negative. Patients with normal results on imaging studies who report bloody or watery nipple discharge that cannot be reproduced on clinical examination require close interval follow-up. Surgical duct excision should be performed if the involved duct subsequently can be identified.

- Approximately 5% of all cases of nipple discharge are due to cancer.
- Typical clinical scenario: A 56-year-old woman with bloody discharge and the presence of a mass.

Benign Breast Disease

Simple cysts are the most common cause of discrete benign breast lumps. They occur most often in women between the ages of 35 and 50 years. Fibroadenomas are the most common cause of solid benign masses. The median age at diagnosis is 30 years, but fibroadenomas also can be found in postmenopausal women. There are many other histologic classifications of benign breast disease. The main significance of these distinctions lies in whether they confer an increased risk for the subsequent development of breast cancer. Patients with findings that confer a moderately or markedly increased risk should be counseled about options to reduce the risk of breast cancer (Table 25-6).

Breast Cancer: Risk Assessment and Prevention

Women at increased risk for breast cancer should be identified and counseled about options for risk reduction. The most widely used method of risk assessment is the National Cancer Institute Risk Assessment Tool, a computerized version of the Gail model that incorporates some but not all risk factors for breast cancer: current age, age at menarche, age at first live birth, number of previous breast biopsies, presence of atypical hyperplasia, and number of first-degree relatives affected by breast cancer. The relative risks associated with these risk factors are listed in the oncology chapter. The tool cannot be applied to young women or to women with a history of breast cancer, ductal carcinoma in situ, or lobular carcinoma in situ. The tool overestimates the risk of breast cancer in women with numerous previous biopsies for nonproliferative breast disease and underestimates the risk of breast cancer in women with a family history of breast cancer that includes early-onset breast cancer or numerous second-degree relatives affected by breast cancer. Alternative risk assessment models, such as the Claus model, are more appropriate in women whose predominant risk factor is a family history of breast cancer.

Only 5% to 10% of all breast cancers are due to an inherited gene mutation. Approximately one-third of hereditary breast cancers are due to a mutation in the *BRCA1* gene and approximately one-third are due to a mutation in the *BRCA2* gene. Both genes follow an autosomal dominant inheritance pattern. Women with a mutation in either of these genes have a lifetime risk of breast cancer ranging from 55% to 80% and a lifetime risk of ovarian cancer of 15% to 40%. Features of a family history suggestive of *BRCA* involvement include early-onset breast cancer, cases of breast and ovarian cancer within the same individual or family, cases of bilateral breast cancer, male breast cancer, and Ashkenazi Jewish heritage. Women with family histories suggestive of an inherited gene mutation should be referred for genetic counseling and consideration of gene testing.

Women with a known or suspected *BRCA1* or *BRCA2* mutation require increased surveillance. Monthly breast self-examination should begin in early adult life. Annual or semiannual clinical breast examination should begin at age 25 to 35 years, and annual mammography should begin at age 25 to 35 years, depending on the particular family history of the individual. Annual breast magnetic

Table 25-6 Relative Risk for Invasive Breast Carcinoma Based on Type of Benign Breast Disease

No increased risk
Duct ectasia
Fibroadenoma without proliferative epithelial changes
Fibrosis
Mastitis
Mild hyperplasia without atypia
Cysts
Simple apocrine metaplasia
Squamous metaplasia
Slightly increased risk (1.5-2.0 times)
Fibroadenoma with proliferative epithelial changes
Moderate or florid hyperplasia without atypia
Sclerosing adenosis
Papilloma
Radial scar
Moderately increased risk (4.0-5.0 times)
Atypical ductal hyperplasia
Atypical lobular hyperplasia
Markedly increased risk (8.0-10.0 times)
Lobular carcinoma in situ (controversial as to whether this is benign)

resonance imaging also has been recommended in this population. Because of the increased risk of ovarian cancer, annual or semiannual pelvic ultrasonography and CA 125 measurement also are recommended.

Once an increased risk of breast cancer has been confirmed, options for surveillance and risk reduction should be reviewed, depending on the woman's preferences and level of risk. Women at increased risk may adopt one or more of the following options for risk reduction:

Lifestyle modification. Factors found to be associated with an increased risk of breast cancer include postmenopausal weight gain, alcohol intake more than 2 drinks per day, and physical inactivity. Corresponding lifestyle modifications may have a beneficial effect on the risk of breast cancer. Although an association between the risk of breast cancer and use of oral contraceptives is controversial, postmenopausal combination hormone therapy (estrogen and progestogen) has been shown in numerous studies to increase slightly the risk of breast cancer. Therefore, avoidance of postmenopausal hormone use is prudent in women at increased risk for breast cancer.

Chemoprevention. Tamoxifen reduces the risk of breast cancer by 50% among women at increased risk. Women must weigh this potential benefit against the risks of tamoxifen, which include an increased risk of endometrial cancer, deep venous thrombosis, pulmonary embolus, stroke, and cataracts. Because most cases of tamoxifen-associated endometrial cancer present with vaginal bleeding, women taking tamoxifen should be asked about vaginal bleeding but do not need routine surveillance with pelvic ultrasonography or endometrial biopsy. Like tamoxifen, raloxifene is a selective estrogen receptor modulator. Some studies have suggested that it may be more favorable than tamoxifen for reducing the risk of breast cancer, although results of a direct comparison study (the STAR study) have not yet been published. Like tamoxifen, it does increase the risk of deep venous thrombosis and pulmonary embolus. Unlike tamoxifen, it does not increase the risk of endometrial cancer. The influence of tamoxifen on cognition is not fully understood. Women taking raloxifene had similar rates of overall mental decline relative to women taking placebo, although they had less decline in verbal memory and attention. Because selective estrogen receptor modulators reduce the incidence of estrogen-receptor–positive breast cancer but not estrogen-receptor–negative breast cancer, they are not as effective in the subset of women with *BRCA1* mutations whose tumors are more likely to be estrogen-receptor–negative. It should be noted that raloxifene decreases total cholesterol and low-density lipoprotein and has no effect on levels of high-density lipoprotein, triglycerides, or high-sensitivity C-reactive protein.

Prophylactic surgery. Prophylactic surgery is an option usually reserved for women with a significantly increased risk of breast cancer. Prophylactic mastectomy is associated with a 90% reduction in the risk of breast cancer. Bilateral oophorectomy in women younger than 40 years is associated with a decrease in the risk of breast cancer of approximately 50% and perhaps even more among women with *BRCA* mutations.

- 5% to 10% of all breast cancers are due to an inherited gene mutation.
- One-third of these are due to mutations in the *BRCA1* gene and one-third are due to mutations in the *BRCA2* gene.
- In women who are *BRCA*-positive, the lifetime risk of breast cancer is 55%-80% and of ovarian carcinoma 15%-40%.

Cardiovascular Disease in Women

Although cardiovascular disease (CVD) is the leading cause of death among women in the United States, it is underrecognized and undertreated in women. Critical differences exist between men and women in the epidemiology, prevention, clinical presentation, diagnosis, and treatment of CVD. A thorough understanding of the differences may assist in early diagnosis of CVD in women.

One in 2.5 women dies of CVD, whereas 1 in 30 women die of breast cancer. Coronary heart disease, which includes coronary atherosclerotic disease (CAD), myocardial infarction, acute coronary syndromes, and angina, accounts for the largest proportion of CVD deaths. The prevalence of CAD in premenopausal women is much lower than the prevalence among similarly aged men. The incidence of CAD in women lags 10 to 15 years behind the incidence in men until the seventh decade of life. The overall number of coronary deaths in men in the United States has declined, but the number of coronary deaths in women has stabilized or increased, depending on the study referenced.

Risk factors for men and women are similar. However, the magnitude of the effect of certain risk factors differs by sex, and diabetes mellitus and tobacco use have a higher relative risk in women than in men. Women also are more likely to underestimate the impact of CVD risk factors on their health.

The mortality rate from CVD is higher in women than in men: 38% of women and 25% of men will die within 1 year after a heart attack. The mortality rate from CVD is higher in African-American women than in white women. Underrecognition of CAD risk in women contributes to this higher mortality rate. Physicians tend to rate women as being at lower risk than men, even in patients with equivalent risks. Physicians are also less likely to recommend established preventive therapies (such as statin medications) to women, which may be due to the false perception of lower risk. Furthermore, sex-specific data on effective primary and secondary CVD prevention are limited. In one recent study of primary prevention of CVD in women, low-dose aspirin lowered the risk of stroke without affecting the risk of myocardial infarction or death from CVD.

Underdiagnosis of CAD also contributes to the higher postmyocardial infarction mortality rate among women. Women having a heart attack are less likely to have a correct diagnosis than men. This difference is due, in part, to the higher likelihood of atypical symptoms in women. Up to 50% of women present with atypical symptoms of heart disease and heart attack, which may include any of the following: pain in the neck, shoulder, upper back or abdomen; indigestion; belching; "gas" pains; nausea or vomiting; weakness; unexplained fatigue; shortness of breath; or a sense of doom. Women are more likely than men to avoid or delay seeking medical care for cardiac symptoms. In addition, because women tend to be older when symptoms of CAD develop, comorbid conditions (i.e., arthritis) may cause symptoms that mask cardiac symptoms.

Women are less likely than age-matched men to have obstructive CAD, particularly triple-vessel or left main coronary artery CAD. The higher prevalence of nonobstructive CAD and single-vessel disease in women results in a decreased accuracy of treadmill electrocardiography. Additional factors also may contribute to the decreased accuracy of treadmill electrocardiographic findings in women, including more frequent resting ST-T changes, lower electrocardiographic voltage, and hormonal factors. The false-positive rate of treadmill electrocardiographic testing is higher in women than in men (particularly in young women with a low likelihood of CVD) and the false-negative rate is also higher. Exercise electrocardiography does have a high negative predictive value in women with a low pretest probability of CAD and a low-risk Duke treadmill score.

Despite these limitations, guidelines still support the use of exercise testing in women at intermediate pretest risk of CAD on the basis of symptoms and risk factors who have normal results of resting electrocardiography and are capable of maximal exercise. Exercise stress echocardiography is recommended for symptomatic women with an intermediate to high pretest probability of CAD, and dobutamine stress echocardiography is recommended for women with normal or abnormal electrocardiographic results who are incapable of exercise. Imaging stress tests (echocardiography, nuclear perfusion) have similar sensitivity and specificity in women and men.

In regard to invasive testing, women are less likely than men to be referred for coronary angiography. Women also are more likely to require urgent or emergency coronary artery bypass grafting. In-hospital mortality after coronary artery bypass grafting is higher in women than men, which is largely explained by their higher risk profile: compared with men, women undergoing coronary artery bypass grafting are older and have more comorbidities, such as diabetes, hypertension, and obesity. Long-term outcomes after coronary artery bypass grafting are similar for women and men. Women with multivessel disease treated with coronary artery bypass grafting have better long-term survival than women treated medically.

For secondary prevention, the Cholesterol and Recurrent Events (CARE) study found that cholesterol lowering with a statin drug was more effective in women than in men. Prospective studies have shown that hormone therapy should not be used for the purpose of secondary prevention. The HERS (Heart and Estrogen/Progestin Replacement Study) trial found no overall effect of 4.1 years of hormone therapy on risk of myocardial infarction or fatal coronary artery events in women with known CAD; coronary events increased in the first year after randomization. The Estrogen Replacement and Atherosclerosis trial showed no benefit of hormone therapy on angiographic progression in postmenopausal women with documented coronary stenosis.

The Women's Health Initiative was the first randomized trial to investigate the effects of hormone therapy as primary prevention for CVD in healthy postmenopausal women. For women receiving combination therapy (conjugated equine estrogen and medroxyprogesterone acetate), the rate of coronary events increased (an additional 7 events per 10,000 person-years of use) and the rate of stroke increased (an additional 8 strokes per 10,000 person-years of use). For women receiving unopposed conjugated equine estrogen, there was no effect on the incidence of coronary events but an increased risk of stroke (12 additional strokes per 10,000 person-years of use). As a result of these prospective randomized controlled trials that contradicted the results of numerous prior observational studies, hormone therapy is not recommended for primary or secondary prevention of CVD. Hormone therapy should be discontinued if a CVD event occurs.

The lipid alterations associated with hormone therapy are complex and include both favorable and unfavorable changes. Hormone therapy leads to reductions in low-density lipoprotein cholesterol and lipoprotein (a) levels and increases in high-density lipoprotein cholesterol levels. Oral estrogen (but not transdermal estrogen) leads to increases in triglyceride and C-reactive protein levels.

- Cardiovascular disease is the leading cause of death in women in the United States.
- The magnitude of diabetes mellitus and tobacco use as risk factors is higher in women than in men.
- 38% of women compared with 25% of men will die within 1 year after a myocardial infarction.
- Up to 50% of women present with atypical symptoms of heart disease.
- Hormone therapy should not be used for the purpose of secondary prevention.

Heart Failure in Women

Heart failure (HF) affects approximately 2.5 million women in the United States. Women account for nearly 50% of all hospital admissions for HF. HF tends to develop at an older age in women than men. During the past 50 years, the incidence of HF has declined among women but not among men. Sex-related differences in the pathophysiologic mechanisms of heart failure likely exist. Women with HF are more likely to have hypertension, diabetes, obesity, tobacco use, and atrial fibrillation; men with HF are more likely to have CAD and left ventricular systolic dysfunction. Relative to men, women tend to have diastolic HF with a preserved ejection fraction. In general, women survive longer than men with HF, but they have more dyspnea on exertion and functional impairment. Depression frequently is associated with HF and is more common in women than men.

Depression and Anxiety in Women

The lifetime prevalence of depression is 21% in women and 12% in men. The peak age at onset of depression is 33 to 45 years in women and more than 55 years in men. Women are less likely to commit suicide but twice as likely to make a suicide attempt. Caucasian women are twice as likely to commit suicide as African-American women. The lifetime prevalence rate for dysthymia is 8% in women and 4.8% in men. There is no sex difference for bipolar disorder.

Studies have not found an association between natural or surgical menopause and rate of depression in women. Hormone therapy has been associated with improved scores on the Beck Depression Inventory for nondepressed women but not for clinically depressed women. Estrogen may improve symptoms in women with mild

depressive symptoms, but hormone therapy alone is not sufficient therapy for clinical depression in postmenopausal women.

Postpartum depression affects approximately 10% to 15% of women. It develops during the first 4 weeks after childbirth, although it often is not recognized by the woman or health-care provider. Risk factors for postpartum depression include prior history of major depression, prior postpartum depression, depression during the pregnancy, unmarried status, or unplanned pregnancy. Because of overlap in the symptoms of postpartum depression and thyroid disease, it is essential to measure thyroid-stimulating hormone in all women who present with symptoms of postpartum depression. In a small fraction of women with postpartum depression, psychosis develops, and this usually requires acute hospitalization.

Anxiety disorders that are more prevalent in women than in men include panic disorder, agoraphobia, social phobia, generalized anxiety disorder, and posttraumatic stress disorder. Women with a panic disorder frequently present with a comorbid psychiatric condition, such as major depression, generalized anxiety disorder, or substance abuse. An anxiety disorder may underlie persistent somatic complaints. If nonpharmacologic measures do not provide sufficient relief, combined medication and cognitive behavioral therapy should be offered. The risks and benefits of pharmacologic therapy need to be measured carefully in the woman who is breastfeeding: tricyclic antidepressants and some selective serotonin reuptake inhibitors seem to be relatively safe, although there are isolated adverse reports in infants exposed through breast milk.

- The lifetime risk of depression in women is 21% and 12% in men.

Domestic Violence

Domestic violence is defined as abuse between intimate or formerly intimate partners. Of reported domestic violence cases, 95% involve a male perpetrator and a female victim. Over a lifetime, at least one of three American women is physically assaulted by a partner. Female victims of this abuse most often present for care that is not directly related to abuse injuries. Battered women use health services six to eight times more than nonbattered women and have a higher incidence of headaches, sexually transmitted diseases, irritable bowel syndrome, depression, and anxiety. Aspects of the history that may suggest domestic violence include chronic pain syndromes, gastrointestinal complaints, an overprotective partner, injuries during pregnancy, frequent visits for injuries, a history of depression, or a history of childhood abuse. All women should be asked about domestic violence. Routine prenatal screening for domestic violence is particularly important, because abuse occurs in one of six pregnancies and often begins or escalates in early pregnancy.

Physical examination findings that are suggestive of domestic violence include injuries incompatible with a given history, multiple injuries in various stages of healing, injuries suggestive of a defensive posture (such as ulnar fractures), and pattern injuries (such as burns, choking marks, bite marks, or wrist or ankle abrasions).

Documentation of domestic violence in the medical record is essential and may provide evidence to help the victim separate from the perpetrator. If the victim consents, photographs of injuries should be obtained, which may be helpful in court proceedings. Physical evidence, such as torn or bloody clothes or sexual assault evidence, should be preserved.

Victims of domestic violence need treatment of their injuries, support and reassurance that the abuse is not their fault, safety assessment, and referral to appropriate resources to prevent further abuse. A safety assessment is a critical part of the domestic violence evaluation. When possible, it should be done by a victim's advocate, social worker, or law enforcement personnel. When these services are not available, it should be done by the clinician or nurse. An immediate psychiatric referral should be arranged for any patient expressing suicidal or homicidal intentions. The assessment also must include inquiries regarding children in the home: any child abuse must be reported to child abuse authorities. Some jurisdictions require reporting to the child abuse authorities of any domestic violence in a home where children reside. Because domestic violence homicides are more likely to occur immediately after separation, ensuring the safety of the victim during separation is critical. Strategies include relocation of the victim or arrest of the perpetrator.

Referral to a victim's advocate group, women's shelter, or social worker should be arranged. Immediate contact with the referral source is best, because this is the time when the victim is more likely to make a change.

Get Succinct Diagnosis and Treatment Guidance!

With 300 Illustrations

Now for the first time, a new diagnosis and treatment guide with even more focus on the most commonly encountered disorders than ever before. This new, up-to-date guide from Mayo Clinic includes:

- ALL MAJOR INTERNAL MEDICINE DISEASES & DISORDERS – provides a unique succinct approach for commonly seen disorders
- EVIDENCE-BASED – supports and guides clinicians toward optimal treatment outcomes
- ORGANIZED BY BODY SYSTEM – provides easy access to diagnosis and treatment options
- POINT-OF-CARE TOOLS – summary tables, algorithms, and summary points support the need for quick and accurate patient care resources
- DRUG GUIDANCE – Easy access to tables of current medications, indications, and side effects saves time and improves treatment outcomes
- Special USMLE section – provides expert guidance on preparation for the USMLE Step 2 Clinical Knowledge and Clinical Skills examinations
