TABLE OF CONTENTS

PUBLISHER'S NOTE

Magill's Encyclopedia of Science: Plant Life is designed to meet the needs of college and high school students as well as nonspecialists seeking general information about botany and related sciences. The definition of "plant life" is quite broad, covering the range from molecular to macro topics: the basics of cell structure and function, genetic and photosynthetic processes, evolution, systematics and classification, ecology and environmental issues, and those forms of life—archaea, bacteria, algae, and fungi—that, in addition to plants, are traditionally studied in introductory botany courses. A number of practical and issue-oriented topics are covered as well, from agricultural, economic, medicinal, and cultural uses of plants to biomes, plant-related environmental issues, and the flora of major regions of the world. (Readers should note that, although cultural and medicinal uses of plants are occasionally addressed, this encyclopedia is intended for broad information and educational purposes. Those interested in the use of plants to achieve nutritive or medicinal benefits should consult a physician.)

Altogether, the four volumes of *Plant Life* survey 379 topics, alphabetically arranged from *Acid precipitation* to *Zygomycetes*. For this publication, 196 essays have been newly acquired, and 183 essays are previously published essays whose contents were reviewed and deemed important to include as core topics. The latter group originally appeared in the following Salem publications: *Magill's Survey of Science: Life Science* (1991), *Magill's Survey of Science: Life Science, Supplement* (1998), *Natural Resources* (1998), *Encyclopedia of Genetics* (1999), *Encyclopedia of Environmental Issues* (2000), *World Geography* (2001), and *Earth Science* (2001). All of these previously published essays have been thoroughly scrutinized and updated by the set's editors. In addition to updating the text, the editors have added new bibliographies at the ends of all articles.

New appendices, providing essential research tools for students, have been acquired as well:

- a "Biographical List of Botanists" with brief descriptions of the contributions of 134 famous naturalists, botanists, and other plant scientists
- a Plant Classification table
- a Plant Names appendix, alphabetized by common name with scientific equivalents
- another Plant Names appendix, alphabetized by scientific name with common equivalents
- a "Time Line" of advancements in plant science (a discursive textual history is also provided in the encyclopedia-proper)
- a Glossary of 1,160 terms
- a Bibliography, organized by category of research
- a list of authoritative Web sites with their sponsors, URLs, and descriptions

Every essay is signed by the botanist, biologist, or other expert who wrote it; where essays have been revised or updated, the name of the updater appears as well. In the tradition of Magill reference, each essay is offered in a standard format that allows readers to predict the location of core information and to skim for topics of interest: The title of each article lists the topic as it is most likely to be looked up by students; the "Category" line indicates pertinent scientific subdiscipline(s) or area(s) of research; and a capsule "Definition" of the topic follows. Numerous subheads guide the reader

through the text; moreover, key concepts are italicized throughout. These features are designed to help students navigate the text and identify passages of interest in context. At the end of each essay is an annotated list of "Sources for Further Study": print resources, accessible through most libraries, for additional information. (Web sites are reserved for their own appendix at the end of volume 4.) A "See also" section closes every essay and refers readers to related essays in the set, thereby linking topics that, together, form a larger picture. For example, since all components of the plant cell are covered in detail in separate entries (from the *Cell wall* through *Vacuoles*), the "See also" sections for these dozen or so essays list all other essays covering parts of the cell as well as any other topics of interest.

Approximately 150 charts, sidebars, maps, tables, diagrams, graphs, and labeled line drawings offer the essential visual content so important to students of the sciences, illustrating such core concepts as the parts of a plant cell, the replication of DNA, the phases of mitosis and meiosis, the world's most important crops by region, the parts of a flower, major types of inflorescence, or different classifications of fruits and their characteristics. In addition, nearly 200 black-and-white photographs appear throughout the text and are captioned to offer examples of the important phyla of plants, parts of plants, biomes of plants, and processes of plants: from bromeliads to horsetails to wheat; from Arctic tundra to rain forests; from anthers to stems to roots; from carnivorous plants to tropisms.

Reference aids are carefully designed to allow easy access to the information in a variety of modes: The front matter to each of the four volumes includes the volume's contents, followed by a full "Alphabetical List of Contents" (of all the volumes). All four volumes include a "List of Illustrations, Charts, and Tables," alphabetized by key term, to allow readers to locate pages with (for example) a picture of the apparatus used in the *Miller-Urey Experiment*, a chart demonstrating the genetic offspring of *Mendel's Pea Plants*, a map showing the world's major zones of *Desertification*, a cross-section of *Flower Parts*, or a sampling of the many types of *Leaf Margins*. At the end of volume 4 is a "Categorized Index" of the essays, organized by scientific subdiscipline; a "Biographical Index," which provides both a list of famous personages and access to discussions in which they figure prominently; and a comprehensive "Subject Index" including not only the personages but also the core concepts, topics, and terms discussed throughout these volumes.

Reference works such as *Magill's Encyclopedia of Science: Plant Life* would not be possible without the help of experts in botany, ecology, environmental, cellular, biological, and other life sciences; the names of these individuals, along with their academic affiliations, appear in the front matter to volume 1. We are particularly grateful to the project's editor, Bryan Ness, Ph.D., Professor of Biology at Pacific Union College in Angwin, California. Dr. Ness was tireless in helping to ensure thorough, accurate, and up-to-date coverage of the content, which reflects the most current scientific knowledge. He guided the use of commonly accepted terminology when describing plant life processes, helping to make *Magill's Encyclopedia of Science: Plant Life* easy for readers to use for reference to complement the standard biology texts.

CONTRIBUTOR LIST

About the Editor: Bryan Ness is a full professor in the Department of Biology at Pacific Union College, a four-year liberal arts college located atop Howell Mountain in the Napa Valley, about ninety miles north of San Francisco. He received his Ph.D. in Botany from Washington State University. His doctoral work focused on molecular plant systematics and evolution. In addition to authoring or coauthoring a number of scientific papers, he has contributed to *The Jepson Manual: Higher Plants of California*, *The Flora of North America*, a multivolume guide to the higher plants of North America, and more than a dozen articles for various Salem Press publications, including *Aging*, *Encyclopedia of Genetics*, *Magill's Encyclopedia of Science: Animal Life*, *Magill's Medical Guide*, and *World Geography*. For four years he managed The Botany Site, a popular Internet site on botany. He is currently working on a book about plant myths and misunderstandings.

ACID PRECIPITATION

Categories: Environmental issues; pollution

Acid precipitation is rain, snow, or mist which has a pH lower than unpolluted precipitation. Increased levels of acid precipitation have significant effects on food chains and ecosystems.

Precipitation—rain, snow, hail, sleet, or mist—is naturally acidified by carbonic acid (H_2CO_3). Carbon dioxide (CO_2) in the atmosphere reacts with water molecules, lowering the pH of precipitation to 5.6. A pH scale is used to measure a solution's acidity or alkalinity; pH is defined as the negative logarithm of the concentration of hydrogen ions, H^+. A solution with a pH of 7.0 is neutral. A pH lower than 7 is acidic, and a pH greater than 7 is alkaline. Other acidic substances are also present in the atmosphere, causing "unpolluted" precipitation to have a pH approaching 5.0. Solutions with a pH of 5.0 or less have concentrations of hydroxyl ion, or OH^-, and carbonate ion, or CO_3^-, approaching zero.

Acid precipitation is the name given to rain or snow contaminated with oxides of sulfur (SO_x) and oxides of nitrogen (NO_x). These chemicals combine with water droplets to form sulfuric acid and nitric acid. SO_x is formed by combustion of materials containing sulfur, and NO_x is formed by oxidation of molecular nitrogen in the atmosphere during combustion. SO_x sometimes arises from natural sources such as volcanoes and geyser fields, and NO_x is formed by lightning. Downwind of smelting facilities, hydrochloric acid (HCl) and hydrofluoric acid (HF) may also contribute to acid precipitation. Acid precipitation may detrimentally change soil chemistry, either by stripping nutrients, especially magnesium and calcium, or mobilizing *phytotoxic trace elements* (elements toxic to plants).

Geographic Extent of Damage

Acid precipitation is a regional problem. SO_x and NO_x can travel many thousands of kilometers in the atmosphere after being emitted by large, stationary sources, especially those that have very high smokestacks. These pollutants are slowly transformed into sulfuric and nitric acid aerosols and are incorporated into precipitation, which eventually makes contact with the earth's surface. Acid precipitation in the eastern United States contains more SO_x than precipitation in the western United States, which contains more NO_x.

In North America, acid precipitation and *dry deposition* (of acid aerosol particles) are major environmental problems in New England and New York State and in Ontario and Quebec. These regions attribute much of their acid precipitation to emissions from large coal-burning plants in the American Ohio Valley. Scandinavian activists blame coal-burning power plants and factory emissions in the British Isles for that region's acid rain problems. Central Europe—including Poland, the Czech Republic, Slovakia, and eastern Germany—has many power plants and factories that burn high-sulfur coal. Acid-laden pollution plumes stretch thousands of kilometers downwind from smokestacks in that region.

Controlled Studies

Controlled experiments on individual plant species have revealed short-term damage to a limited number of those species. Experiments using *simulated acid rain* (SAR) are difficult to extrapolate to field conditions, where the specific pollutants and pH levels vary widely over time. In controlled conditions, studies showed no link between SAR and yield in Amsoy soybeans. However, field studies demonstrated that acid deposition does decrease yield in Amsoy soybeans.

Acid precipitation influences plant diseases by acting on both pathogens and host organisms. Seedlings of *Pinus rigida*, *Pinus echinata*, *Pinus taeda*, and *Pinus strobus* exposed to SAR of pH 3.0 had a 100 percent mortality rate because of fungal *damping-off*, a diseased condition of seedlings marked by wilting or rotting. Red spruce seedlings subjected to dilute sulfuric acid mist developed brown lesions on their needles, followed by needle drop. Studies showed a reduction in the growth of sugar maple seedlings following exposure to low-pH moisture, and that seedling survival decreased with increasing acidity.

Crop and Forest Decline

In field experiments, soybeans have shown reduced yields with decreasing pH (increasing acidity) of moisture applied. Yields of seed and seed protein are both reduced in soybeans exposed to high acidity. A lower number of seed pods were found in plants exposed to high acidity, compared to control plants.

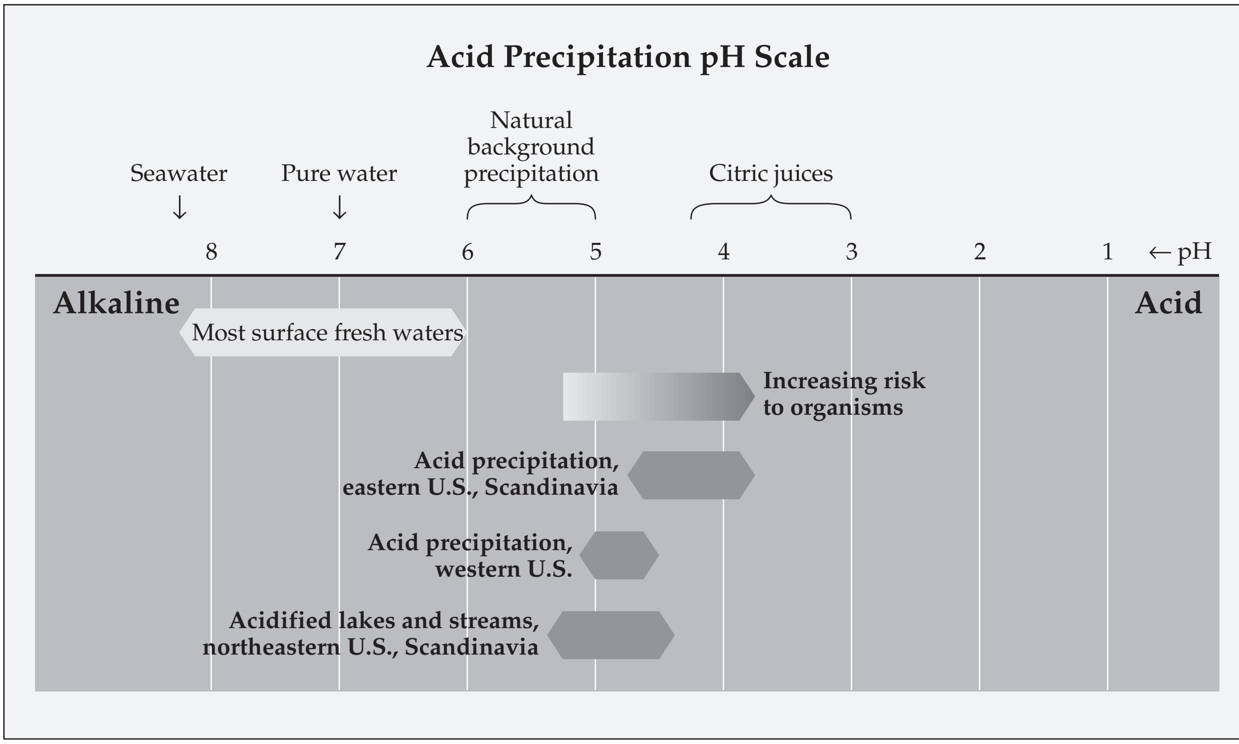
Acid precipitation causes detrimental long-term effects in most ecosystems, especially forests. Root systems under acidic stress show great variability in tolerance and injury. Acidic stress on roots decreases root growth, measured by a reduction in root length, and severely damaged trees have more fine roots with opaque tip zones than do slightly damaged trees. Some scientists have suggested that the radical growth rate in yellow pines in the southeastern United States may be reduced by acid precipitation.

PhotoDisc

Activists blame coal-burning power plants and factory emissions for acid rain problems. After being emitted by large, stationary sources, especially those that have very high smokestacks, pollutants can travel thousands of kilometers in the atmosphere. Those that are transformed into sulfuric and nitric acid aerosols are incorporated into precipitation, which eventually makes contact with the earth's surface.

Since the 1960's Central European soils have been progressively acidified, altering soil buffering capacities. Acid rain containing nitrates (which are not immobilized in soil) played an important role in this soil acidification. Acidification has reduced the magnesium, calcium, and potassium available for nutrient uptake by plants and has affected root growth. One-quarter of European forests are moderately or severely damaged by acid precipitation, with dry deposition believed (by scientists and politicians) to be largely responsible. This pattern of damage, first detected in the 1980's, has been called *neuartige Waldschäden* (literally, "new-type forest decline"). It has been detected throughout Central Europe at all elevations and on all soil types. *Waldschäden* is most pronounced downwind of major air pollution sources.

Abnormally high numbers of red spruce have died in the high-elevation northern Appalachian Mountains since the 1960's. This die-off has been attributed to high rates of acid deposition (up to 4 kiloequivalents of hydronium ions per hectare per year) and exposure to acid fog droplets for up to two thousand hours per year. Very high levels of trace metals (known to be phytotoxic) have accumulated in the region.



Note: The acid precipitation pH ranges given correspond to volume-weighted annual averages of weekly samples.
Source: Adapted from John Harte, "Acid Rain," in *The Energy-Environment Connection*, edited by Jack M. Hollander, 1992.

Aquatic Ecosystems

Most freshwater ecosystems range from pH 6.0 to pH 8.0. In limestone terrain, acid precipitation is neutralized by dissolution of calcium carbonate. As a freshwater environment becomes acidified, the number of species it supports declines. When conditions are more acidic than pH 5.5, dissolved inorganic carbon exists only as dissolved carbon dioxide. Planktonic algae, which can use low levels of dissolved inorganic carbon, are favored in these environments. Acid environments greatly reduce the numbers of herbivores that graze on aquatic plants; this is thought to explain why filamentous green algae are found in most acidified lakes. Scientists point out that it is difficult to separate the effects that acidification alone produces in an aquatic ecosystem.

Sources for Further Study

Adriano, D. C., and A. H. Johnson, eds. *Biological and Ecological Effects*. Vol. 2 in *Acidic Precipitation*. New York: Springer-Verlag, 1989. Extremely detailed volume contains individual chapters by different authors, devoted to the effects of acid precipitation on trees, crops, and freshwater biota. Reviews damage to North American and European forests. Each chapter offers an extensive bibliography of acid precipitation research relevant to the topic. Includes many charts and diagrams, fully indexed.

Ahrens, C. Donald. *Meteorology Today*. 6th ed. Pacific Grove, Calif.: Brooks/Cole, 2000. College meteorology text reviews the sources of acid precipitation and where its major effects occur. Includes illustrations, bibliography, index, and glossary.

Canter, Larry W. *Acid Rain and Dry Deposition*. Chelsea, Mich.: Lewis, 1989. About sixty pages of this book are devoted to geographic extent of acid rain and the chemical transformations and transport of pollutants in the atmosphere. Covers the effects of acid rain on vegetation, crops, and floral species. It is a guide to research done through the 1980's on acid rain. Comprehensive literature review and bibliography; index.

Lutgens, Frederick K., and Edward J. Tarbuck. *The Atmosphere*. 8th ed. Upper Saddle River, N.J.: Prentice Hall, 2001. Excellent introductory meteorology text with good description of acid precipitation and its effects, including a color photograph of trees in the Great Smokey Mountains severely damaged by acid precipitation. Color illustrations, bibliography, index, and glossary.

ACTIVE TRANSPORT

Categories: Cellular biology; physiology; transport mechanisms

Active transport is the process by which cells expend energy to move atoms or molecules across membranes, requiring the presence of a protein carrier, which is activated by ATP. Cotransport is active transport that uses a carrier that must simultaneously transport two substances in the same direction. Countertransport is active transport that employs a carrier that must transport two substances in opposite directions at the same time.

Biologists in nearly every field of study have discovered that one of the major methods by which organisms regulate their metabolisms is by controlling the movement of molecules into cells or into organelles such as the nucleus. This regulation is possible because of the semipermeable nature of *cellular membranes*. The membranes of all living cells are fluid mosaic structures composed primarily of lipids and proteins. The lipid molecules are *aliphatic*, which means that their molecular structure exhibits both a hydrophilic (water-attracted) and a hydrophobic (water-repelling) portion. These aliphatic molecules form a double layer: The hydrophilic heads are arranged opposite one another on the inner and outer surfaces, and the hydrophobic tails are aligned across from one another within the interior, sandwiched between the hydrophilic heads. The protein in the membrane is interspersed periodically throughout the lipid bilayer. Some of the protein, referred to as *peripheral protein*, penetrates only one of the lipid layers. The *integral protein*, as the remaining protein is called, extends through both layers of lipid to interface with the environment on both the internal and external surfaces of the membrane. These integral proteins can serve as transport channels and carriers.

Cellular Energy

Transport across the membrane is accomplished by three different mechanisms: *simple diffusion*, *facilitated diffusion*, and active transport. The first two mechanisms are referred to as passive processes because they do not require the direct input of cellular energy, and they involve transport down a *concentration gradient*, that is, from the side with a higher concentration to the side with a lower concentration of the substance being transported. In many instances, however, substances are transported across a membrane from the side with a low concentration to the side containing a greater concentration. This "uphill" movement across membranes is called active transport, and it requires the expenditure of cellular energy.

Cellular energy, produced by the biological oxidation of fuels such as carbohydrates, is stored as adenosine triphosphate (ATP). When this high-energy phosphate is hydrolyzed, the stored energy is released to drive cellular reactions such as active transport. The ATPase protein located in membranes belongs to one of the groups of enzymes which hydrolyze ATP. The mechanism has not been completely deciphered, but it appears as though a protein carrier molecule binds with the substance to be transported at the surface on one side of the membrane. This binding occurs at a specific activated region on the carrier protein called the *active site*. After combining with the carrier, the substance is moved across the membrane and released at the surface on the other side of the membrane. ATP is then hydrolyzed by an ATPase, and the energy released in this reaction prepares the protein carrier for attachment to another molecule to be transported by reactivating the active site. There is some question as to whether ATPase is a component of the carrier molecule or functions separately from it. Regardless of the spatial arrangement, the two molecules are intimately related in the active transport process.

Cotransport and Countertransport

There are two important modifications of the active transport process: *cotransport* and *countertransport*. Cotransport, or *symport*, involves a specialized protein molecule referred to as a symport carrier. A symport carrier has two attachment sites. One site is for the attachment of the molecule to be transported, and the other is for the attachment of a second molecule, which can be referred to as the *synergist*. Both the molecule to be transported and the synergist must be bound to the symport carrier before transport across the membrane can take place. The synergist is moved down a concentration gradient, and this downhill flow of the synergist drives the carrier to transport both molecules. In order to keep the synergist moving down a concentration gradient when attached to the symport carrier, the synergist must be pumped back across the membrane. This movement of the synergist in the opposite direction is mediated by a protein carrier activated by the energy released from the hydrolysis of ATP by an ATPase.

Countertransport, or *antiport*, also utilizes a specialized carrier with two attachment sites. This antiport carrier binds with the molecule to be transported at one of the attachment sites, and a second molecule, which can be called the *antagonist*, binds at the other. The carrier moves the molecule to be transported across the membrane while simultaneously moving the antagonist in the opposite direction. Again, both molecules must be attached to the antiport carrier before either can be transported, and the flow of the antagonist down a concentration gradient drives the transport by the carrier in both directions. The antagonist is pumped back across the membrane by a protein carrier activated by the energy released from the hydrolytic action of an ATPase on ATP. This action maintains a concentration gradient favorable for transport when the antagonist is attached to the antiport carrier.

Transport in Action

The presence of these three active transport mechanisms has been well documented. Calcium, for example, has been shown to be pumped from the cell by a carrier protein activated by the hydrolysis of ATP. Sugars for energy and carbohydrate structure must be cotransported into the cell by a symport carrier that utilizes the sodium ion as a synergist. At least two countertransport ion pumps have been identified. One pumps the potassium ion into the cell at the same time that it pumps the hydrogen ion out. The second pumps the potassium ion into the cell while the antagonist, sodium, is moved in the opposite direction. It is likely that numerous other active transport systems exist that have not yet been positively identified.

A protein carrier is one of the basic components of any active transport mechanism. Although no specific carrier molecule has yet been positively identified, there is ample indirect evidence to support the presence of such a protein. Much of this evidence comes from studies showing that active transport exhibits *saturation kinetics*. This means that the transport of a specific ion will increase as the concentration increases, up to a certain point. At this point, further increases in concentration will have no effect on transport. These results strongly suggest that the ion is binding with another molecule in the membrane, such as a carrier protein, which is limited in concentration and becomes saturated. Studies have also shown the transport of some substances to be competitively inhibited by the presence of another, very similar, substance. This indicates that both substances are competing for the same site on a membrane molecule, such as a protein carrier.

Role of Active Transport

The ability to accumulate substances against a concentration gradient is necessary for the normal function and survival of cells. There are numerous examples, however, of active transport being intimately involved in the regulation of some important biological processes. In the plant kingdom, sugar is produced by photosynthesis in the green leaves. This sugar must be transported out of the leaves and into nonphotosynthetic tissues, such as roots or fruit, through specialized transport cells in the *phloem*. The loading of sugars into the phloem is dependent on an active cotransport mechanism.

Almost every field of life science is concerned with *gene regulation*. Genes are continually being induced (activated) or repressed (deactivated) as organisms develop and change from the time of their conception until their death. Repression is usually caused by the presence of a protein molecule in the cell nucleus, but induction may very often be the result of metabolites being actively transported into the cell or nucleus. Hence, the active transport mechanisms may be a very important component of gene regulation.

ADAPTATIONS

Categories: Evolution; genetics

The results of natural selection in which succeeding generations of organisms become better able to live in their environments are called adaptations. Many of the features that are most interesting and beautiful in biology are adaptations. Specialized structures, physiological processes, and behaviors are all adaptations when they allow organisms to cope successfully with the special features of their environments.

Adaptations ensure that individuals in populations will reproduce and leave well-adapted offspring, thus ensuring the survival of the species. Adaptations arise through *mutations*—inheritable changes in an organism's genetic material. These rare events are usually harmful, but occasionally they give specific survival advantages to the mutated organism and its offspring. When certain individuals in a population possess advantageous mutations, they are better able to cope with their specific environmental conditions and, as a result, will contribute more offspring to future generations than those individuals that lack the mutation. Over time, the number of individuals that have the advantageous mutation will increase in the population at the expense of those that do not have it. Individuals with an advantageous mutation are said to have a higher *fitness* than those without it, because they tend to have comparatively higher survival and reproductive rates. This is *natural selection*.

Natural Selection

Over very long periods of time, evolution by natural selection results in increasingly better adaptations to environmental circumstances. Natural selection is the primary mechanism of evolutionary change, and it is the force that either favors or selects against mutations. Although natural selection acts on individuals, a population gradually changes as those with adaptations become better represented in the total population. Most flowering plants, for example, are unable to grow in soil containing high concentrations of certain elements (for example, heavy metals) commonly found in mine tailings. Therefore, an adaptation that conferred resistance to these elements would open up a whole new habitat where competition with other plants would be minimal. Natural selection would favor the mutations, which confer specific survival advantages to those that carry them and impose limitations on individuals lacking these advantages. Thus, plants with special adaptations for resistance to the poisonous effects of heavy metals would have a competitive advantage over those that find heavy metals toxic. These attributes would be passed to their more numerous offspring and, in evolutionary time, resistance to heavy metals would increase in the population.

Types of Adaptations

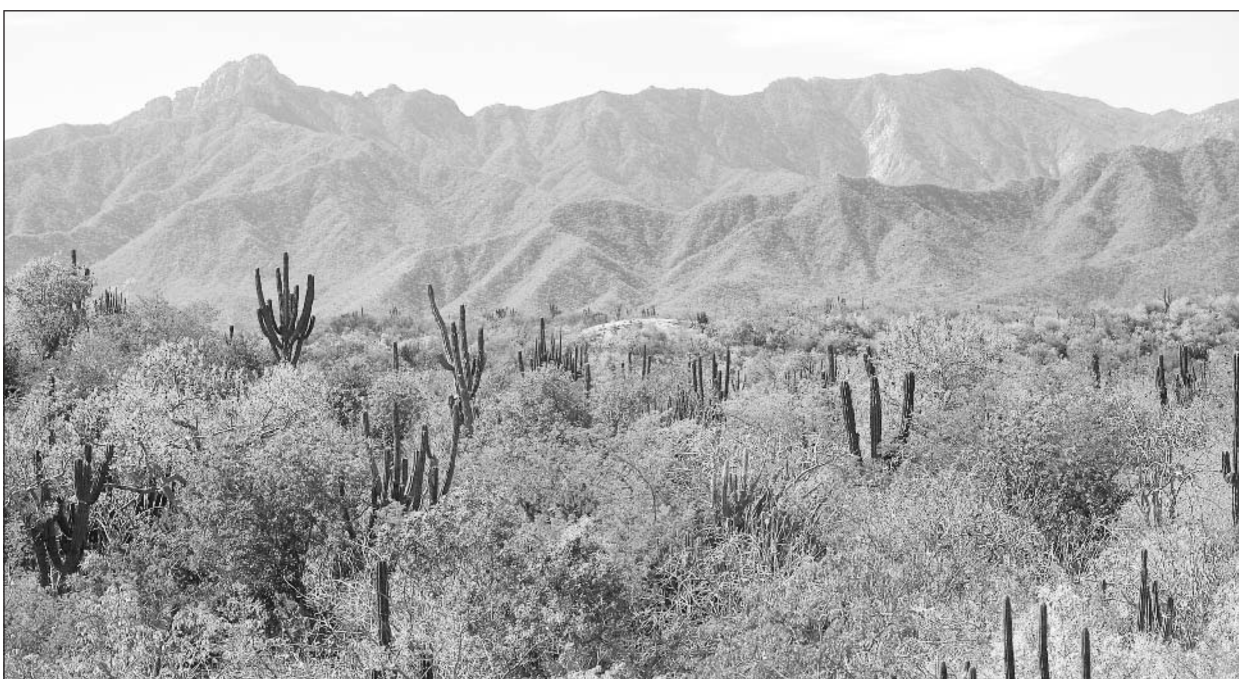
Although natural selection serves as the instrument of change in shaping organisms to very specific environmental features, highly specific adaptations may ultimately be a disadvantage. Adaptations that are specialized may not allow sufficient *flexibility* (generalization) for survival in changing environmental conditions. The degree of adaptative specialization is ultimately controlled by the nature of the environment. Environments, such as the tropics, that have predictable, uniform climates and have had long, uninterrupted periods of climatic stability are biologically complex and have high species *diversity*. Scientists generally believe that this diversity results, in part, from complex competition for resources and from intense predator-prey relationships. Because of these factors, many narrowly specialized adaptations have evolved when environmental stability and predictability prevail. By contrast, harsh physical environments with unpredictable or erratic climates seem to favor organisms with general adaptations, or adaptations that allow flexibility. Regardless of the environment type, organisms with both general and specific adaptations exist because both types of adaptation enhance survival under different environmental circumstances.

Structural adaptations are parts of organisms that enhance their survival ability. Camouflage that enables organisms to hide from predators or their prey; protective spines on cacti that inhibit organisms that might feed on them; color, scent, or shape of flowers that promotes seed production—these are all structural adaptations. These adaptations enhance survival because they assist individuals in dealing with the rigors of the physical environment, obtaining nourishment, competing with others, or attracting pollinators.

Metabolism is the sum of all chemical reactions taking place in an organism, whereas physiology consists of the processes involved in an organism carrying out its function. *Physiological adaptations* are changes in the metabolism or physiology of organisms, giving them specific advantages for a given set of environmental circumstances. Because organisms must cope with the rigors of their physical environments, physiological adaptations for temperature regulation, water conservation, varying metabolic rate, and dormancy allow organisms to adjust to the physical environment or respond to changing environmental conditions.

Adaptations and Environment

Desert environments, for example, pose a special set of problems for organisms. Hot, dry environments require physiological mechanisms that enable organisms to conserve water and resist prolonged periods of high temperature. Evolution has favored a specialized form of photosynthesis in cacti and other succulents inhabiting arid regions. Crassulacean acid metabolism (CAM) photosynthesis allows plants with this physiological adaptation to absorb carbon dioxide at night, when relative humidity is comparatively high and air temperatures relatively low. Taking in carbon dioxide during the day would dehydrate plants, because opening the pores through which gas exchange takes place al-



Corbis

Structural adaptations are parts of organisms that enhance their survival ability. For example, protective spines on cacti can inhibit organisms that might feed on them.

lows water to escape from the plant. CAM photosynthesis, therefore, allows these plants to exchange the atmospheric gases essential for their metabolism at night, when the danger of dehydration is minimized.

Because organisms must also respond and adapt to an environment filled with other organisms—including potential predators and competitors—adaptations that minimize the negative effects of biological interactions are favored by natural selection. Often the interaction among species is so close that each species strongly influences the others and serves as the selective force causing change. Under these circumstances, species evolve together in a process called *coevolution*. The adaptations resulting from coevolution have a common survival value to all the species involved in the interaction. The coevolution of flowers and their pollinators is a classic example of these tight associations and their resulting adaptations.

Speciation

Adaptations can be general or highly specific. General adaptations define broad groups of organisms whose lifestyles are similar. At the species level, however, adaptations are more specific and give narrow definition to those organisms that are more closely related to one another. Slight variations in a single characteristic, such as bill size in the seed-eating Galapágos finches, are adaptive in that they enhance the survival of several closely related species. An understanding of how adaptations function to make species distinct also furthers the knowledge of how species are related to one another.

Why so many species exist is one of the most intriguing questions of biology. The study of adaptations offers biologists an explanation. Because there are many ways to cope with the environment, and because natural selection has guided the course of evolutionary change for billions of years, the vast variety of species existing on the earth today is simply an extremely complicated variation on the theme of survival.

Arms, Karen, and Pamela Camp. *Biology: Journey into Life*. 3d ed. Fort Worth, Texas: Saunders, 1994. This college-level text is well written and easily understandable because the authors use nontechnical language. Gives an excellent overview of evolution and natural selection. Several good examples of adaptations.

Brandon, Robert N. *Adaptation and Environment*. Princeton, N.J.: Princeton University Press, 1990. Explains the concept of selective environment and its influence on adaptation.

Futuyma, Douglas. *Science on Trial*. Reprint. Sunderland, Mass.: Sinauer Associates, 1995. Written for readers with little background in science; gives evidence for the theory of evolution. In presenting this evidence, Futuyma also shows how the views of creationists contrast with those of evolutionists. The illustrations and examples of adaptations are excellent.

Gould, Stephen J. *Ever Since Darwin*. Reprint. New York: W. W. Norton, 1992. Gould is well known for his ability to write humorous, slightly irreverent biological literature that the nonscientist can enjoy. No exception, this book gives an interesting view of evolution.

Ricklefs, Robert E. *Ecology*. 4th ed. New York: W. H. Freeman, 2000. The section on evolutionary ecology offers the reader an excellent but technical description of adaptations in their ecological context. Although this is an advanced college text, the material is accessible with little difficulty. The introduction gives the current views in evolutionary ecology, and the chapter summaries are excellent.

Rose, Michael R., and George V. Lauder, eds. *Adaptation*. San Diego: Academic Press, 1996. A discussion of new developments in adaptation, with new methods and new theoretical foundations and achievements. Rose provides an insightful reintroduction to the themes that Charles Darwin and his successors regarded as central to any profound understanding of biology.

Whitfield, Philip. *From So Simple a Beginning: The Book of Evolution*. New York: Maxwell Macmillan, 1993. A well-organized and well-written introduction to the concepts of evolution, written for the general reader. Illustrated.

Wickler, Wolfgang. *Mimicry in Plants and Animals*. New York: McGraw-Hill, 1968. This intriguing, small book takes up the fascinating subject of mimicry, the resemblance of one organism to another or to some object that gives the mimic a specific offensive or defensive advantage. Highly adaptive forms are beautifully illustrated in color; most examples are from the insect world.

ADAPTIVE RADIATION

Categories: Ecology; ecosystems; evolution; genetics

In adaptive radiation, numerous species evolve from a common ancestor introduced into an environment with diverse ecological niches. The progeny evolve genetically into customized variations of themselves, each adapting to survive in a particular niche.

In 1898 Henry F. Osborn identified and developed the evolutionary phenomenon known as adaptive radiation, whereby different forms of a species evolve, quickly in evolutionary terms, from a common ancestor. According to the principles of *natural selection*, organisms that are the best adapted (most fit) to compete will live to reproduce and pass their successful traits on to their offspring. The process of adaptive radiation illustrates one way in which natural selection can operate when members of one population of a species are cut off or migrate to a different environment that is isolated from the first. Such isolation can occur from one patch of plantings to another, from one mountaintop or hillside to another, from pond to pond, or from island to island. Faced with different environments, the group will diverge from the original population and in time become different enough to form a new species.

Genetic Changes

In a *divergent population*, the relative numbers of one form of *allele* (characteristic) decrease, while the relative numbers of a different allele increase. New environmental pressures will select for favorable alleles that may not have been favored in the old environment. Over successive generations, therefore, a new gene created by random *mutation* (change) may replace the original form of the gene if, for example, the trait encoded by that gene allows the divergent group to cope better with environmental factors, such as food sources, predators, or temperature. The result in the long term is that deoxyribonucleic acid (DNA) changes sufficiently through the growth of divergent populations to allow new generations to become significantly different from the original population. In time, they are unable to reproduce with members of the original species and become a new species.

Galápagos Islands Case Study

Adaptive radiation occurs dramatically when a species migrates from one landmass to another. This may occur between islands or between continents and islands. A classic example of adaptive radiation is the evolution of finches noted by Charles Darwin during his trips to the Galápagos Islands off the west coast of South America. Several species of plants and animals had migrated to these islands from the South American mainland by means of flight, wind, ocean debris, or other means of transport. Finches from the mainland—perhaps aided by winds—settled on fifteen of the islands in the Galápagos group and began to adapt to the various unoccupied *ecological niches* on those islands, which differed. Over several generations, natural selection favored a variety of finch species with beaks adapted for the different types of foods available on the different islands. As a result, several species of different finches evolved, roughly simultaneously, on these islands.

Hawaiian Silversword Alliance

Although plants seem unable to "migrate" as birds and other animals do, adaptive radiation occurs in the plant world as well. In the Hawaiian Islands, for example, twenty-eight species of the *Asteraceae* family are known together as the Hawaiian silversword alliance. The entire group appears to be traceable to one ancestor, thought to have arrived on the island of Kauai from western North America. The silverswords—which compose three genera, *Argyroxiphium*, *Dubautia*, and *Wilkesia*—have since evolved into twenty-eight species, and this speciation came about due to major ecological shifts. These plants are therefore prime examples of adaptive radiation.

Within the silversword alliance, different species have adapted to widely varying ecosystems found throughout the islands. *Argyroxiphium sandwicense*, for example, is endemic to the island of Maui and grows at high elevations from 6,890 to 9,843 feet (2,100-3,000 meters) on the dry, alpine slopes of the volcano Haleakala. This species has succulent leaves covered with silver hairs. It is thought that the hairs lessen the pace of evaporative moisture loss and protect the leaves from the sun. In contrast, species of the genus *Dubautia* that grow in wet, shady forests have large leaves that lack hairs.

Despite their "customized" physiologies, the silverswords that have evolved in Hawaii are all closely related to one another, so much so that any two can hybridize. Studies of the silverswords have provided what geneticist Michael Purugganan called a "genetic snapshot of plant evolution." Adaptive radiation is one window into how new plant structures arise.

AFRICAN AGRICULTURE

Categories: Agriculture; economic botany and plant uses; food; world regions

Soil and climatic conditions throughout Africa determine not only agricultural practices, such as which crops can be grown, but also whether plant life is capable of sustaining livestock on the land and enabling fishing of the oceans.

Rainfall—the dominant influence on agricultural output—varies greatly among Africa's fifty-six countries. Without irrigation, agriculture requires a reliable annual rainfall of more than 30 inches (75 centimeters). Portions of Africa have serious problems from lack of rainfall, such as increasing desertification and periods of drought.

Food output has declined, with per capita food production 10 percent less in the 1990's than it was in the 1980's. In most African countries, however, more than 50 percent, and often 80 percent, of the population works in agriculture, mostly subsistence agriculture. Large portions of the continent, such as Mali and the Sudan, have the potential of becoming granaries to much of the continent and producing considerable food exports.

Traditional African Agriculture

Traditionally, agriculture in Africa has been subsistence farming in small plots. It has been labor-intensive, relying upon family members. New land for farming was obtained by the *slash-and-burn* method (*shifting cultivation*). The trees in a forested area would be cut down and burned where they fell. The ashes from the burned trees fertilized the soil. Both men and women worked at such farming. Slash-and-burn agriculture is common not only in Africa but also in tropical areas around the world. In areas of heavy rainfall, the rains wash out the nutrients from soil and burned trees in a period of two to three years.

The crops grown depend upon the region. In the very dry, yet habitable, parts of Africa—such as the Sudano-Sahelian region that stretches from Senegal and Mali in the west of Africa to the Sudan in the east—a key subsistence crop is green millet, a grain. Ground into a type of flour, it can be made into a bread-like substance. In moister areas, traditional crops are root and tuber crops, such as yams and cassava. Cassava has an outer surface or skin that is poisonous, but it can be treated to remove the poison. The tuber then can be ground and used to make a bread-like substance. Other important traditional crops are rice and corn, which were introduced by Europeans when they came to Africa.

Animal husbandry, or seminomadic herding, is another form of traditional agriculture. Problems that have arisen with this type of agriculture are the availability of water and grass or hay for cattle. Regions that are very moist, such as the Gulf of Guinea, which has rain forest, are not good for cattle because of the tsetse fly, which carries diseases such as sleeping sickness.

Crops

The most widely grown crop is rice, which is grown on more than one-third of the irrigated crop area in Africa. Cultivated mostly in wetlands and valley bottoms, rice is the most common crop in the humid areas of the Gulf of Guinea and Eastern Africa. It is also grown on the plateaus of Madagascar. In the northern and southern regions, rice represents only a small portion of the total crops under water management. Wheat and corn are cultivated and irrigated, mostly in Egypt, Morocco, South Africa, Sudan, and Somalia.

Vegetables, including root and tuber crops, are present in all regions and almost every country. Vegetables are grown on about 8 percent of the cultivated areas under water management. In Algeria, Mauritania, Kenya, Burundi, and Rwanda, they are the most widespread crops under water management. *Arboriculture* (growing of fruit trees), which represents 5 percent of the total irrigated crops, is concentrated in the northern region and consists mostly of citrus fruits. Commercial crops (for cash and export) are grown mostly in the Sudan and in the countries of the southern region and consist mostly of cotton and oilseeds. Other commercial crops in Africa are sugarcane, coffee, cocoa, oil and date palm, bananas, tobacco, and cut flowers. Sugarcane is grown in all countries except in the northern region. The other commercial crops are concentrated in a few countries.

North Africa

In Morocco, Algeria, Tunisia, Libya, and Egypt, the region's agricultural resources are limited by its dry climate. Its products are those typical of the Mediterranean, steppe, and desert regions: wheat, barley, olives, grapes, citrus fruits, some vegetables, dates, sheep, and goats.

Selected Agricultural Products of Africa

Agriculture employs less than 20 percent of the working population in Libya and as much as 55 percent in Egypt. From about the middle of the twentieth century, North Africa's production failed to keep pace with its population growth and remained susceptible to large annual fluctuations. Cropland occupies about 33 percent of Tunisia but less than 3 percent of Algeria, Egypt, and Libya. Some export crops, such as citrus fruits, tobacco, and cotton, have suffered from strong international competition. The northern region is not a major contributor to the continent's fish catch. Morocco, however, with its cool, plankton-rich Atlantic waters and access to the Mediterranean Sea, is one of the world's largest fish producers.

Sudano-Sahelian Region

This region comprises Mauritania, the western Sahara, Senegal, Gambia, Mali, Burkina-Faso, Niger, Chad, and the Sudan. Because of the region's extreme dryness, mostly subsistence farming and seminomadic herding are practiced. Millet is the primary crop. In the late twentieth century, this region was devastated by long droughts that caused famine and starvation. Mali and the Sudan have the Niger and Nile Rivers flowing through them. These great rivers provide plenty of water for irrigation of fields. During the rainy season in Mali—typically June through September—the Niger River widens into a great, extensive floodplain. This area is good for the growing of rice. Similarly, in the Sudan the Blue and White Niles meet at Khartoum to form the Nile River.

Gulf of Guinea

This region comprises Guinea-Bissau, Cape Verde, Guinea, Liberia, Sierra Leone, Côte d'Ivoire, Togo, Ghana, Benin, and Nigeria. With the exception of Nigeria, agriculture there is dominated by rice cultivation. The percentage of total land area that is under cultivation ranges from 60 percent in Liberia to just 9 percent in Sierra Leone.

The total cultivable area of Ghana is 39,000 square miles (100,000 square kilometers), or 42 percent of its total land area. Only 4.8 percent of the total land area was under cultivation at the end of the twentieth century. Much of the cultivation is subsistence farming of yams and other crops. Ghana's efforts in agriculture have been hampered by droughts. Additional problems are that organic matter has been leached out of the soils by heavy rainfall and that increasing deforestation has led to additional erosion. This is the situation in much of the Gulf of Guinea and the central regions.

About half of Nigeria's available land is under cultivation. Increasing rainfall from the semiarid north to the tropically forested south allows for great crop diversity. Principal food crops are corn, millet, yams, sorghum, cassava, rice, potatoes, and vegetables. Nigeria was the world's fourth-largest exporter of cocoa beans in 1990-1991, accounting for about 7.1 percent of world trade in this commodity. However, Nigeria's share of the world cocoa market has been substantially reduced because of aging trees, low prices, black pod disease, smuggling, and labor shortages.

Central Region

This region comprises the Central African Republic, Cameroon, Congo-Brazzaville, Congo-Kinshasa, Gabon, Equatorial Guinea, Burundi, Rwanda, and São Tomé and Príncipe. Cameroon has 14.7 million acres of arable land. In 1997, 55,000 tons of rice were produced, but the country imported 124,000 tons in 1995. In the central region, the percentage of arable land ranges from 0.4 percent for the Congo-Brazzaville to 47 percent for Rwanda. Cassava is harvested in Congo-Brazzaville, Congo-Kinshasa, Equatorial Guinea, and Gabon. Corn is harvested in Congo-Brazzaville, Congo-Kinshasa, and Burundi. In Rwanda, 17 percent of the harvested land is used to grow sweet potatoes. Agriculture is not important in the economy of São Tomé and Príncipe.

Eastern Region

This region comprises Eritrea, Djibouti, Ethiopia, Somalia, Kenya, Uganda, and Tanzania. Agriculture employs about 80 percent of the labor force in Uganda and Ethiopia. Approximately 2.5 million small farms dominate agriculture in both countries. About 84 percent of Uganda's land is suitable for agriculture—a high percentage compared to the majority of African countries, such as Ethiopia with only 12 percent. Food crops account for about 74 percent of agricultural production. Only one-third is marketed; the rest is for home consumption. In four years out of five, the minimum needed rainfall may be expected in 78 percent of Uganda but in only 15 percent of Kenya. Somalia and Ethiopia receive almost none of the needed minimum.

Tanzania has almost four million farms. Traditional export crops include coffee, cotton, cashew

Leading Agricultural Crops of African Countries with More than 15 Percent Arable Land

Country	*Products*	*Percent Arable Land*
Burundi	Coffee, cotton, tea, corn, sorghum, sweet potatoes, bananas, manioc	44
Comoros	Vanilla, cloves, perfume essences, copra, coconuts, bananas, cassava	35
Gambia	Peanuts, millet, sorghum, rice, corn, cassava, palm kernels	18
Malawi	Tobacco, sugarcane, cotton, tea, corn, potatoes, cassava, sorghum, pulses	18
Mauritius	Sugarcane, tea, corn, potatoes, bananas, pulses	49
Morocco	Barley, wheat, citrus, wine, vegetables, olives	21
Nigeria	Cocoa, peanuts, palm oil, corn, rice, sorghum, millet, cassava, yams, rubber	33
Rwanda	Coffee, tea, pyrethrum (insecticide made from chrysanthemums), bananas, beans, sorghum, potatoes	35
Togo	Coffee, cacao, cotton, yams, cassava, corn, beans, rice, millet, sorghum	38
Tunisia	Olives, dates, oranges, almonds, grain, sugar beets, grapes	19

Source: Data are from *The Time Almanac 2000*. Boston: Infoplease, 1999.

nuts, tobacco, and tea. Major staple foods (corn, rice, and wheat) are exported in times of surplus. Tanzania's climatic growing conditions are favorable for the production of a wide range of fruits, vegetables, and flowers. Drought-resistant crops (sorghum, millet, and cassava) and other substaples such as onions, Irish potatoes, sweet potatoes, bananas, and plantains are also produced.

Areas that have 20-30 inches (50-75 centimeters) of rainfall per year rely on a mixture of agriculture and livestock herding. Regions with a smaller annual rainfall or a long dry season can support only drought-resistant crops such as sorghum, millet, and cassava. Over large areas of eastern Africa, rainfall is inadequate for crop cultivation. The whole of Somalia and 70 percent of Kenya receive less than 20 inches (50 centimeters) of rain four years out of five. In these areas, the only feasible use of land is for raising livestock. Agriculture is not an important factor in the economies of Eritrea and Djibouti.

Southern Region

This region comprises Angola, Namibia, Zambia, Zimbabwe, Malawi, Mozambique, Botswana, Lesotho, Swaziland, and South Africa. The arable percentage of the total land area ranges from 14 percent in Malawi to just 1 percent in Namibia. With the exception of Mozambique, where cassava predominates, corn is the major crop in the countries in this region.

About 13 percent of South Africa's land area can be used for crop production. Rainfall varies across the country, and varied climatic zones and terrains enable the production of almost any kind of crop. The largest area of farmland is planted with corn, followed by wheat, then oats, sugarcane, and sunflowers. The nation is well known for the high quality of its fruits, such as apples and citrus.

Agriculture is the predominant economic activity in Zimbabwe, accounting for 40 percent of total export earnings—about 22 percent of the total economy—and employing more than 60 percent of the country's labor force. The main export crops are tobacco, cotton, and oilseeds. Zimbabwe is usually self-sufficient in food production. Its main food crops are corn, soybeans, oilseeds, fruits and vegetables, and sugar.

Mozambique's agriculture has been badly hindered by civil war. However, the country has considerable potential for irrigation due to the Zambezi and Limpopo Rivers. The irrigation potential is estimated to be 7.5 million acres. In the 1990's, only 110,000 acres were irrigated, growing rice, sugarcane, corn, and citrus.

Agriculture and livestock production employ about 62 percent of Botswana's labor force. Most of the country has semidesert conditions with erratic rainfall and poor soil conditions, making it more suitable to grazing than to crop production. The principal food crops are sorghum and corn. Namibia's cultivated area is only 506,000 acres—only 0.8 percent of the cultivable area. Agriculture makes up approximately 10 percent of the economy but employs more than 80 percent of the population. The major irrigated crops are corn, wheat, and cotton.

Indian Ocean Islands

This region comprises Madagascar, Mauritius, the Comoros, and the Seychelles. During the 1990's an estimated 8.7 million people lived in the rural areas, 65 percent of whom lived at the subsistence level. Only 5.2 percent of Madagascar's total land area (7.4 million acres) was under cultivation. Of the total land area, 50.7 percent supported livestock production, while 16 percent (1.2 million acres) of the land under cultivation was irrigated.

Cassava, planted almost everywhere on the island, is grown as well as corn and sweet potatoes, with smaller quantities of cotton, bananas, and cloves. The fisheries sector, especially the export of shrimp, has been the most rapidly growing area of the agricultural economy in the Indian Ocean Islands region.

Mauritius has 30,000 acres of sugarcane plantations that have had one of the highest sugarcane and sugar yields in the world. The Seychelles have a total land area of only 72 square miles (187 square kilometers), of which only 3,000 acres are cultivated. This 3 percent of the land area accounts for only 4 percent of the island nation's economy. The Comoros' agriculture is heavily weighted toward rice, the staple food of the populace.

AFRICAN FLORA

Category: World regions

With few exceptions, Africa's flora (vegetation) is tropical or subtropical. This is primarily because none of the African continent extends far from the equator, and there are only a few high-elevation regions that support more temperate plants.

Listed in order of decreasing land area, the three main biomes of Africa are subtropical desert, tropical savanna, and tropical forest. The flora in southern Africa has been most studied. The flora of central and northern Africa is less known.

The subtropical desert biome is the driest of the biomes in Africa and includes some of the driest locations on earth. The largest desert region is the Sahara in northern Africa. It extends from near the west coast of Africa to the Arabian Peninsula and is part of the largest desert system in the world, which extends into south central Asia. A smaller desert region in southern Africa includes the Namib Desert, located along the western half of southern Africa, especially near the coast, and the Kalihari Desert, which is primarily inland and east of the Namib Desert.

Where more moisture is available, grasslands predominate, and as rainfall increases, grasslands gradually become tropical savanna. The difference between a grassland and a savanna is subjective but is in part determined by tree growth, with more trees characterizing a savanna. The grassland/tropical savanna biome forms a broad swath across much of central Africa and dominates much of eastern and southern Africa.

Tropical forests make up a much smaller area of Africa than the other two biomes. They are most abundant in the portions of central Africa not dominated by the grassland/tropical savanna biome and are not far from the coast of central West Africa. Scattered tropical forest regions also occur along major river systems of West Africa, from the equator almost to southern Africa.

Subtropical Desert

The subtropical deserts of Africa seem, at first, to be nearly devoid of plants. While this is true for some parts of the Sahara and Namib Deserts that are dominated by sand dunes or bare, rocky outcrops, much of the desert has a noticeable amount of plant cover. The Sahara is characterized by widely distributed species of plants that are found in similar habitats. The deserts of southern Africa have more distinctive flora, with many species endemic to specific local areas.

Succulents of the Subtropical Desert

To survive the harsh desert climate, plants use several adaptations. *Mesembryanthemum*, whose species include ice plant and sea figs, is a widespread genus, with species occurring in all of Africa's deserts. It typically has thick, succulent leaves. Such *succulents* store water in their leaves or stems, which they retain by using a specialized type of photosynthesis. Most plants open their stomata (small openings in the leaves) during the day to get carbon dioxide from the surrounding air. This would lead to high amounts of water loss in a desert environment, so succulents open their stomata at night. Through a biochemical process, they store carbon dioxide until the next day, when it is released inside the plant so photosynthesis can occur without opening the stomata.

To prevent water loss, many succulents have no leaves at all. *Anabasis articulata*, found in the Sahara desert, is a leafless succulent with jointed stems. Cacti are found only in North and South America, but a visitor to the Sahara would probably be fooled by certain species in the spurge family that resemble cacti. For example, *Euphorbia echinus*, another Saharan plant, has succulent, ridged stems with spines. The most extreme adaptation in succulents is found in the living stones of southern Africa. Their plant body is reduced to two plump, rounded leaves that are very succulent. They hug the ground, sometimes partially buried, and have camouflaged coloration so that they blend in with the surrounding rocks and sand, thus avoiding being eaten by grazing animals. Other succulents, such as the quiver tree, attain the size and appearance of trees.

Water-Dependent Plants of the Subtropical Desert

Water-dependent plants are confined to areas near a permanent water source, such as a spring. The most familiar of these plants is the date palm, which is a common sight at desert oases. Tamarind and acacia are also common where water is available. A variety of different sedges and rushes occur wherever there is abundant permanent freshwater, the most famous of these being the papyrus, or bulrush.

Ephemerals of the Subtropical Desert

Annuals whose seeds germinate when moisture becomes available and quickly mature, set seed, and die, are called *ephemerals*. These plants account for a significant portion of the African desert flora. A majority of the ephemerals are grasses. Ephemerals are entirely dependent on seasonal or sporadic rains. A few days after a significant rain the desert turns bright green, and after several more days flowers, often in profusion, appear. Some ephemerals germinate with amazing speed, such as the pillow cushion plant, which germinates and produces actively photosynthesizing seed leaves only ten hours after being wetted. Reproductive rates for ephemerals, and even for perennial plants, are rapid. Species of morning glory can complete an entire life cycle in three to six weeks.

Tropical Savanna

Tropical savanna ranges from savanna grassland, which is dominated by tall grasses lacking trees or shrubs, to thicket and scrub communities, which are composed primarily of trees and shrubs of a fairly uniform size. The most common type of savanna in Africa is the savanna woodland, which is composed of tall, moisture-loving grasses and tall, deciduous or semideciduous trees that are unevenly distributed and generally well spaced. The type of savanna familiar to viewers of African wildlife documentaries is the savanna parkland, which is primarily tall grass with widely spaced trees.

Savanna Grasses and Herbs

Grasses represent the majority of plant cover beneath and between the trees. In some types of savanna, the grass can be more than 6 feet (1.8 meters) high. Although much debated, two factors seem to perpetuate the dominance of grasses: seasonal moisture with long intervening dry spells and periodic fires. Given excess moisture and lack of fire, savannas seem inevitably to become forests. Activities by humans, such as grazing cattle or cutting trees, also perpetuate, or possibly promote, grass dominance.

A variety of herbs exist in the savanna, but they are easily overlooked, except during flowering periods. Many of them also do best just after a fire, when they are better exposed to the sun and to potential pollinators. Plants such as hibiscus and coleus are familiar garden and house plants popular the world over. Vines related to the sweet potato are also common. Many species from the legume or pea and sunflower families are present. Wild ginger often displays its showy blossoms after a fire.

Savanna Trees and Shrubs

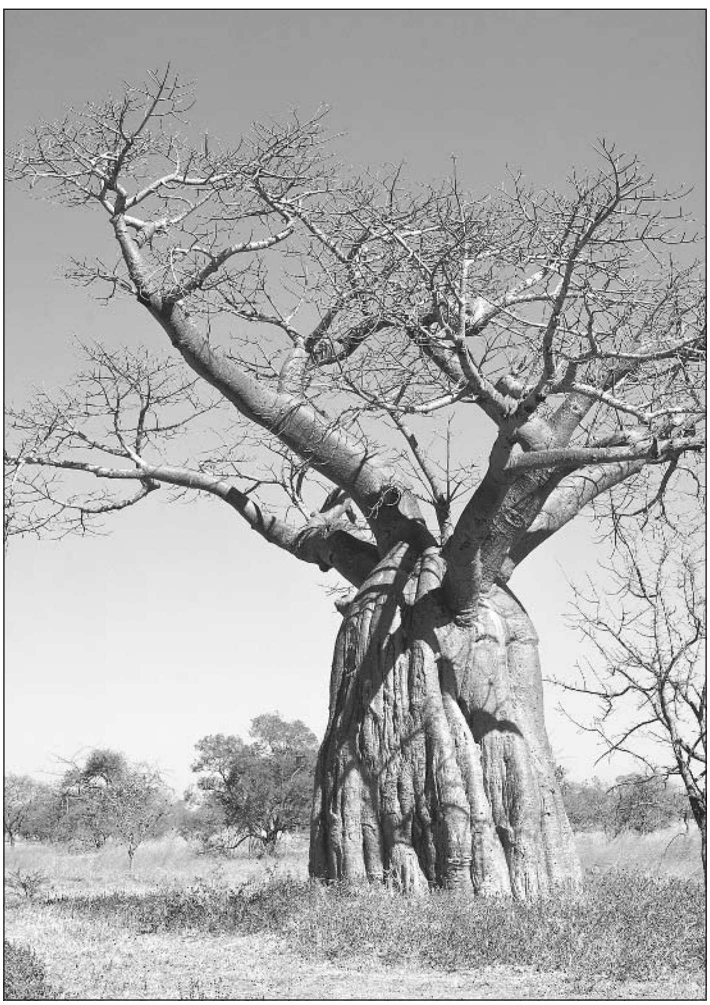
Trees of the African savanna often have relatively wide-spreading branches that all terminate at about the same height, giving the trees a flat-topped appearance. Many are from the legume family, most notably species of *Acacia*, *Brachystegia*, *Julbernardia*, and *Isoberlinia*. With the exception of acacias, these are not well known outside Africa. There is an especially large number of *Acacia* species ranging from shrubs to trees, many with spines. A few also have a symbiotic relationship with ants that protect them from herbivores. The hashab tree, a type of acacia that grows in more arid regions, is the source of gum arabic.

Although not as prominent, the baobab tree is renowned for its large size and odd appearance and occurs in many savanna regions. It has an extremely thick trunk with smooth, gray bark and can live for up to two thousand years. Many savanna trees also have showy flowers, such as the flame tree and the African tulip tree.

Tropical Forest

The primary characteristics of African tropical forests are their extremely lush growth, high species diversity, and complex structure. The diversity is often so great that a single tree species cannot be identified as dominant in an area. Relatively large trees, such as ironwood, iroko, and sapele, predominate. Forest trees grow so close together that their crowns overlap, forming a *canopy* that limits the amount of light that falls beneath them. A few larger trees, called emergent trees, break out above the thick canopy.

A layer of smaller trees live beneath the main canopy. A few smaller shrubs and herbs grow near the ground level, but the majority of the herbs and other perennials are *epiphytes*, that is, plants that grow on other plants. On almost every available space on the trunks and branches of the canopy trees there are epiphytes that support an entire, unique community. All this dense plant growth is supported by a monsoon climate in which 60 inches (150 centimeters) or more of rain often falls annually, most of it in the summer.



Corbis

Baobab tree in Zambia.

Lianas and Epiphytes

Lianas are large, woody vines that cling to trees, many of them hanging down near to the ground. They were made famous by Tarzan movies. Many lianas belong to families with well-known temperate vine species, such as the grape family, morning glory family, and cucumber family. Other, related plants remain intimately connected to the trunks of trees. One of these, the strangler fig, is a strong climber that begins life in the canopy.

The fruits are eaten by birds or monkeys, and the seeds are deposited in their feces on branches high in the canopy. The seeds germinate and send a stem downward to the ground. Once the stem reaches the ground, it roots; additional stems then develop and grow upward along the trunk of the tree. After many years, a strangler fig can so thoroughly surround a tree that it prevents water and nutrients from flowing up the trunk. Eventually, the host tree dies and rots away, leaving a hollow tube of mostly strangler fig. Other climbers include members of the *Araceae* family, the most familiar being the ornamental philodendron.

The most common epiphytes are bryophytes, lower plants related to mosses, and lichens, a symbiotic combination of algae (or cyanobacteria) and fungus. The most abundant higher plants are ferns and orchids. As these plants colonize the branches of trees, they gradually trap dust and decaying materials, eventually leading to a thin soil layer that other plants can use. Accumulations of epiphytes can be so great in some cases that tree branches break from their weight. Epiphytes are not parasites (although there are some parasitic plants that grow on tree branches); they simply use the host tree for support.

Tropical Forest Floor Plants

Grasses are almost entirely absent from the forest floor; those that grow there have much broader leaves than usual. Some forest-floor herbs are able to grow in the deep shade beneath the canopy, occasionally being so highly adapted to the low light that they can be damaged if exposed to full sunlight. Some popular house plants have come from among these plants, because they do not need direct sunlight to survive. Still, the greatest numbers of plants occur beneath breaks in the canopy, where more light is available.

AGRICULTURAL CROPS: EXPERIMENTAL

Categories: Agriculture; economic botany and plant uses; food

Experimental crops are foodstuffs with the potential to be grown in a sustainable manner, produce large yields, and reduce people's reliance on the traditional crops wheat, rice, and corn.

Shifting from a hunter-gatherer society to an agrarian society led to increasingly larger-scale agricultural production that involved selecting local crops for domestication. In recent history there has been a reduction in the number of agricultural crops grown for human consumption. There are estimated to be at least 20,000 species of edible plants on earth, out of more than 350,000 known species of higher plants. However, only a handful of crops feed most of the world's people. These include wheat, rice, corn, potatoes, sugar beets, sugarcane, cassava, barley, soybeans, tomatoes, and sorghum. Rice, wheat, and corn together account for a majority of calories consumed. In the effort to develop experimental crops, agricultural goals include expanding the diversity of plant food in the human diet.

Recent Successes

Soybeans (*Glycine max*) are a relatively new crop that gained worldwide acceptance and widespread cultivation in the second half of the twentieth century. Originally cultivated in China, soybeans gradually spread throughout Asia and became a staple food there. High in protein, soybeans were first grown in the Western world as animal feed. Concerted breeding efforts have resulted in many locally adapted varieties. Today, soybeans as both meal and oil are commonplace. Worldwide soybean production is now the greatest of any legume.

Triticale (*x Triticosecale*) is a hybrid created to combine the ruggedness and high protein content of rye (*Secale cereale*) with the high yield of wheat (*Triticum aestivum*). Triticale has not replaced wheat or rye in bread-making due to its rather low gluten content but is used to supplement bread flours. Triticale is also adaptable to marginal agricultural soils.

Kiwifruit (*Actinidia deliciosa*) is another recent success story. A previously little-known fruit originally called Chinese gooseberry, it was introduced to New Zealand at the turn of the twentieth century and renamed kiwifruit. The name change was a marketing strategy that led to worldwide popularity. Today kiwifruit cultivation and consumption are increasing worldwide. Kiwifruit grows on a deciduous vine, much like grapes. It can be harvested and then stored for several months without loss of quality.

Grains and Cereals

Quinoa (*Chenopodium quinoa*) is a grain native to the Andes Mountains of South America. It has been a staple in the diets of people living in that region for centuries. Although the leaves are edible, it is principally the tiny seed which is consumed. The seeds contain high amounts of protein, calcium, phosphorus, and the essential amino acid lysine, which is typically lacking in other cereals such as wheat, rye, and barley. Quinoa seeds must be washed or otherwise processed to remove the bitter saponins contained in the pericarp and can then be cooked and eaten much like rice. Quinoa can also be ground into flour as a supplement for bread making. Cultivation and use of quinoa have increased steadily since the 1980's.

Grain amaranths (*Amaranth*) are being rediscovered and developed as a potential new source of grain. Amaranth was a staple crop for centuries in Mexico, Central America, and South America. Amaranth is grown as an annual and yields thick, heavy seed heads containing numerous tiny seeds. The hard seed coat is removed by heating or boiling and can be prepared much like corn. Amaranth is comparable to other grains in protein, contains high amounts of lysine, and can be consumed by those allergic to typical grains. Breeding efforts over the last few decades involving *A. hypochondriacus*, *A. cruentus*, and *A. hybridus* have greatly increased seed yield as well as desirable plant growth habit. Another important characteristic is amaranth's drought resistance.

Legumes

Members of the *Leguminosae* family are particularly valuable as food sources because they contain high levels of protein. This is in part due to their ability to fix atmospheric nitrogen in *root nodules* that contain *nitrogen-fixing bacteria*. This symbiotic relationship with the bacteria means relatively little nitrogenous fertilizer is required for agricultural production of legumes. Tarwi (*Lupinus mutabilis*) is a legume native to the South American Andes that has a high protein and oil content, similar to the soybean. Tarwi is also high in the essential amino acid lysine. It grows well in poor soils and is drought-resistant. Current breeding efforts focus on reducing the bitter alkaloids, which can be removed by rinsing in water.

The winged bean (*Psophocarpus tetragonolobus*), native of tropical Asia, is entirely edible—leaves, flowers, seeds, pods, and tuberous roots. Like most legumes, the winged bean has a high protein content. This species could have tremendous potential in many tropical regions of the world, rivaling the success of the soybean.

A native of North America, the groundnut (*Apios americana*) was a major food source of many American Indian tribes. It is purported to have been offered to the Pilgrims to avert starvation. The numerous underground tubers can be prepared (cooking is necessary) like potatoes yet have a much higher protein content.

Several other legumes whose use and acceptance are likely to increase include the tepary bean (*Phaseolus acutiflius*), the pigeon pea (*Cajanus cajan*), and the bambara groundnut (*Voandzeia subterranea*).

Other Crops

There are many other potential food crops. Most have been cultivated on a small scale for years and are being rediscovered and researched for commercial production. Some of these include potato-like oca tubers (*Oxalis tuberosa*), fruits such as cherimoya (*Annona cherimola*), pepino (*Solanum muricatum*), and feijo (*Acca sellowiana*), and nuts such as egg nut (*Couepia longipendula*).

AGRICULTURAL REVOLUTION

Categories: Agriculture; economic botany and plant uses; history of plant science

The agricultural revolution marked the transition by humans from hunting and gathering all their food to domesticating plants for food.

People first obtained their food by scavenging kills made by other animals, by hunting animals, and by gathering wild food plants. Between ten thousand and twelve thousand years ago, people began to use plants in new ways. Some scientists and historians call this period of time the "agricultural revolution."

Agricultural Beginnings

Before the 1960's, many scientists and historians believed that hunter-gatherers abruptly switched from foraging to farming. Those who thought that agriculture arose quickly coined the term "agricultural revolution." They suggested that this revolution spread rapidly because it was a tremendous improvement over the old foraging lifestyle, with the availability of cultivated food sources far more dependable than those of wild sources.

Since the 1960's, scientists and historians have challenged this view of agricultural beginnings. Later studies have shown that modern hunting-gathering societies have a remarkably sophisticated knowledge about native plants and plants' life cycles. Gatherers use a large number of plant species for food. Hunting and gathering cultures today do not have to plant seeds intentionally to keep from starving and most likely did not have to do so in the past.

Domesticated and Wild Plants

Domesticated plants are genetically distinct from their wild ancestors. *Domestication* involves processes by which a wild plant adapts to the needs of the farmer. The traits that make a plant desirable as a human food plant may not be ones that confer survival value on plants in their natural habitats and may actually be detrimental to the plant's survival in the wild.

People who gathered wild plants looked for traits that made gathering easier and more profitable. They would have gathered grasses, for example, that had bigger seeds or plants, had more seeds or fruits or edible parts, or had seed heads that did not shatter easily. If seeds from such plants are the ones that were planted, accidentally or on purpose, their useful traits would be reinforced in successive generations. The appearance of a domesticated plant in the archaeological record is the end result of generations of cumulative genetic transformations that might have taken hundreds or even thousands of years. Therefore, it becomes difficult to pick a single point in the past for any continent or geographic region that signals the beginning of an agricultural economy.

Geography of Agricultural Origins

The area of the Middle East called the Fertile Crescent (between the Tigris and Euphrates Rivers in what is now Iraq) seems to be the first area where formal agriculture began. The native grasses were highly productive. Wild wheat and barley grew in dense stands and were valuable food sources before cultivation began. It was this use of gathered wild grasses for food that probably led to their early domestication. Along with the grasses, complementary sources of protein were adopted, namely leguminous crops such as pea and lentil, and animals were domesticated. The plants that were domesticated in the Middle East include einkorn wheat, emmer wheat, bread wheat, barley, lentil, pea, vetch, the fava (or broad) bean, chickpea, lupine, and flax.

Agriculture originated in northeast China with the Yang Shao culture around six thousand years ago and spread quickly into Korea and Japan. Some of the plants brought under cultivation include barley, barnyard millet, common or broomcorn millet, foxtail millet (or foxtail grass), soybean, adzuki and mung beans, hemp, buckwheat, bottle gourd, Chinese cabbage, great burdock, lacquer tree, paper mulberry, and a number of fruit trees, including apricot, pear, peach, and plum.

In Southeast Asia, as well as the Pacific Islands and India, cultivated plants included sesame, the pigeon pea, eggplant, rice, sugarcane, bananas, plantains, coconuts, oranges, mango, Asian yam, betel nut, pepper, taro, bitter gourd, winter melon, snake gourd, luffa, mangosteen, durian, rambutan, breadfruit, and bamboo.

In Africa, plant domestication took place south of the Sahara Desert and north of the equator. Many crops were grown, including various kinds of millet, sorghum, okra, coffee, watermelon, several species of yam, African rice, cowpea, African oil palm, and cola nut. In Ethiopia, Ethiopian oats, coffee, enset, tef, noog, and chat were cultivated.

In Central America, archaeological evidence suggests that squash and pumpkins may have been cultivated before corn, especially in the Oaxaca region. In Oaxaca and Tamaulipas, along with squash and pumpkins, people were cultivating beans and bottle gourds, followed later by corn. In the Tehuacán Valley of Central Mexico, corn, chile peppers, avocado, beans, amaranth, and foxtail grass were among the very earliest cultivated plants. Cultivated plants either originating or cultivated early in South America include quinoa, white potato, peanut, cacao, jicama, lima bean, common bean, pineapple, chile pepper, papaya, sweet potato, yucca, and avocado. Tomatoes were cultivated in both Central and South America.

In North America, prior to the diffusion of the corn-squash-beans complex from the southwest after 1000 C.E., Indians of Eastern North America were cultivating a number of plants, including bottle gourd, erect knotweed, sumpweed, goosefoot, maygrass, little barley, and sunflower.

AGRICULTURE: HISTORY AND OVERVIEW

Categories: Agriculture; disciplines; economic botany and plant uses

Agriculture is the ability to produce sufficient food and fiber to feed and shelter the population, the most important natural resource a nation can have. In modern urban societies, it is also the natural resource that is most often taken for granted.

The beginnings of agriculture predate written history. No one knows when the first crop was cultivated, but at some time in the distant past humans discovered that seeds from certain wild grasses could be collected and planted in land that could be controlled and the grasses later gathered for food. Most scholars believe this occurred at about the same time in both the Eastern and Western Hemispheres, some eight thousand to ten thousand years ago.

Ephemeral Archives

The earliest agricultural centers were located near large rivers that helped maintain soil fertility with the deposition of new topsoil during each annual flooding cycle.

Early Agriculture

The earliest attempts to grow crops were primarily to supplement the food supply provided by hunting and gathering. However, as the ability to produce crops increased, people began to *domesticate* plants and animals, and their reliance on hunting and gathering decreased, allowing the development of permanent settlements in which humans could live. As far back as six thousand years ago, agriculture was firmly established in Asia, India, Mesopotamia, Egypt, Mexico, Central America, and South America.

The earliest agricultural centers were located near large rivers that helped maintain soil fertility by the deposition of new *topsoil* with each annual flooding cycle. As agriculture moved into regions that lacked the annual flooding of the large rivers, people began to utilize a technique known as *slash-and-burn agriculture*. In this type of agriculture, a farmer clears a field, burns the tress and brush, and farms the field. After a few years soil nutrients become depleted, so the farmer must repeat the process at a new location. This type of agriculture is still practiced in some developing countries and is one reason tropical rain forests are disappearing at a fast rate.

Until the nineteenth century, most farms and ranches were family-owned, and most farmers practiced *sustenance agriculture*: Each farmer produced a variety of crops sufficient to feed his or her family as well as a small excess which was sold for cash or bartered for other goods or services. Agricultural tools such as plows were made of wood, and almost all agricultural activities required human or animal labor. This situation placed a premium on large families to provide the help needed in the fields.

The arrival of the Industrial Revolution changed agriculture, just as it did almost all other industries. Eli Whitney invented the cotton gin in 1793. The mechanical reaper was invented by Cyrus McCormick, and John Lane and John Deere began the commercial manufacture of the steel plow in 1833 and 1837, respectively. These inventions led the way to the development of the many different types of agricultural machinery that resulted in the *mechanization* of most farms and ranches. By the early part of the twentieth century, most agricultural enterprises in the United States were mechanized. American society was transformed from an agrarian society into an urban society. People involved in agricultural production left farms to go to cities to work in factories. At the same time, there was no longer a need for large numbers of people to produce crops. As a result, fewer people were required to produce the growing amounts of agricultural products that supplied an increasing number of consumers.

Modern Agriculture

As populations continued to grow, there was a need to select and produce crops with higher yields. The *Green Revolution* of the twentieth century helped to make these higher yields possible. Basic information supplied by biological scientists allowed agricultural scientists to develop new, higher-yielding varieties of numerous crops, particularly the *seed grains* which supply most of the calories necessary for maintenance of the world's population. These higher-yielding crop varieties, along with improved farming methods, resulted in tremendous increases in the world's food supply.

The new crop varieties also led to an increased reliance on *monoculture*. While the practice of growing only one crop over a vast number of acres has resulted in much higher yields, it has also decreased the genetic variability of many agricultural plants, increased the need for commercial fertilizers, and produced an increased susceptibility to damage from a host of biotic and abiotic factors. These latter two developments have resulted in a tremendous growth in the *agricultural chemical in-*

Major Crops and Places of Original Cultivation

Crop	*Region*	*Crop*	*Region*
Apples	Central Asia and the Middle East	Olives	Mediterranean

dustry. Today's modern agricultural unit requires relatively few employees, is highly mechanized, devotes large amounts of land to the production of only one crop, and is highly reliant on agricultural chemicals such as fertilizers and pesticides.

Agricultural Diversity

Modern agriculture is subdivided into many different specialties. Those agricultural industries that deal with plants include *agronomy*, the production of field crops; *forestry*, the growth and production of trees; and *horticulture*. Horticulture is subdivided into *pomology*, the growth and production of fruit crops such as oranges and apples; *olericulture*, the growth and production of vegetable crops (tomatoes, lettuce); *landscape horticulture*, the growth and production of trees and plants that are used in landscape design; and *floriculture*, the growth and production of flowering plants used in the floral industry.

The various agriculture industries produce a tremendous number of agricultural products. Agricultural products that are derived from plants can be subdivided into timber products (lumber, furniture), grain products (wheat, oats), fiber products (cotton, flax), fruit products (grapes, peaches), nut crops (pecans, hazelnuts), vegetable products (lettuce, cabbage), beverage products (tea, coffee), spice and drug crops (garlic, mustard, opium, quinine), ornamental crops (carnations, chrysanthemums), forage crops (alfalfa, clover), and other cash crops such as sugarcane, tobacco, artichokes, and rubber.

Impact on Soil Resources

While there have been tremendous increases in agricultural productivity through the use of modern agricultural practices, these practices have had a significant impact on some other natural resources. *Soil* is one of the most overlooked and misunderstood resources. Most people think of soil as an inert medium from which plants grow. In reality, *topsoil*—that upper 15 to 25 centimeters (6 to 10 inches) of the earth's terrestrial surface in which nearly all plants grow—is a complex mixture of weathered mineral materials from rocks, partially decomposed organic molecules, and a large number of living organisms.

The process of soil formation is very slow. Under ideal conditions, enough topsoil can form in one year to produce a layer of about 1 millimeter (0.04 inch) thick when spread over 1 hectare (2.5 acres). With proper management, topsoil can be kept fertile and productive indefinitely. Unfortunately, many agricultural techniques lead to the removal of trees and shrubs, which provide windbreaks, or to the depletion of soil fertility, which reduces the plant cover over the field. These practices expose the soil to increased erosion from wind and moving water. As a result, as much as one-third of the world's current croplands are losing topsoil faster than it can be replaced.

Water and Irrigation

Because plants require water in order to grow, agriculture represents the largest single use of global water. About 73 percent of all fresh water withdrawn from groundwater supplies, rivers, and lakes is used in the irrigation of crops. Almost 15 percent of the world's croplands are irrigated. Water use varies among countries. Some countries have abundant water supplies and irrigate liberally, while water is very scarce in other countries and must be used very carefully. Because as much as 80 percent of the water intended for irrigation is lost to evaporation before reaching the plants, the efficiency of water use in some countries can be very low.

There is no doubt that irrigation has dramatically increased crop production in many areas, but some irrigation practices have been detrimental. Overwatering can lead to a *waterlogging* of the soil. Waterlogging cuts off the supply of oxygen to the roots, and the plants die. Irrigation of crops in dry climates can often result in *salinization* of the soil. In these climates, the irrigation water rapidly evaporates from the soil, leaving behind mineral salts that were dissolved in the water. As the salts accumulate, they become lethal to most plants. Some experts estimate that as much as one-third of the world's agricultural soil has been damaged by salinization. There is also an argument as to whether the increased usage of water for agriculture has decreased the supply of potable water fit for other uses.

Fertilizers

Plants require sunshine, water either from rainfall or irrigation, carbon dioxide from the atmosphere, and thirteen mineral nutrients from the soil. Of these, calcium, magnesium, nitrogen, phosphorus, and potassium are required in the greatest amounts. Calcium and magnesium are plentiful in soils located in dry climates, but in wetter climates these nutrients are often *leached* through the soil. In these regions, calcium and magnesium are returned to the soil in the form of lime, which is also sometimes added to soil to raise its pH (increase its alkalinity). Nitrogen, phosphorus, and potassium are the nutrients which are most often depleted from agricultural soils, and these nutrients are often referred to as the *fertilizer elements*. Because these nutrients stimulate plant growth and can greatly increase crop yields, it is necessary to apply them to the soil regularly in order to maintain fertility.

The amount of fertilizer applied to the soil increased more than 450 percent in the second half of the twentieth century. While this increase in the use of fertilizers has more than doubled worldwide crop production, it has also caused some problems. The increased production of fertilizers has required the use of energy and mineral resources that could have been used elsewhere. In many cases, farmers tend to overfertilize. Overfertilization not only wastes money but also contributes to environmental degradation. Fertilizer elements, particularly nitrogen and phosphorus, are carried away by water runoff and are eventually deposited in the rivers and lakes, where they contribute to pollution of aquatic ecosystems. In addition, nitrates can accumulate in underground water supplies. These nitrates can be harmful if ingested by newborns.

Other Resources

Modern agriculture, as it is practiced in the United States, consumes large amounts of energy. Farm machinery used in planting, cultivating, harvesting, and transporting crops to processing plants or to market consumes large supplies of liquid fossil fuels such as gasoline or diesel. The energy required to produce fertilizers, pesticides, and other agricultural chemicals is the second largest energy cost associated with agriculture. The use of fuel required by pumps to irrigate crops is also a major energy consumer. Additional energy is used in food processing, distribution, storage, and cooking after the crop leaves the farm. The energy used for these activities may be five times as much as that used to produce the crop.

About 16 percent of the total energy used in the United States is consumed by systems devoted to feeding people, and most of the foods consumed in the United States require more calories of energy to produce, process, and distribute to the market than they provide when they are eaten. The next major development in agriculture will be the *biotechnical revolution*, in which scientists will be able to use molecular biological techniques to produce new crop varieties. In the future, agricultural scientists may be able to develop crop plants that can be produced, processed, and distributed with less impact on other resources.

Commercial Impact

While fewer than 1 percent of Americans are directly involved in agricultural production, agriculture in the United States employs about seventeen million people in some phase of the industry, from production to retail sales. This includes workers hired by agricultural chemical companies which produce or sell agricultural implements and machinery, processing and canning plants, and wholesale and retail marketing firms such as grocery stores. In 1997 there were six thousand to eight thousand different agricultural products on the market. Agriculture is also big business, with assets of about one hundred billion dollars. This figure equals 88 percent of the combined capital assets of all the major U.S. corporations. American farmers now produce 76 percent more crops than the previous generation did on the same amount of land, and one-third of all American agricultural products are exported. This makes the United States the world's most agriculturally productive country and the largest exporter of agricultural products.

AGRICULTURE: MARINE

Categories: Agriculture; economic botany and plant uses; food; water-related life

Marine agriculture uses techniques of artificial cultivation, such as growing, managing, and harvesting, and applies them to marine plants and animals. The products are then used for human consumption.

Marine agriculture is also known as *mariculture* or *aquaculture*, although aquaculture is a more general term referring to both freshwater and marine farming of organisms. The world's oceans cover approximately three-fourths of the globe, including vast regions of unexplored life and landforms. The potential for exploiting the oceans agriculturally is great but currently meets significant obstacles. Because of the expense of equipment and personnel involved, most marine species are not cultivated. Coastal pollution, habitat destruction, competition for land use, and economics all limit mariculture programs. Nevertheless, mariculture does offer several food, medical, and other products that are currently being marketed.

Food

Seaweeds are edible, especially the red and brown algae. The three most common types of seaweeds are known by their Japanese names: *nori* (*Porphyra*), a red seaweed high in vitamin C and digestible protein; *kombu* (*Laminaria*); and *wakame* (*Undaria*), high in calcium. They are eaten raw, cooked, or dried and have several vitamins and minerals as well as protein. Seaweeds are low in fats, and 35 to 50 percent of the dry weight of red seaweeds is protein. Seaweeds can be used to add taste and variety to foods. They are used as a hot vegetable, boiled and formed into cakes and fried, in salads, and in preparing desserts, breads, soups, casseroles, sandwiches, teas, and candy.

The world's yearly harvest of seaweeds is approximately 8.4 million tons of green seaweed, 2.8 million tons of brown seaweed, and 1.2 million tons of red seaweed. The total seaweed market in 1998 was worth more than $5 billion, with $600 million deriving from food additives alone. China is the leading harvester and the world's biggest seaweed consumer. Japan is the leading seaweed importer and, at the end of the twentieth century, employed more than thirty-five thousand people in the industry. Harvesting and marketing edible seaweed is a growing business in the United States, especially on the West Coast.

Seaweeds produce several types of *phycocolloids*, starchlike chemicals used in food processing and manufacturing. An important type called *algin*, which makes up alginic acid and alginates, is used in manufacturing dairy products such as ice cream, cheese, and toppings as well as to prevent frostings and pies from desiccation. Another extract is *agar*, used to form jellies and protect fish and meats during canning. Agar is also used in low-calorie foods and as a thickener. Red algae is a source of the agglutinant *carrageenan*, which is used in many food products as an emulsifier to give body to dairy products and other processed foods, including instant puddings. Additionally, seaweed-based food additives are common in prepared and fast foods, including hamburgers and yogurt.

Kelp farming is a major livelihood in the eastern Pacific, with approximately 140,000 tons harvested each year for the extraction of alginates used in food and food additives. Kelp is a good source of calcium, potassium, iron, iodine, bromine, and zinc. It is also low-fat, has some protein, and is a natural tenderizer. Kelp flakes are used as a low-sodium salt substitute.

Medicine

The use of marine plants in medicine is still in the early stages of exploration and faces many challenges, including identification of useful chemicals and the cultivation of significant quantities. Dinoflagellates and other microalgae are being investigated for compounds that might fight cancerous tumors. Diluted algae toxins from red tides can be used to inhibit the growth of most bacteria. Green algae has halosphaerin, a strong antibiotic. Seaweed is used in wound dressings in hospitals and as a source of iodine, A, B, D, and E vitamins, calcium, magnesium, potassium, sodium, sulfur, and trace antioxidants such as selenium and zinc. The seaweed extract agar is used in laxatives and as a medium to grow bacteria and molds.

Kelp is rich in *chlorophyll*, which can help detoxify the body, fight inflammations, and increase the formation of oxygen-carrying red blood cells. Chlorophyll is also used to fight bad breath and as an ingredient in deodorants. Kelp is used to reduce cholesterol, treat gastrointestinal, respiratory, and genitourinary disorders, and lower blood pressure. The alginic acid produced by kelp can rid the body of radioactive strontium, the most dangerous to humans of all components in the fallout from atomic explosions.

Other Uses

Marine plants are used for a variety of other purposes. Seaweed is used as a component of many fertilizers, as a food additive in animal feed, and to reduce soil acidity. Research on cattle and swine has revealed that the addition of seaweed to animal feed can enhance the immune system and makes the meat a more desirable color. It can also save cattle from the effects of fungus-infected grass.

Seaweed is used as an ingredient in cosmetics as well as to nourish, revitalize, condition, and improve the skin, hair, and body. It is used in cleansers, toners, moisturizers, scrubs, body lotions, and hair and bath products. The giant kelp (*Macrocystis*) is a major source of algin for commercial uses, as is the brown algae *Laminaria*, which is harvested in the north Atlantic. Algin is used in shampoos, shaving cream, plastics, pesticides, rubber products, paper, paints, and cosmetics. Additionally, kelp is used in emulsifiers for toothpastes and printing inks. Kelp has even been used to make fishing lines. Some research has been done on using kelp as a fuel to produce a clean-burning methane gas. Kelp can be used to ferment human waste and garbage, which can then be sold as fertilizers.

AGRICULTURE: MODERN PROBLEMS

Categories: Agriculture; economic botany and plant uses; environmental issues

Many current problems in agriculture are not new. Erosion and pollution, for example, have been around as long as agriculture. However, agriculture has changed drastically within its ten-thousand-year history, especially since the dawn of the Industrial Revolution in the seventeenth century. Erosion and pollution are now bigger problems than before and have been joined by a host of other issues that are equally critical—not all related to physical deterioration.

Monoculture

Modern agriculture emphasizes *crop specialization*, also known as *monoculture*. Farmers, especially in industrialized regions, often grow a single crop on much of their land. Problems associated with this practice are exacerbated when a single variety or cultivar of a species is grown. Such a strategy allows the farmer to reduce costs, but it also makes the crop, and thus the farm and community, susceptible to widespread crop failure. The corn blight of 1970 devastated more than 15 percent of the North American corn crop. The corn was particularly susceptible to the harmful organisms because 70 percent of the crop being grown was of the same high-yield variety. Chemical antidotes can fight pests, but they increase pollution. Maintaining species diversity or varietal diversity—growing several different crops instead of one or two—allows for crop failures without jeopardizing the entire economy of a farm or region that specializes in a particular monoculture, such as tobacco, coffee, or bananas.

Genetic Engineering

Growing *genetically modified* (GM) crops is one attempt to replace post-infestation chemical treatments. Recombinant technologies used to splice genes into varieties of rice or potatoes from other organisms are becoming increasingly common. The benefits of such GM crops include more pest-resistant plants and higher crop yields. However, environmentalists fear new genes could trigger unknown side effects with more serious, long-term environmental and economic consequences than the problems they were used to solve. GM plants designed to resist herbicide applications could potentially pass the resistant gene to closely related wild weed species that would then become "super weeds." Also, pests, just as they can develop resistance to pesticides, may also become resistant to defenses engineered into GM plants. The high cost of recombinant technologies calls into question the feasibility of continuing development of GM plants.

Erosion

An age-old problem, soil loss from *erosion* occurs all over the world. As soil becomes unproductive or erodes away, more land is plowed. The newly plowed lands usually are considered *marginal*, meaning they are too steep, nonporous or too sandy, or deficient in some other way. When natural vegetative cover blankets these soils, it protects them from erosive agents: water, wind, ice, or gravity. Plant cover "catches" rainwater that seeps downward into the soil rather than running off into rivers. As marginal land is plowed or cleared to grow crops, erosion increases.

Expansion of land under cultivation is not the only factor contributing to erosion. Fragile grasslands in dry areas also are being used more intensively. Grazing more livestock than these pastures can handle decreases the amount of grass in the pasture and exposes more of the soil to wind, the primary erosive agent in dry regions. *Overgrazing* can affect pastureland in tropical regions too. Thousands of acres of tropical forest have been cleared to establish cattle-grazing ranges in Latin America. Tropical soils, although thick, are not very fertile. After one or two growing seasons, crops grown in these soils will yield substantially less than before.

Tropical fields require *fallow periods* of about ten years to restore the soil after it is depleted. That is why tropical farmers using *slash-and-burn agriculture* move to new fields every few years in a cycle that returns them to the same place years later, after their particular lands have regenerated. Where there is heavy forest cover, soils are protected from exposure to the massive amounts of rainfall. Organic material for crops is present as long as the forest remains in place. When the forest is cleared, however, the resulting grassland cannot provide the adequate protection, and erosion accelerates. Lands that are heavily grazed provide even less protection from heavy rains, and erosion accelerates even more.

The use of machines also promotes erosion, and modern agriculture relies on machinery such as tractors, harvesters, trucks, balers, and ditchers. In industrialized nations, machinery is used intensely. Machinery use is on the rise in developing countries such as India, China, Mexico, and Indonesia, where traditional, nonmechanized farming methods are the norm. Farming machines, in gaining traction, loosen topsoil and inhibit vegetative cover growth, especially when farm implements designed to rid the soil of weeds are attached. The soil is then more prone to erode.

Eco-fallow farming has become more popular in the United States and Europe as a way to reduce erosion. This method of agriculture, which leaves the crop residue in place over the fallow (nongrowing) season, does not root the soil in place as well as living plants do. As a result, some erosion

Image Not Available

continues. Additionally, eco-fallow methods require heavy use of chemicals, such as herbicides, to "burn down" weed growth at the start of the growing season. This contributes to increased erosion and pollution.

Pollution and Silt

Besides causing resistance among harmful bacteria, insects, and weeds, pesticides inevitably wash into, and contaminate, surface and groundwater supplies. Chemicals, although problematic, are not as difficult to contend with as the increasingly heavy silt load choking the life out of streams and rivers. Accelerated erosion from water runoff carries silt particles into streams, where they remain suspended and inhibit the growth of many forms of plant and animal life.

The silt load in American streams has become so heavy that the Mississippi River Delta is growing faster than it once did. Heavy silt loads, combined with chemical residues, are creating an expanded dead zone. By taxing the capabilities of ecosystems around the Delta, sediments are filtered out slowly, plant absorption of nutrients is decreased, and salinity levels for aquatic life cannot be stabilized. Most of the world's population lives in coastal zones, and 80 percent of the world's fish catch comes from coastal waters over continental shelves that are most susceptible to this form of pollution.

Pesticide Resistance

With the onset of the *Green Revolution*, the use of herbicides, insecticides, and other *pesticides* increased dramatically all over the world. An increasing awareness of problems caused by overuse of pesticides extends even to household antibacterial cleaning agents and other products. Mutations among the genes of bacteria and plants have allowed these organisms to resist the effects of chemicals that were toxic to their ancestors. Use of pesticides leads to a cycle wherein more, or different combinations of, chemicals are used, and more pests develop resistance to these toxins. Additionally, the development of herbicide-resistant crop plants enables greater use of herbicides to kill undesirable weeds on croplands.

Increasing interest in *biopesticides* may slow the cycle of pesticide resistance. Types of biopesticides include beneficial microbes, fungi, and insects such as ladybugs that can be released in infested areas to prey upon specific pests. Biopesticides used today include naturally occurring and genetically modified organisms. Their use also avoids excessive reliance on chemical pesticides.

Fertilizers and Eutrophication

Increased use of *fertilizers* was another result of the Green Revolution. Particulate amounts of most fertilizers enter the hydrologic cycle through runoff. As a result, bodies of water become enriched in dissolved nutrients, such as nitrates and phosphates. The growth of aquatic plants in rivers and lakes is overstimulated, and this results in the depletion of dissolved oxygen. This process of *eutrophication* can harm all aquatic life in these ecosystems.

Water Depletion

With an increasing reliance on irrigation, groundwater resources are mismanaged and overtapped. The rate of groundwater recharge is slow, usually between 0.1 and 0.3 percent per year. When the amount of water pumped out of the ground exceeds the recharge rate, it is referred to as *aquifer overdraft*. An aquifer is a water-bearing stratum of permeable rock, sand, or gravel.

In Tamil Nadu, India, groundwater levels dropped 25 to 30 meters during the 1970's due to excessive pumping for irrigation. In Tianjin, China, the groundwater level declines 4.4 meters per year. In the United States, aquifer overdraft averages 25 percent over the replacement rate. The Ogallala aquifer under Kansas, Nebraska, and Texas represents an extreme example of overdraft: Depletion is 130 to 160 percent above the replacement rate annually. At this rate, this aquifer, which supplies water to countless communities and farms, has been projected to become nonproductive by 2030.

Soil Salinization

In addition, continued irrigation of arid regions can lead to soil problems. *Soil salinization* is widespread in the small-grained soils of these regions, which have a high water absorption capacity and a low infiltration rate. Some irrigation practices add large amounts of salts into the soil, increasing its natural rate of salinization. This can also occur at the base of a hill slope. Soil salinization has been recognized as a major process of land degradation.

Although surface and groundwater resources cannot be enriched by technology, conservation and improved environmental management can make the use of precious freshwater more efficient.

In agriculture, for example, drip irrigation can reduce water use by nearly 50 percent. In developing countries, though, equipment and installation costs often limit the availability of these more efficient technologies.

Urban Sprawl

As more farms become mechanized, the need for farmers and farm workers is being drastically reduced. From a peak in 1935 of about 6.8 million farmers farming 1.1 billion acres, the United States at the end of the twentieth century counted fewer than 2 million farmers farming 950 million acres.

Urban sprawl converts a tremendous amount of cropland into parking lots, malls, industrial parks, and suburban neighborhoods. If cities were located in marginal areas, then concern about the loss of farmland to commercial development would be nominal. However, the cities attracting the greatest numbers of people have too often replaced the best cropland. Taking the best cropland out of primary production imposes a severe economic penalty.

AGRICULTURE: TRADITIONAL

Categories: Agriculture; economic botany and plant uses

Two agricultural practices that are widespread among the world's traditional cultures, slash-and-burn agriculture and nomadism, share several features. Both are ancient forms of agriculture, both involve farmers not remaining in a fixed location, and both can pose serious environmental threats if practiced in a nonsustainable fashion. The most significant difference between the two is that slash-and-burn is associated with raising field crops, while nomadism usually involves herding livestock.

Slash-and-Burn Agriculture

Farmers have practiced *slash-and-burn agriculture*, which is also referred to as *shifting cultivation* or *swidden agriculture*, in almost every region of the world where farming is possible. Although at the end of the twentieth century slash-and-burn agriculture was most commonly found in tropical areas such as the Amazon River basin in South America, swidden agriculture once dominated agriculture in more temperate regions, such as northern Europe. Swidden agriculture was, in fact, common in Finland and northern Russia well into the early decades of the twentieth century.

Slash-and-burn acquired its name from the practice of farmers who cleared land for planting crops by cutting down the trees or brush on the land and then burning the fallen timber on the site. The farmers literally slash and burn. The ashes of the burnt wood add minerals to the soil, which temporarily improves its fertility. Crops the first year following clearing and burning are generally the best crops the site will provide. Each year after that, the yield diminishes slightly as the fertility of the soil is depleted.

Farmers who practice slash-and-burn do not attempt to improve fertility by adding fertilizers such as animal manure to the soil. They instead rely on the soil to replenish itself over time. When the yield from one site drops below acceptable levels, farmers then clear another piece of land, burn the brush and other vegetation, and cultivate that site while leaving their previous field to lie fallow and its natural vegetation to return. This cycle will be repeated over and over, with some sites being allowed to lie fallow indefinitely, while others may be revisited and farmed again in five, ten, or twenty years.

PhotoDisc

Farm workers in China harvest tea.

Farmers who practice slash-and-burn do not always move their dwelling places as they cultivate different fields. In some geographic regions, farmers live in a central village and farm cooperatively, with fields being alternately allowed to remain fallow and farmed, making a gradual circuit around the central village. In other cases, the village itself may move as new fields are cultivated. Anthropologists studying indigenous peoples in Amazonia, for example, discovered that village garden sites were on a hundred-year cycle. Villagers farmed cooperatively to clear a garden site. That garden would be used for about five years; then a new site was cleared. When the fields in use became an inconvenient distance from the village—about once every twenty years—the entire village would move to be closer to the new fields. Over a period of approximately one hundred years, a village would make a circle through the forest, eventually ending up close to where it had been located long before any of the present villagers had been born.

In more temperate climates, farmers often owned and lived on the land on which they practiced swidden agriculture. Farmers in Finland, for example, would clear a portion of their land, burn the covering vegetation, grow grains for several years, and then allow that land to remain fallow for five to twenty years. The individual farmer rotated cultivation around the land in a fashion similar to that practiced by whole villages in other areas but did so as an individual rather than as part of a communal society.

Although slash-and-burn is frequently denounced as a cause of environmental degradation in tropical areas, the problem with it is not the practice itself but the length of the cycle. If the cycle of shifting cultivation is long enough, forests will grow back, the soil will regain its fertility, and minimal adverse effects will occur. In some regions, a piece of land may require as little as five years to regain its maximum fertility; in others, it may take one hundred years. Problems arise when growing populations put pressure on traditional farmers to return to fallow land too soon. Crops are smaller than needed, leading to a vicious cycle in which the next strip of land is also farmed too soon, and each site yields less and less. As a result, more and more land must be cleared.

Nomadism

Nomadic peoples have no permanent homes. They earn their living by raising herd animals, such as sheep, horses, or other cattle, and they spend their lives following their herds from pasture to pasture with the seasons, going wherever there is sufficient food for their animals. Most nomadic animals tend to be hardy breeds of goats, sheep, or cattle that can withstand hardship and live on marginal lands. Traditional nomads rely on natural pasturage to support their herds and grow no grains or hay for themselves. If a drought occurs or a traditional pasturing site is unavailable, they can lose most of their herds to starvation.

In many nomadic societies, the herd animal is almost the entire basis for sustaining the people. The animals are slaughtered for food, clothing is woven from the fibers of their hair, and cheese and yogurt may be made from milk. The animals may also be used for sustenance without being slaughtered. Nomads in Mongolia, for example, occasionally drink horses' blood, removing only a cup or two at a time from the animal.

In mountainous regions, nomads often spend the summers high up on mountain meadows, returning to lower altitudes in the autumn when snow begins to fall. In desert regions, they move from oasis to oasis, going to the places where sufficient natural water exists to allow brush and grass to grow, allowing their animals to graze for a few days, weeks, or months, then moving on. In some cases, the pressure to move on comes not from the depletion of food for the animals but from the depletion of a water source, such as a spring or well. At many desert oases, a natural water seep or spring provides only enough water to support a nomadic group for a few days at a time.

In addition to true nomads—people who never live in one place permanently—a number of cultures have practiced *seminomadic farming*: The temperate months of the year, spring through fall, are spent following the herds on a long loop, sometimes hundreds of miles long, through traditional grazing areas, then the winter is spent in a permanent village.

Nomadism has been practiced for millennia, but there is strong pressure from several sources to eliminate it. Pressures generated by industrialized society are increasingly threatening the traditional cultures of nomadic societies, such as the Bedouin of the Arabian Peninsula. Traditional grazing areas are being fenced off or developed for other purposes.

Environmentalists are also concerned about the ecological damage caused by nomadism. Nomads generally measure their wealth by the number of animals they own and will try to develop their herds to as large a size as possible, well beyond the numbers required for simple sustainability. The herd animals eat increasingly large amounts of vegetation, which then has no opportunity to regenerate. Desertification may occur as a result. Nomadism based on herding goats and sheep, for example, has been blamed for the expansion of the Sahara Desert in Africa. For this reason, many environmental policymakers have been attempting to persuade nomads to give up their traditional lifestyle and become sedentary farmers.

AGRICULTURE: WORLD FOOD SUPPLIES

Categories: Agriculture; food

Soil types, topography, climate, socioeconomics, dietary preferences, stages in agricultural development, and governmental policies combine to give a distinctive personality to regional agricultural characteristics and, hence, food supplies in various areas of the world.

All living things need food to live, grow, work, and survive. Almost all foods that humans consume come from plants and animals. Not all of earth's people eat the same foods, however. The types, combinations, and amounts of food consumed by different peoples depend upon historic, socioeconomic, and environmental factors.

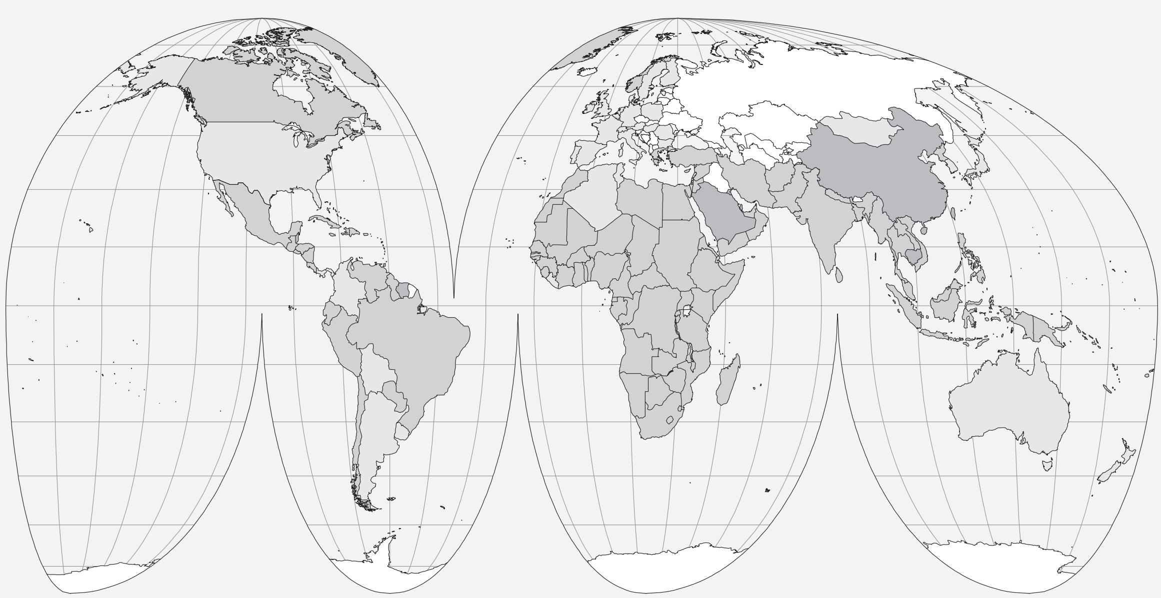
History of Food Consumption

Early in human history, people ate what they could gather or scavenge. Later, people ate what they could plant and harvest and the products of animals they could domesticate. Modern people eat what they can grow, raise, or purchase. Their diets or food composition is determined by income, local customs, religion or food biases, and advertising. There is a global food market, and many people can select what they want to eat and when they eat it according to the prices they can pay and what is available.

Historically, in places where food was plentiful, accessible, and inexpensive, humans devoted less time to basic survival needs and more time to activities that led to human progress and enjoyment of leisure. Despite a modern global food system, instant telecommunications, the United Nations, and food surpluses in some places, however, the problem of providing food for everyone on earth has not been solved.

In 1996 leaders from 186 countries gathered in Rome and agreed to reduce by half the number of hungry people in the world by the year 2015. United Nations data for 1998 revealed that more than 790 million people in the developing parts of

Increases in Land Used for Agriculture by Country, 1980-1994



the world did not have enough food to eat. This is more people than the total population of North America and Europe at that time. The number of undernourished people has been decreasing since 1990. Still, at the current pace of hunger reduction in the world, 600 million people will suffer from "acute food insecurity" and go to sleep hungry in 2015. Despite efforts being made to feed the world, outbreaks of food deficiencies, mass starvation, and famine are a certainty in the twenty-first century.

World Food Source Regions

Agriculture and related primary food production activities, such as fishing, hunting, and gathering, continue to employ more than one-third of the world's labor force. Agriculture's relative importance in the world economic system has declined with urbanization and industrialization, but it still plays a vital role in human survival and general economic growth. Demands on agriculture in the twenty-first century include supplying food to an increasing world population of nonfood producers as well as producing food and nonfood crude materials for industry.

Soil types, topography, weather, climate, socioeconomic history, location, population pressures, dietary preferences, stages in modern agricultural development, and governmental policies combine to give a distinctive personality to regional agricultural characteristics. Two of the most productive food-producing regions of the world are North America and Europe. Countries in these regions export large amounts of food to other parts of the world.

North America is one of the primary food-producing and food-exporting continents. After 1940 food output generally increased as cultivated zacreage declined. Progress in improving the quantity and quality of food production is related to mechanization, chemicalization, improved breeding, and hybridization. Food output is limited more by market demands than by production obstacles. Western Europe, although a basic food-deficit area, is a major producer and exporter of high-quality foodstuffs. After 1946 its agriculture became more profit-driven. Europe's agricultural labor force grew smaller, its agriculture became more mechanized, its farm sizes increased, and capital investment per acre increased.

Foods from Plants

Most basic staple foods come from a small number of plants and animals. Ranked by tonnage produced, the most important food plants throughout the world are wheats, corn, rice, potatoes, cassava, barley, soybeans, sorghums and millets, beans, peas and chickpeas, and peanuts. Wheat and rice are the most important plant foods. More than one-third of the world's cultivated land is planted with these two crops. Wheat is the dominant food staple in North America, Western and Eastern Europe, northern China, the Middle East, and North Africa. Rice is the dominant food staple in southern and eastern Asia.

Corn, used primarily as animal food in developed nations, is a staple food in Latin America and southeast Africa. Potatoes are a basic food in the highlands of South America and in Central and Eastern Europe. Cassava is a tropical starch-producing root crop of special dietary importance in portions of lowland South America, the west coast countries of Africa, and sections of South Asia. Barley is an important component of diets in North African, Middle Eastern, and Eastern European countries. Soybeans are an integral part of the diets of those who live in eastern, southeastern, and southern Asia. Sorghums and millets are staple subsistence foods in the savanna regions of Africa and South Asia, while peanuts are a facet of dietary mixes in tropical Africa, Southeast Asia, and South America.

The World's Growing Population

The problem of feeding the world is compounded by the fact that population was increasing at a rate of nearly 80 million persons per year at the end of the twentieth century. That rate of increase is roughly equivalent to adding a country the size of Germany to the world every year. Compounding the problem of feeding the world are population redistribution patterns and changing food consump-

Number of Persons Chronically Undernourished in Developing Countries by Region

tion standards. By 2001, the world had exceeded the six billion mark, and the world population was projected to reach approximately ten billion people by 2050—four billion people more than were on the earth in 2000. Most of the increase in world population was expected to occur within the developing nations.

Urbanization

Along with an increase in population in developing nations is massive urbanization. City dwellers are food consumers, not food producers. The exodus of young men and women from rural areas has given rise to a new series of megacities, most of which are in developing countries. By the year 2015, twenty-six cities in the world are expected to have populations of ten million people or more.

When rural dwellers move to cities, they tend to change their dietary composition and food-consumption patterns. Qualitative changes in dietary consumption standards are positive, for the most part, and are a result of educational efforts of modern nutritional scientists working in developing countries. During the last four decades of the twentieth century, a tremendous shift took place in overall dietary habits. Dietary changes and consumption trends have contributed to a decrease in child mortality, an increase in longevity, and a greater resistance to disease. This globalization of people's diets has resulted in increased demands for higher quality, greater quantity, and more nutritious basic foods.

Perspectives

Humanity is entering a time of volatility in food production and distribution. The world will produce enough food to meet the demands of those who can afford to buy food. In many countries, however, food production is unlikely to keep pace with increases in the demand for food by growing populations. The food gap—the difference between production and demand—could more than double in the first three decades of the twenty-first century. Such a development would increase the dependence of developing countries on food imports. About 90 percent of the rate of increase in aggregate food demand in the early twenty-first century is expected to be the result of population increases. Factors that could lead to larger fluctuations in food availability include weather variations, such as those induced by El Niño and climatic change, the growing scarcity of water, civil strife and political instability, and declining food aid.

AGRONOMY

Categories: Agriculture; disciplines; economic botany and plant uses; soil

Agronomy is a group of applied science disciplines concerned with land and soil management and crop production. Agronomists' areas of interest range from soil chemistry to soil-plant relationships to land reclamation.

The word "agronomy" derives from the ancient Greek *agros* (field) and *nemein* (manage) and therefore literally means "field management." The American Society of Agronomy defines agronomy as "the theory and practice of crop production and soil management." There are many specialties within the study of agronomy.

PhotoDisc

Agronomy is a family of disciplines, including soil management; a component of soil management is tilling and plowing techniques. This field has been plowed by tractor.

Agronomic Specialties

Agronomy is the family of disciplines investigating the production of crops supplying food, forage, and fiber for human and animal use. It studies the stewardship of the soil upon which those crops are grown. Agronomy covers all aspects of the agricultural environment, from agroclimatology to soil-plant relationships. It includes crop science, soil science, weed science, and biometry (the statistics of living things) as well as crop, soil, pasture, and range management; turfgrass; agronomic modeling; and crop, forage, and pasture production and utilization.

Within each area are subdisciplines. For example, within soil science are traditional disciplines such as soil fertility, soil chemistry, soil physics, soil microbiology, soil taxonomy and classification, and *pedogenesis*, the science of how soils form. Newer disciplines within soil science include such studies as *bioremediation*, or the study of how living organisms can be used to clean up toxic wastes in the environment, and land reclamation, the study of how to reconstruct landscapes disturbed by human activities, such as surface mining.

Scientific Goals

Chief among detrimental human activities is poor field management, which leads to reduced productivity and reduced environmental quality. Historical examples abound; one is that of the 1930's Dust Bowl in the United States. In the early 1900's much of the American Southern Plains, which had been natural grassland, was converted to wheatland. Planting and plowing methods of the time did not enable wheat to protect the ground against winds. Additionally, *overgrazing* of livestock had destroyed what grassland remained by the 1930's. The soil eroded, drought conditions which would last for most of the decade set in, and a series of wind and dust storms whipped through the region.

An estimated 50 million acres of land were destroyed before soil conservation measures, implemented under the administration of Franklin Roosevelt, began to improve the situation.

It is the role of agronomy to manage soil and crop resources as effectively as possible so that the twin goals of productivity and environmental quality are preserved. Agronomy treats the agricultural environment as humankind's greatest natural resource: It is the source of food, clothing, and building materials. The agricultural environment purifies the air humans and other animals breathe and the water they drink.

Agronomists, whatever their specific field, seek to utilize soil and plant resources to benefit society. Crop breeders, for example, use the genetic diversity of wild varieties of domesticated plants to obtain the information needed to breed plants for greater productivity or pest resistance. Soil scientists study landscapes to determine how best to manage soil resources. Integrating agricultural practices with the environment maintains soil fertility and keeps soil in place so that erosion does not reduce the quality of the surrounding environment.

AIR POLLUTION

Categories: Environmental issues; pollution

Air pollution results from the contamination of air with naturally occurring or synthesized gases and particulates that reach levels that are harmful to biological systems. Air pollution damages plants in both natural and agricultural systems.

D*ry air* is a mixture of gases composed of approximately 78.08 percent nitrogen, 20.95 percent oxygen, 0.93 percent argon, and 0.036 percent carbon dioxide. The remainder is composed of trace amounts of gases, such as helium, hydrogen, neon, methane, nitrogen oxides, sulfur oxides, and others. *Environmental air* contains additional quantities of water vapor and other components related to natural geological and biological activities and human activities. The composition of environmental air is variable by time of day, season, geographic location, and altitude. Those components added by human activity are often linked to air pollution.

Types of Pollutants

Air pollutants may be classified as primary or secondary. *Primary pollutants* are classified as gaseous or particulate. *Gaseous pollutants* include compounds such as sulfur oxides, nitrogen oxides, and various types of hydrocarbons, such as methane, benzene, and chlorofluorocarbons (CFCs). Gaseous pollutants may impact plant health by directly damaging plant structure or by altering physiological processes. *Particulates* are irritants, such as soot and dust that clog plant stomata (pores). In addition, particulates may serve as carriers for harmful chemicals that adhere to the particulates' surfaces.

Secondary pollutants are produced as a result of the interactions of primary gaseous pollutants with one another or with other atmospheric components. For example, sulfur dioxide and nitrogen dioxide react with water to form sulfuric and nitric acids, respectively, which are important components of *acid precipitation*. Production of some secondary pollutants requires the presence of ultraviolet radiation. In the presence of ultraviolet light, nitrogen dioxide loses an oxygen atom, which then reacts with molecular oxygen to form the secondary pollutant, ozone. Ozone in the upper atmosphere protects the earth from harmful ultraviolet radiation but is, itself, harmful to organisms in the lower atmosphere. Peroxyacetyl nitrates (PAN) are secondary pollutants that result from the reaction of nitrogen oxides and hydrocarbons with ozone in the presence of ultraviolet light. Ozone and PAN are major components of *photochemical smog*.

Sources of Air Pollution

Anthropogenic air pollution is a result of human activities. Burning fossil fuels, such as coal and petro-

leum products (including natural gas, gasoline, and fuel oil), leads to the release of large quantities of carbon dioxide. Atmospheric carbon dioxide levels have increased approximately 25 percent since the beginning of the Industrial Revolution as a result of fossil fuel burning. Carbon dioxide, as a result of the *greenhouse effect*, increases the atmosphere's heat-trapping capacity and is therefore a major factor in *global warming*. Sulfur oxides are released in the burning of fossil fuels and in mineral ore processing. Nitrogen oxides are produced in side reactions during fossil fuel combustion, in which high heat induces the oxidation of atmospheric nitrogen into nitrogen oxides. Hydrocarbons are released from industrial processes such as petroleum distillation and from incomplete fuel combustion. Particulates are products of farming, industrial processes, construction, demolition, and mining. Governments of many, but not all, countries continually monitor air quality and impose regulations to control anthropogenic pollution.

Some pollutants are released from natural sources. Bacterial decomposition of organic materials in oxygen-depleted swamps leads to methane production. Methane, an important greenhouse gas, is also a product of organic decomposition in landfills and is a waste gas associated with cattle feeding operations. The haze above some forests is caused by the release of volatile organic compounds, called *terpenes*, from trees. Ultraviolet light degrades some of the terpenes and induces synthetic reactions among various molecules, leading to the production of larger secondary compounds. Sulfur oxides and particulates are released during volcanic eruptions.

Plant Damage from Air Pollution

Air pollution damages plant life in both natural and agricultural ecosystems. Pollution effects on plants depend on several factors, including pollutant concentration, duration of exposure, and life stage of the plant, along with physical factors, such as temperature, light density, humidity, and season. Resistance to pollution stress is highly variable within and among plant species. Damage usually occurs after a specific threshold is reached. Although individual compounds are often studied, pollutants do not occur independently. Thus, harmful pollutant effects may be amplified or decreased by pollutant interactions.

High atmospheric carbon dioxide levels increase biomass production in most plants and improve water-use efficiency, while sometimes reducing overall plant protein and nitrogen contents. Increased growth at the expense of nutritional quality for the ecosystem's herbivores and for livestock may be a costly exchange, leading to reduced ecosystem stability and reduced nutritional value for consumers.

Nitrogen oxides enter plants through the stomata or by diffusion through the epidermis. Low levels of nitrogen oxides may have a fertilizing effect on nitrogen-limited plants, while higher levels may lead to direct toxicity through the production of nitric acid in the cytoplasm. Reduced cytoplasmic pH (greater acidity) may influence the movement and availability of nutrients in cells. Nitrogen oxides may cause chloroplasts to swell, thus affecting photosynthesis. Visible symptoms of plant damage from nitrogen oxides include *chlorosis* (yellowing) of the leaf tips and margins, which may progress into *necrosis* (tissue death).

Ozone causes direct *oxidation damage* to cuticles and enters plants through the stomata. Inside cells, ozone acts as a strong oxidant, reacting with many cellular components. Cell walls may become thickened and pigmented, leading to a characteristic *stippling*. White to red necrotic lesions may form, as well as chlorotic flecks and general leaf chlorosis.

Sulfur oxides enter plants through the stomata. In cells, sulfur oxides enter chloroplasts and cause acidification of the stroma, which contains enzymes responsible for photosynthetic carbohydrate production. Stroma pH (alkalinity versus acidity, where a measure of 7 is considered neutral) needs to be around 9 for proper enzyme function. Acidification by only 0.5 pH units may reduce net photosynthesis by 50 percent. Long-term effects of sulfur oxide damage include decreased growth and early leaf fall. Visible signs of injury include a characteristic chlorosis of leaf margins and interveinal spaces, while tissues next to veins remain green. Leaf undersurfaces may become silver or bronze in color. Necrotic areas may be ivory, brown, black, or red, or they may fall out completely.

ALGAE

Categories: Algae; microorganisms; *Protista*; water-related life

Algae comprise a diverse group of (with few exceptions) photosynthetic oxygen-producing organisms, ranging in size from microscopic single cells to gigantic seaweeds.

The study of algae is known as *phycology* (in Greek, *phycos* means "algae"). Currently, most authors place eukaryotic algae in the kingdom *Protista* (domain *Eukarya*) and prokaryotic algae in the domain *Bacteria*. In the past algae were considered to be lower plants because some forms look like plants. As in plants, the primary photosynthetic pigment in algae is chlorophyll *a*, and oxygen is produced during photosynthesis.

What Are Algae?

Algae can be found nearly everywhere on earth: oceans, rivers, lakes, in the snow of mountaintops, on forest and desert soils, on rocks, on plants and animals (such as within the hollow hair of the polar bear), or even on other algae. They are involved in diverse interactions with other organisms, including symbiosis, parasitism, and epiphytism. *Lichens* are symbiotic associations between algae (blue-green algae, or *cyanobacteria*) and fungi. Atmospheric nitrogen-fixing cyanobacteria occur in symbiotic associations with plants such as bryophytes, water ferns, gymnosperms (such as cycads), and the angiosperms. The aquatic fern *Azolla*, commonly used as a biofertilizer in rice fields in Asian countries, harbors the symbiotic cyanobacterium *Anabaena azollae*. *Gunnera*, the only flowering plant to house symbiotic cyanobacterium *Nostoc*, is widely distributed in the tropics.

Symbiotic dinoflagellates known as *zooxanthellae* live within the tissues of corals. Corals get their colors and obtain energy from their photosynthetic symbionts. About 15 percent of red algae occur as parasites of other red algae. Parasitic algae may even transfer nuclei into host cells and transform them. After transformation, the reproductive cells of the host algae carry the parasite's genes. Various algae live on the surfaces of plants and other algae as epiphytes. Sometimes algae can be found in strange places—the pink color of flamingos originates, for example, comes from a pigment in the algae consumed by these birds.

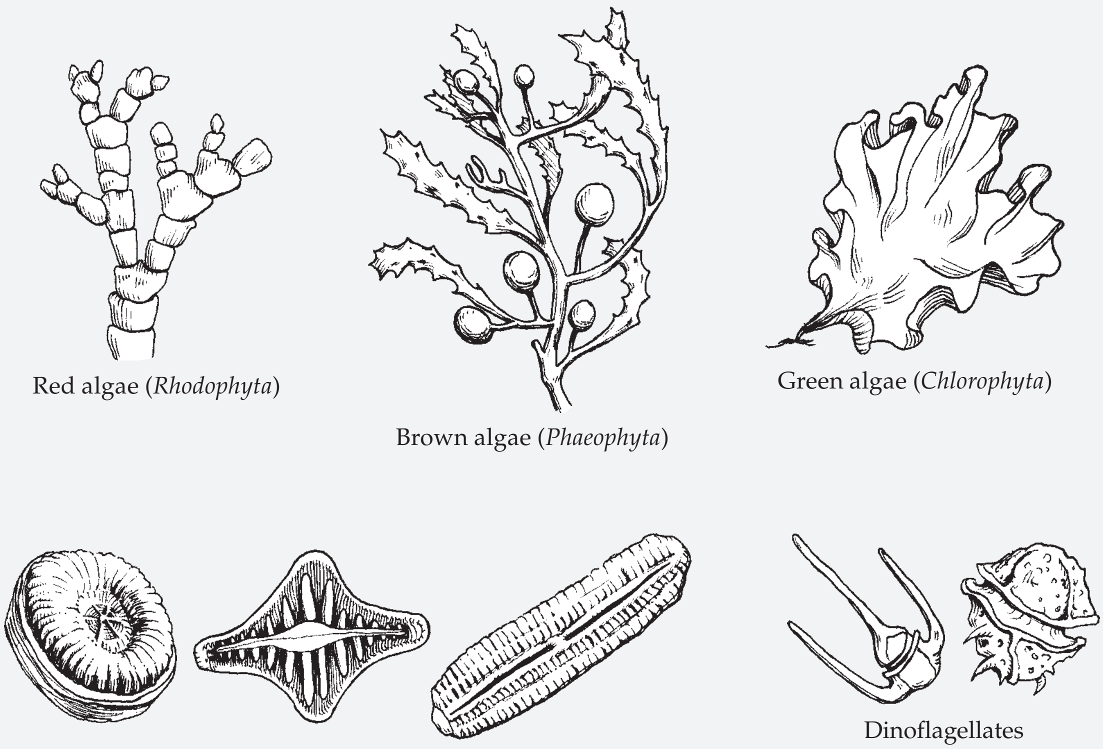
Algal Structure and Properties

Algal cells are bounded by a cell wall. Algal cells are either prokaryotic or eukaryotic. All prokaryotic algae belong to *Cyanophyta* (cyanobacteria) and lack both a nucleus and complex membrane-bound organelles, such as chloroplasts and mitochondria. Photosynthesis occurs in cyanobacteria in thylakoid membranes similar to those of plants. However, there is no double membrane surrounding the thylakoids of cyanobacteria.

All other algal groups are eukaryotic. Eukaryotic algae differ from cyanobacteria in that they possess chloroplasts and flagella with associated structures and in their cell wall composition. According to the *endosymbiont hypothesis*, some eukaryotic algae (red and green algae) obtained their chloroplasts by acquiring symbiotic prokaryotic cyanobacteria. This is known as primary endosymbiosis. Other eukaryotic algae probably obtained their chloroplasts by taking up eukaryotic endosymbiotic algae, a process known as secondary *endosymbiosis*. The existence of secondary endosymbiosis is indicated by the occurrence of more than two membranes around the chloroplasts of some algae, such as haptophytes, euglenophytes, dinoflagellates, and cryptomonads.

Pigments found in algae include chlorophylls, phycobilins, and carotenoids. All algae contain chlorophyll *a*. Accessory pigments vary among different algal groups.

Types of Algae



Kimberly L. Dawson Kurnizki

Photoautotrophy is the principal mode of nutrition in algae; in other words, they are "self-feeders," using light energy and a photosynthetic apparatus to produce their own food (organic carbon) from carbon dioxide and water. The majority of algal groups contain *heterotrophic* species, which obtain their organic food molecules by consuming other organisms. Numerous algae are *mixotrophs*; that is, they use different modes of nutrition (such as autotrophy and heterotrophy), depending on the availability of resources. The molecules used as food reserves differ among and are characteristic for algal groups. Food reserve molecules are polymers of glucose with different links between monomers.

Many algae are capable of movement. Movement is accomplished by means of flagellar action and by extrusion of mucilage. There are also peristaltic and amoeba-like algal movement. Within algal cells, movement of the cytoplasm, plastids, and nucleus also occurs. Advantages conferred by mobility include achieving optimal light conditions for photosynthesis, avoiding damage caused by excess light, and obtaining inorganic nutrients.

Algal Reproduction and Life Cycles

Algae may reproduce either asexually or sexually. Asexual reproduction among algae includes production of unicellular spores that germinate without fusing with other cells, fragmentation of filamentous forms, and cell division by splitting. In sexual reproduction, parent cells release gametes, which then fuse to form a zygote. Zygotes may either develop into new filaments or produce haploid spores by meiotic division.

Algae exhibit different types of life cycles. Some algal life cycles are characterized by an alteration of generations similar to that of plants. Two phases occur: sporophyte (usually diploid) and gametophyte (usually haploid). The sporophyte produces haploid spores through meiosis, and the haploid gametophyte produces male or female gametes by mitosis. Gametophyte and sporophyte may be structurally identical or dissimilar, depending on the algal group.

Roles of Algae

Algae have played significant roles in the earth's ecosystems since the origin of cyanobacteria (also known as blue-green algae) more than three billion years ago. Early cyanobacteria were responsible for the development of significant amounts of free oxygen in the atmosphere, which then made aerobic respiration possible. More than 70 percent of all photosynthetic activity on earth is carried out by *phytoplankton*—floating microscopic algae—rather than plants. Phytoplankton recharge the atmosphere with oxygen and simultaneously absorb carbon dioxide, helping to support the complex web of aquatic biota.

Algae are also very important in the global cycling of other elements, such as carbon, nitrogen, phosphorus, and silicon. Several algal groups—such as cyanobacteria, green algae, red algae, and the haptophyte algae—are able to generate calcium carbonate. Sedimented algae are the major contributors to deep-sea carbonate deposits (sand), which cover about half of the world's ocean floor. Calcified coralline red algae contribute to coral reefs in tropical waters. Silica sediments in oceans (sand) are based on abundant growth of another algal group, the diatoms, which contain silica in their cell walls.

Some algae (cyanobacteria) are able to fix atmospheric nitrogen and convert it to ammonia. Ammonia, in turn, can be a nitrogen source for plants and animals. On the other hand, high levels of nitrogen and phosphorus in rivers and lakes owing to pollution can cause the rapid and uncontrollable growth of algae, known as *algal blooms*. A bloom of algae is a threat to human and marine health, both directly and indirectly. It clogs fishes' gills, interferes with water filters, and ruins recreation sites. More than 50 percent of algal blooms produce toxins. Cases of human respiratory, skin, and gastrointestinal disorders associated with algal toxins have been reported. Certain blooms of algae are called *red tides*. The water appears to be red or brown because of the color of algal bodies, mainly dinoflagellates that contain the pigment xanthophyll.

Classification of Algae

Phylum	*Common Name*	*Species*
Bacillariophyta	Diatoms	100,000 or more
Chlorophyta	Green algae	17,000
Chrystophyta	Chrysophytes	1,000
Cryptophyta	Cryptomonads	200
Dinophyta	Dinoflagellates	4,000
Euglenophyta	Euglenoids	1,000
Haptophyta	Haptophytes	300
Phaeophyta	Brown algae	1,500
Rhodophyta	Red algae	6,000

Source: Data on species adapted from Peter H. Raven et al., *Biology of Plants*, 6th ed. (New York: W. H. Freeman/Worth, 1999).

Technological Applications

Algae have been used as food, medicine, and fertilizer for centuries. The earliest known reference to the use of algae as food occurs in Chinese poetic literature dated about 600 B.C.E. More recently, algae have begun to play important roles in certain biotechnological processes.

Several algae, including reds, browns, greens, and cyanobacteria, are used for food in Pacific and Asian countries, especially Japan. The annual harvest of the red alga *Porphyra* worldwide is worth several billion dollars. *Porphyra* (Japanese *nori*, Chinese *zicai*) is used as a wrapper for sushi or may be eaten alone. Another edible alga with a high iodine content is the brown alga *Laminaria* (Japanese *kombu*). The cyanobacterium *Spirulina*, with a protein level of 50 to 70 percent, was cultivated for centuries by indigenous Central Americans at Lake Texcoco near modern-day Mexico City for use as human food.

Several gelling agents are produced from red and brown algae. Agar from red algae is used as a medium for culturing microorganisms including algae, as a food gel, and in pharmaceutical capsules. Red algal carrageenan is used in toothpaste, cosmetics, and food such as ice cream and chocolate milk. Alginates from brown algae have extensive applications in the cosmetics, soap, and detergent industries. Sources of alginates are *Laminaria*, some *Fucus* species, and the giant kelp *Macrocystis*, which can grow to more than 60 meters long. Algae are also used as feed in the culture of commercially important fish and shrimp.

Mass cultivation of algae (microalgae)—in open ponds and photobioreactors for production of fuels (such as biomass) and biochemicals (such as carotenoids, amino acids, and carbohydrates) and for water purification—is a rapidly developing area based on the use of solar energy as energy source. The green alga *Dunaliella* is used in the industrial production of carotene. In wastewater treatment plants, algae are used to remove nutrients and heavy metals and to add oxygen to the water.

Algae are used worldwide as indicators (biomonitors) of water quality, helping to detect the presence of toxic compounds in water samples. Several fast-growing algae are used, including the green alga *Selenastrum capricornutum*. Many algae are widely employed as research tools because they are easy to culture and manipulate. Danish biologist Joachim Hammerling's experiments with the green alga *Acetabularia* identified the nucleus as the likely storage site of hereditary information.

Diversity

Taxonomists believe that there are between thirty-six thousand and ten million species of algae. Molecular comparisons using nucleotide sequences in ribosomal RNA (ribonucleic acid) suggest that algae do not fall within a single group linked by a common ancestor but that they evolved independently. The algae are divided into nine major phyla, which differ in their photosynthetic pigments, food reserves, cell structure, and reproduction. These groups include euglenoids, cryptomonads, dinoflagellates, haptophytes, and red algae.

Phylum *Euglenophyta* contains mostly unicellular forms with one or two flagella. Only one-third of this group possess chlorophyll-containing chloroplasts. Other euglenoids are strictly heterotrophic. The phylum contains more than nine hundred, mostly freshwater, species. The food reserve is the carbohydrate paramylon, a polymer of glucose. Euglenophytes have chlorophyll *a* and *b* as well as carotenoids as their photosynthetic pigments. There is no cell wall. Cells have several small chloroplasts; each is surrounded by three membranes. A close relative of euglenophytes is the protozoan *Trypanosoma*, which causes the human disease African sleeping sickness. Reproduction in the euglenophytes occurs by division of cells. Sexual reproduction is unknown.

Phylum *Cryptophyta* includes unicellular biflagellates. In addition to chlorophyll *a*, chloroplasts can contain chlorophyll *c*, carotenoids, and phycobilins. The carotenoid pigment alloxanthin is unique to *Cryptophyta*. Four membranes surround each chloroplast. Chloroplast endoplasmic reticulum borders the chloroplasts. The principal food reserve is starch. Instead of a typical cell wall, a periplast composed of protein plates occurs beneath the cell membrane. There are about two hundred freshwater and marine species. Reproduction is primarily asexual.

Members of the phylum *Dinophyta*, or dinoflagellates, have unicellular forms with two different flagella. There are between two thousand and four thousand marine species and about two hundred freshwater forms. Many have chlorophylls *a* and *c* as well as the unique carotenoid peridinin. Some members of *Dinophyta* have fucoxanthin. Chloroplasts have three closely associated membranes. The primary food reserve is starch, but lipids are also important storage molecules. A dinoflagellate cell is not surrounded by a cell wall but has a theca (a sort of armor) made of cellulose. Dinoflagellates can reproduce asexually and sexually.

Phylum *Haptophyta* includes primarily marine unicellular biflagellated algae. A haptophyte cell also has a flagellum-like haptonema, used to capture food. There are about three hundred species. The photosynthetic pigments include chlorophyll *a* and accessory pigments chlorophyll *c* and the carotenoid fucoxanthin. Each chloroplast has four membranes. The food reserve is chrysolaminarin, which is a polymer of glucose. Several layers of scales, or coccoliths, composed primarily of calcium carbonate may cover the haptophyte cell. Asexual and sexual reproduction is widespread.

Phylum *Rhodophyta*, or the red algae, has between four thousand and six thousand species. Red algae lack any flagellated stages. The photosynthetic pigments include chlorophyll *a* as well as accessory phycobilins and carotenoids. Two membranes surround each chloroplast. The food reserve is a floridean starch. A red algal cell is encircled by a wall composed of cellulose. Asexual and sexual reproduction, as well as alteration of generations, are widespread among *Rhodophyta*. A triphasic life cycle is unique for this group of algae.

ALLELOPATHY

Categories: Physiology; poisonous, toxic, and invasive plants

Allelopathy refers to all the biochemical interactions, both beneficial and harmful, among all types of plants, including microorganisms.

For an allelopathic interaction to occur, chemicals must be released into the environment by one plant that will affect the growth of another. In this way allelopathy differs from *competition*, which involves removal of some factor from the environment that is shared with other plants. Allelopathy was recognized as early as Theophrastus (300 B.C.E.), who pointed out that chick pea plants destroy weeds growing around them.

Image Not Available

Methods of Action

A variety of different allelochemicals are produced by plants, usually as secondary metabolites that do not have a specific function in the growth and development of the host plant but that do affect the growth of other plants. Originally plant physiologists thought these secondary products were simply metabolic wastes which plants had to store because they do not have an excretory system as animals do. Their various functions are now beginning to be understood.

One class of allelochemicals, *coumarins*, block or slow cell division in the affected plant, particularly in root cells. In this way growth of competing plants is inhibited, and seed germination can be prevented. Several kinds of allelochemicals, including *flavonoids*, *phenolics*, and *tannins*, suppress or alter hormone production or activity in competing plants. Other chemicals, including *terpenes* and certain antibiotics, alter membrane permeability of host cells, making them either leaky or impermeable. In some cases, membrane uptake can be enhanced, particularly for micronutrients in low concentration in the soil. Finally, a variety of allelochemicals have both positive and negative effects on metabolic activity of the affected plant.

Allelopathy in Agriculture

Most of the negative effects of weeds on crop plants have been attributed to competition; however, experiments using weed extracts have demonstrated that many weeds produce allelochemicals. Similarly, some crop plants are allelopathic to others and themselves, including wheat, corn, and rice. In these cases the residues of one year's crop can interfere with crop growth in subsequent years. This is increasingly important for farmers to consider who are incorporating low-tillage methods to reduce soil erosion. To minimize these effects, some of the traditional techniques of cover cropping, companion cropping, and crop rotation must be employed. Known allelopaths are also beginning to be used as biological control agents to manage invasive and weedy plant species.

Allelopathy in Nature

Several tree species, including black walnut, black locust, and various pines, are known to produce allelochemicals that inhibit the growth of understory species. In some cases this is a result of drip from the foliage or leachate from fallen leaves and fruit. In other cases, roots secrete allelochemicals that kill seedlings of other plants. Bracken fern (*Pteridium aquilinum*) is known to affect the growth of many other plants.

ALTERNATIVE GRAINS

Categories: Agriculture; economic botany and plant uses; food

Alternative grains refers to alternatives to high-yield grain crops, the harvest of which has led to severe soil erosion and increased use of fertilizers and pesticides.

More than one-half of the calories consumed daily by humans comes from grains. Most of these grains are produced by plants of the *grass* family, *Poaceae*. Major *cereal* plants domesticated centuries ago include rice (*Oryza sativa*), wheat (*Triticum aestivum*), and corn (*Zea mays*). Other important grain crops, also plants of the grass family, include barley (originating in Asia), millet and sorghum (originating in Africa), and oats and rye (originating in Europe).

Grain Genetics

Since the early twentieth century, the scientific principles of genetics have been applied to improvements of crop plants. Some notable improvements occurred between 1940 and 1970. As a result of irrigation, improved genetic varieties, and the use of large amounts of fertilizers and pesticides, yields of major crops greatly increased. Norman Borlaug received a Nobel Prize in 1970 for his contributions to these developments, which came to be called the *Green Revolution*. However, it soon became apparent that the Green Revolution was not the boon first envisioned. For maximum yield, large-scale farming involving huge capital investment is required. Also, environmentalists became concerned over the erosion and other environmental damage caused by the use of large amounts of fertilizers and pesticides.

Minor Cereals

Various alternatives have been proposed. For grain crops, several approaches offer promise, including more widespread use of minor cereals, especially those tolerant of unfavorable growing conditions; development of new cereal plants by hybridization or other genetic manipulation; and use of pseudocereals, nongrass crop plants that produce fruits (grains) similar to those of cereal plants.

Most *sorghum* (*Sorghum bicolor*) grown in the United States is used for silage or molasses. In Africa and India, various grain sorghums are grown in regions where rainfall is too low for most other grain crops. Well adapted to hot, dry climates, their grains are used to make a pancakelike bread. *Millet* refers to several grasses that are also useful cereal plants because they tolerate drought well. In Africa the most important are pearl millet (*Pennisetum glaucum*) and finger millet (*Eleusine coracana*). Grains of both species can be stored for long periods and are used to make bread and other foods. Other, perhaps less important, grain plants also called millet include foxtail millet (*Setaria italica*), native to India but now grown in China; proso millet (*Panicum milaeceum*), native to China but grown in Russia and central Asia; sanwa millet (*Echinochloa frumentacea*), cultivated in East Asia; and teff (*Eragrostis teff*), an important food and forage plant of Ethiopia. Such grain sorghums and millets have the potential to grow in areas with hot, dry climates far beyond the regions where they are now being utilized.

In a distinct category is *wild rice* (*Zizania aquatica*). Native to the Great Lakes region of the United States and Canada, it has been, and still is, harvested by American Indians. Like the common but unrelated rice (*Oryza sativa*), wild rice grows in flooded fields. Attempts to cultivate it since the 1950's have been somewhat successful as the result of the development of nonshattering varieties. However, it remains an expensive, gourmet item. Two cereal plants have promise because of the high-protein content of their grains. Wild oat (*Avena sterilis*) is a disease-resistant plant with large grains. Job's tears (*Coix lachryma-jobi*), native to Asia, is now planted throughout the tropics. Research on these and related species continues.

Although all important cereal plants have been improved by genetic techniques, the most notable new alternative grain plant is triticale (*Triticosecale*). The first human-made cereal, it is the result of crossing wheat with rye. The sterile hybrid from such a cross was made fertile by doubling its chromosomes. Thus, triticale varieties produce viable seeds. Triticale combines the superior traits of each of its parents: the cold tolerance of rye and the higher yield of wheat. The protein content of triticale compares favorably with that of wheat, and its quality, as measured by lysine content, is higher. However, flour made from triticale is not suitable for making bread unless mixed with wheat flour.

Pseudocereals

Pseudocereals are plants that are not of the grass family but produce nutritious, hard, grainlike fruits that can be stored, processed, and prepared for food much like grains. They belong to several plant families. Many grow under conditions not suitable for the major cereal crops. Buckwheat (*Fagopyrum esculentum*), of the *Polygonaceae* family, probably originated in China. It tolerates cool conditions and is adapted to short growing seasons, thus permitting it to be grown in the temperate regions of North America and Europe. In the United States, it is often associated with pancakes but is used in larger quantities for livestock feed. In Eastern Europe, the milled grain is used for soups.

Quinoa (*Chenopodium quinoa*) of the goosefoot family, *Chenopodiaceae*, has been cultivated by Indians of the Andes Mountains for centuries. The leafy annual produces grainlike fruits (actually achenes) with a high protein content and exceptional quality, high in lysine and other essential amino acids. After its bitter saponins have been removed, it can be cooked and eaten like rice or made into a flour. Quinoa has been cultivated in the Rocky Mountains since the 1980's and has become a gourmet food in the United States.

Most amaranths (*Amaranthus*) plants are New World weeds. They belong to the amaranth family, *Amaranthaceae*. A few species were used by Aztecs and other North American peoples, but amaranth use was banned by the Spanish. Since the late 1970's, plant breeders have targeted several species for improvement. The results are highly nutritious grains, rich in lysine, that are suitable for making flour. Research in Pennsylvania and California has resulted in improved varieties.

ANAEROBES AND HETEROTROPHS

Categories: Cellular biology; evolution; microorganisms

The first organisms to evolve on the earth are thought to have been heterotrophs and anerobes. Heterotrophs are organisms that cannot produce their own food but must fill their energy requirements by consuming organic molecules produced by other processes or organisms. Anaerobes are organisms that do not require free oxygen gas in order to survive; for some anaerobes, free oxygen may be poisonous.

Heterotrophs include many familiar organisms (such as animals) whose existence is tied to *primary producers*, those organisms that create energy-storing molecules, such as photosynthesizing plants. Anaerobes also are common, though less apparent. Typically, they are microscopic organisms restricted to living in a few surface environments where oxygen is absent. It may seem strange, then, that these organisms were perhaps the first organisms to have evolved on the earth. Yet the combination of the heterotrophic lifestyle and the anaerobic life requirement is consistent with what is known about the conditions of the early earth's surface environment.

The earliest anaerobic heterotrophs laid the biochemical foundations for the evolution of photosynthesis, free oxygen in the atmosphere, and the rise of complex organisms. All those events had the adverse impact of limiting the range of environments available to the anaerobes.

The world's first organism evolved in what has been called a "prebiotic soup" of energy-rich organic molecules. Heterotrophic organisms would exploit this environment by absorbing the molecules. A continuing supply of energy-rich molecules depended on the absence of free oxygen in the early atmosphere and the functioning of the *abiotic synthesis*.

Fermentation

The energy-rich molecules of the soup were converted to energy by a series of biochemical reactions. One of the simplest, and therefore perhaps one of the oldest, types of energy conversion reactions is *anaerobic fermentation*. During anaerobic fermentation, an energy-rich molecule, such as the simple sugar glucose, is dismantled to release energy and waste by-products. Several lines of evidence suggest that this form of energy conversion was utilized by the early heterotrophs.

One indicator that fermentation is a very ancient biochemical process is that the reaction used to release energy from the glucose molecule is very common among modern organisms. The ability to utilize the *fermentation* reaction is evident in the anaerobic reaction of yeast using sugar and releasing ethyl alcohol. Although it is not the primary energy-releasing reaction for most organisms, fermentation's widespread availability suggests that it is very old and perhaps inherited from an early, simpler ancestor.

The fermentation reaction is not very efficient. For example, it releases two units of energy for every glucose molecule, whereas oxidation of the same glucose molecule releases more than thirty energy units. Such an inefficient reaction for energy release could not be tolerated by an advanced organism with many energy demands. Alternatively, single-celled heterotrophs surrounded by, and absorbing, energy-rich molecules such as glucose (which is unlikely to decompose in an anoxic environment) do not expend much energy in gathering their food.

The Earliest Organisms

Thus, two very different types of evidence—that which points to an anoxic early atmosphere and evidence for the ancient ancestry of the glucose fermentation reaction—suggest that the earliest organism was a single-celled heterotroph that absorbed energy-rich molecules from the surrounding anaerobic environment. Modern analogues for such an organism exist. Single-celled bacteria, called *obligate anaerobes*, exist in a few anoxic environments today. It is likely that the modern obligate anaerobes have not changed significantly (especially in their morphology, or shape and size) from their Precambrian ancestors. Given this much information, paleontologists know that their search for early Precambrian fossils, the petrified remains of organisms, is not easy.

The process of fossilization—that is, the preservation of the shape of an organism in rock—is best at preserving the details of hard body parts. Hard skeletons and shells or their impressions are easier to preserve than are soft body parts. In the case of early Precambrian fossils, the most likely organisms (bacteria) not only are small but also contain no hard body parts.

Despite these barriers to preservation and despite the very poorly preserved Precambrian rock record, some early Precambrian fossil remains have been found and described. The fossils are usually found preserved in rock called chert, which probably began as a gelatinous material. Microscopic remains of organisms embedded in this gelatin were delicately preserved when the chert lost some of its water and solidified.

The oldest fossil remains identified have been found in cherts from southern Africa. These cherts, part of what is called the Fig Tree Formation, are more than three billion years old. The fossils consist of the wispy, spherical remains of what may have been a type of alga and the rod-shaped remains of a possible heterotrophic bacterium.

ANAEROBIC PHOTOSYNTHESIS

Categories: Photosynthesis and respiration; physiology

Anaerobic photosynthesis, also known as anoxygenic photosynthesis, is the process by which certain bacteria use light energy to create organic compounds but do not produce oxygen. Anaerobes are those bacteria that cannot use oxygen to generate energy.

The photosynthetic process in all plants and algae, as well as in specific types of bacteria, involves the reduction of carbon dioxide to carbohydrate and the removal of electrons from water, resulting in the release of oxygen. This process is known as oxygenic or *aerobic photosynthesis*. Water is oxidized by a multi-subunit protein located in the photosynthetic membrane. This is a molecular protein feature shared among more than 500,000 species of plants on earth.

While this is a common feature among nearly every form of plant life on earth, some photosynthetic bacteria can use light energy to extract electrons from molecules other than water. These bacteria are of ancient origin and are believed to have evolved before aerobic photosynthetic organisms. These anaerobic photosynthetic organisms occur in the domain *Bacteria*. Anaerobic photosynthetic bacteria, also known as anoxygenic photosynthetic bacteria, differ from aerobic organisms in that each species of these bacteria has only one type of reaction center. In some photosynthetic bacteria the reaction center involves the oxidation of water and the reduction of the aromatic molecule plastoquinone. In

Heliobacteria, *shown in this scanning electron micrograph, one of five groups of photosynthetic bacteria, are anaerobic photosynthetic bacteria.*

other species it involves the oxidation of plastocyanin and the reduction of ferredoxin protein.

Photosynthetic bacteria are typically aquatic microorganisms inhabiting marine and freshwater environments, including wet and muddy soils, stagnant ponds, sulfur springs, and still lakes. They are classified into five groups based on pigment composition, metabolic requirements, and membrane structure: green bacteria, purple sulfur bacteria, purple nonsulfur bacteria, heliobacteria, and halophilic archaebacteria. Some of these organisms are *strict anaerobes*; that is, they can grow only in the complete absence of oxygen. They cannot use water as a substrate, and they do not produce oxygen during photosynthesis. *Facultative anaerobes*, on the other hand, can grow either in the presence or in the absence of oxygen.

Green bacteria include two families, the *Chloroflexaceae* and the *Chlorobiaceae*. The *Chlorobiaceae* are strict anaerobes that grow by utilizing sulfide, thiosulfate, or organic hydrogen as an electron source. *Chloroflexaceae* are facultative aerobes which use reduced carbon compounds as electron donors. Purple sulfur bacteria uses an inorganic sulfur compound, such as hydrogen sulfide, as a photosynthetic electron donor. Purple nonsulfur bacteria depend on the availability of simple organic compounds such as alcohols and acids as electron donors, but they can also use hydrogen gas. Purple sulfur bacteria must fix carbon dioxide to live, whereas nonsulfur bacteria can grow aerobically in the dark by respiration on an organic carbon source.

Heliobacteria are anaerobic photosynthetic bacteria that contain a special type of bacteriochlorophyll, BChl *g*, that works as both antenna and reaction center pigment. *Halobacteria* are very unusual. They cannot grow in low salt concentrations (or their cell walls collapse). Typically, they are heterotrophs with an aerobic electron-transport chain, but they can also respire anaerobically, with nitrate or sulfur. In the absence of suitable electron acceptors they can ferment carbohydrates. Halobacteria, when exposed to light in the absence of oxygen, can synthesize a purple membrane containing a single photosensitive protein called bacteriorhodopsin which, when illuminated, begins cyclic bleaching and regeneration, extruding protons from the cell. This light-stimulated proton pump operates without electron transport. The mechanism by which halobacteria convert light is fundamentally different from that of higher organisms because there is no oxidation/reduction chemistry, and halobacteria cannot use carbon dioxide as their carbon source. As a result, some scientists do not consider halobacteria as being photosynthetic.

Process

The common features to both aerobic and anaerobic photosynthesis have been known since the mid-twentieth century:

Green plants:

$$CO_2 + 2H_2O + \text{light} \rightarrow (CH_2O) + O_2 + H_2O$$

Green sulfur bacteria:

$$CO_2 + 2S + H_2O + \text{light} \rightarrow (CH_2O) + 2S + H_2O$$

In each case, inorganic carbon (CO_2) is fixed into organic carbon (CH_2O), the source of reductant is hydrogen in either water or hydrogen sulfide, and the chemical energy required for this activity is derived from light energy. The sulfur produced anaerobically is analogous to the oxygen produced by the oxygenic photosynthesis of green plants. Photochemical processes in photosynthetic bacteria require three major components: an antenna of light-harvesting pigments, a reaction center within an intra-cytoplasmic membrane containing at least one bacteriochlorophyll, and an electron transport chain.

All photosynthetic bacteria can transform light energy into a transmembrane proton gradient used for the generation of adenosine triphosphate (ATP) and production of oxidase, but none of the anaerobic photosynthetic bacteria are capable of extracting electrons from water, so they do not evolve oxygen. Many species can only survive in low-oxygen environments. To provide the necessary electrons for carbon dioxide reduction, anoxygenic photosynthetic bacteria must oxidize inorganic or organic molecules from their immediate environment.

Despite basic differences, the principles of energy transductions are the same in anaerobic and aerobic photsynthesis. Anaerobic photosynthetic bacteria depend on bacteriochlorophyll, a group of molecules similar to chlorophyll, that absorbs in the infrared spectrum between 700 and 1,000 nanometers. The antenna systems in these bacteria consist of bacteriochlorophyll and carotenoids, serving a reaction center where primary charge separation occurs. Electron carriers include quinone and cytochrome *bc* complex. Electron transfer is coupled to the generation of electrochemical potential that drives phosphorylation by ATP synthase, and the energy required for the reduction of carbon dioxide is provided by ATP and dehydrogenase.

ANGIOSPERM CELLS AND TISSUES

Categories: Anatomy; angiosperms; cellular biology; physiology

Some cell types and tissues which are not found in any other groups of plants occur in angiosperms (flowering plants).

Angiosperms are a group of plants with seeds that develop within an ovary and reproductive organs in flowers. They are commonly referred to as flowering plants and represent the most successful group of plants on earth, with approximately 235,000 species. Various cell types and tissues, many of which are not found in any other groups of plants, occur in angiosperms. These cells and tissues perform varied functions, which are very efficient compared to their counterparts in other plants. These include *dermal*, *vascular* (xylem and phloem), and *ground tissues* (such as parenchyma, collenchyma, and sclerenchyma).

The growth of plants is carried on by a group of cells at their tips. These groups of cells are referred to as *apical meristems*, which are composed of *initials* and their most recent *derivatives*. The initials are the main source of body cells in plants, while the derivatives become any of the cells and tissues in the plant body. The apical meristems of both the shoot and the root show continued cell division, with cells enlarging, elongating, and differentiating in regular, distinctly organized patterns. Apical meristems bring about the increase in the length of the stems and roots and are responsible in the formation of the primary plant body. The shoot apical meristem may continually initiate the aerial components of the plant or may enter a state of periodic quiescence. In some plants, the shoot apical meristem transforms into a floral or inflorescence meristem that eventually terminates in a single flower or clusters of flowers, respectively. The *root apical meristem* is enclosed by a thimble-shaped *root cap* that hastens the penetration of roots between soil particles. Unlike the shoot apical meristem, the root apical meristem forms no appendages. In fact, the site of lateral root initiation is far removed from it.

Shoot Apex

The shoot apical meristem is typically dome-shaped but flattened, and concave outlines also exist. The outline is not constant but changes in response to *plastochron* (the time interval between the initiation of one leaf primordium and the next). At least three models describe the shoot apical meristems. Although each of these is based on one or two unique criteria, they also have a few overlapping features.

Cell Lineage Analysis

This model holds that three clonally related layers of cells characterize the shoot apical meristem. These layers can be more than one cell layer thick. L1 is the outermost layer and gives rise to the *epidermis*, L2 is the middle layer and gives rise to the *vascular tissues* and *cortex*, and L3 is the innermost layer and gives rise to the *pith*. This model was based on studies using periclinal chimeras (organs or parts of tissues of diverse genetic constitution), where one of the cell layers was genetically altered using drugs that inhibit separation of chromosomes.

Tunica-Corpus Concept

This model is based on microscopic analysis of constituent cells. It says that the shoot apical meristem is made up of two groups of cells. The *tunica*, a group of cells that form one or two stratified layers, undergoes anticlinal divisions only and gives rise to the epidermis. Partly enclosed by the tunica is the *corpus*, a group of loosely arranged cells that divide in various planes and give rise to the vascular and ground tissues. The tunica maintains its individuality by surface growth, whereas the corpus adds bulk by increase in volume.

Cytohistological Zonation

This model recognizes various definable zones in the shoot apical meristem. Three zone boundaries are distinguished by cell size: staining quality, degree of vacuolation, and frequency of cell division. The central (mother cell) zone represents a conspicuous group of enlarged and isodiametric cells that undergo infrequent cell division, possess prominent nuclei, and are often highly vacuolated. The flanking peripheral zone is derived from, and partly surrounds, the central zone. Cells of this zone are smaller, are mitotically active, and have dense cytoplasms. They give rise to the epidermis, vascular tissues, and cortex. The rib zone is located at the base of the central and peripheral zones. This zone is directly formed from the central zone, produces longitudinal files of cells by periclinal divisions, and gives rise to the pith.

Root Apex

The organization of the root apical meristem is different from that of the shoot apical meristem. Root apical meristems are commonly interpreted as having either a close or open type of organization. In a close type of organization, the dermal, vascular, and ground tissues each have their own set of initials. This organization shows a clear boundary between root cap and other tissues of the root apex. In an open type of organization, all of the root tissues share a group of initials, and therefore the boundary of the root cap is indistinguishable from the other tissues of the root apex.

Developmental Processes

The cells produced by apical meristems undergo several key developmental processes, which include growth, differentiation, and morphogenesis. Although each of these can be separated individually, they overlap in highly complex fashion. *Growth* refers to the quantitative increase in a cell's volume or mass due to enlargement and multiplication. *Differentiation* is the qualitative change in the form and function of organelles, cells, tissues, and organs, resulting in the establishment of new structures and functions. From an anatomical point of view, cell differentiation is related to changes in cell size and shape, modifications of the wall, and changes in staining characteristics of nucleus or cytoplasm, as well as the degree of vacuolation and the ultimate loss of the protoplast in some cases. *Morphogenesis* is the visible manifestation of all of the changes, brought about by growth and differentiation, as expressed in the overall morphology of the plant.

Dermal Tissues

The primary plant body is composed of three basic tissues: dermal, vascular, and ground tissues. The *dermal tissue* (or epidermis) is made up of several cell types and is involved in a variety of functions, including retention and absorption of water and minerals, protection against herbivores, and control of gas exchange. Each of these functions is attributable to one or more of the unique features of the epidermis. Most epidermal cells are flat and tightly packed, forming a single layer around stems, leaves, and other organs. The outer walls of epidermal cells are equipped with a waterproof layer made up of a fatty material called *cutin*. The tightly packed and cutinized epidermis protects the plants from desiccation by keeping moisture in.

Epidermal cells lack chloroplasts and are transparent. It is the underlying cells that give leaves and stems their green color. However, the vacuoles of some epidermal cells occasionally contain pigments and are responsible in the coloration of flowers and colored parts of variegated leaves.

Stomata are specialized structures that form part of the epidermis of leaves, stems, flowers, and fruits. They are involved in regulating the intake of carbon dioxide for photosynthesis as well as the release of oxygen. *Trichomes* are single-celled or multicellular outgrowths of epidermal cells that are involved in deterring herbivores and restricting transpiration. *Root hairs* are also outgrowths of epidermal cells that are specialized for absorbing water and minerals from soil. They occur near the tip of the root and function to increase its absorptive surface area several-thousandfold.

Vascular Tissues

Vascular tissues are of two types: xylem and phloem. *Xylem* occurs throughout the plant body, and the type that differentiates directly from the apical meristem is called primary xylem. (Secondary xylem is formed from the vascular cambium.) Primary xylem is formed as stems and roots elongate. The two kinds of conducting cells in xylem are tracheids and vessels, or vessel elements. Both are dead at maturity and have thick, lignified secondary cell walls. *Tracheids* are long, slender cells with tapered, overlapping ends. They are the only water-conducting cells in most gymnosperms (an evolutionary line of plants that includes conifers). Water moves upward in roots and stems from tracheid to tracheid through thin areas in their cell walls called pits. With only a few exceptions, all angiosperms contain vessel elements and tracheids. *Vessel elements* are short, wide in diameter, and connected end to end. Their end walls are partly or wholly dissolved, forming long hollow vessels through which water moves. All these features of vessels enable them to transport water more rapidly than tracheids.

Phloem transports dissolved organic materials throughout the plant. The conducting cells of the phloem are called *sieve elements*, which are devoid of nuclei but otherwise have intact cytoplasm. They also have thin areas along their cell walls called sieve areas that are perforated. Solutes move from sieve element to sieve element through these pores.

Ground Tissues

The three types of *ground tissue* are parenchyma, collenchyma, and sclerenchyma. *Parenchyma cells* are the most abundant and versatile cells in plants. These cells are isodiametric, are alive at maturity, are highly vacuolated, and have a primary cell wall. Parenchyma functions as food- and water-storage tissue as well as sites of metabolism in plants. Chlorenchyma cells are chloroplast-containing parenchyma specialized for photosynthesis.

Collenchyma cells are relatively long, with unevenly thickened primary walls. They support growing regions of shoots and are common in petioles, elongating stems and expanding leaves. Collenchyma cells are well adapted for support because their cell walls are able to stretch. They often form in strands or a cylinder just beneath the epidermis; such location maximizes support, as would a rod located in the center of a stem or petiole (leaf base).

Sclerenchyma cells are rigid; produce thick, nonstretchable secondary walls; and are usually dead at maturity. They occur in, support, and strengthen mature regions of plants, including stems, roots, and leaves. There are two types of sclerenchyma cells: sclereids and fibers. *Sclereids* are relatively short and variable in shape and usually occur in small groups. *Fibers* are long and slender and occur in strands or bundles. Sclereids are found in the roots, leaves, and stems. They produce the gritty texture of pears and mostly make up the tough core of apples as well as the seed coats of peanuts and walnuts. Fibers are often associated with vascular tissues and, compared to sclereids, are typically elongated cells that vary in length from a few millimeters to more than half a meter long.

ANGIOSPERM EVOLUTION

Categories: Angiosperms; evolution

Angiosperms (flowering plants) appeared about 130 million years ago and today dominate the plant world, with approximately 235,000 species.

In early Devonian-age rocks, approximately 363-409 million years old, fossils of simple vascular and nonvascular plants can be seen. Ferns, lycopods, horsetails, and early *gymnosperms* became prominent during the Carboniferous period (approximately 290-363 million years ago). The gymnosperms were the dominant flora during the Age of Dinosaurs, the Mesozoic era (65-245 million years ago). More than 130 million years ago, from the Jurassic period to early in the Cretaceous period, the first flowering plants, or angiosperms (phylum *Anthophyta*), arose. Over the following 40 million years, angiosperms became the world's dominant plants.

The angiosperms show high species diversity, and they occupy almost every habitat on earth, from deserts to high mountain peaks and from freshwater ecosystems to marine estuaries. Angiosperms range in size from eucalyptus trees well over 100 meters (328 feet) tall with trunks nearly 20 meters (66 feet) in circumference to duckweed, simple floating plants barely 1 millimeter (0.003 inch) long.

Special Characteristics

Some of the defining characteristics of angiosperms involve their physical appearance or morphology and internal anatomy: the presence of flowers and fruits containing seeds, stamens with two pairs of pollen sacs, a microgametophyte (the male, haploid stage of the life cycle contained in the pollen) with three nuclei, a megagametophyte (the female, haploid stage of the life cycle enclosed in the ovary) with eight nuclei, companion cells, and sieve tubes in the phloem (vascular tissue important in the transport of organic molecules). Some of these characteristics involve life-cycle features, such as *double fertilization*, that are distinct from almost all other members of the plant kingdom. (Double fertilization is also known in the genera *Ephedra* and *Gnetum*, members of the gymnosperms.)

Because angiosperms possess so many unique features, plant taxonomists have long believed that angiosperms originated from a single common ancestor. Because the first flowers and pollen grains appear in fossils from the early Cretaceous period, up to about 130 million years ago, it is probable that angiosperms actually arose more than 130 million years ago. As the findings of *paleobotanists* (botanists who study plants in the fossil record) have been combined with more recent knowledge from evolutionary genetics and biochemistry, a clearer picture of angiosperm evolution has emerged.

Proposed Ancestors

Because gymnosperms (the other large group of seed plants) have long been considered ancestral to the angiosperms, researchers have attempted to develop models for the evolution of the ovule-bearing structures of flowering plants from the similar, naked ovule-bearing structures of gymnosperms. Some lines of evidence indicate that groups of extinct cycad-like gymnosperms known as the *Bennettitales* and the *gnetophytes*, a modern division of the gymnosperms which show up in the fossil record about 225 million years ago, are the seed plants most closely related to angiosperms. All three groups, the *Bennettitales*, the gnetophytes, and the angiosperms, share, or shared, superficially similar flowerlike reproductive structures. The strobili, or cones, of some gnetophytes closely resemble flowers, and the xylem (vascular tissue specialized for transporting water) of some gnetophytes is similar to the xylem found in angiosperms.

Image Not Available

Seed Ferns

Other lines of evidence suggest that a group of plants called the seed ferns, or *pteridosperms*, might represent the ancestors of the angiosperms. The seed ferns, which predate the angiosperms by many millions of years, had seed-bearing cupules and specialized organs that produced pollen. Many plant taxonomists believe that the seed-bearing cupules in some groups of seed ferns could have evolved into the carpels of flowers.

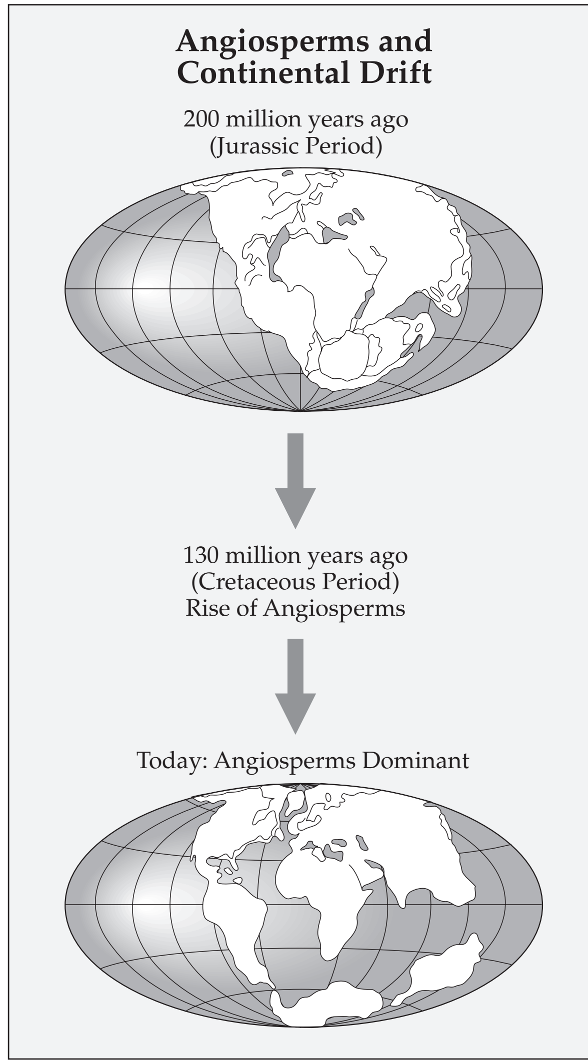
Earliest Flowers

Most paleobotanists assume that the first flowers were small, simple, and green in color and by modern standards were rather unattractive. Their petals and sepals were probably not clearly differentiated. In November of

1998, Ge Sun and David Dilcher and their colleagues published their discovery of the oldest angiosperm fossil to date, estimated to be at least 122 million years old and possibly as old as 145 million years. Either age qualifies it as the oldest. The fossils were discovered in China, and the fruits show the characteristic enclosed ovule (a *carpel*) that is distinctive to angiosperms. It was given the scientific name *Archaefructus liaoningensis*. Given its great age, this find implies that angiosperms may have arisen as early as the Jurassic period, more than 145 million years ago.

Other early flowers produced pollen with a single *aperture*, or opening, a trait that the monocot branch of the angiosperms shares with cycads and ginkgos. Plant taxonomists believe that pollen with a single opening is an ancestral feature that some plants have kept as they evolved. The pollen of eudicots, with its three apertures, is thought to be a derived feature (that is, a later evolutionary development).

Recent studies of angiosperm evolution, using data from deoxyribonucleic acid (DNA) sequences, have led to the proposal that an obscure shrub from the South Pacific island of New Caledonia, called *Amborella trichopoda*, represents what is left of the ancestral *sister group* (a related organism that branched off before the evolution of another group of organisms) to all the angiosperms. As a sister group to all the angiosperms, it is considered to be the most primitive (in an evolutionary sense) of the angiosperms and therefore should resemble what the ancestor to the angiosperms was like. It does possess some of the expected primitive traits for a primitive angiosperm, such as small, greenish-yellow flowers and a lack of vessels for conducting water from the ground to the leaves.



Angiosperms are proposed to have evolved approximately 130 million years ago, sometime between the Late Jurassic period (208-144 million years ago) and the Early Cretaceous period (144-65 million years ago), when South America, Africa, and India were much closer together.

Angiosperm Classification

Approximately 97 percent of angiosperm species are classified as either *Monocotyledones* (monocots), with approximately 65,000 species, or *Eudicotyledones* (eudicots), with about 165,000 species. The monocots include such familiar plants as the grasses, lilies, irises, orchids, cattails, and palms. The more diverse eudicots include most of the familiar trees and shrubs (other than the conifers) and many of the herbaceous plants. The remaining 3 percent of angiosperms are called the *magnoliids*, a group of plants considered to have primitive features, among them pollen with a single aperture. Many magnoliids also feature oil cells with ether-containing oils providing the characteristic scents of laurel and pepper, for example. The magnoliids are typically divided into the woody magnoliids and paleoherbs.

Woody magnoliids have large, often showy, bisexual flowers with multiple free parts. Magnolia trees and tulip trees (both in *Magnoliaceae*, or the magnolia family) are examples of this group. The *paleoherbs* have small, often unisexual flowers and usually just a few flower parts. Modern paleoherbs include the pepper family (*Piperaceae*), the birthwort family (*Aristolochiaceae*), and the water lily family (*Nymphaeaceae*).

Recent studies of angiosperm evolution, using data from DNA sequences, have also sharpened the understanding of some of the relationships among monocots, eudicots, and magnoliids. If these groups are displayed as an evolutionary tree (or *phylogenetic* tree), the magnoliids are *polyphyletic* (that is, they do not share a single common ancestor). The magnoliids branch off near the base of the tree on several different branches. The monocots are monophyletic (that is, they share a single common ancestor) and form a separate branch from among the magnoliid branches. The eudicots branch off last and represent the most diverse and evolutionarily complex group.

Geographic Origins

As hotly debated, perhaps, as exactly which group of plants were ancestral to the angiosperms is the question of where the angiosperms first evolved. Some botanists believe that angiosperms first developed in the Northern Hemisphere; others look at the Southern Hemisphere. At the time angiosperms are proposed to have evolved, the continents were not arranged the way they are now. At that time, all of the world's major landmasses were grouped into a supercontinent called Pangaea. The southern part of this continent is referred to as Gondwanaland, and the northern part is called Laurasia. Based on what is known about late Cretaceous angiosperms and their habitats, some scientists suggest that the westernmost, semiarid regions of Gondwanaland may be the place where angiosperms first evolved.

As Pangaea broke up, the separate continents moved in different positions, resulting in new configurations. India collided with Asia, raising the Himalaya Mountains and the Tibetan Plateau. Antarctica slipped over the South Pole, and Australia became isolated. These plate movements created new climatic regimes, opening up new niches that were rapidly exploited by the angiosperms.

Diversification and Spread

Regardless of their geographic origins, by about ninety million years ago the flowering plants were well on their way to dominating the world's flora. The early angiosperms were well adapted to drought and cold. Adaptations that conferred resistance to these conditions included strong leaves, efficient water-conducting cells, and tough, resistant seed coats. Some woody flowering plants evolved the ability to lose their leaves, called the *deciduous habit*. This characteristic allows the shutdown of metabolism during adverse environmental conditions, such as during seasonal droughts or winter weather. Because of greater climate instability during the past fifty million years or so compared to earlier times, the above-mentioned traits were important in allowing the flowering plants to adapt to different and often harsher climatic conditions.

Pollination

A major innovation that likely led to some of the great diversity seen in angiosperms was pollination by insects or other animals. As plants adapted to the various available pollinators, the pollinators also adapted to the plants, sometimes in very specific ways. Many pollination systems include specialized colors or markings, flower shapes, and flower scents. This process of evolving "together" is called *coevolution*. Coevolution has also occurred between plants and their predators. Evolution of chemical compounds to deter herbivory have, in turn, led to adaptations in many animal groups to circumvent the toxicity of the chemical compounds.

ANGIOSPERM LIFE CYCLE

Categories: Anatomy; angiosperms; physiology; reproduction and life cycles

The word "angiosperm" comes from the Greek words for "vessel" and "seed" and translates roughly as "enclosed seed." In part, angiosperms (the flowering plants, phylum Anthophyta*) are defined by the fact that their seeds are enclosed by an ovule. The life cycle of an angiosperm is defined by the formation of the seed and its development to a full-grown plant which, in turn, produces seeds.*

Angiosperms are vascular plants with flowers that produce seeds enclosed in an *ovule*—a fact that is recognized as the *angiospermy condition*.

Reproductive Flower Parts

In general, angiosperms have a floral axis with four floral parts, two of which are fertile. At the receptacle, or tip, of the axis there is an ovule-bearing leaf structure known as the carpel. The ovule or ovules can be found inside the *pistil*. Three portions compose the pistil: the ovary, the style, and the stigma, where the pollen usually germinates. The mature ovule consists of the placenta, the integuments that are modified leaves that cover the entrance to the embryo sac, the micropyle, and the chalaza. These latter two parts of the ovule complement each other in their positions and functions. While the micropyle receives and guides the pollen tube, the chalaza relates to the vascular supply of the ovule, nutrition, and support. The *stamens*, which are often composed of the filament and sporangia sacs that make up the anther, surround the pistil. Stamens carry the male gametes, and the pistil carries the female gamete needed for sexual reproduction.

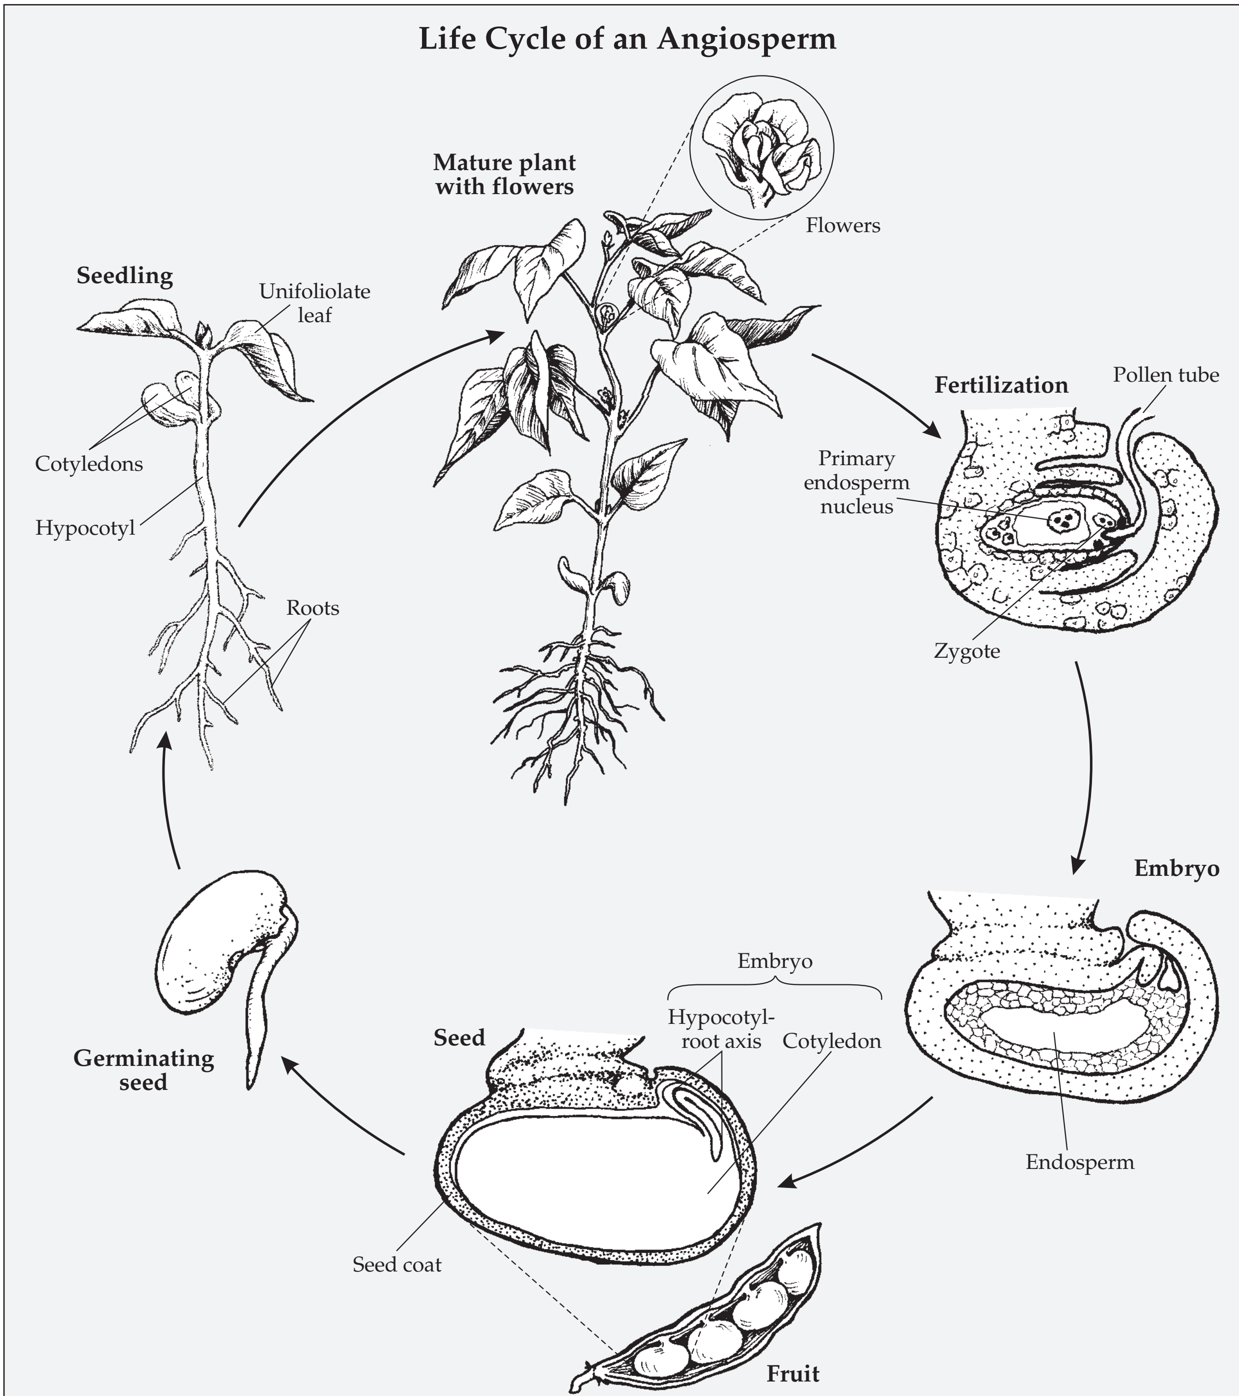
It is believed that the great diversity and adaptability of the angiosperms is related to the presence of a unique reproductive cycle. This cycle consists of an *alternation of generations* and the production of a pair of spores on two types of sporophylls: microspores (which become male gametophytes) and megaspores (which become female gametophytes).

Male Gamete Development

The angiosperm reproductive cycle begins with the process of *microsporogenesis*, or microspore formation. The stamen consists of a filament and the anther, also known as the *microsporangium*. In most of the cases, the anther consists of four pollen sacs, or locules. Within each locule, the archesporial cell develops through mitosis and extends as a row of cells throughout the entire length of the young anther. These mitotic cell divisions generate the anther wall, which is made up of several cell layers, the outermost of which transforms itself into the epidermis. The layer of cells below the epidermis is known as the endothecium. During anther development, the endothecial cells acquire thickenings whose function is related to anther opening and pollen release. The innermost layer of the anther wall is the tapetum, whose primary function correlates with the nourishment of the young pollen and the deposition of the exine, a coating of the pollen grain.

As development proceeds, the sporogenous cells located below the tapetum transform into microsporocytes. These microsporocytes will undergo meiosis, and tetrads (units of four) of microspores will form. Shortly after their formation, the tetrads separate into individual microspores. Each microspore is haploid, and often it will enlarge and separate from the tetrad, becoming sculptured by the deposition of sporopollenin and other substances that will turn into the ornamented surface of the pollen grain.

The second phase of pollen development is known as *microgametogenesis*. The microspore is the first cell of the gametophytic generation, the cell that generates the mature pollen. The single-nucleus microspore develops into the male gametophyte before the pollen is released. This developmental process occurs through two or three unequal mitotic divisions of the nucleus and subsequent cytokinesis (cell separation). The two daughter nuclei and cells differ in size and in form. The larger cell represents



Kimberly L. Dawson Kurnizki

the tube cell and nucleus, while the smaller cell represents the generative cell and nucleus. At maturity, the grain can be shred in two or three nucleate conditions. When the anther opens, the mature male gametophytes or pollen grains will be disseminated and ready for germination.

Female Gamete Development

The ovule (female sex organ) consists of two opposite ends: the micropyle, where the integuments come together, and a more distant end, where the ovular tissue is more massive. This part is also known as the chalaza, and it lies directly opposed to the micropyle. The mature ovule is composed of three layers: the outer integument; the inner integument; and, underneath the integuments, the nucellus. During ovular development, one cell lying below the nucellar epidermis changes into a primary archesporial; this will divide to form the primary parietal cell and primary sporogenous cell. The primary sporogenous cell functions as the megaspore mother cell, which divides meiotically, originating four haploid megaspores. In the majority of angiosperms, three of the megaspores will degenerate, and only the chalazal one will develop into the megagametophyte (embryo sac).

After the completion of the embryo sac stage, a series of cellular events occurs, ending with the formation of the mature embryo sac, ready for fertilization by the male gametes. The chalazal megaspore enlarges and undergoes three mitoses, giving rise to eight haploid cells. The mature megagametophyte consists of two groups of four cells located at both ends of the embryo sac. The result is three antipodals at the chalazal end: the egg apparatus (consisting of the egg and two synergids at the micropylar end) and the polar nuclei. These two cells, present at both ends, usually fuse before pollination, and during fertilization they form the primary endosperm nucleus.

Pollination

The plant reproductive structures are now ready for the union of male and female gametes or fertilization, which eventually will produce a seed with a viable embryo and cotyledons. Before that step takes place, however, the pollen must be transferred from the anther to the stigma. Biotic agents (such as birds, insects, or mammals) or abiotic agents (such as wind or water) can accomplish this transfer process, known as *pollination*.

After landing on the stigma, pollen tubes will emerge through the grain apertures if the environment is high in humidity. Successful germination of the pollen in the stigma requires nutrients. In most plants, growth of the pollen tube lasts between twelve and forty-eight hours, from pollen germination to fertilization. Pollen germination starts with pollen-tube initiation, elongation, and penetration of the stigmatic tissue. During this period intense metabolic activity takes place, for the tube must synthesize membrane material and cell wall for growth and expansion. Simultaneously, at its tip the tube carries the vegetative cell nucleus, followed by the germinative cell.

Angiosperms have evolved complex breeding systems that ensure they will be pollinated by their own species. Today it is recognized that two pollination syndromes exist: *self-pollination* and *cross-pollination*. In self-breeding species, the pollen comes from the anther of the same flower. In cross-pollination (or outcrossing) species, the pollen comes from the anthers of a different flower or even a different plant of the same species. In these plants, incompatibility in the stigma guarantees that only pollen from other flowers will germinate.

Fertilization

The union of one sperm with the egg is known as *fertilization*. However, several developmental processes in the vegetative and germinative cells prepare the two sperms for a process known as *double fertilization*. A mitotic division of the germinative cell generates the sperm cells. This process that can take place on the growing pollen tube or inside the pollen grain. In a growing pollen tube, the vegetative nucleus disintegrates and the sperm cells will take the lead and enter the embryo sac for successful fertilization. Usually, the interactions between the pollen grain and the pistil ensure that the sperm cells will often reach the micropyle of the ovule.

Once the sperm reach the micropyle, the growth of other tubes stops. In the embryo sac (female gametophyte), four cells are located at the micropylar side. Of those four, the first pair that the sperm cells will encounter are the synergids. One of these is always bigger than the other and carries the filiform apparatus, a structure resembling hairs that degenerates after pollination and before fertilization. The synergids act as chemical attractants to the pollen tube, which penetrates the synergids via the filiform apparatus and then releases the two sperm cells. One of the sperm cells will fuse with the egg, producing the zygote; the other sperm cell will fuse with the primary endosperm nucleus, generating the endosperm. The remaining cells of the female gametophyte are the antipodals; they usually degenerate after fertilization has taken place.

Seed and Fruit Formation

Once fertilization has occurred, the ovule will go through a series of metabolic steps ending with the formation of the *seed* and the *fruit*. The recently created zygote transforms into a multicellular and complex *embryo* that has two well-defined polar ends: the radicle, or primary root, and the embryonic apical meristem with the first leaves. After successive mitosis, the mature endosperm usually grows close to the embryo and may provide nutrients needed for germination. The integuments will undergo further transformation, replication, and elongation and will become the seed coat—of variable texture, consistency, and colors, depending on the type of plant.

In general, after pollination or during fertilization, the ovary undergoes a series of physiological changes regulated by synchronized hormonal and genetic alterations that will modify the size of the parenchyma cells and its sugar and organic acids contents. This process turns the ovary into fruit—in many cases familiar as the edible fruits familiar in human diets. The fruit provides nourishment for the seed until it ripens and drops to the ground, where the next stage in the life cycle begins.

Germination, Seedling Development, and Maturation

Seeds are released from the fruit in a large variety of ways that have evolved to ensure the survival of species. Whether ingested by mammals and passed through their feces to the ground, borne by wind on feathery "wings," or simply falling from rotting fruit that has abscissed and dropped from the plant, the seed must next undergo a process called *germination*, in which the embryo enclosed in the seed begins its growth. The embryo develops a *hypocotyl* (root axis) and a fleshy part known as the *cotyledon*; in monocots there is one cotyledon, in dicots, two.

Germination requires certain conditions, such as the softening of the seed coat, moisture, and adequate warmth, to occur. During germination, the hypocotyl begins growing downward to become the root; the cotyledon(s) will develop into the shoot, stems, and leaves. The process of germination results in the sprouting through the ground's surface of the *seedling*, which will develop into the mature plant with flowers. The cycle then begins again.

ANGIOSPERM PLANT FORMATION

Categories: Anatomy; angiosperms; physiology; reproduction and life cycles

Angiosperms are flowering plants. Their formation entails development from embryo to seed, through germination to seedling, and finally to mature plant.

The life cycle of angiosperms (flowering plants) involves an alternation of generations between a dominant sporophytic (spore-producing) phase and a reduced gametophytic (gamete-producing) phase. The first cell of the sporophyte is the fertilized egg, or *zygote*, which undergoes repeated divisions, growth, and differentiation to form an embryo enclosed in the ovule. After fertilization, the ovule is transformed into the seed, which germinates into a seedling. The seedling becomes the adult plant; the plant produces flowers in which the sperm and egg—representing, respectively, the male and female gametophytic generations—are formed. Fertilization occurs, and seeds are produced to continue the life cycle.

Dicot Embryo Formation

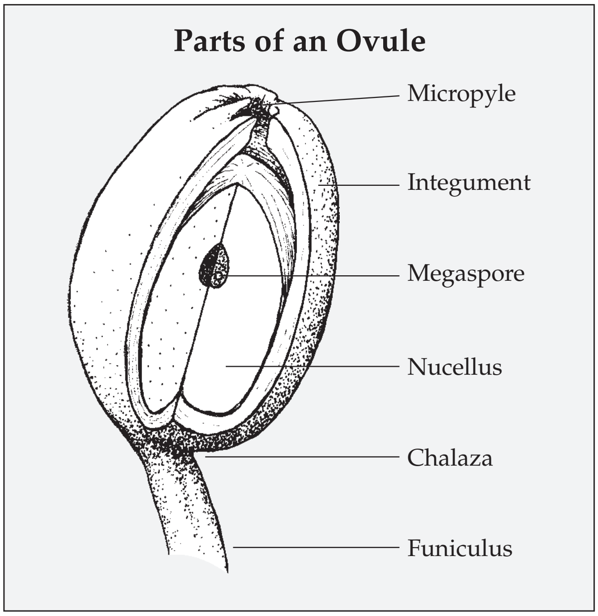
In most angiosperms, embryo development, or *embryogenesis*, is initiated with a division of the fertilized egg into a small apical cell and a large basal cell, forming a two-celled proembryo. The apical cell generates the embryo proper, and the basal cell forms a filamentous *suspensor* that anchors the embryo. Two weeds, *Capsella bursa-pastoris* (shepherd's purse) and *Arabidopsis thaliana* (mouse ear cress or wall cress), both belonging to the *Brassicaceae* family, have attained prominence as textbook examples of embryogenesis in typical *dicots* (plants with two *cotyledons*, or seed leaves; a *monocot* has one seed leaf).

In these plants, the apical cell of the proembryo divides by two successive longitudinal walls to form a quadrant that is immediately partitioned by transverse walls into an octant, composed of an upper and lower tier of four cells each. The fates of the two tiers are already fixed in the octant embryo, as the upper tier forms the *shoot apex* and much of the cotyledons. The lower tier, in addition to providing derivatives to the remaining part of cotyledons, generates the *hypocotyl*, the *radicle*, and the *root apex*. However, the central region of the root cap, known as the columella, and the quiescent center of the root apical meristem are derived from the terminal cell of the *suspensor* closest to the embryo, known as the *hypophysis*. The apicobasal pattern of the future seedling plant is established in the octant embryo.

A series of divisions separating eight peripheral cells from a core of eight inner cells heralds histogenesis in the embryo. The result is the formation of a sixteen-celled, globular embryo, in which the peripheral cells form the protoderm (precursor cells of the embryonic epidermis), and the inner cells differentiate into the procambium and ground meristem (precursors of the vascular tissues and ground tissues, respectively) of the mature embryo. This initiates the formation of radial-pattern elements made up of concentric tissue layers in the basal part of the embryo.

The globular stage of the embryo is completed by approximately three additional rounds of divisions, mostly in the inner core of cells. The suspensor attains its genetically permissible number of six to nine cells by this stage. Gradually the cells begin to lose connection from one another and from the embryo and disintegrate.

Emerging from the globular stage, the embryo expands laterally by cell divisions to form the cotyledons and becomes heart-shaped. The heart-shaped stage is followed by the torpedo-shaped



Angiosperms are vascular plants with flowers that produce seeds enclosed in an ovule (female sex organ), a fact that is recognized as the "angiospermy condition." The ovule consists of two opposite ends: the micropyle, where the integuments come together, and the chalaza, where the ovular tissue is more massive. The mature ovule is composed of three layers: the outer integument; the inner integument; and, underneath the integuments, the nucellus (megasporangium), in which the megaspore, which will become the female gametophyte, is embedded. The stalk to which the ovule is attached is the funiculus.

stage, in which elongation of the cotyledons and hypocotyl, as well as extension of the vascular tissues, occurs. The basic body plan of a shoot-root axis becomes unmistakably clear at this stage, with the establishment of the shoot apical meristem in the depression between the cotyledons and the organization of a root apex by incorporation of derivatives of the hypophysis at the opposite end of the embryo.

During further growth, the cotyledons bend toward the hypocotyl (bent cotyledon or walking-stick shaped stage), and the embryo is phased into the mature stage. A mature embryo of *Arabidopsis* has fifteen thousand to twenty thousand cells and, under favorable conditions of growth, develops in about nine days from the time of fertilization to the mature embryo stage. Sensitive genetic screens have led to the isolation of *Arabidopsis* mutants defective in apicobasal and radial patterning of embryos. Characterization of the mutant genes and their protein products has unraveled to some extent the molecular components of the embryonic pattern-forming system in this plant.

Monocot Embryo Formation

The early divisions of the zygote in monocots follow the same pattern as in dicots. However, in the *Poaceae* (grasses) family, which includes wheat and the other cereals, the sequence and orientation of later divisions in the proembryo are irregular, resulting in highly complex mature embryos. The main feature of the cereal embryo is the development of an absorptive organ known as the *scutellum* (considered equivalent to the single cotyledon). Other organs of the embryo for which there are no counterparts in the dicot embryo are a sheathlike tissue covering the root (*coleorhiza*), a tissue that covers the shoot (*coleoptile*), and an internode known as the *mesocotyl*. On one side of the coleorhiza there is also a small, flaplike outgrowth called the *epiblast*.

Embryo Maturation to Seed

As the embryo matures, the ovule progressively desiccates to become the seed enclosed within the ovary. Concomitantly, the integuments of the ovule harden to form the protective seed coat. Within the ovule itself, the primary endosperm nucleus formed after double fertilization begins to divide, ahead of the zygote, to produce the endosperm charged with nutrient substances. In seeds of many plants, including *Arabidopsis*, *Capsella*, bean, and pea, the endosperm is utilized by the developing embryo.

In other plants, especially the cereals, the bulk of the seed (grain) is made up of the endosperm surrounding the small embryo. The mature embryo enclosed in the seed consists of an axis bearing the *radicle* (embryonic root) at one end and the *plumule* (the embryonic shoot consisting of the shoot apex and one or two leaves) at the other end, and one (in monocots) or two (in dicots) cotyledons. The part of the embryo axis above the point of attachment of the cotyledon(s) is known as the *epicotyl*, whereas the part below the attachment point connecting to the radicle is called the *hypocotyl*.

Seed Germination

The dry seed enclosing the mature embryo may not germinate immediately; if it does not, it enters a period of *quiescence* or dormancy. Quiescent seeds germinate when provided with the appropriate conditions for growth, such as water, a favorable temperature, and the normal composition of the atmosphere. Dormant seeds germinate only when some additional hormonal, environmental, metabolic, or physical conditions are met. In almost all seeds, the first part of the embryo to emerge during germination is the radicle. It forces it way through the soil and forms the primary root of the seedling. However, the manner in which the shoot emerges and develops varies considerably in different seeds.

In the *epigeous* type of germination (for example, in beans), emergence of the radicle is followed by the elongation of the hypocotyl, which arches above the soil surface as a hook. As the hook straightens, it pulls out the cotyledons and plumule above the soil surface. In the *hypogeous* type of germination (in peas, for example) the cotyledons enclosed within the seed coat remain in the soil during germination. It is the epicotyl that arches above the soil surface, and as the hook straightens out, it carries the plumule along with it to the surface of the soil. In the monocot, such as the onion, after emergence of the radicle the single cotyledon arches aboveground and subsequently straightens.

Members of the *Poaceae* display a type of germination in which, following the outgrowth of the radicle, the coleoptile enclosing the plumule grows out of the grain and appears above the soil. The seedling leaves force their way, breaking the coleoptile, and appear outside as the first photosynthetic organs. The growth of the coleoptile during germination of grains is facilitated by the elongation of the mesocotyl. These various types of germination ensure an efficient use of food materials stored in the embryo or in the endosperm for the growth of the seedling until it becomes autotrophic.

Embryo to Adult Plant

Although the question as to whether the seedling will become a gigantic tree or a small, herbaceous plant is determined by its genetic blueprint, certain common postgermination growth and developmental episodes mark the development of the seedling into an adult plant. In dicots, continued growth of the primary root produces an extensively branched root system consisting of secondary roots or lateral roots. In monocots, the primary root disintegrates shortly after it is formed, and so the root system is constituted of numerous adventitious roots which arise from the base of the stem.

Although the cotyledons retain their photosynthetic capacity for some time after germination of the seed, the seedling becomes completely autotrophic as the shoot apex produces new leaves and branches arise in the axils of leaves. These activities are coordinated by the division of cells in the root and shoot apical meristems and the differentiation of cells into specialized tissues and organs. The shoot and root apical meristems, considered analogous to the stem cells of animals, remain active throughout the life of the plant and, hence, are known as indeterminate meristems.

ANGIOSPERMS

Categories: Angiosperms; economic botany and plant uses; food; medicine and health; *Plantae*; taxonomic groups

The name "angiosperms" has long been used by botanists to refer to the flowering plants, a group of approximately 235,000 species. All angiosperms are members of the phylum Anthophyta.

The name "angiosperm" is actually derived from two Greek words, *angeion*, meaning "vessel" or "container," and *sperma*, meaning "seed." The name was given in reference to the fact that the seeds of all flowering plants develop from *ovules* that are enclosed in a structure called a *carpel*. This characteristic sets the angiosperms apart from all other plants, which either do not have seeds or have seeds that are not developed in structures resembling a carpel. Although the name angiosperm is used widely, plant taxonomists and many botanists typically refer to them by the more formal name *Anthophyta*, the phylum that contains the flowering plants.

Unique Features of Angiosperms

In addition to possessing enclosed seeds, *Anthophyta* differs from other plant phyla in a number of ways. The most obvious distinguishing feature is the *flower*, a complex structure containing the reproductive parts of the plant. The reproductive structures in other plants are much less complex and showy. The angiosperm life cycle differs from that of almost all other plants. The *sporophyte* is the dominant, *diploid* stage and is the more visible form of the plant, with the leaves, stems, roots, and flowers. The *haploid gametophyte* is confined to life inside the *ovary* or *anther* of the flower, unlike the typically free-living gametophytes of most other plants.

Fertilization is also unique in angiosperms. Many angiosperms rely on insects or other animals to transfer pollen from one flower to another. *Pollen grains* produce two haploid *sperm* that travel through a *pollen tube* from the *stigma* into the ovary of the flower and into one of the *embryo sacs*. Within the embryo sac one of the sperm fertilizes the egg, which will lead to formation of the diploid embryo, and the other sperm fuses with two or more polar nuclei to form the *endosperm*, which will nourish the embryo and young seedling. This process is often referred to as *double fertilization*. Other, less obvious features set *Anthophyta* apart as well, including a unique *vascular anatomy*, pollen structure, and various biochemical characteristics.

Size and Geographic Diversity

There are approximately 235,000 species of flowering plants, and they are found in almost all terrestrial habitats, with the exception of extremely high elevations and some polar regions. A small proportion of flowering plants are aquatic (that is, found in

Common Monocot Families

There are at least four major taxonomic systems for classifying flowering plants, as well as less formal systems. While names of phyla (divisions), subdivisions, classes, subclasses, and orders vary, along with the placement of families within those larger groups, the names of families, genera, and species remain fairly constant, with fewer alterations and controversies (although subject to changes as well). Families found in the United States are followed by their common names in parentheses.

Acoraceae (calamus)
Agavaceae (century plant)
Alismataceae (water plantain)
Aloeaceae (aloe)
Aponogetonaceae (cape pondweed)
Araceae (arum)
Arecaceae (palm)
Bromeliaceae (bromeliad)
Burmanniaceae (burmannia)
Butomaceae (flowering rush)
Cannaceae (canna)
Centrolepidaceae
Commelinaceae (spiderwort)

freshwater habitats), and an even smaller number are marine (found in saltwater habitats). The greatest species richness is in tropical regions, especially tropical rain forests, and species richness steadily decreases at increasing latitudes north and south of the equator.

Angiosperms have been so successful in terrestrial ecosystems that they represent the majority of the herbs and shrubs and many of the trees as well. The diversity of growth forms is tremendous, represented by such diverse families as *Poaceae* (grasses and bamboos), which have greatly reduced and modified flowers; *Cactaceae* (cactuses), which have spines instead of leaves and very showy flowers; and *Lemnaceae* (duckweed), which has a highly reduced plant body sometimes comprising a single leaf with no true roots or stem and the smallest flowers of any angiosperm. Other families include *Asteraceae* (sunflower or aster family), with reduced disc and ray flowers crowded together into *inflorescences* called heads; *Salicaceae* (willow family), a widespread, water-loving family of trees and shrubs with reduced flowers arranged in catkins; and *Orchidaceae* (orchid family), with some of the showiest and most intricate flowers of all, which have extremely numerous and minute seeds.

Economic Importance

Economically, angiosperms have made a profound impact. Essentially all of the world's food crops, from rice, wheat, and corn to other fruits and vegetables, are derived from flowering plants. In fact, it is almost impossible to think of more than a handful of foods or food ingredients from plants that are not flowering plants. The same is true of ornamental plants. Although a few gymnosperms (such as conifers) and ferns are common as ornamentals, most of the remaining plants, even many valued for their foliage rather than their blooms, are flowering plants. The only area where angiosperms do not dominate economically is in forest products, where conifers account for a significantly larger proportion of the harvest, but even there, hardwoods predominate for certain applications.

Medicine has also reaped many benefits from angiosperms. In fact, it was primarily the herbalists, from the Middle Ages to the Scientific Revolution, who expanded humankind's understanding of flowering plants. Knowledge of flowering plants for food and medicine among many indigenous peoples has always been widespread. Modern medicine has capitalized on much of this knowledge and has

Common Dicot (Eudicot) Families

even expanded the search for new medicines. Flowering plants have been the original source of many precursors to modern medicines, including aspirin (willows, *Salix*), quinine (*Cinchona* species), and digitalin and digoxin (*Digitalis* species).

Lifestyle Diversity

Along with the diversity in structure comes a diversity in lifestyles. Most angiosperms are free-living, that is, receiving their primary energy and carbon from photosynthesis and their nutrients from the soil. A few groups of plants receive their energy or nutrients in other ways. Some are *saprophytes*, which receive their energy and carbon from decaying organic material in the soil and their nutrients from other soil components, much like other plants. Some of the best-known saprophytes are in *Ericaceae* (heath family). Their most distinc-

tive feature is that they are either white or some shade of pink or red and are never green. *Monotropa uniflora* (Indian pipes), for example, is a ghostly white and has no chlorophyll.

Parasitism is an alternative for some angiosperms. One well-known parasite is the mistletoe (*Loranthaceae*), popular as a Christmas decoration, which is a branch parasite on trees. Many types of mistletoe have green foliage and therefore receive some of their energy from photosynthesis, but their primary nourishment comes from the host tree. Some species have foliage that is brown or yellow and do not photosynthesize much at all. The seeds of mistletoe are spread from tree to tree when birds eat their berries and defecate the seeds on the branch of another tree. Probably the most unusual

parasite is *Rafflesia*, from Malaysia and Sumatra. It parasitizes species of *Tetrastigma*, a vine that grows on the forest floor and has no stems or leaves of its own. When it blooms it has the largest flowers in the world, and it is often called the corpse flower because it has a very strong odor, like that of rotting flesh.

Other parasites receive varying proportions of their energy and nutrients from their host and conventional means, and when the contributions are nearly equal they are referred to as *hemiparasites*. Hemiparasites are common in *Castilleja* (paintbrushes), and many species invade the roots of other plants to obtain part of their nutritional needs.

A unique approach to obtaining nutrients is represented by *insectivorous plants*, commonly known as *carnivorous plants* These plants use a variety of adaptations for trapping and absorbing nutrients from insects. Sundews (*Droseraceae*) have special glands on their leaves that excrete a sticky fluid that traps insects like flypaper. Pitcher plants (*Nepenthaceae* and *Sarraceniaceae*) have special tubular leaves that resemble cups or pitchers. The inside of the leaves fill with water near the base, and the lip and inside surface of the pitcher are slippery. Once an insect gets inside, it slips into the water at the bottom. Venus's flytrap (*Dionaea*, also in *Droseraceae*) is even more intricate, with leaves specially modified with traps that spring shut when an insect lands or walks on them. There is even an aquatic carnivore, the bladderwort (*Utricularia*), which has saclike leaves with small openings that can close after a small aquatic insect or crustacean is sucked in. Although insectivorous plants do obtain some of their nutrients from insects, they also obtain nutrients from the soil or, in the case of bladderworts, surrounding water.

Angiosperm Classification

Traditionally *Anthophyta* has either been considered as a single class *Angiospermae* or *Magnoliopsida*, with two subclasses, or has been divided into two classes, *Eudicotyledones,* or *Magnoliopsida*, and *Monocotyledones*, or *Liliopsida*. The second of these two options is more commonly accepted by contemporary plant taxonomists, and the two classes are often referred to by the common names dicotyledons or dicots and monocotyledons or monocots, respectively.

The monocot/dicot dichotomy has long been considered a major evolutionary split in the angiosperms. The two classes a differ from each other in a number of ways. Monocots generally have bladelike leaves with parallel venation, whereas dicots more typically have pinnate or palmate venation. Monocots have fibrous root systems without taproots; dicots typically have taproots. The flower parts in monocots occur typically in threes, whereas they occur most often in fours and fives in dicots. Monocots lack cambial secondary growth, which is common in dicots. Monocots have scattered vascular bundles in their stems, as opposed to the more orderly arrangement seen in dicot stems.

It has long been proposed that the monocots branched off from the dicots very early in the evolution of the angiosperms, but until recently it was difficult to sort out the probable events and the resulting classification system that would be needed to reflect them. With the advent of molecular tools, such as deoxyribonucleic acid (DNA) sequencing, the study of early angiosperm evolution is getting much more attention. It has now become clear that, if the classification system is to reflect evolutionary history, *Anthophyta* must be divided into more than just two classes. Currently there is no agreement on how many other classes there should be, but *Monocotyledones* and *Eudicotyledones* will retain most of the taxa. This new approach to the classification of *Anthophyta* has also resulted in changing the common name of the "dicots" to "eudicots," meaning "true dicots."

Many of the remaining taxa not included in the monocots or eudicots are now often referred to as *magnoliids* and are considered to represent taxonomic groups that have branched off from the early angiosperms before the monocot/eudicot split. Some of these groups include the orders *Magnoliales* (which includes *Magnoliaceae*, long considered as having many primitive characteristics), *Winterales*, and *Laurales*. The placement of a few taxa, such as *Ceratophyllaceae* and *Chloranthaceae*, is particularly controversial. With continued analyses of DNA sequences it is hoped that a clearer picture of the relationships among the magnoliids and related taxa will be obtained and a more phylogenetically based classification system can be devised.

ANIMAL-PLANT INTERACTIONS

Categories: Animal-plant interactions; ecology; ecosystems; evolution

The ways in which certain animals and plants interact have evolved in some cases to make them interdependent for nutrition, respiration, reproduction, or other aspects of survival.

Ecology represents the organized body of knowledge that deals with the relationships between living organisms and their nonliving environments. Increasingly, the realm of ecology involves a systematic analysis of plant-animal interactions through the considerations of nutrient flow in *food chains* and *food webs*, exchange of such important gases as oxygen and carbon dioxide between plants and animals, and strategies of mutual survival between plant and animal species through the processes of *pollination* and *seed dispersal*.

A major example of animal-plant interactions involve the continual processes of photosynthesis and cellular respiration. Green plants are classified as ecological *producers*, having the unique ability, by photosynthesis, to take carbon dioxide and incorporate it into organic molecules. Animals are classified as *consumers*, taking the products of photosynthesis and chemically breaking them down at the cellular level to produce energy for life activities. Carbon dioxide is a waste product of this process.

Mutualism

Mutualism is an ecological interaction in which two different species of organisms beneficially reside together in close association, usually revolving around nutritional needs. One such example is a small aquatic flatworm that absorbs microscopic green algae into its tissues. The benefit to the animal is one of added food supply. The mutual adaptation is so complete that the flatworm does not actively feed as an adult. The algae, in turn, receive adequate supplies of nitrogen and carbon dioxide and are literally transported throughout tidal flats in marine habitats as the flatworm migrates, thus exposing the algae to increased sunlight. This type of mutualism, which verges on parasitism, is called *symbiosis*.

Coevolution

Coevolution is an evolutionary process wherein two organisms interact so closely that they evolve together in response to shared or antagonistic selection pressure. A classic example of coevolution involves the yucca plant and a species of small, white moth (*Tegitecula*). The female moth collects pollen grains from the stamen of one flower on the plant and transports these pollen loads to the pistil of another flower, thereby ensuring cross-pollination and fertilization. During this process, the moth will lay her own fertilized eggs in the flowers' undeveloped seed pods. The developing moth larvae have a secure residence for growth and a steady food supply. These larvae will rarely consume all the developing seeds; thus, both species (plant and animal) benefit.

Corbis

Nonsymbiotic mutualism, one kind of animal-plant interaction, can be demonstrated in the often unusual shapes and colorations that flowering plants have developed to attract birds, such as this hummingbird, as well as insects and mammals, for pollination and seed dispersal purposes.

Although this example represents a mutually positive relationship between plants and animals, other interactions are more antagonistic. *Predator-prey relationships* between plants and animals are common. Insects and larger herbivores consume large amounts of plant material. In response to this selection pressure, many plants have evolved *secondary metabolites* that make their tissues unpalatable, distasteful, or even poisonous. In response, herbivores have evolved ways to neutralize these plant defenses.

Mimicry and Nonsymbiotic Mutualism

In *mimicry*, an animal or plant has evolved structures or behavior patterns that allow it to mimic either its surroundings or another organism as a defensive or offensive strategy. Certain types of insects, such as the leafhopper, walking stick, praying mantis, and katydid (a type of grasshopper), often duplicate plant structures in environments ranging from tropical rain forests to northern coniferous forests. Mimicry of their plant hosts affords these insects protection from their own predators as well as camouflage that enables them to capture their own prey readily. Certain species of ambush bugs and crab spiders have evolved coloration patterns that allow them to hide within flower heads of such common plants as goldenrod, enabling them to ambush the insects that visit these flowers.

In *nonsymbiotic mutualism*, plants and animals coevolve morphological structures and behavior patterns by which they benefit each other but without living physically together. This type of mutualism can be demonstrated in the often unusual shapes, patterns, and colorations that more advanced flowering plants have developed to attract various insects, birds, and mammals for pollination and seed dispersal purposes. Accessory structures, called fruits, form around seeds and are usually tasty and brightly marked to attract animals for seed dispersal. Although the fruits themselves become biological bribes for animals to consume, often the seeds within these fruits are not easily digested and thus pass through the animals' digestive tracts unharmed, sometimes great distances from the parent plant. Some seeds must pass through the digestive plant of an animal to stimulate germination. Other types of seed dispersal mechanisms involve the evolution of hooks, barbs, and sticky substances on seeds that enable them to be easily transported by animal fur, feet, feathers, or beaks. Such strategies of dispersal reduce competition between the parent plant and its offspring.

Pollinators

Because structural specialization increases the possibility that a flower's pollen will be transferred to a plant of the same species, many plants have evolved a vast array of scents, colors, and nutritional products to attract *pollinators*. Not only does pollen include the plant's sperm cells; it also represents a food reward. Another source of animal nutrition is a substance called nectar, a sugar-rich fluid produced in specialized structures called nectaries within the flower or on adjacent stems and leaves. Assorted waxes and oils are also produced by plants to ensure plant-animal interactions. As species of bees, flies, wasps, butterflies, and hawkmoths are attracted to flower heads for these nutritional rewards, they unwittingly become agents of pollination by transferring pollen from stamens to pistils.

Some flowers have evolved distinctive, unpleasant odors reminiscent of rotting flesh or feces, thereby attracting carrion beetles and flesh flies in search of places to reproduce and deposit their own fertilized eggs. As these animals copulate, they often become agents of pollination for the plant itself. Some tropical plants, such as orchids, even mimic a female bee, wasp, or beetle, so that the insect's male counterpart will attempt to mate with them, thereby encouraging precise pollination.

Among birds, hummingbirds are the best examples of plant pollinators. Various types of flowers with bright, red colors, tubular shapes, and strong, sweet odors have evolved in tropical and temperate regions to take advantage of hummingbirds' long beaks and tongues as an aid to pollination. Because most mammals, such as small rodents and bats, do not detect colors as well as bees and butterflies do, some flowers instead focus upon the production of strong, fermenting, or fruitlike odors and abundant pollen rich in protein. In certain environments, bats and mice that are primarily nocturnal have replaced day-flying insects and birds as pollinators.

ANTARCTIC FLORA

Categories: Ecosystems; world regions

The harsh climate of Antarctica makes it one of the most inhospitable places on the earth, allowing only a relatively small number of organisms to live there. Permanent terrestrial (land) animals and plants are few and small. There are no trees, shrubs, or vertebrate land animals. Native organisms are hardy, yet the ecosystem is fragile and easily disturbed by human activity, pollution, global warming, and ozone layer depletion.

The Antarctic continent has never had a native or permanent population of humans. In 1998 the United States, Russia, Belgium, Australia, and several other countries signed one of an ongoing series of treaties to preserve Antarctica. The continent is used for peaceful international endeavors such as scientific research and ecotourism.

Terrestrial Flora

There are only two types of flowering plants in Antarctica, a grass and a small pearlwort (*Deschampsia antarctica*). These are restricted to the more temperate Antarctic Peninsula. Antarctic hairgrass (*Colobanthus quitensis*) forms dense mats and grows fairly rapidly in the austral summer (December, January, and February). At the end of summer, the hairgrass's nutrients move underground, and the leaves die. Pearlwort forms cushion-shaped clusters and grows only 0.08 to 0.25 inch (2 to 6 millimeters) per year.

Numerous species of primitive plants, such as lichens, mosses, fungi, algae, and diatoms, live in Antarctica. *Lichens* are made up of an alga and a fungus in a symbiotic (interdependent) relationship. They can use water in the form of vapor, liquid, snow, or ice. Lichens grow as little as 0.04 inch (1 millimeter) every one hundred years, and some patches may be more than five thousand years old. Mosses are not as hardy as lichens and also grow slowly; a boot print in a moss carpet may be visible for years. Fungi are found in the more temperate peninsula, and most are microscopic.

Algae grow in Antarctic lakes, runoff near bird colonies, moist soil, and snow fields. During the summer, algae form spectacular red, yellow, or green patches on the snow. Bacteria are found in lakes, meltwater, and soils. As elsewhere on the earth, bacteria play a role in decomposition. Because of the extreme conditions, they are not always as efficient in Antarctica as they are in warmer climates, and carcasses may lie preserved for hundreds of years.

AQUATIC PLANTS

Categories: Economic botany and plant uses; *Plantae*; water-related life

Aquatic plants are any "true" plants, members of the kingdom Plantae*, that are able to thrive and complete their life cycle while in water, on the surface of water, or on hydric soils.*

Hydric soils develop when the ground is flooded or ponded long enough during the growing season to become anaerobic (depleted of oxygen) in the rooting zone. These soils include organic (peats and mucks) and inorganic (mineral) sediments. Aquatic plants grow in fresh, brackish, and salt water but are most common in fresh water. Their habitats include flowing waters (rivers, streams, brooks), standing waters (lakes, ponds), and *wetlands* (bogs, fens, marshes, swamps), which are categorized as *riverine*, *lacustrine*, and *palustrine* communities, respectively. Wetland plants are sometimes referred to as *helophytes*. Marshes are dominated (that is, more than half covered) by herbaceous species and swamps by woody species. Bog plants are aquatics that grow in acidic organic soils. Fen plants occur in alkaline organic soils.

Aquatic plants (also known as *hydrophytes*, *macrophytes*, and *water plants*) occur throughout the plant kingdom. The term "macrophyte" distinguishes them from microscopic aquatic algae, which are not true plants. Aquatic plants have evolved repeatedly, having more than 250 independent origins by some estimates. They occur occasionally in spore-producing plants such as ferns, liverworts, lycopods, and mosses but are relatively rare among nonflowering seed plants (gymnosperms), with bald cypress (*Taxodium*) a notable exception. Flowering plants (angiosperms) contain the greatest hydrophyte diversity, with more species proportionally in monocotyledons than in dicotyledons. Nevertheless, fewer than 2 percent of flowering plant species are aquatic.

Life-Forms

Regardless of their taxonomic affinities, aquatic plants are often classified ecologically by their life-forms. Categories include the following:

- Floating (*acropleustophytes*), with stems and leaves floating completely on the water surface and stems not rooted in the bottom, such as duckweed (*Lemna*) and water hyacinths (*Eichhornia*).
- Emergent (*hyperhydrates*), with stems and leaves extending mainly above the water surface and stems rooted in the bottom, such as cattails (*Typha*) and reeds.
- Phragmites (*planmergents* or *ephydrates*), floating-leaved, with some or all leaves floating on the water surface and stems rooted in the bottom, such as floating-leaved pondweed (*Potamogeton natans*), water chestnut (*Trapa natans*), and water lily (*Nymphaea*).
- Submersed (*hyphydrates*), with stems and leaves completely under water and stems rooted in the bottom, such as Eurasian water milfoil (*Myriophyllum spicatum*) and wild celery (*Vallisneria*).
- Suspended (*mesopleustophytes*), with stems and leaves completely under water and stems not rooted in the bottom, such as the bladderwort (*Utricularia vulgaris*) and the coontail (*Ceratophyllum*).

Benthophyte and *pleustophyte* are used respectively to differentiate between forms that are either rooted in the substrate or unrooted. Species with elongate, leafy stems are termed *vittate* or *caulescent* (such as coontail). Those with leaves clustered in a basal rosette are *rosulate* (such as wild celery), and those not clearly differentiated into stems and leaves are *thalloid* (such as duckweed). Species whose floating or emergent leaves differ morphologically from their submersed leaves are *heterophyllous* (such as floating-leaved pondweed).

Adaptations

Water plants are anatomically and structurally reduced. Watermeal (*Wolffia*), the world's smallest angiosperm, contains plants only 0.4 millimeter long. Submersed species often lack water-conducting tissue (xylem), mechanical tissue (sclerenchyma), and cuticle. Some lack roots entirely. Support and floatation of underwater stems are accommodated by buoyant tissue (aerenchyma) and extensive air spaces (lacunae) which also transport oxygen throughout the plant. Submersed plants usually possess either highly dissected (compound) or thin, ribbonlike leaves. Some leaves become fenestrate, that is, lacking tissue between the veins. Such leaf shapes increase surface area-to-volume ratios for more efficient nutrient uptake and to reduce damage from water currents.

Floating leaves are normally flat and circular, with stomata on their upper surfaces. They may reach 2.5 meters in diameter (such as *Victoria*). For stability, the stalks (petioles) of most floating leaves are positioned centrally by emargination of the base, as in the water lily, or are peltate by complete fusion of leaf lobes, as in the water shield (*Brasenia*) and *Victoria*. Physiological adaptations enable aquatic plants to tolerate deleterious effects of anaerobic hydric soils.

Reproduction

Most aquatic plants are perennials that reproduce vegetatively (asexually). Species survive winters or other unfavorable periods as intact plants, by dying back to dormant stem apices, by means of modified stems (rhizomes, stolons, tubers), or by use of specialized dormant structures (*hibernacula*) in the sediment. "Winter buds" are a kind of hibernaculum; buds are insulated by normal foliage leaves on shortened internodes. They usually remain attached to the plant. *Turions* are specialized hibernacula that produce modified, morphologically distinct leaves to protect the enclosed buds. Turions always detach from the plant and function as propagules for dispersal. Water plants also disperse vegetatively by fragmentation of stems, which are characteristically brittle, due to the lack of mechanical tissue. Detached stems can establish themselves by production of adventitious roots.

The few aquatic plants that are annuals produce seeds as their dormant stage. Some aquatic annuals also multiply vegetatively by fragmentation during the growing season. Generally, sexual reproduction is rare in submersed species, more common in floating-leaved species, and quite common in emergent species (and annuals).

Pollination in water plants is facilitated by insects (entomophily), wind (anemophily), and water (hydrophily). Most aquatics are insect-pollinated; about one-third of them are wind-pollinated. Less than 5 percent of aquatic species are hydrophilous, with pollen transported on the water surface (ephydrophily) or under the water surface (hyphydrophily). Most marine angiosperms (seagrasses) are hydrophilous.

Seeds, fruits, and vegetative propagules are dispersed locally by water currents and more widely by waterfowl. Waterfowl transport propagules in plumage, in mud adhering to their feet, and by excretion of seeds consumed as food. Many water plants are distributed broadly, with some species achieving worldwide distributions.

NOAA/National Estuarine Research Reserve Archive

A freshwater pond with large water lilies near Charleston, South Carolina.

Uses

Aquatic plants are important economically. Foods include rice (*Oryza sativa*), which sustains more human life than any other plant on earth. Aquatic plants are important horticulturally as aquarium and water-garden ornamentals. Some aquatic plants, such as the water hyacinth, are invasive weeds that interfere with shipping, irrigation, or recreation and cost millions of dollars to eradicate. The beauty of many water plants, especially water lilies, has inspired art and religion since ancient times.

ARCHAEA

Categories: Bacteria; evolution; paleobotany; taxonomic groups

The domain Archaea *represents a diverse group of prokaryotes originally found in environments once considered to be hostile to life, now known to be widely distributed in nature.*

The cycling of plant nutrients, such as carbon, nitrogen, and sulfur, requires the activity of microorganisms that convert these elements to forms readily available to plants. These microorganisms, which are generally found in both soil and water, include both prokaryotic organisms of the domain *Bacteria* and the domain of prokaryotes called *Archaea*, which play significant roles in nutrient cycling. Along with *Eukarya*, to which protists, fungi, plants, and animals belong, the *Archaea* form one of the three domains of life. The *Archaea* are related to both *Bacteria* and *Eukarya* and, in some respects, appear to be more closely related to *Eukarya*. Biochemical and genetic studies, including information obtained from whole genome sequencing, suggest that *Archaea* may be closely related to an ancestor that gave rise to both *Bacteria* and *Eukarya*. Thus, *Archaea* may provide some insight into the processes that resulted in the evolution of higher lifeforms, including plants and animals.

A Third Domain

For more than fifty years, biologists categorized living organisms into two groups based on their cellular organization and complexity: prokaryotes (originally all classified in kingdom *Monera*), the single-celled organisms whose chromosomes are not compartmentalized inside a nucleus (which include the domain *Bacteria*), and eukaryotes, consisting of all other organisms, whose cells contain a nucleus. In the late 1970's studies on a unique group of microorganisms led investigators to question the accepted classification of prokaryotes. Originally called *Archaebacteria* by molecular biologist Carl Woese and his colleagues in 1977, these microorganisms were isolated from environments characterized by extremes in heat, acidity, pressure, or salinity, and many were found to be able to utilize sulfur and molecular hydrogen as part of their growth process.

Like all prokaryotes, *Archaea* do not have a nucleus. However, in their biochemistry and the structure and composition of their molecular machinery, they are as different from bacteria as they are from eukaryotes. Woese and his colleagues analyzed and compared specific molecules of ribonucleic acid (RNA) present within the ribosome in all organisms, called *ribosomal RNA* (rRNA). Their findings suggested that all extant life is composed of three distinct groups of organisms: the eukaryotes, or domain *Eukarya*, which includes plants and animals, and two different prokaryotes, domains *Bacteria* and *Archaea*. In 1990 Woese and others recommended the replacement of the simple prokaryote/eukaryote view of life with a new tripartite scheme based on three domains: the *Bacteria*, *Archaea*, and *Eukarya*. Since 1990 the three-domain classification has been the subject of considerable debate, and as a consequence, both old and new terminology are used in scientific and popular literature.

Characteristics

Generally, the size and shape of *Archaea* are similar to those of *Bacteria*. They are single-celled microscopic organisms that, in some cases, are motile (capable of self-movement) and may be found in chains or clusters. *Archaea* multiply in the same manner as bacteria: via *binary fission*, budding, or fragmentation. Like *Bacteria*, archaeal chromosomes are circular, indicating the absence of breaks or discontinuities, and many genes are organized in the same fashion as those found in *Bacteria*. On the other hand, the specific chemical composition of *Archaea* plasma membranes and cell walls is unique to the *Archaea* and is quite different from the composition of these structures typically found in either *Bacteria* or *Eukarya*. In fact, the distinctive ether-linked isoprenoid lipids that compose the external membranes of *Archaea* are a hallmark of these microorganisms.

Another unique characteristic of *Archaea* is the composition of the molecular genetic machinery, which is a mosaic of the components found in *Bacteria* and *Eukarya*. For example, the ribosomes (which are responsible for protein synthesis) of *Archaea* resemble the ribosomes of *Bacteria* in shape and composition and are distinct from the ribosomes of *Eukarya*. On the other hand, the enzyme utilized by *Archaea* in the production of RNA, namely RNA polymerase, is quite different from the enzyme found in *Bacteria*. In *Bacteria*, RNA polymerase molecules are composed of four major proteins, while in the *Archaea*, RNA polymerase molecules consist of more than ten proteins and are surprisingly similar to the enzyme found in *Eukarya*. In fact, archaeal RNA polymerase is so similar to the eukaryotic enzyme that combining certain proteins from both archaeal and eukaryotic sources results in a functional enzyme, a manipulation that is not possible with any bacterial RNA polymerases.

Among species of the *Archaea*, there is a variety of metabolic processes that differ greatly from the better-known metabolic routes of *Bacteria* and *Eukarya*. Many of the archaeal pathways used to convert food sources to energy and building blocks for growth involve enzymes having biological activities not found in any other biological systems. In some cases, the enzymes require the involvement of rare metals, such as tungsten. While a requirement for metals in the activity of many bacterial and eukaryotic enzymes is ubiquitous, the use of tungsten appears to be unique to *Archaea*.

Diversity

A fascinating feature of *Archaea* is that they are found in niches that support the growth of few other organisms. These include highly reduced (oxygen-free) environments or very high-temperature environments found near hot springs or undersea hydrothermal vents as well as sites that are sulfur-rich and highly acidic. *Archaea* are also found in highly saline marine environments and hypersaline lakes where the salinity is as much as ten times that in seawater.

Based on the comparison of ribosomal RNA sequences as well as physiological and metabolic characteristics, the *Archaea* have been divided into three subdomains: *Euryarchaeota*, *Crenarchaeota*, and *Korarchaeota*. The *Euryarchaeota* includes members of the *methanogenic* (methane-producing) and halophilic (salt-requiring) *Archaea* as well as many that grow at very high temperature, the thermophilic and extremely thermophilic, or hyperthermophilic, *Archaea*. Representatives of hyperthermophilic *Archaea* are found in the *Crenarchaeota*, which also includes cold-dwelling *Archaea* that have been isolated in association with certain marine sponges. The *Korarchaeota* also includes hyperthermophilic

Archaea, although these were not isolated or characterized as of 2001, but whose presence in hot spring and deep-sea samples has been identified by molecular biological techniques.

Methanogenic *Archaea*

Methane-producing *Archaea* are found in strictly anaerobic environments. They have no tolerance for oxygen: Trace amounts are inhibitory for growth, and too much is lethal. These *Archaea* obtain energy for growth by a process called *methanogenesis*, which results in the conversion of carbon dioxide to methane gas.

Methane production requires several enzymes that use coenzymes unique to methanogenic *Archaea*. The production of methane is of great importance to carbon cycling in many anaerobic environments, and microorganisms that produce this gas have been known for centuries. In 1776 the scientist Alessandro Volta demonstrated that air generated from sediments rich in decaying vegetation, such as those present in bogs, streams, and lakes, could be ignited. It is now known that methanogenic *Archaea* are responsible for generating this "marsh gas."

Because methanogens require an oxygen-free environment for growth, they are found only where carbon dioxide and hydrogen are available and oxygen has been excluded. Thus, methanogens thrive in stagnant water, natural wetlands, paddy fields, and in the rumen of cattle and other ruminants as well as in the intestinal tracts of animals and the hindguts of cellulose-digesting insects, such as termites. Methanogens are also found in hot springs and the deep ocean and are major components of the anaerobic process in waste treatment facilities. It has been estimated that production of methane by the methanogenic *Archaea* may account for almost 90 percent of the total methane released into the atmosphere each year. In addition to playing a role in carbon cycling, several methanogenic *Archaea* are also involved in nitrogen cycling, as they are able to convert molecular nitrogen into organic nitrogen via nitrogen fixation, a process that is shared by only a few prokaryotes.

Thermophilic *Archaea*

Thermophilic *Archaea* live in environments ranging in temperature from 55 degrees Celsius (131 degrees Fahrenheit) to 80 degrees Celsius (176 degrees Fahrenheit). Hyperthermophilic *Archaea* grow at temperatures near or greater than the boiling point of water and as high as 113 degrees Celsius (235 degrees Fahrenheit). These *Archaea* have been isolated from hot sulfur springs, sulfur-laden mud at the base of volcanoes, and near very hot deep-sea hydrothermal vents where superheated water is emitted at very high temperatures under pressure. Species that can use oxygen, as well as those that have no tolerance for oxygen, are known. Many of the anaerobic representatives obtain energy for growth by the metabolism of elemental sulfur.

In addition, many are found in environments that are extremely acidic, including those that are members of *Thermoplasmatales*. This group is noted for its ability to grow at a pH of 2.0 and below (on a scale where pH 7.0 is neutral), which is equivalent to the acid in car batteries. A representative is *Thermoplasma*, which does not possess a cell wall but has

PhotoDisc

Hyperthermophilic Archaea *grow at temperatures as high as 113 degrees Celsius.* Archaea *have been isolated from hot sulfur springs, such as those at Yellowstone National Park.*

a chemically unique structure composed of a lipid-polysaccharide (tetraether lipid with mannose and glucose units) that is distinctly different from the unusual ether-linked lipids found in the membrane components of typical *Archaea*.

Halophilic *Archaea*

The salt-dependent halophilic *Archaea* require extremely high concentrations of salt for survival, and some grow readily in saturated brine, where the salt concentration reaches 32 percent (in seawater it is approximately 3.5 percent) and where very alkaline conditions are not uncommon. Halophilic *Archaea* are found in salty habitats along ocean borders and inland waters such as the Dead Sea and the Great Salt Lake.

The reddish-purple color observed in salt evaporation ponds is due to production of red- and orange-colored carotenoids and other pigments associated with the massive growth of halophilic *Archaea*.

Some halophilic *Archaea* are capable of harvesting light to provide energy for growth by a mechanism that does not involve chlorophyll pigments. Light harvesting by these halophilic *Archaea* is done by a membrane-bound protein called *bacteriorhodopsin* that is equivalent to the mammalian eye pigment *rhodopsin* in both function and structure. Bacteriorhodopsin contains retinal, a purple carotenoidlike molecule used for light trapping. Interestingly, retinal is produced via a pathway that contains many of the same enzymes used for the production of lycopene by tomatoes during ripening.

Window to the Past

The extreme conditions in which *Archaea* are found suggests that these organisms have adapted to environments thought to exist during early life on earth, three billion to four billion years ago. Thus, the *Archaea* might be considered as a window into the past, and they may shed light on the processes involved in evolution as well as their relationships with *Bacteria* and *Eukarya*. In order to survive in their unique environments, *Archaea* possess molecules that withstand heat or cold, acids, salt, and in some cases, pressure—characteristics that are tailor-made for specific applications in molecular biology and biotechnology.

Uses

A number of important applications have been developed as a consequence of studying the *Archaea*. These include the identification of heat-stable enzymes for analyses used in genetic fingerprinting and cancer detection (certain polymerase chain reaction enzymes), the use of halophilic pigments for holographic applications, optical signal processing and photoelectric devices, and methanogenesis as an alternative fuel source.

ARCTIC TUNDRA

Category: Biomes

The Arctic tundra is a biome representing the northernmost limit of plant growth on earth. Arctic tundra has a circumpolar distribution in the Northern Hemisphere, extending from the ice cap southward to the forested taiga of North America, Europe, and Asia. Tundra is also found on islands within the Arctic Ocean and along coastal Greenland.

The term "tundra" was derived from the Finnish word for a treeless or barren landscape. The Arctic tundra biome is located within one of the harshest climates on earth for plant growth, with winter temperatures averaging –34 degrees Celsius (–30 degrees Fahrenheit). The climate is comparatively dry, with annual precipitation of 150 to 250 millimeters (6 to 10 inches). Locked in snow or frozen within soil, the majority of moisture is not available for plant use.

In addition to surviving extreme temperatures and dry conditions, plants must adapt to seasonal variation in available sunlight; winter nights, for example, last twenty-four hours. The tundra's growing season is very short, extending over only about sixty days. Continuous sunlight during warmer months, July and August, contributes to the productivity of tundra plant communities that can yield 227-454 kilograms (500-1,000 pounds) of vegetation per acre. This *biomass* serves as an important food source for caribou, musk ox, and migratory waterfowl. Tundra vegetation is made up of *herbaceous* plants (grasses, forbs, and sedges), mosses, lichens, and shrubs that grow close to the ground, where temperatures are highest. By providing an insulating layer, snowfall is advantageous for tundra plants during cold winter months.

Herbaceous Plants

Rushlike tundra sedges belong to the flowering plant family *Cyperacaeae*. Common to the tundra, cottongrass is really a sedge within the genus *Eriophorum*. Perennial forbs are broadleaf plants that survive winter months as bulbs that are protected below the ground level. During warm months the plants begin to grow rapidly and will develop flowers and seeds when temperatures climb above 10 degrees Celsius (50 degrees Fahrenheit).

Lichens and Low-Growing Shrubs

Acting as a single organism, pioneering lichens growing on rock surfaces represent a symbiotic relationship between fungi and algae. The fungi anchor to the rock, absorbing water directly into their cells, while the algae occupy this moist area, creating food through photosynthesis that is shared with the fungi. Tundra lichens are found in fruiticose (stalklike), crustose (crustlike), or foliose (leaflike) forms.

The heath (*Ericaceae*) family includes several species of shrub, many of which have tough, evergreen leaves. Examples include rhododendron, cranberry, blueberry, and Labrador tea. Another heath, the alpine azalea (*Loiseleuria procumbens*), forms a mat or cushion where several plants clump tightly together.

Adaptations

In many ways tundra vegetation must adapt to many of the same environmental conditions as *grasslands* or *deserts*, such as little precipitation, strong winds, and extreme temperature variations. As a result of the brief growing season, plant reproduction in the tundra must take place rapidly. Other adaptations include compact plant size that protects from cold temperatures, hairy stems that help retain heat, and dark-colored leaves that absorb sunlight. Some plants have hollow stems that require fewer nutrients to grow. A unique adaptation made by the Arctic poppy (*Papaver radicatum*) and mountain aven (*Dryas integrifolia*) allows them to orient their flowers to track the sun's movement across the sky, maximizing solar radiation received.

Although sunlight is usually beneficial to plant growth, some plants such as Arctic algae must implement protective measures to avoid damage from ultraviolet radiation. The green alga *Ulva rigida*, also called sea lettuce, produces amino acids and carotenoid pigments that absorb harmful radiation. Cushion plants grow in tight but low-profile clumps, forming windbreaks that protect them from the cold, and may trap airborne dust and soil used as a source of nutrients. Many tundra plants are capable of carrying out photosynthesis under relatively low light intensities. With short growing seasons, some plants reproduce by budding and division instead of by the creation of seeds. Plants may also store nutrients in *rhizomes*, underground stems that survive after root systems die.

Edaphic Influences

Soils of the tundra are principally thin soils (inceptisols). Contributing to the lack of soil development are cold temperatures that inhibit the growth of soil-producing organisms such as bacteria. The tundra's treeless plain may be interrupted by patterned ground made up of stone polygons, soil circles, or soil stripes. These unusual features are formed by the thrusting action of repeated freezing and thawing in soil that overlies rock or permanently frozen ground called *permafrost*. Impenetrable permafrost that inhibits root system development, rather than cold temperatures, is thought to be responsible for the lack of tree growth in the tundra. Warmer summer temperatures lead to a thaw in permafrost that extends only about a meter below the surface. Ponds and boggy areas form in places where soil above the permafrost melts and cannot move downward, creating a source of moisture for plants.

Environmental Concerns

As a result of growing under harsh conditions, tundra plants are slow to recover from disturbances. Vehicles can destroy tundra plants. Other concerns include oil spillage, damage caused by pipeline construction, and other impacts tied to petroleum production.

ASCOMYCETES

Categories: Economic botany and plant uses; fungi; microorganisms; taxonomic groups

The ascomycetes are fungi (phylum Ascomycota *or* Ascomycotina*) that produce sexual spores in a specialized cell called an ascus. These diverse fungi, with more than thirty thousand species, can be found in almost every ecosystem worldwide. One of the most famous members of the ascomycetes is the truffle.*

Ascomycetes, one of the four phyla of the fungus kingdom, by definition possess an *ascus*, a single cell inside of which sexual spores are produced. The reproductive process has been well documented and occurs when the *dikaryotic mycelium* (the mass of hyphae forming the body) undergoes changes that precede the formation of the ascus. Dikaryotic is the genetic state in which two haploid nuclei are present in the cell. One nucleus is donated by each parent.

The first change occurs when the end cell of a hyphal strand begins to form a small bend. The cell divides into three cells; the outer two cells are haploid, and the middle cell is dikaryotic. The middle cell then elongates, and the nuclei migrate into its center. The two haploid nuclei then fuse to form a single diploid nucleus, which undergoes mitosis and meiosis to form eight haploid nuclei. Cell walls form around the nuclei producing eight haploid *ascospores*. The ascospores are then liberated from the ascus.

The ascus wall determines the kind of dispersal of the spores. Some asci have a thin, single-layer wall, which breaks down to liberate spores. *Unitunicate* asci have a multilayer cell wall with a pore at the end of the ascus. Spore release is active through the pore. *Bitunicate* asci have multilayer cell walls, and release of spores is by the separation of the layers of the cell wall, with the inner layer inflating to several times its normal size and then lifting off of the ascus, allowing the spores to be released. The spores are released into the environment, where they germinate and produce haploid hyphae. The haploid hyphae fuse with compatible haploid hyphae, forming dikaryotic hyphae, and the process begins to repeat itself.

There are five different ways in which asci are formed in nature. First, asci can be produced by exposure to the environment, as are the asci of yeasts or the ascus of the peach leaf-curl pathogen *Taphrina deformans*. With these fungi, the ascospores are released by the breakdown of the ascus wall.

The other four ways of production of asci all take place inside structures made from mycelium, called *ascocarps*. These structures range from totally closed to open, like a cup. The totally closed ascocarps are called *cleistothecia*. Within these, the asci are scattered, and the spores are released by breakdown and decomposition of the fungal tissue.

Ascomycetes as Pathogens

Some members of the ascomycetes are very important plant and animal pathogens, causing serious diseases. One of the more impressive plant pathogens is the ergot fungus (*Claviceps purpurea*). This fungus colonizes the ovaries of grains, such as rye (*Secale cereale*). It produces a mass of mycelium, called a *sclerotium*, which is hard and has a density similar to that of a seed. Because of this, the sclerotia are often found in the threshed grain. Sclerotia contain an accumulation of alkaloids and other secondary metabolites. When the sclerotia are ground into flower and baked into bread, many of these secondary metabolites are passed into the bread. During the Middle Ages this fungus was responsible for a human disease called St. Anthony's Fire. Today, this fungus is used for the natural production of a coagulant which is used in medicine.

Image Not Available

Another group of plant pathogens are the powdery mildews. There are several hundred species of these fungi, which produce a powdery spore mass on the outer surfaces of plant leaves. If a leaf is infected before it has expanded, it will remain small and puckered and may drop from the plant. The powdery mildews are superficial and send hyphae through the leaf cuticle into the epidermis. The fungus then grows over the surface of leaf, giving it a powdery appearance. During the winter, the fungus produces cleistothecia on the surface of the leaf. Powdery mildew can occur on most plant species and can be very damaging to crop and ornamental plants.

Economic Uses

Truffle is a generic term for fungi that form mycorrhizae (a symbiotic association) with the roots of various trees. The fungus grows into the roots and helps the plant tolerate stress, providing the plant with increased absorption of phosphorus from the soil. In return, the plant gives the fungus metabolites that it needs for growth. These fungi then produce fruiting bodies, either in the soil or upon the surface of the soil. The truffles are produced in the soil up to a depth of 1 foot.

Truffles can be located in the soil using a trained sow or dog that is able to sniff out the volatile chemicals that are produced. However, it is important to note that edible fungi such as truffles can often be mistaken for highly toxic fungi and should never be gathered or eaten without expert identification. Truffles are used as condiments and are able to impart unique aromas and sensations to food. They are shaped like small balls, varying in size from that of a pea to that of a golf ball. Truffles are only produced in nature and therefore fetch high prices. The price of truffles depends on the species, size, and freshness. Prices of the famous French Black Périgord truffle (*Tuber melanosporum*) can reach into thousands of dollars per kilogram (2.2 pounds). In the United States, the Oregon white truffle is quite appealing and can be found in the Pacific Northwest.

Morels (*Morchella*) are another choice edible ascomycete. Shaped like a little hat sitting upon a stalk, they are brown in color and have an appealing aroma. They add flavor to any food and are a favorite of many wild animals.

Scientific Uses

Some members of the ascomycetes are used for genetic studies. Such is the case for *Neurospora*, a common fungus found growing on soil and organic matter and one of the first organisms to be found in an area after a fire. As with all ascomycetes, there are two compatible mating types, which makes for easy genetic study. Using spore characteristics of shape, color, and texture, it is possible to see how mitosis and meiosis occur in the ascus by determining the placement of the spores. The fungus is readily mutated, which further enhances genetic study.

ASIAN AGRICULTURE

Categories: Agriculture; economic botany and plant uses; food; world regions

Land constraints and growing population and urbanization throughout Asia underscore the need for environmentally sound technologies to sustain agricultural growth.

The first agricultural revolution occurred in Asia and involved the domestication of plants and animals. It is believed that *vegeculture* first developed in Southeast Asia more than eleven thousand years ago. In vegeculture, a part of a plant—other than the seed—is planted for reproduction. The first plants domesticated in Southeast Asia were taro, yam, banana, and palm. *Seed agriculture*, now the most common type of agriculture, uses seeds for plant reproduction. It originated in the Middle East about nine thousand years ago, in the basins of the two major rivers of present-day Iraq, the Tigris and the Euphrates. Wheat and barley were probably the first crops cultivated there. Although many plants were domesticated simultaneously in different parts of the world, rice, oats, millet, sugarcane, cabbage, beans, eggplant, and onions were domesticated originally in Asia.

Asia supports about 60 percent of the global population on only about 23 percent of the world's agricultural land. As a result, Asian agriculture is far more intensive than on any other continent. Despite the population pressure on arable land, Asia has made remarkable progress in agricultural productivity. Between 1966 and 1995, wheat production grew 5.5 percent annually, and rice production 2.2 percent. In Asia as a whole, food production has outpaced the growth of population. In most Asian countries, particularly in the low-income countries of South Asia, per-capita food availability has risen.

Agrarian Structure

Most people in Asia are farmers, owning an average of about 2.5 acres (1 hectare) of land per family. Topographic and climatic conditions, to a large extent, determine farm size. Agricultural potential is limited in Nepal, for example, because of the Himalaya Mountains, and in Saudi Arabia because of the Arabian Desert. In these countries, average farm size is larger relative to countries like Bangla-

Leading Agricultural Crops of Asian Countries with More than 15 Percent Arable Land

Country	*Products*	*Percent Arable Land*
Armenia	Fruit, vegetables	17
Azerbaijan	Cotton, grain, rice, grapes, fruit, vegetables, tea, tobacco	18
Bangladesh	Rice, jute, tea, wheat, sugarcane, potatoes	73
Burma (Myanmar)	Paddy rice, corn, oilseed, sugarcane, pulses, hardwood	15
India	Rice, wheat, oilseed, cotton, jute, tea, sugarcane, potatoes	56
Israel	Citrus and other fruits, vegetables, cotton	17
Korea, South	Rice, root crops, barley, vegetables, fruit	19
Lebanon	Citrus, vegetables, potatoes, olives, tobacco, hemp (hashish)	21
Nepal	Rice, corn, wheat, sugarcane, root crops	17
Pakistan	Cotton, wheat, rice, sugarcane, fruits, vegetables	27

desh, which contains a vast, fertile floodplain and receives abundant rainfall.

Another feature of Asian agrarian structure is the inequitable distribution of farmland. For example, in India more than 25 percent of cultivated land is owned by less than 5 percent of farming families. Farm holdings in most Asian countries are highly fragmented, and tenancy is widespread. Fragmentation of farms inhibits agricultural mechanization, and land consolidation efforts have had limited success in most Asian countries.

Most Asian farmers are subsistence farmers, cultivating crops for family consumption. Almost all farm operations are done manually or with the help of draft animals. Exceptions are found in Japan, South Korea, and Taiwan, where small-scale equipment similar to garden tractors is widely used. Only recently have Asian farmers started to use chemical fertilizer; for water, they largely depend on rain. As a result, yields are low, which compels farmers to cultivate the land intensively. Double-cropping is the norm; some farmers grow three crops a year. Therefore, only a small fraction of the arable land in humid regions of Asia remains fallow. Farming is labor-intensive, and the extended family is the main source of labor. This helps to explain why family size is generally large in agrarian countries of Asia.

Rice and Wheat

The coastal areas and inland river valleys of East, Southeast, and South Asia are the agricultural cores of the continent. More than half of the crop area of these regions is used to cultivate food crops such as rice and wheat. Rice is the principal food crop of all Asian countries located east and north of India and for the people of southern and eastern India.

Rice is the staple food of more than half of the world's population, and 90 percent of it is grown in coastal and deltaic plains and in the river valleys of Monsoon Asia. This region encompasses a broad geographic area characterized by a distinctive climate, stretching from Japan in the east, through Indonesia in the south, and west to Pakistan. Rice farming there is practiced mostly at the subsistence level, using traditional methods.

Wheat is the primary food crop of northern and western India and all Asian countries located west of India. People of the wheat-producing region consume rice as a secondary staple. Eighteen of the twenty-five top rice-producing countries of the world are in Asia. India has the largest area devoted to rice cultivation of the world's countries, but China is first in total production. Indonesia and Bangladesh rank third and fourth in world rice production.

With the exceptions of Japan, South Korea, China, and Taiwan, yields of all crops—particularly rice and wheat—are low in Asia compared to world standards. Although crop yields increased significantly after 1970, typical yields in Asia remained low for several reasons: Fertilizer use and the area under irrigation are among the lowest in the world. Also, most Asian farmers practice traditional farming methods, where high yields are atypical. Another major obstacle to increasing crop yields is the preponderance of small farms. Because small farms do not have access to assured irrigation and cannot afford modern agricultural inputs, their average yield is generally much lower than that of medium and large farms.

Slash-and-Burn Agriculture

In the tropical rain forests of Southeast Asia, the mountainous and hilly parts of South Asia, and in southern China, a type of primitive agriculture known as *shifting cultivation* or *slash-and-burn agriculture* is practiced. Shifting cultivators plant different crops, such as rice, corn, millet, yams, sugarcane, oilseeds, potatoes, taro, vegetables, and cotton, on one site. These farmers must abandon their fields and establish new ones every few years. As a result, a large area of land is required to support a small population. The land devoted to shifting cultivation is declining at a rapid rate worldwide because of the demand for forest resources for other uses.

Dry Agriculture

Farmers in the colder, drier parts of Asia (northeastern China, northern Japan, southeastern East Asia, northeastern Southeast Asia, and the western half of South Asia) and the river valleys of the Middle East practice a system of intensive subsistence agriculture called peasant grain-and-livestock farming, or *dry agriculture*. The dominant grain crops are wheat, barley, sorghum, millet, oats, and corn, while cotton, tobacco, and sugarcane are grown as cash crops. In arid areas, such as the Middle Eastern river valleys, irrigation helps support dry farming. Traditional water-lifting devices, such as the shaduf (a counterweighted, lever-mounted bucket), and the naria (waterwheel), permit limited double-cropping in the dry season near the rivers of the Middle East.

In the arid and semiarid parts of South Asia and the Middle East, and in the dry and cold western two-thirds of East Asia, nomadic herders graze cattle, sheep, goats, and camels. Nomadic herders move from place to place with their livestock in search of forage. As in other places, nomadic herding is declining in Asia.

Mediterranean Agriculture

A distinctive type of subsistence agriculture, called *Mediterranean agriculture*, is practiced along the Mediterranean coast of the Middle East and in the northern part of Turkey that borders the Black Sea. Traditional Mediterranean agriculture is based on wheat and barley cultivation in the rainy winter season. Farmers of this region also cultivate vine and tree crops, such as grapes, olives, and figs, and raise small livestock.

Export Crops

Plantation crops such as tea, rubber, coconuts, and coffee are grown in Asia. Tea is indigenous to China, which is the world's largest producer, fol-

PhotoDisc

An elephant works a rice field in Thailand.

lowed by India, Sri Lanka, and Bangladesh. Tea is Sri Lanka's largest export crop, accounting for about one-third of annual exports by value. Tea is grown in the central highlands of Sri Lanka and in the hilly regions of northeastern India and Bangladesh. Rubber is grown in Malaysia and Indonesia—which account for about 75 percent of total world production—and Cambodia, India, and Sri Lanka. Malaysia, Indonesia, and Sri Lanka are world-leading exporters of coconuts and coconut products.

Green Revolution

A dramatic growth in food production in Asia began with the *Green Revolution* in the late 1960's, particularly for wheat and rice. Cultivation of the new varieties of rice and wheat caused an impressive increase in the use of fertilizer and the expansion of irrigation, particularly the exploitation of groundwater through tube wells. With proper and timely application of fertilizers and water, yields of wheat can be tripled, and yields of rice can be doubled.

Critics of the Green Revolution have concentrated on the negative impacts of increased use of fertilizer and pesticides, which causes surface water pollution. With high-yield seeds, three crops a year can be cultivated. Adopting this practice has two consequences: It causes overuse of land, a major source of land degradation, and it leads to increasing monocultures of rice and wheat, reducing the genetic diversity of food crops.

Without the Green Revolution, feeding current Asian populations at prevailing nutritional standards would have been impossible. New agricultural practices enabled Asia to avoid the famine that was widely predicted in the 1970's. The new rice and wheat varieties also have stimulated agricultural employment, because more people are needed to cultivate, harvest, and handle the increased production.

Throughout Asia, agricultural growth and the increase in food production were somewhat slower in the 1990's than in the 1980's. The opportunity for bringing more land under cultivation has largely been exhausted. Therefore, any increase in crop output will have to come largely from an increase in yields. Rice and wheat yields are still relatively low in many Asian countries, primarily because of low use of modern agricultural inputs. For example, the use of chemical fertilizer in South Asian countries has not reached the levels of neighboring regions.

Demand for fruits, vegetables, meat, fish, milk, and eggs is likely to grow with the increased urbanization and industrialization of Asia. This will reduce the demand for cereal crops. In Japan, South Korea, and Taiwan, consumption of rice has already begun to decline. Increased crop production is required to feed the growing populations of most Asian countries. While increasing agricultural production, Asian policymakers must also promote environmentally sound technologies and implement effective land reforms to address the problems of inequality and poverty caused by landlessness. Better crop management and better management of irrigation water are also needed to sustain agricultural growth in Asian countries.

Forestry

Forests of significant economic importance are found primarily in northeastern East Asia and Southeast Asia. The softwood forests of northeastern East Asia cover most of Japan and parts of North Korea. Trees grown there are used for construction lumber and to produce pulp for paper. Tropical hardwood forests cover all Southeast Asian countries and the south central part of China, several places in India, and the northern part of Iran.

Trees grown in those forests are used primarily for fuel wood and charcoal, although an increasing quantity of special-quality woods are cut for export as lumber. Nearly 80 percent of the world's hardwood log exports in the early 1990's came from Malaysia. Cambodia, Malaysia, Indonesia, the Philippines, Thailand, and Myanmar export large quantities of forestry products.

Overexploitation of hardwoods and conversion of forest lands for other uses have become serious concerns. Rates of forest conversion are most rapid in continental Southeast Asia, averaging about 1.5 percent a year. *Deforestation* has important local, regional, and global consequences, ranging from increased soil and land degradation to greater food insecurity, escalating carbon emissions, and loss of biodiversity. Small-scale, poor farmers clearing land for agriculture to meet food needs and the gathering of wood to be used for cooking account for roughly two-thirds of the deforestation in Southeast Asia. Commercial logging and urban expansion account for most of the remaining deforestation.

ASIAN FLORA

Category: World regions

Asia has the richest flora of the earth's seven continents. Because Asia is the largest continent, it is not surprising that 100,000 different kinds of plants grow within its various climate zones, which range from tropical to Arctic.

Asian plants, which include ferns, gymnosperms, and flowering vascular plants, make up 40 percent of the earth's plant species. The endemic plant species come from more than forty plant families and fifteen hundred genera. Asia is divided into five major vegetation regions based on the richness and types of each region's flora: tropical *rain forests* in Southeast Asia, temperate *mixed forests* in East Asia, tropical rain/dry forests in South Asia, *desert* and *steppe* in Central and West Asia, and *taiga* and *tundra* in North Asia.

Tropical Rain Forests

The Asian regions richest in flora, tropical rain forests, are found in the island nations of Southeast Asia, which extend from Kinabalu in the north to Java in the south, and from New Guinea in the east to Sumatra in the west. In this vast archipelago, the longest island chain between Asia and Australia, are thirty-five thousand to forty thousand vascular plant species. Tropical rain forests grow there year-round because of the region's warm temperatures and plentiful rainfall. The forests contain great varieties of tall trees, some towering 148 feet (45 meters) high. Within any 1-square-mile area, one can see as many as one hundred tree species with no single species dominant.

The rain forests have mostly broad-leafed *evergreens*, with some palm trees and tree ferns. The uppermost branches of the trees form *canopies* that cover and protect the earth below. Because little sunlight penetrates the dense canopies, few shrubs or herbs grow in the rain forests. Instead, many vines, *lianas*, *epiphytes*, and *parasites* are twined on tree branches and trunks. Mangroves fringe the tropical rain forests along the coasts.

Temperate Mixed Forests

Second in floral richness, East Asia's temperate mixed forests contain thirty thousand to thirty-five thousand plant species. This region ranges from Japan in the east to the Himalayan nations (Bhutan, Sikkim, and Nepal) in the west, and from Russia's Amur River Valley in the north to China's Hainan Island in the south. East Asia's temperate weather is similar to the climate of eastern North America, with hot summers and cool winters. From south to north and from the east coasts to lower elevations in mountainous areas in the west, the vegetation changes from evergreen to *deciduous* broad-leafed forests, with dense shrubs, bamboo, and herbs in different layers beneath the forest canopy. The major tree species are of the magnolia, oak, tea, laurel, spurge, azalea, and maple families. Herbs include members of the primrose, gentian, pea, carrot, foxglove, composite, buttercup, and rose families.

The Himalayan range is the point where the regions of South Asia, East Asia, and Central and West Asia join. From the Qinghai-Tibet Plateau in southwest China to the lower areas of the Himalayas, elevation usually is between about 5,000 and 13,000 feet (1,500 and 4,000 meters). Mountains with deep valleys showcase complex, multiple vegetation types—from mixed forests and dense shrubs to alpine meadows in mountain plains. Many *primary seed plants* (gymnosperms and flowering plants), grow there.

Untouched native vegetation in East Asia is usually found only in mountainous or remote areas. On mountains at high elevations, the points where the temperatures are so cold that trees cannot grow form what is called the *tree line*. Near the tree line, only plants related to *coniferous* and *alpine* species grow. Above about 13,000 feet (4,000 meters) in high mountain areas, no vegetation grows. Instead, snowcaps or icebergs exist year-round.

Tropical Rain/Dry Mixed Forests

The third-richest region, tropical rain/dry forests, is found in South Asia, which reaches from the Philippines in the east to Pakistan in the west, and from the Himalayas in the north to Thailand in the south. Twenty-five thousand to thirty thousand species of plants grow there. This region has both tropical rain forests and tropical seasonal dry forests. The tropical rain forest is mainly found in the region's lowlands and the seasonal dry forests in the highlands or mountainous areas. More often, these two types of forests are combined.

The tropical seasonal dry forests usually grow in a climate with wet and dry seasons or under a somewhat cooler climate than the tropical rain forests. The canopy, formed from primarily deciduous broad-leafed species, is much thinner than the canopy in the tropical rain forest, so more sunlight reaches plants below. Many different plant species live together, forming tropical jungles. Tall, thick-trunked trees, colorful orchids, ferns, dense mosses, and twined vines and lianas dominate this vast region. The major components of these kinds of forests are members of the dipterocarpas, sweetsop, laurel, piper, fig, dissotis, akee, gardenia, periwinkle, milkweed, African violet, palm, and aroid families. In central and southern India and in some areas of Pakistan there are tropical *grasslands*, called the *savanna*. Because of the savanna's hot, dry weather, mainly coarse grasses grow there.

Desert and Steppe

The desert and steppe region in Central and West Asia has twenty to twenty-five thousand species of plants. This region stretches from north and northwest China and Mongolia in the east to Turkey in the west, and from Kazakhstan in the north to the Arabian Peninsula in the south. This region's vegetation changes from semidesert or desert to the temperate grassland called the steppe.

Central and West Asia contains the largest desert-steppe landscape in the Northern Hemisphere. Few plant species grow in the steppe and nearly none in the desert. The herbs and few woody plants that grow in these dry areas are members of the grass, pink, mustard, pea, saxifrage, stonecrops, lignum vitae, forget-me-not, and lily families. Because the desert environment is so dry, plant species must be able to survive in the arid weather for long periods of time. Central and West Asia—with its steppe between the desert in the south and coniferous forests in the north—forms one of the world's largest foraging areas, providing food resources for both wild and domestic animals, such as camels, sheep, goats, cows, and horses.

Taiga and Tundra

The poorest region in floral richness, with only about five thousand vascular plant species, is North Asia. This region is primarily Siberia, the eastern part of Russia, reaching from the Ural Mountains in the west to the Bering Strait in the east and from the Arctic Circle in the north to Mongolia and Kazakhstan in the south. The region's weather is temperate, with short, mild summers and long, cold winters. The predominant vegetation in North Asia is *coniferous* (boreal) forest. This region, called the taiga, contains mainly pine, spruce, fir, larch, and some species in the birch, aspen, and willow families. Because the trees there are straight and tall, the taiga provides timber for Russia's forestry industry. Small, perennial herbs and a few types of shrubs grow in the taiga's swamps or marshes.

Farther north is the cooler Arctic area called the tundra. Plants that grow in tundra are resistant to the cold climate. During the summer they complete their life cycle quickly, before winter comes. Tundra plant species are members of such common families as composites, peas, grasses, and reeds. Far beyond the tundra is Arctic ice.

Asia's native plant species provide shelter and food for animals. For example, arrow bamboo and umbrella bamboo, found in the forests of central to southwest China, are the main food of the giant panda. Many plants in Asia also provide food, ornaments, or medicine for humans.

Food Crops

Rice is the main food for humans in Asia, especially in the tropics. In temperate Asia, wheat—one of the world's main food sources—joins rice as a primary food source. Various beans and peas provide plant protein in the human diet and are eaten with vegetables and grains. Asia has many tropical fruit plants, such as the mango, banana, litchi, citrus fruits, and breadfruit. Pears, apples, grapes, peaches, and strawberries are temperate fruits. The kiwi, one of the most nutrient-rich fruits, is cultivated in New Zealand but originally came from central China. The Chinese not only eat kiwi but also make kiwi wine. Palm dates are another important fruit in West and Southwest Asia (the Arabian Peninsula). Vegetables grown in Asia include various cabbages, lettuce, onions, garlic, celery, carrots, soybeans, cucumbers, and squash. Ginger originally came from Asia.

Soybean oil is the major cooking oil in Asia. Although soybeans are native to Asia, they have become the biggest crop grown in the United States. According to the U.S. Department of Agriculture, in 1999 U.S. farmers harvested 73.3 million acres of soybeans, 2.3 million acres more than corn and 18.6 million acres more than wheat. Another oil plant, the sunflower, is grown in temperate Asia. In tropical Asia, people use mustard oil, palm oil, cotton oil, and peanut oil. In Central and West Asia, the most popular oil is olive oil. Many other foods people enjoy throughout the world are native Asian plants, for example, tea and coconuts. Black pepper and sugarcane also are grown in tropical Asia.

Ornamental and Medicinal Plants

Many of Asia's plant species have great ornamental value. Azaleas, dogwood, primroses, camellias, peonies, roses, lotus, daisies, cherries, and begonias are frequently planted in gardens. Ornamental conifers from Asia include pines, spruces, cedars, junipers, umbrella pines, and yews. Thousands of wildflowers originating in Asia include poppies, snapdragons, slippers, columbine, trillium, marigolds, buttercups, gentian, lilies, bluebells, and violets. Europeans who explored Asia centuries ago brought ornamental plants back to their home countries. As a result, many of these plants are now grown throughout the world. The world's largest flower, *rafflesia*, grows in the tropical rain forests of Sumatra. In full bloom, the flower's diameter is about 3 feet (1 meter).

Plants make up a large part of traditional Chinese medicine, which has been practiced for thousands of years. Today, some of these plants are used in alternative medicine in the West. They include ephedra, eucommia, cinnamon, ginseng, sanqi, and ginkgo.

Scientific Value

Botanists view the region ranging from central China to the Himalayas to the northern part of South Asia as a key area for research into the origin of flowering plants. Native plant species in Asia are numerous; botanists also study Asian plants that are relics of ancient times, from millions of years ago, as well as fossils.

Ancient species include such gymnosperms as the dawn redwood of central China. Dawn redwood is similar to California's redwood and giant sequoia. Another fossil-like tree is East Asia's ginkgo. This species not only has great ornamental value but also has great commercial value as an alternative medicine. Ginkgo trees are also dust-resistant, which makes them a favorite in urban landscaping and the ornamental industry. Other Asian plants such as the magnolia and its allied families may represent the most primitive flowering plants.

Introduced Plants

Asian flora today also includes introduced plant species from other parts of the world that play important roles in people's lives. For example, the rubber tree of South America is cultivated in tropical Asia. This tree produces raw material for the natural rubber industry, in which Asia is the largest producer in the world. Cacao, a tree species that provides the basis of chocolate, was introduced from tropical America. Corn, one of the most common crops in Asia, was introduced from America several thousand years ago. Several vegetables, including the tomato, potato, eggplant, green pepper, hot pepper, and chili (all from the nightshade family), were introduced to Asia long ago. Peanuts, originally from Brazil, are also cultivated in Asia.

Coffee, an increasingly popular beverage in Asia, came originally from Africa. An introduced fruit is the pineapple, which came from tropical America but now is popular in tropical Asia. The sweet potato, from Central America, is also cultivated in Asia. Tobacco is another crop introduced to and cultivated in Asia. It originally came from tropical America, but its yield in China has made that nation a leading producer.

Impact of Human Activity

Asia's highly diversified flora have contributed positively to the daily lives of people around the world, but the demands of a rapidly growing population are a constant threat. *Deforestation*, *overgrazing*, and *urbanization* have become major reasons for heavy losses of Asian flora, especially in South and East Asia. In China alone, eight key plant species were added to the first-class protection list in the Red Book of 1992 (equivalent to the U.S. endangered species list). Among them are the Chinese silver fir, dawn redwood, and ginseng. These plants only grow in several isolated locations and are rare in their original range. As natural vegetation is cut for farming, grazing, or simply for cooking and heating fuel, fewer plants remain. Although scientists from around the world have worked on this problem for decades, the situation has not improved.

ATP AND OTHER ENERGETIC MOLECULES

Categories: Cellular biology; physiology

All cells contain a small collection of compounds called common intermediates. These compounds transfer energy between processes that produce energy and those that require it. The best-known example is adenosine triphosphate (ATP), but several other esters play a similar role. Because of their function in energy transfer, cells are absolutely dependent on such compounds, and a cell deprived of ATP will quickly die.

ATP (adenosine triphosphate) is the principal energy carrier for most life processes, including those carried out within plant cells, including the chemical reactions of photosynthesis. The central importance of *common intermediates* (energy-transferring compounds) is evident in the effects of various chemicals that prevent ATP synthesis. For example, in cells that require oxygen, ATP synthesis is coupled to the oxidation of food-related molecules. Cyanide and carbon monoxide interfere with such cellular oxidations and, therefore, completely prevent the ATP synthesis that is coupled to them. Thus, these compounds are extremely toxic, and cells are often killed by them in a matter of seconds.

Free Energy

Many biological processes require energy in order to occur; that is, they are not by themselves spontaneous. Examples of energy-requiring processes include contraction of muscle, beating of cilia, emission of light by fireflies, heat production by birds and mammals, and establishment of a voltage difference across a cellular membrane. The synthesis of proteins from their constituent amino acids, the formation of complex membrane fats, and, indeed, the synthesis of many other chemical compounds are not themselves spontaneous and, hence, require energy. Energy-dependent processes and reactions are referred to as *endergonic*.

On the other hand, many processes in organisms are spontaneous and do occur without any other energy source. Most of these are chemical reactions, and all such reactions, being spontaneous, can serve as energy producers. For this reason, they are often called *exergonic*. They can, in principle, provide energy for events, such as the secretion of nectar or aromatic oils by flower cells, that require it. The form of that energy is *free energy*.

There is a change in free energy, measured in units of calories or joules, associated with any chemical reaction or physical event. If the change in free energy is more than zero, the process requires energy to proceed; if less than zero, it yields energy and is spontaneous. Thus, the numerical value for the change in free energy of a reaction is very useful for predicting whether it can occur.

The other important aspect of free energy is that its numerical value can be altered by changing the concentrations of the chemicals reacting or the product formed when the chemicals react. For example, consider a hypothetical biochemical reaction in which A is the reactant and B is the product. Imagine that this reaction is not spontaneous; therefore, its free energy change is greater than zero, and it does not "go." Yet, though A becoming B is not spontaneous, its reverse, B becoming A, is. In other words, if a reaction in one direction has a change in free energy greater than zero, the reverse reaction will have one less than zero. Most important, if a reaction in a particular direction is not spontaneous, it can be made to "go" anyway, simply by increasing the concentration of the reactant until the change in free energy falls below zero. This is called the *law of mass action*: Adding more reactant (or subtracting some of the product) will often force a reaction. Stubborn reactions can be pushed or pulled.

Spontaneous Reactions

A second law explains completely how spontaneous reactions can provide energy for those that are not spontaneous. It is called the *law of the common intermediate* and states that reactions can be linked, as far as energy is concerned, by the products of one reaction serving as the reactants of another. Here are two biochemical reactions:

$$A + B \leftrightarrow C + D$$

$$X + D \leftrightarrow Y + Z$$

If the first reaction is spontaneous, with a change in free energy less than zero, it produces a substantial amount of C and D. The second reaction would not normally be spontaneous (with its positive change in free energy), but notice that D, the product of the first reaction, is a reactant in the second. When the two reactions are together in the same cell, the buildup of D tends to push the second reaction, reducing the difference in free energy between reactants and products. In other words, the energy produced by the first reaction is being transferred to the second reaction, allowing it to occur. In this case, D is the common intermediate that connects the two.

ATP

In organisms, the sum of all chemical reactions is called *metabolism*. All the systems of reactions that require energy are called *anabolism* and those producing it, *catabolism*. Anabolism and catabolism are tightly linked by common intermediates. A good example of a common intermediate is ATP. Using ATP as an example, it can be seen that the linkage between anabolism and catabolism is a two-way street. ATP is synthesized from adenosine diphosphate (ADP) and phosphate, with the required energy often coming from light (photosynthesis) or from the oxidation of foods (respiration). When ATP is used to provide energy for muscle, for example, it is broken down by hydrolysis to ADP plus phosphate. Thus, the product of catabolism (ATP) is utilized in anabolism, and the products of anabolism (ADP plus phosphate) are utilized in catabolism to regenerate ATP. Thus, the role of ATP is cyclic.

Most common intermediates are *phosphate esters* such as ATP, although a few are *thioesters*. It was once thought that such ester bonds were somehow unusual, perhaps containing an abnormally large amount of available free energy. They were often called high-energy bonds. In fact, these ester bonds are not particularly abnormal in their energy; there are many esters with much more energy—compounds that are not important common intermediates. Apparently, the reason that so few compounds have evolved as links between catabolism and anabolism is that their chemical structures are unique in enabling them to participate readily in both.

It appears likely that a very early common intermediate in ancient cells was not ATP but pyrophosphate, which is simply two phosphates hooked together by an ester bond. Apparently, cells evolved the central role for ATP at a later stage. In all these cases, when the energy of a common intermediate is utilized in an anabolic reaction, it is by means of a *hydrolysis reaction*, the breaking of an ester bond by the addition of water. In many instances, the hydrolysis occurs in more than one step, but it is a hydrolysis, nevertheless, and the free energy that matters in such cases is the free energy of the hydrolysis.

Other Intermediary Compounds

ATP usually gets the most attention, which is proper, because evolution, over the long run, appears to have exhibited the same preference. There are, however, a few other compounds that serve as common intermediates. Several are quite similar to ATP, with a ring-shaped organic part and three phosphates attached in series at one end. The organic parts are a little different, however, and the compounds have different names, with abbreviations such as GTP, UTP, and ITP. These compounds, which are, with ATP, termed *nucleoside triphosphates*, are readily interchangeable with ATP. For example, ATP can be manufactured from ADP by a phosphate transfer reaction:

$$ADP + GTP \leftrightarrow ATP + GDP$$

In addition, pyrophosphate, a common intermediate in early cells, transfers energy today in a variety of plant, animal, and bacterial species. In some organisms, pyrophosphate is made (and used) under conditions in which it is, for whatever reason, difficult to make ATP. A few reactions use energy from the hydrolysis of acetyl phosphate, which can be chemically described as a derivative of acetic acid (the active ingredient of vinegar) with a phosphate attached. Also, a number of thioesters, esters with sulfur in place of oxygen, are important common intermediates; they are often large, complicated molecules.

Finally, one may wonder why ATP and similar compounds have as large negative free energies as they do. A complete answer would involve advanced chemistry, but one factor is both important and readily understood. When ATP is hydrolyzed,

$$\text{ATP} + \text{water} \leftrightarrow \text{ADP} + \text{phosphate}$$

both of the products happen to be negatively charged. It is well known that unlike charges attract each other and like charges repel. Therefore, the two products are driven apart from each other, and they are unlikely to react together to produce a back reaction. Thus, the reaction tends to go well in the direction of ADP and phosphate but not the reverse. Another way of saying it is that the reaction is highly spontaneous, or that the reaction exhibits a solidly negative change in free energy, making such compounds good candidates for energy transfer.

Discusses high-energy compounds and coupling between different chemical reactions.

AUSTRALIAN AGRICULTURE

Categories: Agriculture; economic botany and plant uses; food; world regions

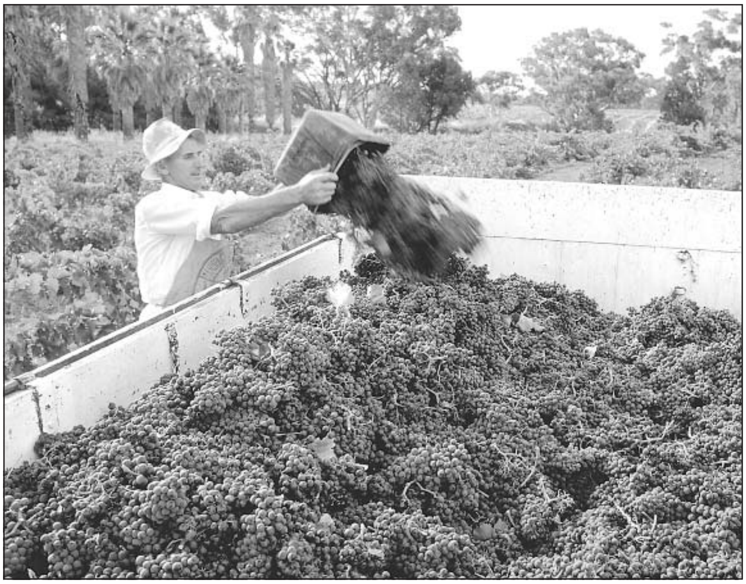
Agriculture is an important part of Australia's economy. Australia's exports were overwhelmingly agricultural products until the 1960's, when mining and manufacturing grew in importance.

Agriculture occupies 60 percent of the land area of Australia, but much of this is used for open-range cattle grazing, especially in huge areas of the states of Queensland and Western Australia. Only 5 percent of Australia's agricultural land is used for growing crops. Western Australia and New South Wales have the largest areas of cropland. The limited area suitable for growing commercial crops is limited mainly by climate, because Australia is the world's driest continent.

Annual rainfall of about 20 inches (500 millimeters) is necessary to grow crops successfully without irrigation; less than half of Australia receives this amount, and the rainfall is often variable or unreliable. Years of drought may be followed by severe flooding. High temperatures throughout most of Australia also mean high evaporation rates, so rainfall figures alone are not a good guide to the feasibility of agriculture.

Australian soils usually require the application of fertilizer to grow crops successfully. The east coast of Australia is suitable for growing sugarcane,

Selected Agricultural Products of Australia



Australia has 242,060 acres of vineyards and more than one thousand wineries.

while the cooler southern parts are suited to growing wheat. Irrigation has opened up large areas of drier land to agriculture, especially for growing fruit, but *salinization* (the buildup of salt in the soil) has become a major problem in some areas, especially near the mouth of the Murray River. Major agricultural plant exports from Australia are wheat and sugar. Other important agricultural exports are fruits, cotton, rice, and flowers.

Wheat

Long the most important crop of Australia, wheat is produced in the Wheat Belt, a crescent of land just west of the Eastern Highlands, or Great Dividing Range, which extends from central Queensland through New South Wales to Victoria, as well as in the south of South Australia and southwest Western Australia. More than 120,000 farms in Australia grow grains, and wheat is the principal crop on some 25,000 farms. The average Australian wheat farm is family-owned and has an area of 3,700 acres (1,500 hectares). Crops are rotated, usually because of low soil fertility.

Australian wheat is planted during the winter, which is much milder than winter on the prairies of North America. Harvesting begins in September in the warm state of Queensland and moves south to Victoria and Western Australia by January. Australian wheat is high in quality and low in moisture, so it is easy to mill. Wheat crops are frequently affected by drought; another problem is Australia's markets, because the nation competes with the United States in wheat export.

When the British first came to Australia, convicts planted wheat on a government farm in what is now inner Sydney. They had difficulty growing wheat because of poor soils, unfamiliar climate, and inexperience, causing fear of widespread hunger. As settlement spread beyond the coastal plain and into the interior, wheat production rose dramatically. The rapid increase in population after the gold discoveries of the 1850's also led to increased demand for wheat. Australia began exporting wheat in 1845 and is now the world's fourth-largest exporter of wheat.

Sugar

Sugarcane is grown in a series of small regions along the tropical coast of Queensland, extending slightly across the border into northern New South Wales. A warm, wet climate is required for successful cultivation of sugarcane, so it is confined to parts of the coastal plain with good, deep soils and reliable rainfall. Australia is the world's third-largest exporter of sugar. Sugar is grown on more than six thousand small, individually owned farms. Until the 1960's, cane was cut by hand. Now it is harvested mechanically and taken by light rail to a nearby mill. There are twenty-five mills in Queensland and three in New South Wales.

Fruit

Fruit growing has a long history in Australia and is strongly influenced by climatic considerations. In Queensland, tropical fruits such as bananas, pineapples, mangoes, and papaya (called pawpaw in Australia) are cultivated. In the cooler south, apples, peaches, apricots, cherries, and grapes are grown.

Grapes are grown for eating and are dried as raisins, but more important is wine production, especially in the Barossa Valley (South Australia), Hunter Valley (New South Wales), Margaret River area (Western Australia), and the Murrumbidgee Irrigation Area and Riverina. John Macarthur, the founder of the Australian wool industry, established the first commercial vineyard, in New South Wales. Later European settlers planted vineyards in Victoria and South Australia. In the 1960's modern plantings and production methods were introduced. Australia has 242,060 acres (98,000 hectares) of vineyards and more than one thousand wineries. Wine is an important export for Australia, with the European Union purchasing 60 percent of wine exported.

Other Agricultural Products

Cotton is grown in drier interior parts of northern New South Wales and in part of central Queensland. Cotton is usually grown in conjunction with sheep farming, on family farms. Indonesia is the major customer for Australian cotton. Rice has been grown commercially in Australia since 1924, using irrigation. New South Wales is the main producer, where the Murrumbidgee Irrigation Area dominates rice production. Australia exports most of its rice crop and in 1999 was the world's eighth-largest exporter of rice. Oats are grown where the climate is too cool and too moist for wheat. In Australia, this is in the interior southeast with a small area in Western Australia. This state and New South Wales are the biggest producers of oats, which is used mainly for livestock fodder.

Other agricultural products of Australia include barley; grain sorghum; corn, called maize in Australia; vegetables, including potatoes, peas, tomatoes, and beans; oil seeds such as sunflower; soybeans; and tea and coffee in northern Queensland. Australia is a major producer of honey, with more than eight hundred commercial apiarists. Blossoms of the eucalyptus tree produce distinctive-tasting honey, which is sold mainly to European Union countries.

AUSTRALIAN FLORA

Category: World regions

Australia broke off from the supercontinent Pangaea more than fifty million years ago, and the species of plants living at that time continued to change and adapt to conditions on the isolated island. This led to distinctive plants, differing from those of the interconnected Eurasian-African-American landmass, where new immigrant species changed the ecology.

Many species of plants in Australia are found nowhere else on earth, except where they have been introduced by humans. Such species are known as endemic species. This distinctiveness is the result of the long isolation of the Australian continent from other landmasses. Australian vegetation is dominated by two types of plants—the eucalyptus and the acacia. There are 569 known species of eucalypts and 772 species of acacia. Nevertheless, a great deal of botanical diversity exists throughout this large continent.

Climate and Ecology

Climate is a major influence on Australian flora, and the most striking feature of the Australian environment as a whole is its aridity. Nutrient-poor soils affect the nature of Australia's vegetation, especially in arid areas. Half of the continent receives less than 11.8 inches (300 millimeters) of rainfall per year; small parts of Australia receive annual rainfall of 75 inches (800 millimeters). Therefore, forests cover only a small percentage of Australia. A close correlation exists between rainfall and vegetation type throughout Australia. Small regions of tropical *rain forest* grow in mountainous areas of the northeast, in Queensland. In the cooler mountains of New South Wales, Victoria, and Tasmania, extensive temperate rain forests thrive.

More extensive than rain forest, however, is a more open forest known as *sclerophyllous forest*, which grows in the southern part of the Eastern Highlands in New South Wales and Victoria, in most of Tasmania, and in southwest Western Australia. A huge crescent-shaped region of woodland vegetation, an open forest of trees of varying height, with an open canopy, extends throughout northern Australia, the eastern half of Queensland and the inland plains of New South Wales, and to the north of the Western Australian sclerophyllous forest.

Beyond this region, the climate is arid, and shrubs, forbs (smaller herbaceous plants), and grasses predominate. The tropical north of inland Queensland, Northern Territory, and a smaller part of Western Australia have extensive areas of *grassland*. Much of Western Australia and South Australia, as well as interior parts of New South Wales and Queensland, are *shrubland*, where grasses and small trees grow sparsely. In the center of the continent is the desert, which has little vegetation, except along watercourses.

Eucalypts

Many people familiar with the song "Kookaburra Sits in an Old Gum Tree," may not realize that *gum tree* is the common Australian term for a eucalyptus tree. When the bark of a eucalyptus tree is cut, sticky drops of a transparent, reddish substance called *kino* ooze out. In 1688 the explorer William Dampier noticed kino coming from trees in Western Australia and called it "gum dragon," as he thought it was the same as commercial resin. Kino is technically not gum, as it is not water-soluble.

The scientific name *Eucalyptus* was chosen by the first botanist to study the dried leaves and flowers of a tree collected in Tasmania during Captain James Cook's third voyage in 1777. The French botanist chose the Greek name because he thought that the bud with its cap (*operculum*) made the flower "well" (*eu*) "covered" (*kalyptos*). The hard cases are commonly called gum nuts.

The more than five hundred species of eucalypts in Australia range from tropical species in the north to alpine species in the southern mountains. Rainfall, temperature, and soil type determine which particular eucalypt will be found in any area. Eucalyptus trees dominate the Australian forests of the east and south, while smaller species of eucalyptus grow in the drier woodland or shrubland areas. It is easier to mention parts of Australia where eucalypts do not grow: the icy peaks of the Australian Alps, the interior deserts, the Nullarbor Plain, and the tropical and temperate rain forests of the Eastern Highlands.

The scientific classification of the eucalypts proved difficult to European botanists. Various experts used flowers, leaves, or other criteria in their attempts to arrange the different species into a meaningful and useful taxonomy, or classification scheme. George Bentham eventually chose the shape of the anthers—the part of the *stamen* that holds the pollen—together with fruit, flowers, and nuts.

A simpler classification of the eucalypts, commonly used by foresters, gardeners, and naturalists, arranges them into six groups based on their bark: gums have smooth bark, which is sometimes shed; bloodwoods have rough, flaky bark; ironbarks have very hard bark with deep furrows between large pieces; stringybarks have fibrous bark that can be peeled off in long strips; peppermints have mixed but loose bark; boxes have furrowed bark, firmly attached. This system was devised in 1859 by Ferdinand von Müller, the first government botanist of the Colony of Victoria and the father of Australian botany.

A eucalyptus forest in Victoria, Australia.

Many of the native plants of Australia, along with eucalypts, show typical adaptations to the arid climate, such as deep taproots that can reach down to the water table. Another common feature is small, shiny leaves, which reduce transpiration. Eucalyptus leaves are tough or leathery and are described as sclerophyllous. Sclerophyllous forests of eucalypts cover the wetter parts of Australia, the Eastern Highlands, or Great Dividing Range, and the southwest of Western Australia. The hardwood from these forests is generally not of a quality suitable for building, so areas are cleared and the trees made into wood chips that are exported for manufacture of newsprint paper. This has been a controversial use of Australian forests, especially where the native forest has been cleared and replaced with pine plantations.

The southwest corner of Western Australia has magnificent forests featuring two exceptional species with Aboriginal names, *karri* and *jarrah*. Karri is one of the world's tallest trees, growing to 295 feet (90 meters) tall. This excellent hardwood tree is widely used for construction. The long, straight trunks are covered in smooth bark that is shed each year, making a colorful display of pink and gray. These forests are now protected. Jarrah grows to 120 feet (40 meters) in height and is a heavy, durable timber. It was used for road construction in the nineteenth century, but now the deep red timber is prized for furniture, flooring, and paneling.

During the nineteenth century, Australia could also claim to be home to the world's tallest trees, the mountain ash. The tallest tree, which observers claimed was 433 feet (132 meters) high and with the top broken away, was felled in 1872. The tallest accurately measured tree was 374 feet (114 meters) high.

The most widely distributed of all Australian eucalypts is the beautiful river red gum. These trees grow along riverbanks and watercourses throughout Australia, especially in inland areas; their spreading branches provide wide shade and habitat for many animals. Koalas eat leaves from this tree. In the song "Waltzing Matilda," Australia's unofficial national anthem, a man camps "under the shade of a coolabah tree." This word might apply to any eucalypt, but it is most likely a river red gum.

In drier interior areas and in some mountain areas, there are more than one hundred smaller species of eucalypts that are known by the Aboriginal name *mallee*. These many-trunked shrubs have underground lignotubers, roots that store water. Much of this marginal country was cleared for farming, creating a situation similar to that of the 1930's Dust Bowl in the United States. In the dry Australian summers bushfires are a great danger in the mallee and in any eucalyptus forest. The volatile oils of the eucalyptus trees can lead to rapid spread in the tree crowns, jumping across human-made firebreaks. On the other hand, several Australian trees not only can survive fires but actually require fire for their seeds to germinate. Eucalypts have been introduced to many countries, including Italy, Egypt, Ethiopia, India, China, and Brazil, and they are common in California, where they have been growing as introduced trees for 150 years.

Acacias

These plants are usually called *wattles* in Australia, because the early European convicts and settlers used the flexible twigs of the plant for wattling, in which twigs are woven together, making a firm foundation for a thatched roof or for walls. The walls are then covered inside and out with mud. This style of building, known as wattle-and-daub, was common throughout Australia in pioneering days.

Wattles frequently have masses of colorful flowers, usually bright yellow. One species is the national flower of Australia. Other interesting acacias include the mulga, which has an attractive wood.

Rain Forests

Although rain-forest vegetation covers only a small area of Australia, it is exceptionally varied and of great scientific interest. Neither of the two general types of rain forest found in Australia has eucalypts. Rain forests are located along the Eastern Highlands, or Great Dividing Range, where rainfall is heavy. In small areas of tropical Queensland, where rainfall is also heavy, true tropical rain forest is found. The flora are similar to those in Indonesian and Malaysian rain forests. The tropical rain forest contains thousands of species of trees, as well as lianas, lawyer vine, and the fierce *stinging tree*, whose touch could kill an unwary explorer. Toward the north of New South Wales, a kind of subtropical to temperate rain forest grows. Cool, wet Victoria and Tasmania have extensive areas of temperate rain forest, where only a few species dominate the forests. Arctic beech trees are found, as well as sassafras and tall tree ferns.

Sclerophyllous Forest

This is the typical Australian *bush*, which grows close to the coast of New South Wales, Victoria, and Tasmania. The bright Australian sun streams down through the sparse crowns and narrow leaves of the eucalypts. As the climate becomes drier, farther inland from the coast, the open forest slowly changes to a shrubbier woodland vegetation.

Grasslands

Moving farther inland, to still drier regions, woodlands give way to grasslands, where cattle are raised for beef in the tropics, and sheep are raised for wool in the temperate areas. Before Europeans came to Australia, there were native grasslands in the interior—tropical grasslands in the monsoonal north, and temperate grasslands in the south and southwest. Kangaroo grass and wallaby grass once grew in the temperate interior of New South Wales, but much of this has been cleared for agriculture, especially for wheat farming. Mitchell grass is another *tussock grass*, which grows in western Queensland and into the Northern Territory. Cattle and sheep graze extensively on this excellent native pasture.

The most common grassland type in Australia is dominated by *spinifex*, a spiky grass that grows in clumps in the arid interior and west. Even cattle cannot feed on spinifex grass, so this ecosystem is less threatened than most other grasslands. The northern grasslands are dotted with tall red termite mounds; those that are aligned north-south for protection from the hot sun are built by so-called magnetic termites.

Other Trees and Plants

Many people think that *macadamia* nuts are native to Hawaii, which produces 90 percent of the world's crop, but in fact, the tree is native to Australia. It was discovered by Ferdinand von Müller in 1857 on an expedition in northern Australia. Müller named the tree after his Scottish friend, John Macadam. The trees were introduced to Hawaii in 1882.

Cycads are plants from an ancient species which still thrive in Australia. The *Macrozamia* of North Queensland is a giant fernlike plant. Similarly old are the *Xanthorrhea* grass-trees, which used to be called "blackboys." A single spearlike stem rises from a delicate green skirt on this fire-resistant species.

In northwest Australia, the *baobab*, or bottle tree, can be found. This fat-trunked tree collects water in its tissue. One is said to have served as a temporary prison. The only other baobabs are found in Africa, a reminder that these continents were once joined. *Bottlebrush* is an Australian shrub with colorful flowers that has become popular with gardeners in many parts of the world.

Extinct and Endangered Plants

Human activities in Australia have led to the extinction of more than eighty species of plants, and the list of endangered plants contains more than two hundred species. Many nonnative species have been introduced to Australia by Europeans. Some have become pests, such as the blackberry in Victoria, the lantana in north Queensland, and water hyacinth, found throughout the continent. There are 462 national parks in Australia, as well as other conservation areas, where native flora are protected.

Aboriginal Plant Use

The Australian Aborigines used plants as sources of food and for medicinal purposes. Food plants included nuts, seeds, berries, roots, and tubers. Nectar from flowering plants, the pithy center of tree ferns, and stems and roots of reeds were eaten. Fibrous plants were made into string for weaving nets or making baskets. Weapons such as spears, clubs, and shields, as well as boomerangs, were made from hardwoods such as eucalyptus. The bunya pine forests of southeast Queensland were a place of great feasting when the rich bunya nuts fell.

AUTORADIOGRAPHY

Category: Methods and techniques

Autoradiography produces an image formed by a substance's own radioactivity when exposed to a photographic film. This technique is often used for investigation of biological processes.

In 1896 Antoine-Henri Becquerel was working with rocks containing uranium ore. By chance, he put one rock sample into a dark drawer on top of a box of unexposed photographic film. When the film later was developed, it showed a clear outline of the uranium rock. Evidently, some radiation had been emitted from the rock, penetrated through the wrapping paper, and exposed the film inside. An autoradiograph, that is, an image produced by radioactivity, was visible on the film. Autoradiography, much refined, is now a valuable technique for investigating biological processes.

Hungarian chemist Georg von Hevesy pioneered the use of radioactive tracers in biological research in the 1920's, and two developments in the 1930's greatly expanded their use. First was the discovery of *induced radiation* by Frédéric Joliot-Curie and Irène Joliot-Curie, which raised the exciting possibility that artificially created radioactivity could be induced in almost any element found in nature. The second development was the invention of the *cyclotron*. The cyclotron beam was used to bombard various elements to produce new *radioactive isotopes*, including radioactive sodium, potassium, sulfur, and iron. After 1950 radioactive hydrogen and carbon also became available as *tracers*, allowing organic molecules such as carbohydrates and proteins to be labeled.

Macroautoradiography

Whole-body autoradiography has been widely used to trace the routes of molecules in *metabolism*. First, a radioactive tracer is administered to an organism by ingestion or injection. After a period of time, individual samples of tissue are removed and pressed directly against X-ray film for several days, to expose the film wherever the radioactivity has become concentrated. The film is then developed and viewed, frequently with the aid of a microscope. This process has been used to trace the uptake of nutrients by plants from the soil into the leaves or buds. Experimentation with whole organisms is called *macroautoradiography*.

Microautoradiography

A refinement of this methodology, called *microautoradiography*, has been developed for studying subcellular structures, even those as small as individual strands of deoxyribonucleic acid (DNA). Much interesting information has been learned about the mechanisms of cell division and other processes in cell biology. The cells being studied are given a nutrient solution containing molecules that have been labeled, usually with radioactive tritium, carbon, or phosphorus.

After a period of incubation, some cells are transferred to a glass slide. The slide is dipped into a liquid photographic emulsion containing light-sensitive silver bromide, which clings to the slide in a thin layer. The slide with the cells covered by emulsion is then placed into a light-tight box for several days to allow time for radioactive decay. The beta particles from tritium cause the photographic emulsion to become exposed.

The emulsion is then developed and fixed as any photographic negative would be. The developer washes the soluble silver bromide away and leaves behind the insoluble grains of silver, which show up as small black dots. A stain may be applied to show the outlines and structures within. Finally, the cell is examined with a microscope. Autoradiographs typically show the black dots of exposed silver grains against a faint background of the surrounding cell structure. When higher magnification and resolution are desired, an electron microscope can be used.

In some studies, the radioactive nutrient is supplied to the cell for a short time interval, perhaps only a few minutes. This procedure is called *pulse-labeling*. Only those molecules that are being freshly synthesized in the cell during the "pulse" will incorporate radioactive atoms. Autoradiography will then show which cells were active.

When autoradiography is applied to chromosomes or other subcellular structures, the matter of resolution becomes very important. For high resolution to be obtained, the radioactive particles should have a short range within the photographic emulsion; the black dots of silver in the developed film should pinpoint the source of radioactive decay as precisely as possible. Tritium works very well because it emits low-energy beta particles, which travel only a few millimeters in the emulsion, producing a well-localized image on the film. Radioactive carbon 14 emits higher-energy beta particles, so the silver grains in the film are more diffuse and the resolution is not as high.

Autoradiography and Electrophoresis

Autoradiography also has been very useful in biochemistry research when combined with the methodology of *electrophoresis*. Living cells are exposed to radioactively labeled amino acids, which are gradually absorbed into the proteins. For electrophoresis, the cells are transferred to a gel to which a voltage has been applied. The protein molecules will diffuse along the gel and be sorted out by their relative molecular weights. A photographic emulsion then is placed over the gel. Radioactivity from the proteins exposes the film, producing an image with black spots that show the distances that the different molecules drifted in the gel. The relative molecular weight of complex molecules that contain many thousands of atoms can be determined in this way.

One commercial catalog of radioactive materials lists many hundreds of organic chemicals that have been labeled with radioactive tritium. The other most common radioactive isotopes used for autoradiography are carbon 14, phosphorus 32, and sulfur 35. A large inventory of labeled chemicals has become available for the continuing use of radioactive tracers in biological research.

Applications

Autoradiography has been used in biology on the macroscopic level to study the uptake of radioactive tracers by both plant leaves and animal organs. Since the 1960's the technique has been applied to successively smaller structures, such as individual cells, chromosomes and organelles within a cell, strands of DNA, and protein molecules. It is easier to understand the microscopic applications after first looking at a large-scale example.

In one experiment, bean plants were grown in a nutrient solution containing radioactive phosphorus. The phosphorus moved from the roots to the leaves as expected, shown by an autoradiograph of a leaf pressed against photographic film. When the bean plant is allowed to continue growing in a nonradioactive solution, autoradiography shows that radioactive phosphorus is withdrawn from older leaves and translocated to new leaves and buds. Evidently, nutrients not only travel up from the roots but also move around the plant. In another experiment, a solution containing phosphorus was sprayed directly onto the leaf surface and was shown to migrate away from it. Redistribution of nutrients on an even larger scale takes place in deciduous trees, where as much as 90 percent of some minerals are withdrawn from leaves before they fall.

Practical Applications

In agricultural research, the effectiveness of herbicides, insecticides, and fertilizers is studied to determine which ones can increase productivity without causing serious environmental problems. Radioactive phosphorus can be used in this regard to study plant metabolism. The uptake of iron or zinc from the soil and their circulation in a plant can be studied to ascertain the effect of soil acidity and chemical form. Sometimes the presence or absence of other elements can inhibit translocation of an essential nutrient. New plant growth regulators may move from one plant through the soil to a nearby untreated plant. Autoradiography is an important analytical technique for observing the route of micronutrients and discovering what factors can change their mobility in a plant.

The sequence of bases in DNA molecules can be decoded by using electrophoresis combined with autoradiography, and the study of DNA sequences is crucial to research in many diverse areas of biology. Although alternatives to using autoradiography in DNA sequencing are now common, autoradiography is still a standard technique used in many other aspects of molecular biology.

Prescott, David M. *Cells*. Boston: Jones and Bartlett, 1988. A college-level textbook written by a past president of the American Society for Cell Biology. The technique of combining autoradiography with high-resolution electron microscopy is described, with diagrams included. Replication of the DNA molecule in a chromosome and RNA synthesis in the cell nucleus are shown in a sequence of photographs.

Wharton, John, and Julia M. Polak, eds. *Receptor Autoradiography: Principles and Practice*. New York: Oxford University Press, 1993. A practical guide to the methodology and application of autoradiography. Numerous examples illustrate both the benefits and the potential pitfalls of the technique. Although it concentrates on uses of autoradiography in animal and human subjects, the introductory chapters cover general topics that should be of interest to botanists.

BACTERIA

Categories: Bacteria; medicine and health; microorganisms; taxonomic groups

The earliest organisms to appear on earth, bacteria form one of the three domains of life in the three-domain system. They are structurally the smallest, physiologically the simplest, and ecologically the most widespread and abundant of all living organisms.

Although only a few thousand species are known, Bacteria are often extremely abundant; a handful of soil or a spoonful of the organic muck at the bottom of a pond may hold several million bacteria. So tiny are these smallest of living organisms that a quarter of a million of them can be squeezed into the period at the end of this sentence. Bacteria are undoubtedly the most widely distributed of all organisms in nature. They occur everywhere: in soil, water, and in the air, as well as within the bodies of virtually all plants and animals.

Bacteria represent the earth's earliest, and in many ways the earth's simplest, living organisms. Fossils of bacteria have been found in rocks estimated at 3.5 billion to 3.7 billion years old. Thus, bacteria predate eukaryotic cells by at least a billion years.

Although small and simple, bacteria are ecologically and economically among the most important of all living organisms. They are the major organisms of decay and decomposition, fermentation, and nitrogen fixation. Activities such as spoiling of food, rotting of flesh, decomposition of plants, and causing of disease are all evidence of bacterial activity; although the smallest, bacteria are hardly the safest of organisms. While the vast majority of bacteria are harmless or helpful, a small percentage causes serious and often fatal diseases in humans, other animals, and plants.

Algae and Bacteria

Bacteria are traditionally included in botany studies because they show a number of structural and physiological similarities to algae. One group, the blue-green bacteria (formerly called the blue-green algae), contain chlorophyll and manufacture food via photosynthesis. The bacterium *Prochloron* exemplifies the prochlorophytes, which are a group of photosynthetic bacteria that have chlorophylls *a* and *b* and carotenoids, which are precisely the same pigments that are found in green algae and plants. Other similarities to plants include flagella, found in some bacteria, that are similar to the paired flagella found in some algae but unlike the flagella characteristic of some of the simplest animals, the protozoa.

Characteristics and Classification

All bacteria are single-celled prokaryotic organisms (a prokaryote is a cell that lacks a nucleus). Traditionally, there are two groups of prokaryotic bacteria, the *Archaea* or *Archaebacteria* (ancient bacteria), and the true bacteria, which are classed as *Bacteria* or *Eubacteria*. Both groups comprise minute organisms that vary in size from about 0.2 to 10 micrometers in diameter. In comparison, eukaryotic cells range from about 10 to 100 micrometers in diameter.

Bacteria number some four thousand to five thousand species, but evidence based on recent deoxyribonucleic acid (DNA) studies indicates that many more species probably await identification. Part of the problem in discovering new species of bacteria is their lack of sexual reproduction, which is often an important criterion used in identifying species in other organism groups.

Known bacteria are classified on the basis of shape, DNA or ribonucleic acid (RNA) arrangements, locomotion, pigments, and staining properties. Taxonomists increasingly rely on DNA and RNA comparisons to identify new species and determine relationships among bacteria.

In the five-kingdom classification scheme, all bacteria are placed in the kingdom *Monera*, which consists of all of the prokaryotic animals. In the three-domain classification of life, the bacteria are placed in the domain *Bacteria*, while the other group of prokaryotes, the *Archaebacteria* (ancient, simple bacteria thought to represent earliest forms of life but now limited in distribution) are placed in the domain *Archaea*. All other living organisms, including the protistans, fungi, plants, and animals, are classed in the domain *Eukarya* (because they are formed by eukaryotic cells, that is, cells that have a nucleus).

Structure

Bacteria are single-celled organisms encased within a cell wall and lacking a central nucleus. They have a relatively homogenous cytoplasm devoid of membrane-bound organelles, such as Golgi bodies, endoplasmic reticulum, mitochondria, or plastids, but sites along the cell membrane perform some of these organelle functions. Bacteria do have ribosomes for protein synthesis, but these are about half the size of ribosomes that are found in the eukaryotic cells of higher plants and animals.

The nucleic acid of bacterial DNA occurs as a single naked, ringlike form called a nucleoid, which is attached to the cell wall. Bacteria also have small rings of DNA called plasmids, which are dispersed within the cytoplasm. The plasmids replicate separately from the nucleoid, suggesting that they were originally separate organisms that were somehow incorporated into the bacterial system.

The cell walls of bacteria help maintain shape and provide rigid protection. Unlike cell walls of plants, which are composed mostly of cellulose, bacterial cell walls contains *peptidoglycans*, which consist of large amino acid molecules cross-linked to molecules of polysaccharides. Antibiotics, such as penicillin, work by inhibiting cell wall formation and repair, thereby destroying the bacterial cell.

Reproduction

Most bacterial reproduction is asexual, with individual cells undergoing a form of mitosis called binary fission, during which the nucleoid and plasmids replicate themselves and then migrate to opposite ends of the dividing cell. The cell wall pinches inward to form an interior wall that separates the dividing cell into the two new daughter cells. Under ideal conditions, binary fission can take place every ten to twenty minutes.

Some species can also exchange genetic material by a process called *conjugation*. Conjugation occurs when two compatible bacteria come into close contact with each other. The cell wall of one of the two bacteria evaginates (grows outward) toward its partner and merges with it to form a hollow, connecting tube called a pilus. When the tube is complete, the DNA segment migrates through the tube to the recipient cell, where it merges with and becomes part of the recipient cell's nucleoid.

Another process of genetic transfer occurs when a bacterium picks up fragments of DNA released by fragmented dead bacterial cells and incorporates the fragments into its own nucleoid. The absorbed DNA increases the genetic variability of the bacterial cell, and new characteristics may result from the interactions of the original genetic material with the newly acquired genetic material.

Shapes

Bacteria occur in three basic body forms, which also serve as a simple method for recognizing and classifying them. *Cocci bacteria* are round, elliptical, or spheroid in shape. Rod-shaped bacteria are called *bacilli*. The third bacterial form, called *spirilla*, are greatly elongated coils and are often corkscrew-shaped. Spiral bacteria are often twisted in the form of a helix or spiral. Cocci bacterial cells may occur in several different forms; in irregular clusters they are called staphylococci, which cause the well-known staph infections. Those in filimentlike chains or beadlike chains are called streptococci, which cause strep throat, while cocci that occur in pairs are called diplococcus. In all of these forms, each cell is completely independent.

Sheaths and Surfaces

Bacteria can develop slimy or gummy capsule-like sheaths around their cells, which, in addition to body shapes and pigments, helps taxonomists to classify them. Outside the cell walls of some bacteria are sticky capsules, or slime layers, that are made up of polysaccharide or protein. These capsules help certain bacteria that cause disease avoid being detected by an animal's immune system.

Some bacteria have a mass of hairlike projections called *pili* covering their surface. They are made of protein, and they generally function to attach to the bacteria of other cells. The tubelike pili found in some bacteria serve as attachment structures that enable the bacteria to remain fastened in place to a suitable substrate. Infectious bacteria, such as the bacteria involved in the sexually transmitted disease gonorrhea, use the pili to attach to the cell membranes of the host, causing infection.

Motility

Although many bacteria are nonmotile, some filamentous bacteria have slender flagella that slowly rotate, propelling them through the medium in a spiraling glide. Flagella help bacteria to move into new habitats, to follow nutrients, and to leave environments that are nonbeneficial. Flagellated bacteria may move toward or away from stimuli, a behavior which is known as a *taxis*. Bacteria that move in response to chemicals in their environment are called chemotactic; those that move toward or away from light are *phototactic*, while *magnetotatic* bacteria respond to the earth's magnetic field. Occurring in aquatic habitats, the magnetotatic bacteria are able to detect the earth's magnetic field using iron crystals within their cytoplasm that act as tiny magnets.

If environmental conditions become unfavorable, some bacteria form structures called endospores, which consist of genetic material along with a few enzymes enclosed inside a thick protective layer. Endospores can survive for long periods of time in extremely unfavorable conditions and are also important dispersal mechanisms because they can travel for long distances in the air or water, then produce new bacteria quickly as soon as they find conditions that are favorable.

Nutrition

A major reason for the success of the bacteria is in their various forms of nutrition. All bacteria are either autotrophic (able to manufacture their own food) or heterotrophic (obtaining food by feeding on plants or animals or their remains). The majority of heterotrophic bacteria are saprobes that obtain food directly from the environment by absorbing it across the cell wall, but some are important parasites that cause disease. Other types of bacteria are *chemosynthetic*, gaining energy through reactions that combine oxygen with inorganic molecules, such as sulfur, ammonia, or nitrite. During the process, they release sulfates and nitrates, crucial plant nutrients, into the soil.

Certain types of bacteria have the ability to break down cellulose, the primary component of plant cell walls. Some of these types of bacteria have formed a symbiotic relationship with mammals called ruminants, which include deer, sheep, and cows. The cellulytic bacteria manufacture and release cellulose-digesting enzymes. They are considered symbiotic because they provide enzymes that enable the animal to digest food it would otherwise be unable to process. In turn, they inhabit an optimum environment deep within the animal's stomach and have nutrients supplied directly to them. Other symbiotic bacteria live in the intestines of humans and other animals. They feed on undigested food passing through the gut and synthesize vitamins K and B_{12}, which are absorbed into the human body.

Another extremely important group of symbiotic bacteria are the *nitrogen-fixing bacteria*, which are one of the very few groups of organisms able to extract molecular nitrogen from the atmosphere and incorporate it in organic compounds. This ecologically and economically important group grows within root nodules—small, rounded clumps that cluster along the roots of certain plants, such as alfalfa, soybeans, lupines, and clover.

Archaea

Classed as either the *Archaebacteria* or *Archaea* and considered to be the most primitive prokaryotes, the *Archaea* differ from true bacteria (in some classification schemes) in the unique structure of their RNA molecules, in lacking muramic acid in their cell walls, and in the production of distinctive lipids. The *Archaea* are usually divided today into three groups: methane bacteria, salt bacteria, and thermophilic bacteria.

Methane bacteria are the most diverse *Archaea*. They are anaerobic organisms that live in the mud of swamps and marshes, in the murky debris of ocean floors, hot springs, lake sediments, animal intestines, sewage treatment plants, and other areas in which free oxygen is not available. Methane bacteria are so-named because they metabolically generate methane gas from carbon dioxide and hydrogen during their energy-producing process.

The salt bacteria, or *halophiles*, are another ancient group that today are mostly confined to life in shallow, saltwater evaporation ponds common in parts of the western United States. When abundant, salt bacteria can give these ponds a distinctive red color. Their metabolism enables them to thrive under conditions of extreme salinity. Salt bacteria carry on simple photosynthesis using a red pigment called bacterial rhodopsin.

The *thermophiles*, or heat-loving bacteria, consist mostly of the sulfur-metabolizing bacteria that

Some Bacterial Diseases of Plants

Bacterium	*Diseases*
Argobacterium	Cane gall, crown gall, hairy root, twig gall
Clavibacter, Rhodococcus	Fasciation, spots, ring rots, tomato cankers, wilts
Erwinia	Blights, wilts, soft rots
Pseudomonas	Banana wilts, bud blasts, cankers, leaf spots, lilac blights, olive galls
Xanthomonas	Black venation, bulb rots, citrus cankers, cutting rots, walnut blights
Rhizobium	Root nodules (legumes)
Streptomyces	Potato scabs

Source: Data are from Peter H. Raven et al., *Biology of Plants*, 6th ed. (New York: W. H. Freeman/Worth, 1999).

thrive in sulfur hot springs, thriving at temperatures ranging from 80 degrees Celsius to 100 degrees Celsius. Some of the thermophilic bacteria are heterotrophic, but most are chemosynthetic and obtain their metabolic energy by forming hydrogen sulfide from elemental sulfur and water.

Cyanobacteria

The true bacteria have muramic acid in their cell walls. The majority are heterotrophic or parasitic, but some very important groups are autotrophic. Two groups of true bacteria are recognized, eubacteria and the cyanobacteria or blue-green bacteria.

The *cyanobacteria*, or blue-green bacteria, formally known as the blue-green algae, are different from true algae as they are prokaryotic, while all of the green algae are eukaryotes. Blue-green bacteria possess chlorophyll *a*, which is also found in green plants. Many blue-green bacteria also have a blue pigment called phycobilin, a red pigment called phycoerythrin, and carotenoids, which help gather light energy for photosynthesis. Their distinctive blue-green color is caused by the combination of chlorophyll and phycocyanin pigments. Blue-green bacteria are the only organisms that can fix nitrogen and produce oxygen at the same time, producing a nitrogenous food reserve called cyanophycin. They are also able to produce and store carbohydrates and lipids.

Blue-green bacteria occur in chains or hairlike filaments. Some form irregular, spherical, or plate-like colonies held together by gelatinous sheaths. These sheaths may be colorless or pigmented with shades of yellow, red, brown, green, blue, violet, or blue-black. Blue-green bacteria lack flagella but move by rotating on their longitudinal axis, which gives them a forward-gliding motion.

Blue-green bacteria occur in soil, in water, on moist surfaces, and in root nodules of plants. They are common in temporary pools and ditches and often very abundant in freshwater habitats. Blue-green bacteria are among the first invaders of newly formed habitats, such as the ash fields around volcanoes and newly opened fissures along deep-sea volcanic ridges and mounts. They are even found in tiny fissures in desert rocks. Some species occur in jungle soils and on the shells of turtles and snails. Others live as symbionts within amoebae, protozoans, diatoms, sea anemones, fungi, and the roots of tropical cycads.

Over billions of years, the photosynthetic activity of blue-green bacteria transformed the oxygen-free early atmosphere into the modern atmosphere, in which oxygen plays such an important role for all higher plants and animals. The accumulation of oxygen in the upper atmosphere produced the high-altitude ozone layer, which shields animals and terrestrial plants from the damaging effects of ultraviolet radiation.

Ecologically, blue-green bacteria form the base of many food chains, especially in freshwater and marine habitats. During the warm months of the year, blue-green bacteria can temporarily become abundant and form floating mats of pond scum that often cover quiet waters of ponds and wetlands in late summer. The sudden increase of populations produce algal blooms (eutrophication) that cause massive die-offs of plant and animal populations because the bacteria populations consume all of the available oxygen in the water, thereby asphyxiating other organisms. In reservoirs and other human water supplies, large populations of blue-green bacteria clog filters, corrode steel and concrete structures, and cause a natural softening of water.

They produce odors and discoloration which sometimes make water unpalatable.

Eubacteria

The *eubacteria* include the unpigmented bacteria, purple bacteria, green sulfur bacteria, and the prochlorophytes. The eubacteria also include two groups of uncertain relationships: the mycoplasmas and the prochlorophytes. Most eubacteria are heterotrophic saprobes that absorb food directly from their environment. Many of these bacteria are extremely important decomposing organisms which, along with soil fungi, are responsible for the decay of all types of organic matter and the release of minerals back into the soil.

A few eubacteria are autotrophic. The purple sulfur bacteria, the purple nonsulfur bacteria, and the green sulfur bacteria all are photosynthetic bacteria that use sunlight energy to fragment hydrogen sulfide into sugar, water, and sulfur. Chemoautotrophic bacteria obtain energy by oxidizing compounds of iron, hydrogen, and sulfur. Some of the true bacteria are parasitic, living in or on living organisms and depending on them for food. Many of these parasitic forms are responsible for serious diseases in humans and other animals.

Beneficial True Bacteria

The number of true bacteria that are beneficial organisms for humans is much greater than the number of disease-causing bacteria. The use of bacteria as biological control agents is typified by *Bacillus thuringiensis* (*B.t.*), bacteria available in garden shops as a spray or powder. Placed on plants, it kills caterpillars and worms. It is sold as a mass-produced, stable, moist dust containing millions of spores of the bacteria. It is harmless to humans, birds, earthworms, and other creatures, except moth or butterfly larvae. When the caterpillar ingests the bacterial spores, they develop into bacilli, which multiply in the digestive tract and paralyze the gut of the worm. The crop pest usually dies as a result of ingestion in two to four days. Other varieties, such as *Bacillus thuringiensis* (variety *israelensis*, or *B.t.i.*),is used to control mosquitoes, while Japanese beetles can be controlled by application of a bacterial power containing *Bacillus popilliae*, which is specific to this beetle.

Other bacteria have important uses in the service of humans. Some are used in bioremediation projects, such as the cleanup of oil spills, sewage treatment plants, and toxic waste dumps. *Pseudomonas capacia*, for example, is used to decompose oil spills. More benefits from bacteria are being developed using genetic engineering techniques.

Bacteria also play a major role in the dairy industry as cultures in the production of buttermilk, acidophilus milk, yogurt, sour cream, kefir, and cheese. Whey, the watery part of milk left in cheese production, is used in the manufacture of lactic acid. Lactic acid from lactate bacteria is also used in the textile industry, in the preparation of laundry products, in leather tanning, and in the treatment of calcium and iron deficiencies.

Bacteria are cultured in vats and used to manufacture chemicals, such as acetone, butyl alcohol, dextran, sorbose, citric acid, some vitamins, and medicinal preparations. Bacteria are also used to cure vanilla pods, cocoa beans, coffee, and black tea. They are used in the production of vinegar, sauerkraut, and dill pickles. Fibers from linen cloth are separated from flax stems by bacterial action. Green plant material is fermented in silos, providing food for livestock through the action of bacteria. Lastly, bacteria producing the amino acid glutamic acid are used to produce monosodium glutamate (MSG), a common food ingredient.

Plant-Pathogenic True Bacteria

Almost all plants are susceptible to a host of bacterial diseases which cause infections, rotting, and death. Economically, the plant-pathogenic bacteria result in enormous losses of crops and other plant products. It has been estimated that about one-eighth of crops are annual losses to plant diseases.

Plant diseases caused by bacteria include galls, rots, wilts, spots, fascination, blights, and soft rots. *Blights* are caused when bacteria invade plant tissues of stems, leaves, and flowers, producing dead and discolored areas of infection. Fruits and vegetables not completely destroyed are sufficiently discolored to be unmarketable. *Soft rots* typically occur in fleshy storage organs, such as potatoes, eggplants, squashes, and tomatoes. Bacterial infections that cause drooping or wilting of plant tissues are called *wilts*. Wilts occur when bacteria colonize xylem vessels, where they block or interfere with water transport, eventually leading to dysfunction and destruction of the plant. *Galls* are plant swellings produced when bacteria and other organisms invade leaves and stems and lodge in parenchyma tissue. The infected tissue swells to produce a gall that encases the bacterial colony.

Human-Pathogenic Bacteria

Although bacteria do provide some benefits with their feeding habits, certain bacteria have feeding habits that threaten the health of humans. The largest threats stem from bacterial infection. These disease-producing bacteria, which are scientifically referred to as pathogens, synthesize toxic substances that cause disease symptoms. For example, bacteria such as *Clostridium tetani* and *Clostridium botulinium*, which cause, respectively, tetanus and botulism, the latter a deadly form of food poisoning. These bacteria produce toxins that attack the nervous system. Such bacteria are known as anaerobes, and they thrive as spores until they are introduced into a desirable environment. Tetanus enters the body through a deep puncture wound, protecting the bacteria from having contact with oxygen. As the bacteria multiply, they release their poison into the bloodstream.

Bacteria can enter the human body from the air. Every time someone coughs, sneezes, or speaks loudly, they produce an invisible spray of saliva droplets containing bacteria. The fluid around these bacteria quickly evaporates, but the bacteria cling to protein flakes that were also expectorated and enter the lungs during breathing. Once inside the lungs, bacteria access the circulatory system, via which they are transported to tissues and organ systems. Legionnaire's disease is caused by a bacterium that lives in small amounts of water in air conditioning systems. It can be transmitted throughout an entire building by airborne particles that are blown through the air conditioning ducts. In a particularly deadly form of infection, anthrax bacilli can be inhaled, lodge in the lungs, and quickly kill the host.

Bacteria also gain access to the body through the ingestion of contaminated food and water. Bacterial infections caused by eating contaminated food are widespread, especially in the less developed countries of the world. Open sewers and unsanitary toilet conditions increase the risk of waterborne bacterial diseases, such as cholera, dysentery, and food poisoning, such as salmonella. Bacteria may also be ingested via improperly stored foods, such as raw chicken, shellfish, and eggs. Once ingested, the bacteria multiply in the intestinal tract and can be passed with urine.

Some bacteria gain access to the body through direct contact. Most of the sexually transmitted diseases are caused by bacteria. Examples include syphilis and gonorrhea. Other diseases, such as anthrax and brucellosis, enter the body through the skin or mucous membranes. Contact anthrax (less deadly than inhalational anthrax, if treated quickly) is a disease of cattle and other farm animals which occasionally infects humans. It is transmitted to workers in the tanning industry who handle hides and wool. Brucellosis is also a disease from farm animals and is transmitted by contaminated milk. It is sometimes called undulant fever and is characterized by a daily rise and fall of temperature associated with the cyclic release of the toxins by the bacteria.

Other bacteria that live in the soil enter the body through wounds. The tetanus or "lockjaw" bacterium, mentioned above, is a common soil organism. Puncture wounds caused by stepping on dirty nails and other sharp devices introduce the tetanus bacteria deep into the body. Once inside, it produces toxins that are extremely powerful. Tetanus is easily controlled by immunizations that are developed from an attenuated horse serum. Some soil bacteria can cause a disease called gas gangrene. These bacteria respire anaerobically in the body and basically destroy tissues while emitting damaging gases (hence their name). If untreated, a serious infection by gas gangrene bacteria can result in the loss of a limb.

Many bacteria gain access to the human body through the bites of insects and other organisms. If an organism transmits a disease-causing organism to a different host, the first organism is called a *vector*. Many of the most feared and deadly of human diseases are caused by bacteria that are transmitted by vectors. Bubonic plague (black death) and tularemia are transmitted by fleas, deer flies, ticks, or lice. Of these, the most famous—and historically the most deadly—is bubonic plague, which is transmitted by fleas of rats and other rodents. Throughout recorded history, periodic visitation of plagues resulted in catastrophic die-off of thousands and even millions of people. The populations of Thebes, Athens, Rome, Vienna, and other early cities suffered and survived many plague years. The most potent plague years were in the late Middle Ages, when nearly a third of the European population succumbed to the bacterial disease. Bubonic plague is still found today in the United

States in ground squirrel populations and other rodents as well.

Mycoplasmas and Other "Small" Bacteria

The *mycoplasmas*, *rickettsiae*, and *chlamydiae* are small and simple prokaryotes that are sometimes collectively labeled "small bacteria." Of these, the mycoplasmas are the smallest of all bacteria and therefore the smallest of all living organisms, since viruses do not qualify as life. Mycoplasmas are distinctive in that, unlike other bacteria, they lack a cell wall. The relationships and diversity of mycoplasmas are still poorly understood, but the mycoplasmas have the distinction of being the smallest known organisms to cause human disease. One form causes a sexually transmitted disease and another, *Mycoplasma pneumonia*, causes a form of pneumonia commonly called walking pneumonia.

The *rickettsiae* are tiny bacteria that were first described by Howard Ricketts in 1909. *Rickettsiae* species are mostly transmitted by animal vectors, such as ticks and lice, and cause typhus and Rocky Mountain spotted fever. The *chlamydiae* are usually considered to be a subgroup of rickettsiae. Some *chlamydiae* are airborne diseases, among them *Chlamydia psittaci*, which causes parrot fever, or psittacosis. Humans are exposed to parrot fever by inhaling the dried droppings or dust from infected birds. Another airborne chlamydial disease of humans is transmitted by respiratory droplets containing *Chlamydial pneumonia*. This causes a mild form of walking pneumonia in humans. Other chlamydia cause sexual diseases which resemble gonorrhea and can result in serious infections of the urogenital tract if undetected or left untreated.

Prochlorophytes

Also designated as the *prochlorobacteria*, these bacteria were discovered in 1976 by Ralph Lewin of the Scripps Institute of Oceanography. The prochlorophytes are of considerable scientific interest because they have photosynthetic pigments (chlorophyll *a* and *b*) that are found in higher plants, thereby hinting at possible relationships between this group of bacteria and higher plants. In structure and characteristics, the prochlorophytes are closely related to true bacteria, however.

Genetic Engineering with Bacteria

Since they are relatively simple organisms that can easily be cultivated in large numbers, bacteria are one of the most important of all groups of organisms used in scientific experiments. As a result, they have been the subject of much genetic engineering, which is the artificial introduction of DNA into bacteria to change their characteristics. Genetic engineering is also called gene splicing and begins with the isolation of plasmid DNA from a bacterium. The DNA molecule is broken up into separate genes or groups of genes by special enzymes called restriction enzymes. The resulting DNA fragments are then mixed with repair enzymes and injected into another bacterium, which absorbs the new genes and functions in a new way under the influence of the new genes or combination of genes.

BACTERIAL GENETICS

Categories: Bacteria; disciplines; genetics; microorganisms; reproduction and life cycles

Bacterial genetics is the study of the genetic material of bacterial DNA, which can provide valuable insights into the process of mutation because of bacteria's rapid rate of reproduction.

Plants were the original candidates for genetic studies, which began in the late 1800's. Studies with animals soon followed; bacteria did not become candidates for such study until the mid-1940's, when adequate technology for handling bacteria developed. Bacteria have become extremely useful organisms for genetic studies since the early 1950's. Two major features of bacteria make them desirable subjects. First, bacterial cells typically divide every twenty minutes. Their rapid rate of reproduction allows a very large number of bacteria to be produced in a short time. This, in turn, provides the researcher with more opportunity to detect the "rare genetic events" of *mutation* or *recombination*. Even more important, unlike all other organisms, bacteria have a single *chromosome* with a single set of *genes*. Thus, genetic modifications are more likely to result in immediately observable changes. In organisms that have multiple chromosomes, a change in a single gene may go undetected because its effect is masked by genes on other chromosomes.

Bacterial DNA

All bacteria have a single circular chromosome, composed of deoxyribonucleic acid (DNA). The DNA is subdivided into specific message areas known as genes, and the chromosome carries from four thousand to five thousand individual genes. For many bacteria, this constitutes the entirety of its genetic information. A number of bacteria, however, have additional DNA in the form of *plasmids*. A plasmid is a small additional circular piece of DNA, independent of the chromosome, which can hold an additional twenty to one hundred genes. Plasmid-containing cells often have several plasmids.

Many researchers have described the plasmid genes as nonessential to the normal activities of bacteria. Under certain circumstances, however, those genes might provide a survival advantage to the possessor. For example, genes for antibiotic resistance are often carried on a plasmid. Normally, antibiotics are not present in the bacteria's environment; such resistance genes would therefore be unnecessary. If the bacteria later were to come into contact with antibiotics, however, having antibiotic-resistant genes would be to their distinct advantage.

Two major types of plasmids exist: F plasmids, or *fertility plasmids*, and R plasmids, or *resistance plasmids*. Both types can carry resistance genes. Only the F plasmids, however, are able to control the formation of a special cytoplasmic tube known as the sex pilus. Cells with the F plasmids are known as F+, or donor cells. Cells without the F plasmids are called F-, or recipient cells.

Conjugation

The plasmid is a prerequisite to one type of genetic exchange, conjugation. During conjugation, the donor cell copies its plasmids and transfers them to a recipient cell to which it has attached itself by means of a sex pilus. The recipient cell can now take advantage of whatever additional genes it has received. If, in the process, it received an F plasmid, it has also become a potential donor cell. Whenever bacterial cells undergo cell division, any plasmids they possess are typically passed on to their progeny. Originally it was thought that conjugation could occur only between members of the same species, but that is not always true. For example, it is now known that some strains of the bacteria responsible for causing gonorrhea, *Neisseria gonorrhoeae*, have received antibiotic-resistant genes from unrelated species of bacteria.

There is one other type of donor cell, the Hfr+, or high-frequency recombinant, cell. Instead of the plasmid remaining independent of the cell's chromosome, it inserts itself into the chromosome. When that plasmid gets ready to copy itself, the chromosomal genes are the first to be copied. Unless the donor and recipient cells are able to maintain direct contact for a fairly long period of time, which almost never occurs, the recipient cell will not receive the plasmid. It will, however, receive numerous chromosomal genes from the donor. Those genes may later be incorporated into the chromosome of the recipient, causing gene replacement.

Not all species of bacteria participate in conjugation. Some rely on transduction as a means of receiving new genetic information. This is how *Staphylococcus aureus* has developed resistance to many antibiotics.

Transduction

There are two types of transduction: generalized and specialized. In both cases, a donor cell becomes infected with a *bacteriophage*, a virus that attacks bacteria. Upon the death of that donor cell, fragments of donor DNA are transferred as the escaping bacteriophage infects another bacterium.

In generalized transduction, a bacteriophage infects a bacterial cell. Shortly after infection, the bacterial chromosome becomes fragmented, and viral components are produced. Later the viral components are assembled to form a complete virus particle. Occasionally during this assembly process, a particle becomes contaminated with fragments of the bacterial chromosome or plasmids. After assembly is completed, the bacterial cell ruptures, allowing the escape of all virus particles. Eventually these virus particles will invade other bacterial cells. Any cells that are invaded by contaminated bacteriophage particles are said to be transduced, because they have received DNA from another bacterium. The DNA received in this manner is strictly random.

Specialized transduction involves what is known as a *latent bacteriophage*. After the initial invasion of a bacterium, the bacteriophage inserts itself into a specific region of that cell's chromosome. At some later time, the bacteriophage removes itself from the chromosome and accidentally takes a few bacterial genes located near its original insertion point. When the bacterial cell finally begins making new bacteriophage components, it behaves as if those particular genes are part of the bacteriophage and replicates them as such. Therefore, all the newly formed bacteriophage particles will contain those bacterial genes. Transduction then occurs when these bacteriophage particles invade other bacterial cells.

Transformation

The final method of genetic transfer is transformation. An extensively utilized organism for such investigation has been *Streptococcus pneumoniae*. The most famous studies involved converting nondisease-causing strains of *Streptococcus pneumoniae* into disease-causing strains. Transformation also occurs in a wide variety of other bacteria. The process of transformation requires that a population of actively reproducing bacteria come into contact with DNA fragments, often from closely related dead bacteria. These DNA fragments are referred to as either naked or cell-free DNA.

Genetic Modification

A small portion of that DNA can be absorbed and utilized by the growing bacteria. These recipients can then take advantage of any usable genes that the fragments might contain, incorporating them into their chromosome in place of their own copies of these genes by the process of recombination.

Conjugation, transduction, and transformation are all mechanisms of genetic change within a bacterial population. These mechanisms allow a specific characteristic to be spread throughout the population within a few hours. A wide number of bacterial genes have been found to be transferred by these methods, including genes that control a bacterium's ability to cause disease, to produce toxins, and to develop resistance to antibiotics and other drugs as well as genes that control a number of other characteristics. The purpose of these mechanisms, as far as the bacteria are concerned, is to enable the bacteria to adapt to changing environmental conditions so that their survival is ensured. Scientists, however, have found ways to adapt some of these mechanisms for human benefit.

Scientists have used the mechanisms of genetic transfer along with new technology from DNA research to perform *genetic engineering* on bacteria. They can use genes and specially engineered plasmids, called plasmid vectors, to make recombinant DNA in the laboratory. Recombinant plasmids can then be used to transform bacteria such as *Escherichia coli* (*E. coli*). The bacteria will treat these recombinant plasmids just like ordinary plasmids, replicating them and, for expression vectors, expressing any genes included in them. In this manner, bacteria can be used to produce a wide variety of products for medicine, agriculture, and industry. Genetic engineering and the products that result from it would not be possible without the knowledge of genetic transfer gained from studies of bacterial conjugation, transduction, and transformation.

Brock, Thomas D., and Michael T. Madigan. *Brock Biology of Microorganisms*. 9th ed. London: Prentice Hall, 2000. The chapter on microbial genetics covers kinds of genetic recombination and gene transfer, plasmids, genetic mapping, and general genetics of eukaryotic microorganisms. There are many illustrations and diagrams. Explanations are in-depth and tend to be technical. Aimed toward an intermediate college-level audience. Supplementary references are listed.

Lim, D. V. *Microbiology*. 2d ed. Boston, Mass.: McGraw-Hill, 1998. The chapter "Information Processing: Mutation and Recombination," discusses such topics as mutation, recombination, and genetic engineering. Includes good illustrations and diagrams. Explanations can easily be followed by anyone with an interest in science. Supplementary references are listed.

Tortora, Gerard J., Berdell Funke, and Christine Case. *Microbiology*. 7th ed. San Francisco: Benjamin Cummings, 2001. Includes discussions of DNA replication in general, general bacterial genetics, gene expression, genetic transfer and recombination, and genetic engineering. The chapter on microbial genetics is especially valuable. Well written and not overly technical, it has illustrations and diagrams. References are listed.

BACTERIAL RESISTANCE AND SUPER BACTERIA

Categories: Bacteria; environmental issues; medicine and health; microorganisms

Inappropriate use of antibiotics has caused bacteria to develop resistance to the most common antibiotics. Bacterial pathogens that have developed resistance to multiple antibiotics that previously could be used to control them are referred to as super bacteria.

Bacteria are the most adaptable living organisms on earth, found in virtually all environments—from the lowest ocean depths to the highest mountains. Bacteria can resist extremes of heat, cold, acidity, alkalinity, heavy metals, and radiation that would kill most other organisms. *Deinococcus radiodurans*, for example, grows within nuclear power reactors, and *Thiobacillus thiooxidans* can grow in toxic acid mine drainage. The term "super bacteria" generally refers to bacteria that have either intrinsic (naturally occurring) or acquired resistance to multiple antibiotics. Because many of the bacteria that acquire resistance are pathogens that previously could be controlled by antibiotics, development of antibiotic resistance is regarded as a serious public health crisis, particularly for those individuals who have compromised immune systems.

History of Antibiotic Use

In the early twentieth century German chemist Paul Ehrlich received worldwide fame for discovering Salvarsan, the first relatively specific prophylactic agent against the microorganisms that caused syphilis. Salvarsan had undesirable side effects because it contained arsenic. In addition, secondary infections resulting from hospitalization were still a leading cause of death in the early twentieth century. Scottish bacteriologist Alexander Fleming discovered a soluble antimicrobial compound produced by the fungus *Penicillium*. Two English scientists, Howard Florey and Ernst Chain, took Fleming's fungus and produced purified penicillin just in time for use during World War II.

Antibiotics such as penicillin are low-molecular-weight compounds excreted by bacteria and fungi. Antibiotic-producing microorganisms most often belong to a group of soil bacteria called *actinomycetes*. *Streptomyces* are good examples of antibiotic-producing actinomycetes, and most of the commercially important antibiotics are isolated from *Streptomyces*. It is not entirely clear what ecological role the antibiotics play in natural environments.

The success of penicillin as a therapeutic agent with almost miraculous effects on infection prompted other microbiologists to look for naturally occurring antimicrobial compounds. In 1943 Selman Waksman, an American biochemist born in Ukraine, discovered the antibiotic streptomycin, the first truly effective agent to control *Mycobacterium tuberculosis*, the bacterium that causes tuberculosis. Widespread antibiotic use began shortly after World War II and was regarded as one of the great medical advances in the fight against infectious disease. By the late 1950's and early 1960's, pharmaceutical companies had extensive research and development programs devoted to isolating and producing new antibiotics.

Antibiotics were so effective, and their production ultimately so efficient, they came to be routinely prescribed for all types of infections, particularly to treat upper respiratory tract infections. When it was discovered that low levels of antibiotics also promoted increased growth in domesticated animals, antibiotics began to appear routinely as feed supplements.

Development of Antibiotic Resistance

The widespread use and, ultimately, misuse of antibiotics inevitably caused antibiotic-resistant bacteria to appear, as microorganisms adapted to new selective pressure. There are now many strains of pathogenic organisms on which antibiotics have little or no effect.

Streptococcal infections are the leading bacterial cause of morbidity and mortality in the United States. In the mid-1970's *Streptococcus pneumonia* was uniformly susceptible to penicillin. However, penicillin-resistant strains were being isolated as early as 1967. A study in Denver, Colorado, showed that penicillin-resistant *S. pneumonia* strains increased from 1 percent of the isolates in 1980 to 13 percent of the isolates in 1995. One-half of the resistant strains were also resistant to another antibiotic, cephalosporin.

Tuberculosis was once the leading cause of death in young adults in industrialized countries, so common and feared that it was known as the White Plague. Before 1990 multidrug-resistant tuberculosis was uncommon. However, by the mid-1990's there were increasing outbreaks in hospitals and prisons, in which the death rate ranged from 50 to 80 percent. Likewise, multiple drug resistance in *Streptococcus pyogenes*, the so-called flesh-eating streptococci, was once rare. There are now erythromycin- and clindimycin-resistant strains.

Many old pathogens have become major clinical problems because of increased antibiotic resistance. The number of resistant isolates in England rose from 1.5 percent in 1989 to more than

The Growth of Antibiotic Resistance

Antibiotic	*Enterococcal Species*	*% of Resistant Bacteria*		
		1995	*1996*	*1997*
Ampicillin	*Enterococcus faecium*	69.0	77.0	83.0
	Enterococcus faecalis	0.9	1.6	1.8
Vancomycin	*Enterococcus faecium*	28.0	50.0	52.0
	Enterococcus faecalis	1.3	2.3	1.9

Note: Measurements taken over a three-year period indicate a general rise in enterococcal resistance to two common antibiotics.
Source: U.S. Centers for Disease Control.

34 percent in 1995. Gonorrhea, caused by *Neisseria gonorrhoeae*, is the most common sexually transmitted disease. Physicians began using a class of broad-spectrum cephalosporin antibiotics called fluoroquinolones because *N. gonorrhoeae* had become resistant to penicillin, tetracycline, and streptomycin. There is now real concern in the medical community that exclusive use of fluoroquinolones, the only antibiotics to which *N. gonorrhoeae* are routinely susceptible, has led to rapidly developing resistance. Even newly discovered pathogens such as *Helicobacter pylori*, which is associated with peptic ulcers, are rapidly developing resistance to the antibiotics used to treat them.

The development of resistance to some antibiotics appears to be linked to antimicrobial use in farm animals. Shortly after antibiotics appeared, it was discovered that subtherapeutic levels could promote growth in animals. One such antimicrobial drug, avoparcin, is a glycopeptide (a compound containing sugars and proteins) that is used as a feed additive. Vancomycin-resistant enterococci such as *Enterococcus faecium* were first isolated in 1988 and appeared to be linked to drug use in animals. Antibiotic resistance in enterococci has been more prevalent in farm animals exposed to antimicrobial drugs. Prolonged exposure to oral glycoproteins in tests led to vancomycin-resistant enterococci in 64 percent of the subjects.

Soap and Water

Even the use of household antibacterial agents contributes to bacterial resistance. Following are some everyday ways to deprive harmful bacteria of the chance to build up resistance and become even stronger, from the October, 1998, article "Antibacterial Overkill" in the *Tufts University Health and Nutrition Letter.*

- Use regular soap for hand-washing and regular dishwashing liquid in the kitchen, rather than cleaners containing an antibacterial agent. Soap loosens bacteria from dishes; running water then rinses them away. For the same reason, frequent hand-washing is the best way to get rid of unwanted bacteria.
- Cleaning products that contain bleach and chlorine disinfect (get rid of bacteria on) surfaces in the kitchen and bathroom. Because these cleaners are not antibacterial agents, however, they will not encourage the growth of resistant bacteria.
- Do not insist on antibiotics for a viral infection, such as the flu; they will not work. Antibiotics attack bacteria but not viruses. At a seminar conducted by Dr. Stuart B. Levy of Tufts University, more than 80 percent of the physicians present admitted to having written antibiotic prescriptions against their better judgment because of patient demands.
- Do not share prescription antibiotics with family or friends. Not knowing the dose they may need, or even whether they need any, could encourage the bacteria in their systems to develop resistance they might otherwise not have had.

How Antibiotic Resistance Occurs

Antibiotic resistance occurs because the antibiotics exert a selective pressure on the bacterial pathogens. This pressure eliminates all but a few bacteria that can persist through evasion or mutation. One reason antibiotic treatments may be prescribed for several weeks is to ensure that bacteria that have evaded the initial exposure are killed. Terminating antibiotic treatment early, once symptoms disappear, has the unfortunate effect of stimulating antibiotic resistance without completely eliminating the original cause of infection.

Mutations that promote resistance occur with different frequencies. For example, spontaneous resistance of *Mycobacterium tuberculosis* to cycloserine and viomycin may occur in 1 in 1,000 cells; resistance to kanamycin may occur in only 1 in 1 million cells; and resistance to rifampicin may occur in only 1 in 100 million cells. Consequently, one billion bacterial cells will contain several individuals resistant to at least one antibiotic. Using multiple antibiotics further reduces the likelihood that an individual cell will be resistant to all antibiotics used. However, it can cause multiple antibiotic resistance to develop in bacteria that already have resistance to some of the antibiotics.

Bacterial pathogens may not need to mutate spontaneously to acquire antibiotic resistance. There are several mechanisms by which bacteria can acquire the genes for antibiotic resistance from microorganisms that are already antibiotic-resistant. These mechanisms include *conjugation* (the exchange of genetic information through direct cell-to-cell contact), *transduction* (the exchange of genetic information from one cell to another by means of a virus), *transformation* (acquiring genetic information by taking up deoxyribonucleic acid, or DNA, directly from the environment), and transfer of *plasmids*, small, circular pieces of the genetic material DNA that frequently carry genes for antibiotic resistance.

Genes for antibiotic resistance take many forms. They may make the bacteria impermeable to the antibiotic. They may subtly alter the target of the antibiotic within the cell so that it is no longer affected. The genes may code for production of an enzyme in the bacteria that specifically destroys the antibiotic. For example, fluoroquinolone antibiotics inhibit DNA replication in pathogens by binding to the enzyme required for replication. Resistant bacteria have mutations in the amino acid sequences of this enzyme that prevent the antibiotic from binding to this region.

New Strategies

The increased use of antibiotics has led to increases in morbidity, mortality caused by previously controlled infectious diseases, and health costs. Some of the recommendations to deal with this public health problem include changing antibiotic prescription patterns, changing patient attitudes about the necessity of antibiotics, increasing the worldwide surveillance of drug-resistant bacteria, improving techniques for susceptibility testing, banning the use of antibiotics as animal feed additives, and investing in research and development of new antimicrobial agents.

Gene therapy is regarded as one promising solution to antibiotic resistance. In gene therapy, the genes expressing part of the pathogen's cell are injected into a patient and stimulate a heightened immune response. Some old technologies are also being revisited. There is increasing interest in using serum treatments, in which antibodies raised against a pathogen are injected into a patient to cause an immediate immune response. Previous serum treatment techniques have yielded mixed results. However, with the advent of monoclonal antibodies and the techniques for producing them, serum treatments can now be made much more specific and the antibodies delivered in much higher concentrations.

There have been numerous reports from Russia about virus treatment for pathogenic infections. Viruses attack cells in all living organisms, including bacteria, but are extremely specific, so that they will not infect more than one type of cell. In essence, virus treatments are a form of *biocontrol*. In virus treatments, the patient is injected with viruses raised against specific pathogens. Once injected, the viruses begin specifically attacking the pathogenic bacteria. Although this technology has not been widely used, it is the subject of growing research.

BACTERIOPHAGES

Categories: Diseases and conditions; genetics; microorganisms

Viruses that attack bacterial cells are known as bacteriophages. Many results gained from studying bacteriophages have universal implications. For example, the physical properties of DNA and RNA are remarkably identical in all organisms, and these are perhaps easiest to study in bacteriophage systems.

Bacteriophages, or phages for short, are viruses that parasitize bacteria. Viruses are an extraordinarily diverse group of ultramicroscopic particles, distinct from all other organisms because of their noncellular organization. Composed of an inert outer protein shell, or *capsid*, and an inner core of nucleic acid—either *deoxyribonucleic acid* (DNA) or *ribonucleic acid* (RNA) but never both—viruses are obligate intracellular parasites, depending to a great extent on host cell functions for the production of new viral particles.

There is considerable variation in size and complexity among viruses. Some have fewer than ten genes and depend almost entirely on host functions. Others are known to contain from thirty to one hundred genes and rely more on proteins encoded by their own DNA. Even the largest viruses are too small to be seen under the light microscope, so studies on viral structure rely heavily on observation with the transmission electron microscope.

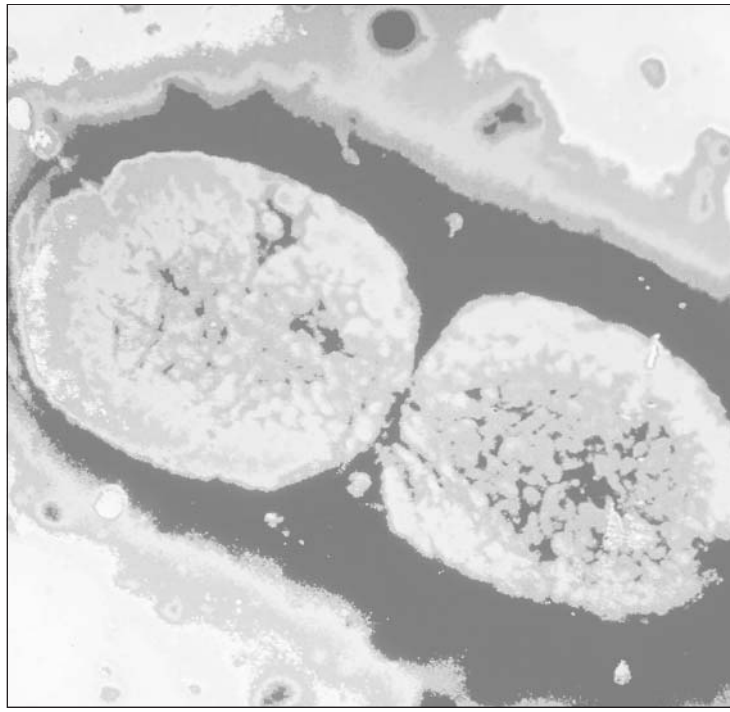
The Study of Bacteriophages

Because scientists know more about the molecular and cell biology of the common bacterium *Escherichia coli* than about any other cell or organism, it is perhaps not surprising that the best-known phages are those that require *E. coli* as a host (*coliphage*). It is not possible to observe phage growth directly (as bacterial growth can be detected by the appearance of colonies on an agar plate), but phage growth can be indirectly observed by the formation of plaques, small clear areas in an otherwise continous lawn of host bacteria growing on a solid growth medium in a petri dish.

Reproductive Cycles

Bacteriophages can multiply by two different mechanisms, termed the *lytic cycle* and the *lysogenic cycle*. Some phages are capable only of lytic growth, while others retain the ability to reproduce by either lytic growth or entry into the lysogenic cycle. In the lytic cycle, phages first attach themselves to specific receptor sites on the host cell wall. The phage nucleic acid (DNA or RNA) is injected inside the host, while the protein capsid of the infecting particle remains outside of the host cell at all times. Once the DNA or RNA is inside, transcription of phage genes begins, and phage-encoded proteins begin to be made. Some of these proteins serve to inactivate and destroy the host cell DNA, ensuring that the cell's energy resources will be directed exclusively toward the production of phage proteins and the replication of phage nucleic acid. Phage DNA or RNA replication ensues quickly and is followed by the packaging of this genetic material into the newly synthesized capsids of the progeny phage particles. The final step is host cell lysis—the bursting of the host cell to release the completed and infective phage progeny. The number of phages released in each burst varies with growth conditions and species, but ideal conditions often result in a burst size of one hundred to two hundred per host cell.

For temperate bacteriophages, those capable of entering the lysogenic cycle, infection of the host cell only rarely causes lysis. Injection of the phage DNA into the host is followed by a brief period of *messenger RNA* (mRNA) synthesis, necessary to direct the production of a phage repressor protein, which inhibits the production of phage proteins involved with lytic functions. A DNA-insertion enzyme is also made, allowing the phage DNA to be physically inserted into the DNA of the host. The cell then can continue to grow and multiply, and new copies of the phage genes are replicated every cell generation as part of the bacterial chromosome. The host cell is said to be lysogenic, for it retains the potential to be lysed if the prophage pops out of the host DNA and enters the lytic cycle. The integrated prophage does confer a useful property on the host cell, however, for the cell will now be immune to further infection from the same phage species.



Tom Broker/Rainbow

Because scientists know more about the molecular and cell biology of the common bacterium Escherichia coli *than about any other cell or organism, it is perhaps not surprising that the best-known bacteriophages are those that require* E. coli *as a host.*

T4 Coliphage

One of the best-known lytic phages, which is often used in genetic studies, is the coliphage T4. Its protein capsid consists of three major sections—the head, the tail, and the tail fibers. The double-stranded circular DNA molecule of T4 is packaged into the icosahedral-shaped head, and during the infection process it is forced through the hollow core of the cylindrical tail and then directly into the host cell. Contact with the cell is established and maintained throughout the infection process by the tail fibers.

Self-assembly of progeny phages occurs in at least three distinct cellular locations, as complete heads, tails, and tail fibers are first assembled separately and then pieced together in one of the last phases of the infection cycle. Packaging of the replicated T4 DNA is an integral part of the head assembly process. Each of the three subassemblies involves a reasonably complex and highly regulated sequence of assembly steps. For example, head assembly is known to require the activity of eighteen genes, even though only eleven different proteins are found as structural components of mature heads. Identification of the number and sequence of genes involved with each subassembly process has been facilitated by the analysis of artificial lysates from t^s mutants.

For those temperate phages capable of entering the lysogenic cycle, many additional strategies for genetic control and regulation have evolved. The most thoroughly studied of the temperate coliphages is phage lambda (λ). Genes controlling phage DNA integration, excision, and recombination, and those involved with repressor functions, have been identified in phage λ as well as structural genes involved with lytic functions that are similar to those studied in T4.

Research Tool

One of the most important conclusions to be drawn from studies on bacteriophages, and viral genetics in general, is that many of the results have universal implications. For example, the physical properties of DNA and RNA are remarkably identical in all organisms, and these are perhaps easiest to study in bacteriophage systems. The experiment that provided the final proof that DNA was the genetic material was performed using a coliphage very similar to T4. Studies on the origin of spontaneous mutations, first performed in phage, have extended to higher forms of life as well. Some of the most basic questions concerning protein-DNA interactions are best addressed in viral systems, and the principles that emerge seem to hold for all other experimental systems. There is every reason to believe that many basic questions in cell and molecular biology will continue to be best studied in viruses such as bacteriophages, and that some of these investigations will spawn applications that can directly benefit humankind.

It is certain that advances in molecular biology that have revolutionized the understanding of cell biology and the molecular architecture of cells will continue to expand the frontiers of knowledge in the study of viral genetics. Applications in human medicine, veterinary medicine, and plant breeding are sure to follow, as scientists continue to unravel the complexities of these simplest of organisms.

An excellent supplementary text for a college student studying viral genetics for the first time. Some useful illustrations. References at end of each chapter are designated either "general" or "specialized."

Maloy, Stanley R., John E. Cronan, Jr., and David Freifelder. *Microbial Genetics*. 2d ed. Boston: Jones and Bartlett, 1994. An intermediate-level college textbook focusing on the genetics of bacteria and their bacteriophages. Provides an excellent summary of the properties and life cycles of phages that is accessible to readers with a limited background in biology. The text is well illustrated throughout, with many references for each chapter.

Russell, Peter J. *Genetics*. 5th ed. Menlo Park, Calif.: Benjamin Cummings, 1998. An introductory college text that is particularly well suited to the problem-solving approach to genetics. Presents a fine overview of gene regulation in phages. Well illustrated with a carefully conceived glossary and reference list.

Stahl, Franklin W. *Genetic Recombination: Thinking About It in Phage and Fungi*. San Francisco: W. H. Freeman, 1979. Probably the most technical of the references listed, this book might nevertheless be useful to interested readers. Chapter 4 provides a nice treatment of phage replication and the single burst experiment. Some illustrations, glossary, references.

Suzuki, D., A. Griffiths, J. Miller, and R. Lewontin. *An Introduction to Genetic Analysis*. 4th ed. New York: W. H. Freeman, 1989. Chapters 10-12 of this intermediate-level college text provide a historical perspective on the development of phage genetics and its applications to DNA structure and mutation. The summary of genetic fine structure and complementation is well described and illustrated. Includes glossary and references.

BASIDIOMYCETES

Categories: Fungi; taxonomic groups

The Basidiomycetes *constitute the largest of the three classes of the* Basidiomycota *(basidiosporic fungi), a very large class of about fourteen thousand species of the most diverse terrestrial fungi.*

The largest fungi belong in the *Basidiomycetes* class, as do some of the most unusual. All members of *Basidiomycetes* produce a *basidium* from hyphal cells and not from spores. (The basidium is a cell produced at the end of a dikaryotic hypha.) The basidium will produce either two or four spores as the result of meiosis. The basidium may be either a nonseptate cell, with two or four sterigmata (the *basidiospore* is produced on the end of the sterigma) at the apex, or it may be septate. The septa can be either horizontal or vertical. When observed from the apex, the vertical septa will produce a crosslike pattern. In either case, septate basidia will have one sterigma per cell. Basidiospores are thin-walled and may be released either actively or passively.

Basidiocarps

The *basidiocarp* is the fruiting body of the fungus. The fungus grows as a dikaryotic mycelium through the substrate. When the fungus has acquired sufficient energy, and environmental conditions are adequate, the fungus will produce a basidiocarp. The basidiocarp often appears overnight and may reach a meter in height. Some basidiocarps are tiny, less than a centimeter in height. The basidiocarp may look like a mushroom or may have the appearance of a golf ball or any variation in between. The basidiocarp may be edible or deadly poisonous. It often serves as food for wild animals and insects.

Classification

The *Basidiomycetes* are divided into two groups based on septa in the sterigma. Those that have a septate sterigma are classified in *Phragmobasidiomycetidae*, while those without septa in the sterigma are classified in *Holobasidiomycetidae*. *Phragmobasidiomycetidae* is a small group that includes some smaller fungi whose basidiocarps often have a gelatinous appearance. *Holobasidiomycetidae* is a large group of fungi and is easily divided into two major groups based on the release of the basidiospore. The hymenomycetes release spores actively, while the gasteromycetes release spores passively.

Hymenomycetes

The *hymenomycetes* are the most familiar fleshy fungi. These are the ones that resemble the common mushroom and can be seen when the weather is warm and damp. These fungi may have gills or pores on the underside of the *pileus* (the cap). The gills or pores are lined with a layer of basidia that produce spores. Some of these fungi are produced on the sides of trees or fallen wood and may be acentric. Many of them appear to arise from the ground. Colors of these fungi can be found anywhere in the rainbow, but most appear in earth tones.

Some of the major orders within the hymenomycetes are the *Agaricales* and the *Boletales*. The *Agaricales* contain the fungi that produce gills on the underside of the pileus. The *Boletales* contains the fungi that produce pores on the underside of the pileus. For the most part, the *Agaricales* are fleshy fungi that are supple at maturity and last for no more than a week or two in nature. The *Boletales* are also fleshy and can be confused with other fungi that have pores and are hard. Some of these hard fungi are common parasites of trees; the "shelves" that they produce can grow for years.

Gasteromycetes

The gasteromycetes are a much more diverse group of fungi. The fungi in this group are often associated with soil or decomposing organic matter, although some may be mycorrhizal (in a symbiotic association with plant roots). There is tremendous diversity in this group, and many scientists believe that this group is artificial (not based on evolutionary relationships).

Some of the more interesting fungi of this group are shaped like balls that lie on the soil. Members of *Lycoperdales* and *Sclerodermatales* produce ball-like basidiocarps that form at the soil line. The size can range from that of a small marble up to that of a soccer ball. These are called *puffballs*, as they release spores in small clouds when kicked. In nature, the upper layers of the basidiocarp crack, and spores are released as drops of water, hitting the outer layer of the basidiocarp. Many of these are edible when properly identified.

Other interesting fungi are found in the order *Nidulariales*. These are called the *bird's nest fungi*, as the basidiocarp resembles a small bowl containing two or three small "eggs," which contain the basidia. When a droplet of water lands in the "nest" the "eggs" are thrown upward and outward. As they are released, a small thread is pulled behind, and the thread sticks onto some part of a plant, such as a blade of grass. The "egg" will then degrade and release the spores to be disseminated in the wind.

Among the most bizarre fungi are the *stinkhorns*. These fungi produce basidiocarps from structures that look like chicken eggs. The elongate structure produces the basidia on the end in a mass of slimy, smelly mucus. Flies are attracted to the smell, land on the mucus, and fly away. The basidiospores adhere to their feet and drop off, thereby disseminating the fungus.

BASIDIOSPORIC FUNGI

Categories: Economic botany and plant uses; fungi; microorganisms; pests and pest control; taxonomic groups

Basidiosporic fungi (also known as the Basidiomycota *or* Basidiomycotina*) are fungi that produce sexual spores on a specialized cell called a basidium.*

The basidiosporic fungi are the most diverse phylum of the fungi world, with more than 22,300 species described. Some of the fungi in this phylum are microscopic, while the larger members of this group produce fruiting structures that are basketball-sized and weigh in excess of 10 pounds. This phylum contains fungi that fall into three classes: mushroom, rusts, and smuts—and range widely in appearance, from the common mushroom to weblike fungi with an odor that can be detected at several feet.

Taxonomy

The basidiosporic fungi are divided into three classes: *Basidiomycetes* (mushrooms); *Teliomycetes* (rusts); and *Ustomycetes* (smuts). The *Basidiomycetes* are the higher basidiosporic fungi, which are normally fleshy. They produce true basidiocarps, and the only spore formed is the basidiospore. The other two classes both have more than one spore form and do not have extensive mycelium. The *Teliomycetes* are commonly called rusts and are serious biotrophic parasites of plants. The rusts are able to complete their life cycle only in the presence of living plant host tissue. The *Ustomycetes* are commonly called smuts and are mostly minor pathogens of plants, especially monocots. Some smuts have been cultured in axenic culture, where they form a "yeastlike" phase. The yeastlike phase has no true mycelium but rather individual cells.

Basidium

The *basidium* is a single cell on which basidiospores are produced externally. The basidium forms either as the terminal cell of a dikaryotic mycelium or from a resting spore that initially is dikaryotic. The dikaryotic mycelium or spore contains two haploid nuclei, one donated by each of the parent strains. As the basidium begins to form, the two nuclei migrate into the center of the cell and fuse, forming a diploid nucleus. This nucleus then undergoes meiosis, forming four haploid nuclei. As this is occurring, the cell wall of the basidium begins to produce little extensions called *sterigmata*, upon which the basidiospores will form. The tips of the sterigmata then inflate, and one nucleus migrates into each forming basidiospore. The basidiospore is haploid and has a very thin cell wall. The spore is normally transmitted in air currents. Upon germination, the basidiospore produces a haploid mycelium which will fuse with a compatible hyphae, producing a dikaryotic mycelium.

Spore release from the basidium can be either active or passive. Passive release occurs when the junction of the sterigma and basidiospore separates, releasing the spore. Active release is more specialized. When the basidiospore is forming, a small segment of the spore wall at the junction with the sterigma loosens and fills with either gas or liquid. At the time of release, the fluid or gas escapes, propelling the basidiospore away from the basidium. The distance traveled is not great, just enough to make sure that the basidiospore is able to enter into air currents for dissemination.

Hyphal Structure

The hyphae of the *Basidiomycetes* are septate and have special modifications at the septa. When a cell divides, a crosswall forms between the two daughter cells. With the dikaryotic hyphae of the *Basidiomycetes*, as the cell divides, the nuclei migrate toward the apex of the hyphae. The nuclei then undergo mitosis, with one of the nuclei migrating into a small outgrowth of the hyphae and the other migrating backward. Septa form, creating a new dikaryotic cell near the apex and two haploid cells, one in line and the other as the outgrowth. The outgrowth then turns and fuses with the haploid cell, and the nucleus migrates back to form a dikaryotic cell. The outgrowth remains visible with a microscope and is called a clamp connection.

The reproductive structure of the *Ustomycetes* is called a sorus. The sorus is a mass of dikaryotic spores that are normally dark brown or black in color. The sorus is formed in meristematic regions of the plants. The spores are called probasidia, because they form basidia when they germinate.

With the *Teliomycetes*, there are up to five distinct spore forms. The basidiospore lands on a susceptible plant and germinates, producing a haploid mycelium that infects the plant. The infection results in the formation of a haploid spermagonium that produces both spermatia and receptive hyphae. When a compatible spermatia and receptive hypha combine, a dikaryotic hypha is produced, which initiates formation of an aecium. The aecium produces dikaryotic spores that are transmitted by air currents and infect another plant. The resultant infection produces a subcuticular or subepidermal mass of thin-walled spores. These dikaryotic spores are called urediniospores and are formed in the uredinium. The urediniospores are blown by air currents and produce reinfection of the same species of plant. At the end of the growing season, infections by urediniospores will result in the formation of a subcuticular or subepidermal mass of thick-walled spores called teliospores which are formed in the telium. These spores are initially dikaryotic but then become diploid and finally germinate by formation of the basidium.

Basidiocarps

The *basidiocarp* is the fruiting body of the higher *Basidiomycetes*. This structure is multicellular and composed of hyphae. The basidiocarp resembles the familiar image of the mushroom. The *mushroom* consists of a stalk (*stipe*) which has a cap (*pileus*) on top. The stipe can be as tall as a meter (40 inches), and the pileus as long as a meter in diameter. Alternatively, both parts could be less than a centimeter in size. The pileus has pores or gills on the underside, where the basidia are produced. The layer of basidia is called a hymenium or "fertile layer."

Other kinds of basidiocarps may be found in nature. Some are totally enclosed and remain on the ground, looking much like a golf ball. These are called *puffballs*. As the puffball matures, the other layers begin to crack at the apex. When drops of rain fall, the force of the impact causes spores to puff out of the opening. Another kind of puffball is the earthstar. In these unique fungi, the outer layers pull away from central part of the puffball and form a starlike pattern on the ground.

Ecological Importance

The basidiosporic fungi all play important roles in ecosystems. The rusts and the smuts are important plant pathogens, capable of great destruction of crops. These fungi have been known for thousands of years and are some of the most devastating fungi around.

The mushrooms are part of the natural cycle of decay. They are found on the ground or on wood and are the later stages of decay of organic matter. Some mushrooms are found on living plants, where they can be serious pathogens. Others are edible and are excellent sources of digestible protein. Still others are toxic or poisonous and can be fatal when eaten.

Stinkhorns and the *bird's nest fungi* are unique basidiosporic fungi. The stinkhorns are basidiocarps that form on the soil and produce the basidia in a mass of putrid cells. The stench from the cells draws flies, which walk over the spores and then disseminate them. These can be found in wooded areas and can be detected by smell at distances of up to several meters.

The bird's nest fungi look like small birds' nests. The outer part of the basidiocarp resembles a small nest, up to an inch in diameter. On the inside, several small puffball-like structures can be found, with basidia on the inside. These look like small eggs. When a drop of water enters the nest, the force thrusts the "egg" upward and extends a small cord from the back. The small cord catches hold of a plant and suspends the egg in the air. As the egg dries, it turns into a powdery mass, which is blown about by the wind.

BIOCHEMICAL COEVOLUTION IN ANGIOSPERMS

Categories: Angiosperms; animal-plant interactions; evolution; physiology; *Plantae*; poisonous, toxic, and invasive plants

Flowering plants, or angiosperms, produce many compounds that are not directly related to growth and development. These secondary metabolites arise from primary metabolic pathways and act as antiherbivory mechanisms, allelochemicals, or attractants.

Secondary metabolites are biochemicals produced by plants in response to selection pressures. These pressures may be from herbivory, competition, or the need for pollination. As plants produce compounds to enhance their survival, predators, competitors, and pollinators react and evolve means of adjusting to the plant's efforts. Chemically simple secondary metabolites may be widespread throughout angiosperm (flowering plant) families, whereas more complex chemicals are often restricted to a single species. Secondary metabolites are often under high selection pressures, causing individual compounds to have very limited distributions and making them useful in determining the evolutionary relationships between taxonomic groups. Presence of secondary compounds influences the activities of organisms interacting with the plants and, over long periods of time, influences evolution of those species.

Antiherbivory Mechanisms

Antiherbivory chemicals may have a wide range of effects on herbivores (plant-eating animals). Many compounds merely deter grazing. Crystals produced from calcium oxalate (raphides) may be ejected from the vacuoles of cells along with proteinaceous toxins, causing tissue swelling in the mouth of an offending herbivore. Many monocotyledonous plant families, such as *Liliaceae*, *Heliconiaceae*, *Rubiaceae*, and *Arecaceae*, produce this type of antiforaging device. This type of defense is especially notable in young tissues that have not developed the toughness found in mature leaves as a herbivory deterrent. Red oaks produce tannins in response to gypsy moth attacks, reducing further herbivory. Continued feeding on plants containing tannins would lead to slow starvation of a herbivore, as its digestive system could not absorb proteins. The same tannins are not deterrents to squirrels. Squirrels harvest acorns and bury them for later consumption, providing a food source for the squirrel and a dispersal mechanism for the acorn.

Beavers provide another example of the interaction between plant and animal evolution. Some of the beaver's preferred foods include species that are unpalatable or toxic to other mammals, such as bracken fern, nettles, thistles, and skunk cabbage. This gives the beaver a largely uncontested food source that may involve a metabolic "cost" to the animal.

Other antiherbivory chemicals result in effects more severe than mere deterrence of feeding. Alkaloids such as caffeine, nicotine, and strychnine are potent antiherbivory mechanisms, causing convulsions, comas, and even death in herbivores. These effects may not occur in all herbivores. Strychnine, for example, is produced by the fruit of some plants that may be eaten by birds without ill effects, but in mammals the same fruit causes failure of the central nervous system and induces seizures. The plant reduces herbivory by mammals, and the seeds get dispersed by birds that are able to detoxify the strychnine. Grains and seed crops, such as wheat and peanuts, which are particularly attractive to animal and insect herbivores, often produce cyanogenic glycosides that release hydrogen cyanide as the tissues are digested. This compound inhibits cellular respiration, thus killing the herbivore. In each case members of a plant population are consumed by the herbivore, but future generations are spared by the loss.

Allelochemicals

Allelochemicals are compounds produced by an organism that interfere with the growth or development of another organism. Many phenolic acids act as allelochemicals, inhibiting root growth of competing species. Many grains are known to release ferulic acid and caffeic acid into the soil, thus inhibiting the germination of weed species. Phenolics may also act as antifungal compounds, increasing in concentration with fungal infection, thus protecting the plant from further attack. Phenolic compounds produced in tobacco and tomato leaves reduce the growth of these plants' natural predator, tobacco hornworm, without affecting the growth or activity of the hornworm's natural predator.

Allelochemicals produced in response to injury by herbivores may also attract predators of the herbivore. Wastes from many species of caterpillars induce the release of terpenoids from green leaves that attract parasitoid insects. Production of specific combinations of volatiles on the part of the plant signals the predator, which will then reduce further herbivory. The plants have evolved the signal in response to herbivory, and the predators have evolved the ability to detect the signal indicating the location of their host.

Lectins are widely distributed carbohydrate-binding proteins, most commonly found in the *Leguminoseae* (legume) family. When found in the seeds, these compounds act as broad-spectrum insecticides, whereas in the roots of legumes they maintain bacterial relationships in nitrogen-fixing nodules, providing the plant with a source of nitrogen unavailable to plants not producing nodules.

Attractants

Terpenoids and aliphatic compounds are often the components of essential oils of plants. The volatile nature of these compounds produces a distinctive odor that attracts pollinators. Composition of the volatile compounds often closely matches the natural pheromones produced by the pollinator, mimicking the chemical scent of a female insect in an attempt to attract male pollinators. Pheromone mimicry is found primarily in members of the *Orchidaceae*, which are often dependent on single species of wasp for pollination. Other plants may mimic the odor of food. The smell of rotting flesh, attractive to flies, is produced via ammonia and alkylamines, such as cadaverine and putrescine. Methylesters may attract moth pollinators by mimicking the sweet smell of fruit.

Flavonoids often provide color to fruits and flowers and act as visual cues for pollination. Reds, blues, or yellows in varying patterns stand out against a background of green leaves, helping pollinators locate the flower. Species may have minor chemical differences in their flavonoids that allow for the determination of identity, hybridization between species, and possible coevolution with pollinators. For example, tropical flowers tend to have a more intense red color from anthocyanins than do temperate flowers. This difference correlates with differences in pollinator preferences, indicating a role by natural selection. Birds, such as hummingbirds, prefer red to yellow, whereas bees are not able to discern reds but are attracted to yellows. Carotenoids, such as xanthophyll and beta-carotene, give fruits and flowers distinctive yellow and orange colors.

Color patterns are also important in attracting pollinators. Butterflies are attracted to red/yellow color patterns. Flavonoid compounds not only impart color but also may modify color patterns by absorbing ultraviolet (UV) light. Bees are capable of seeing in the UV range, so the presence of flavonoids may alter the bees' perception of the flower. The patterns may also create cues as to the location of nectaries within the flower, guiding the pollinator to its reward.

BIOFERTILIZERS

Categories: Agriculture; bacteria; biotechnology; economic botany and plant uses; nutrients and nutrition; soil

The use of biofertilizers, biological systems that supply plant nutrients such as nitrogen to agricultural crops, could reduce agriculture's dependency on chemical fertilizers, which are often detrimental to the environment.

Plants require an adequate supply of the thirteen mineral nutrients necessary for normal growth and reproduction. These nutrients, which must be supplied by the soil, include both *macronutrients* (nutrients required in large quantities) and *micronutrients* (nutrients required in smaller quantities). As plants grow and develop, they remove these essential mineral nutrients from the soil. Because normal crop production usually requires the removal of plants or plant parts, the nutrients are continuously removed from the soil. Therefore, the long-term agricultural utilization of any soil requires periodic fertilization to replace lost nutrients.

Nitrogen is the plant nutrient that is most often depleted in agricultural soils, and most crops respond to the addition of nitrogen fertilizer by increasing their growth and yield. Therefore, more nitrogen is applied to cropland than any other fertilizer component. In the past, nitrogen fertilizers have been limited to either *manures*, which have low levels of nitrogen, or *chemical fertilizers*, which usually have high levels of nitrogen. However, the excess nitrogen in chemical fertilizers often runs off into nearby waterways, causing a variety of environmental problems.

Less Harmful Alternatives

Biofertilizers offer a potential alternative: They supply sufficient amounts of nitrogen for maximum yields yet have a positive impact on the environment. Biofertilizers generally consist of either naturally occurring or *genetically modified* microorganisms that improve the physical condition of soil, aid plant growth, or increase crop yield. Biofertilizers provide an environmentally friendly way to increase plant health and yields with reduced input costs, new products and additional revenues for the agricultural biotechnology industry, and cheaper products for consumers.

Nitrogen Fixing

While biofertilizers could potentially be used to supply a number of different nutrients, most of the interest is focused on nitrogen. The relatively small amounts of nitrogen found in soil come from a variety of sources. Some nitrogen is present in all organic matter in soil; as this organic matter is de-

Image Not Available

graded by microorganisms, it can be used by plants. A second source of nitrogen is *nitrogen fixation*, the chemical or biological process of taking nitrogen from the atmosphere and converting it to a form that can be used by plants. Bacteria such as members of *Rhizobium* can live symbiotically in the roots of certain plants, such as legumes. Rhizobia and plant root tissue form root nodules, which house the nitrogen-fixing bacteria; once inside the nodules, the bacteria use energy supplied by the plant to convert atmospheric nitrogen to ammonia, which nourishes the plant. Natural nitrogen can also be supplied by free-living microorganisms, which can fix nitrogen without forming a symbiotic relationship with plants. The primary objective of biofertilizers is to enhance any one or all of these processes.

One of the major goals for the genetic engineering of biofertilizers is to transfer the ability to form nodules and establish effective symbiosis to nonlegume plants. The formation of nodules in which the *Rhizobia* live requires plant cells to synthesize many new proteins, and many of the genes required for the expression of these proteins are not found in the root cells of plants outside the legume family (*Fabaceae*). If transfer of the appropriate genes could be accomplished, *Rhizobia* could be used as a biofertilizer for a variety of plants.

There is also much interest in using the free-living, soil-borne organisms that fix atmospheric nitrogen as biofertilizers. These organisms, including types bacteria and algae, live in the *rhizosphere* (the region of soil in immediate contact with plant roots) or thrive on the surface of the soil. Because the exudates from these microorganisms contain nitrogen that can be used by plants, increasing their abundance in the soil could reduce the dependency on chemical fertilizers. Numerous research efforts have been designed to identify and enhance the abundance of nitrogen-fixing bacteria in the rhizosphere. Soil microorganisms primarily depend on soluble root exudates and decomposed organic matter to supply the energy necessary for fixing nitrogen. Hence, there is also an interest in enhancing the *biodegradation* of organic matter in the soil. This research has primarily centered on inoculating the soil with cellulose-degrading fungi and nitrogen-fixing bacteria or applying organic matter, such as straw that has been treated with a combination of the fungi and bacteria to the soil.

BIOLOGICAL INVASIONS

Categories: Ecology; ecosystems; environmental issues; poisonous, toxic, and invasive plants

Biological invasions are the entry of a type of organism into an ecosystem outside its historic range. In a biological invasion, the "invading" organism may be an infectious virus, a bacterium, a plant, an insect, or an animal.

Species introduced to an area from somewhere else are referred to as alien or exotic species or as invaders. Because an exotic species is not native to the new area, it is often unsuccessful in establishing a viable population and disappears. The fossil record, as well as historical documentation, indicates that this is the fate of many species in new environments as they move from their native habitats. Occasionally, however, an invading species finds the new environment to its liking. In this case, the invader may become so successful in exploiting its new habitat that it can completely alter the ecological balance of an ecosystem, decreasing *biodiversity* and altering the local *biological hierarchy*. Because of this ability to alter *ecosystems*, exotic invaders are considered major agents in driving native species to extinction.

Biological invasions by notorious species constitute a significant component of earth's history. In general, large-scale climatic changes and geological crises are at the origin of massive exchanges of flora and fauna. On a geologic time scale, migrations of invading species from one continent to another are true evolutionary processes, just as speciation and extinction are. On a smaller scale, physical barriers such as oceans, mountains, and deserts can be over-

Image Not Available

come by many organisms as their populations expand. Organisms can be carried by water in rivers or ocean currents, transported by wind, or carried by other species as they migrate seasonally or to escape environmental pressures. Humans have transplanted plants since the beginning of plant cultivation in pre-Columbian times. The geological and historical records of the earth suggest that biological invasions contribute substantially to an increase in the rate of extinction within ecosystems.

Invasive Plants

In modern times, most people are not aware of the distinction between *native plants* and exotic species growing in their region. Recent increases in intercontinental invasion rates by exotic species, brought about primarily by human activity, create important ecological problems for the recipient lands. Invasive plants in North America include eucalyptus trees, morning glory, and pampas grass.

It would seem logical to assume that invading species might add to the biodiversity of a region, but many invaders have the opposite effect. In all ecosystems the new species are often opportunistic, driving out native species by competing with them for resources. For example, *Pueraria lobata*, or kudzu, is a vine native to Japan. Introduced in the United States at the 1876 Philadelphia Exposition, kudzu was planted to control erosion on hillsides and for livestock forage. By the end of the twentieth century, it could be found from Connecticut to Missouri, extending south to Texas and Florida. Kudzu covers everything in its path and grows as much as 1 foot (0.3 meter) per day. Similarly, English ivy (*Hedera helix*), a native of Eurasia, is considered a serious problem in West Coast states. It forms "ivy deserts" in forests and crowds out native trees and shrubs that make up essential wildlife habitat.

The invasion of an ecosystem by an exotic species can effectively alter ecosystem processes. An invading species does not simply consume or compete with native species but can actually change the rules of existence within the ecosystem by altering processes such as primary productivity, decomposition, hydrology, geomorphology, nutrient cycling, and natural disturbance regimes.

Invasive Insects and Microorganisms

The invasion of native forests alone by nonnative insects and microorganisms has been devastating on many continents. The white pine blister rust and the balsam woolly adelgid have invaded both commercial and preserved forest lands in North America. Both exotics were brought to North America in the late 1800's on nursery stock from Europe. The balsam woolly adelgid attacks fir trees and causes their death within two to seven years from chemical damage and by feeding on the trees' vascular tissue. The adelgid has killed nearly every adult cone-bearing fir tree in the southern Appalachian Mountains. The white pine blister rust attacks five-needle pines; in the western United States fewer than 10 pine trees in 100,000 are resistant. Because white pine seeds are an essential food source for bears and other animals, the loss of the trees is having severe consequences across the food chain.

Since the 1800's the deciduous trees of eastern North America have been attacked numerous times by waves of invading exotic species and diseases. One of the most notable invaders is the gypsy moth, which consumes a variety of tree species. Other invaders have virtually eliminated the once-dominant American chestnut and the American elm. Tree species that continue to decline because of new invaders include the American beech, mountain ash, white birch, butternut, sugar maple, flowering dogwood, and eastern hemlock. It is widely accepted that the invasion of exotic species is the single greatest threat to the diversity of deciduous forests in North America.

Effects on Humans and Humans as Invaders

Some introduced exotic species are beneficial to humanity. It would be impossible to support the present world human population entirely on species native to their regions. Humans, the ultimate biological invaders, have been responsible for the extinction of many species and will continue to be in the future. At the beginning of the twenty-first century, the United States was spending $4 billion annually to eradicate invasive plant species, a figure that does not take into account loss of biodiversity or wildlife habitat.

Hengeveld, Rob. *Dynamics of Biological Invasions*. New York: Chapman and Hall, 1989. Introduces dynamic concepts into biogeography and spatial concepts into ecology. By using mathematical models from epidemiology and human geography, generalizations can be made, and it is shown that apparently static species ranges contain dynamic internal parameters.

BIOLOGICAL WEAPONS

Categories: Economic botany and plant uses; medicine and health; microorganisms; poisonous, toxic, and invasive plants

Biological weapons are biological agents that can be used to destroy living organisms. This general definition includes the use of virtually any kind of microorganism (bacterium or fungus) or biological agent (mycoplasmalike organism, virus, viroid, or prion) to destroy any biologically important plant or animal.

There are two basic ways of using biological weapons against humanity. The first is to attack the food or water supply. This would produce hardship and the possible death from starvation of many individuals. In developed countries such as the United States, total devastation due to such an attack would likely be avoided, as there are considerable stores of food, in dispersed locations, that would mitigate against crop failure of moderate proportions. In addition, most experts agree that the amount of biological contaminant required to overcome the effects of dilution and time in most water reservoirs makes poisoning of water supplies impractical, although not impossible.

The other way of using biological weapons against humanity is to attack individuals directly, using pathogens. Numerous known pathogens could be used, but the most effective biological weapons would creep upon the population with stealth. Naturally occurring agents that have promise as biological weapons are pathogens, which can infect and colonize a host. A pathogen causes *disease*, an alteration in the metabolism of a host.

In order for disease to occur, it is necessary to have a *virulent pathogen*, that is, one that is capable of causing disease; a *susceptible host*, able to be infected; and an environment that is favorable to both the host and the pathogen. When these occur together, disease occurs. For the disease cycle to begin, it is necessary for *propagules* of the pathogen to come in contact with the susceptible host. Propagules include those that cause initial infections, called the *primary inoculum*. As the disease cycle progresses, the host may release other propagules, considered the *secondary inoculum*. When only one progression of disease occurs during a prolonged span of time, the disease is termed *monocyclic*. When more than one cycle of disease takes place in a growing season, the disease is called *polycyclic*.

Monocyclic Diseases

An example of the monocyclic disease cycle occurs with corn smut. The primary inoculum is released in the spring, as the tassel and silk of the corn appear. Infection occurs, symptoms of large black galls develop on the ears, and new inoculum is produced for the following growing season. This kind of disease produces a single cycle during a growing season. The potential for problems depends on the amount of inoculum present at the beginning of the disease cycle. In order to use corn smut as a biological weapon, the initial amount of inoculum must be sufficient to reach all of the plants that are targeted.

This is the same general case as with *anthrax*. Anthrax is a disease of animals that is caused by the bacterium *Bacillus anthracis*. The bacterium is able to survive in nature as small spores that are able to resist extremes of climate and time. These microscopic spores are produced at any time when environmental conditions are unfavorable for growth of the bacterium. The spores are less than 2 microns in diameter, and if they become suspended in the air, they will hang indefinitely. Such small particles are called PM10 (particulate matter less than 10 microns in size). These particles are of extreme importance, as they are not filtered out by common filters and must be removed by HEPA (high-efficiency particulate-arresting) filters, which can remove particles smaller than a micron. When these particles are inhaled, they cause disease of the lung tissue, which will result in destruction of the lungs and the resultant death of the host.

The reasons that *Bacillus anthracis* could be a biological weapon are that it is easily concealed and disseminates quickly as an invisible, airborne powder. The small particle size allows it to be inhaled, after which it lodges in the lungs and begins the process of infection. The infection begins like that of a common chest cold. By the time the host determines that anthrax might have been contracted, the condition is normally fatal. One of the features of anthrax as a biological weapon is that it is not contagious. Spores are not produced until the host is dead, at which time the spores are not placed back into the air currents. This permits anthrax to be used against a specific target.

Polycyclic Diseases

Some kinds of biological weapons can be termed *weapons of mass destruction*. These biological weap-

Image Not Available

ons are able to self-perpetuate and thereby create great amounts of destruction. They are polycyclic in nature.

A plant-based example of this is the epidemic of *potato late blight*, which caused the Irish Potato Famine of the mid-1840's. Most of the people living in Ireland at that time depended on their own harvests for food. During a two-year period, the climate became especially cool and damp, conditions favorable for the spread of potato late blight. Because potatoes are planted from vegetative parts, there was genetic uniformity of the crop, which was highly susceptible. The pathogen is extremely virulent, with the capacity to destroy a single plant overnight. Total crop failure resulted in the reduction of Ireland's population from about six million to about two million people. About one-third of the people emigrated to other lands, and about one-third of the population died from starvation. All of this destruction could have started from a single fungal propagule that infected a plant and then spread. This fungus is still problematic worldwide. However, regular sprays with fungicide reduce the risk of crop destruction.

Pathogens that occur at low levels in any given area are called *endemic* and may, when conditions are favorable, produce a widespread surge of disease in that area. This is called an *epidemic*. Epidemics that occur over wide geographic ranges, such as two or more continents, are called *pandemics*. The endemic potato late blight fungus caused an epidemic, and because it also spread into Europe and North America, the situation could be called a pandemic.

A similar concern is expressed with regard to the disease *smallpox*. Smallpox is caused by a virus that is easily passed from an infected individual to a healthy one. The smallpox virus no longer occurs in nature (is not endemic) anywhere in the world. The last reported case of smallpox in nature occurred in the late 1970's. As a result of a concerted vaccination effort among many nations, this normally fatal disease was eradicated. The last stores of smallpox virus are housed at the Centers for Disease Control (CDC) in Atlanta, the U.S. Army Biological Weapons Research Unit in Fort Detrick, Maryland, and the Russian Academy of Sciences in Moscow. Some people fear some of the inoculum from one of these storehouses could be transported into unconfined areas of the outside world. As such, smallpox would become a very formidable biological weapon.

Smallpox is highly contagious and spreads easily from person to person. Should an infected person walk the streets of a highly populated urban area, it would be possible to infect millions of people within the span of a week or two. Within several weeks, especially in this age of global travel, the infection could spread around the world.

Vectors

One method of spreading disease is through the use of vectors. *Vectors* are arthropods or other invertebrates that have the ability to transmit a pathogen from one host to another. The most famous vector is the mosquito, which can transmit malaria, dengue fever, West Nile virus, and many other diseases. The corresponding vector in plants is the aphid, which can transmit a host of viruses and mycoplasmas (bacteria that lack cell walls). In order for transmission to occur, it is necessary for a vector to first come in contact with an infected host, feed upon that host, and then pass the pathogen to an uninfected host. The most notable vector-borne disease is plague, which is passed from infected animals to humans by fleas. This disease, which was once responsible for hundreds of thousands of deaths, is now readily controlled by the use of insecticides to kill off the vector.

Designer Weapons

With twentieth century advances in technology, the manipulation of the genetics of a pathogen to make it a "super pathogen" is possible. The creation of a genetic code which could be pathogenic is also possible. So-called designer weapons are those that may be envisioned by someone who feels he or she has a need to make a more destructive or more "targeted" weapon. These weapons could then be used on a specific population or area. The creator of the designer weapon would have an advantage, as he or she would also be able to create a vaccine against the designer weapon, which could be administered to a specific group of individuals. Designer weapons, like all biological weapons, work best when there is an abundant supply of susceptible hosts and when the genetics of these hosts do not vary greatly.

Pathogen Dispersal

There is considerable opportunity for the use of any pathogen as a biological weapon. Most pathogens can be cultured with standard laboratory equipment; however, the difficulty is in creating a system of *dispersal* that will effectively spread the inoculum over an area of susceptible hosts. There are innumerable systems that could be used; these include spraying particles into the air, mailing them in an envelope, or placing them into a bomb. One of the less sophisticated methods of dissemination is the use of aircraft that are used for agricultural spraying. These aircraft could spray inoculum over large areas, with the potential of infecting large populations.

BIOLUMINESCENCE

Categories: Algae; cellular biology; fungi; physiology; water-related life

Bioluminesence is the production of light by living organisms, including algae and phytoplankton in the oceans and fungi on land.

Bioluminescence is a specific form of chemiluminescence in which the chemical energy that is produced in a chemical reaction is converted into radiant energy. In bioluminescence the reaction originates in a wide variety of living organisms, including a small number of plants. It should not be confused with fluorescence or phosphorescence, both of which do not involve a chemical reaction. In either of the former cases the energy from a source of light, not from a chemical reaction, is basically absorbed and then re-emitted in some form of another photon. The chemical reactions that lead to bioluminescence release energy in the form of light. Unlike the light bulb, in which electrical energy is converted into light, with some of this energy lost in the form of heat, a bioluminescent reaction is 100 percent efficient and converts all the emitted energy into light. Because there is no heat released, bioluminescence is also known as "cold light."

Species and Habitats

Bioluminescence is primarily marine in nature and is the only source of light in the deep ocean, which is the largest habitable biome of the earth. The phenomenon rarely occurs in any source of fresh water. Bioluminescent organisms include ctenophores, annelid worms, mollusks, insects, and fish. The most common manifestation of this phenomenon on land is seen as a glowing fungus on wood or in the few families of luminous insects. This property can be used as a means of species recognition in the darkness as well as for courtship, preying, and mating.

There are several bioluminescent fungi that are not marine in nature, occurring primarily in the tropics. These fungi appear in different colors. The most common is *Panellus stiptucus*, which is a small decay fungus that is mostly restricted to North America. The jack-o'-lantern mushroom (*Omphalotus olearius*) glows brightly, especially when fresh. A few *Armillaria* species are also reported to glow mildly. No luminous tree or plant is known, however.

Mechanisms of Bioluminescence

Bioluminescence occurs only when two different species are in contact and, almost exclusively, when oxygen is present. The two species are *luciferin*, which produces the light, and *luciferase*, a protein that triggers and catalyzes the reaction. The mechanism involves the loss of two electrons, also known as *oxidation*, by luciferin, a process achieved only through the intervention of luciferase to yield oxyluciferin. Occasionally luciferin, luciferase, and a cofactor such as oxygen are bound together in a single moiety called *photoprotein*, which leads to light formation upon contact with a positively charged species, such as the calcium cation. The mechanism appears to involve a peroxide decomposition with free radical intervention.

Dinoflagellates

Dinoflagellates known as *Pyrrhophyta*, or fire plants, are the most common sources of bioluminescence at the surface of the ocean. They are a group of marine algae that produce light upon mechanical, chemical, or temperature changes. The phenomenon was first observed in the genus *Noctiluca* in the nineteenth century and has since been observed to occur within other species.

Generally, three types of stimuli can cause bioluminescence in dinoflagellates: mechanical, chemical, and temperature stimulation.

Mechanical forms of stimulation, such as the stirring of water from a moving boat, a swimming fish, or a breaking wave, are prevalent in many *Pyrrhophyta*. The light appears to serve as a "burglar alarm" against grazing predators, which are then being seen through the flash by a larger second predator. For example, as a copepod approaches the dinoflagellate, agitation of the seawater stimulates light flashes which a small fish, the secondary predator, uses to pinpoint the position of the copepod and eventually consume it. It appears that the mechanical stimulation deforms the cell membrane to create a short flash as little as one one-hundredth of a second.

Dinoflagellate luciferin is thought to derive from the similarly structured chlorophyll, which is found in most plants. The molecule is protected from luciferase at slightly basic medium by a luciferin-binding protein. However, once the acidity increases, the free luciferin reacts, and light is emitted. The light produced by a single dinoflagellate is only six to eight photons in energy, and the flashing may last only one-tenth of a second. Larger organisms, such as jellyfish, provide flashes that may last up to tens of seconds. Temperature lowering in some dinoflagellate species also creates bioluminescence.

Purpose and Applications

The disappearance of the flash, once oxygen is consumed, has suggested that the bioluminescent reaction was originally used to remove toxic oxygen from primitive types of bacteria that developed at a time when oxygen was not available. Bioluminescence has also played a crucial role in the direct studies of several cellular and biochemical processes, such as in the formation of ultimate carcinogens from benzoapyrene. The phenomenon has served scientists in many ways. Calcium levels are monitored via the jellyfish biochemical system, adenosine triphosphate (ATP) measurements are achieved through the firefly, and the gene activity of organisms can be detected by splicing known bioluminescent proteins.

BIOMASS RELATED TO ENERGY

Categories: Ecology; ecosystems; environmental issues

The relationship between the accumulation of living matter resulting from the primary production of plants or the secondary production of animals (biomass) and the energy potentially available to other organisms in an ecosystem forms the basis of the study of biomass related to energy.

Biomass is the amount of organic matter, such as animal and plant tissue, found at a particular time and place. The rate of accumulation of biomass is termed *productivity*. *Primary production* is the rate at which plants produce new organic matter through photosynthesis. *Secondary production* is the rate at which animals produce their organic matter by feeding on other organisms. Biomass is an instantaneous measure of the amount of organic matter, while primary and secondary production give measures of the rates at which biomass increases. Plant and animal biomass consists mostly of carbon-rich molecules, such as sugars, starches, proteins, and lipids, and other substances, such as minerals, bone, and shell. The carbon-rich organic molecules are not only the building blocks of life but also the energy-rich molecules used by organisms to fuel their activities.

Solar Energy and Photosynthesis

Ultimately, all energy used by organisms to produce the building blocks of life and to drive life processes originated as solar energy captured by plants. Only a small fraction, less than 2 percent, of the total solar light energy received by a plant is absorbed and transformed by photosynthesis into energy-containing organic molecules. The rest of the sun's energy passes out of the plant as heat. The rate at which plants capture light energy and transform it into chemical energy is called primary production. Because plants do not rely on other organisms to provide their energy needs, they are referred to as primary producers, or *autotrophs* (meaning "self-feeding"). In addition to light energy, plants must absorb water, carbon dioxide gas, and simple nutrients, such as nitrate and phosphate, to produce various organic molecules during photosynthesis. Oxygen gas is also produced.

Sugars are the first energy-containing organic molecules produced in photosynthesis, and they can be changed to other, more complex, molecules, such as starches, proteins, and fats. The energy in the sugar molecules can be used immediately by the plants to maintain their own respiration needs, stored as starches and fats, or can be converted to new plant tissue. It is the stored organic matter plus new tissue that contributes to the growth of plants and to biomass.

Because the energy-containing products of photosynthesis can be used either immediately in respiration or in the formation of new plant biomass, two types of primary production can be distinguished. *Gross production* refers to the total amount of energy produced by photosynthesis. It includes both the energy used by the plant for respiration and the energy that goes into new biomass. *Net production* refers only to the amount of energy that accumulates as new biomass. It is only the energy in net production that is potentially available to animal consumers as food.

The rate of primary production varies directly with the rate of photosynthesis; therefore, factors in the environment that affect the rate of photosynthesis affect the rate of primary production. These factors most often include light intensity, temperature, nutrient concentrations, and moisture conditions. Each species of plant has a specific combination of these factors that promotes maximum rates of primary production. If one or more of these factors is in excess or is in short supply, then the rate of primary production is slowed.

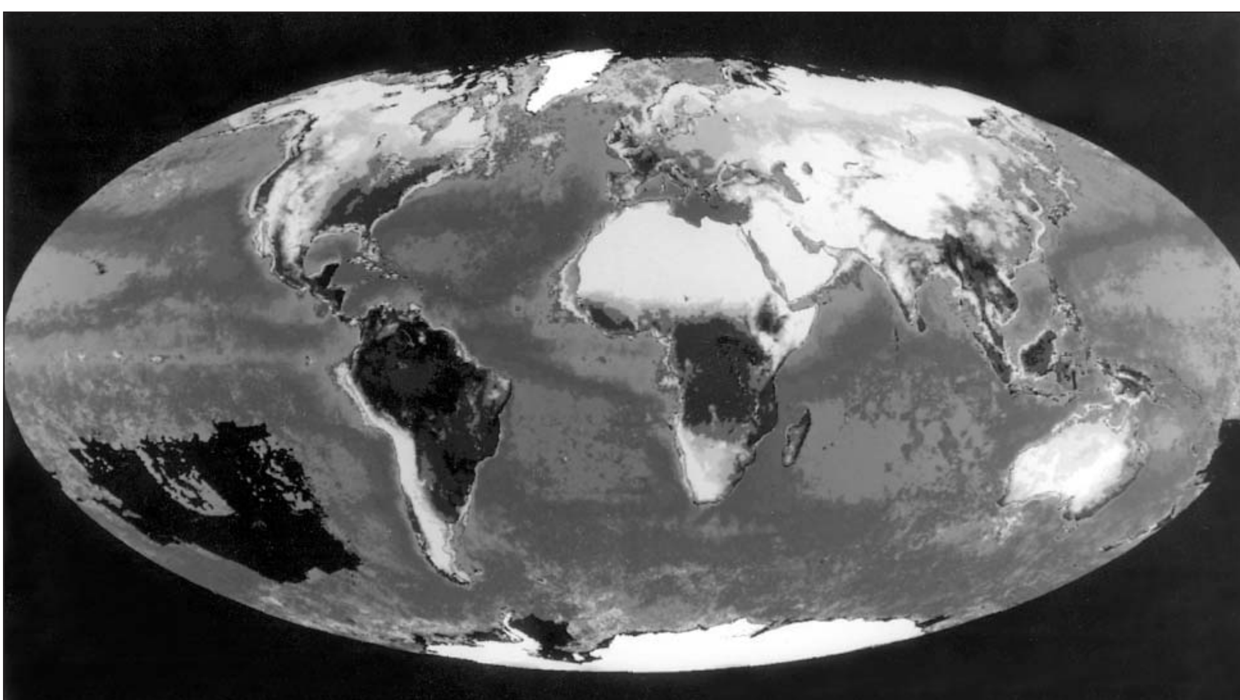
Primary Production

On land, the rate of primary production by plants is determined largely by light, temperature, and rainfall. The favorable combination of intense sunlight for twelve hours per day, warm temperatures throughout the year, and considerable rainfall make the tropical rain forests the most productive ecosystems on land. In contrast, Arctic tundra vegetation is exposed to reduced light intensity, very cold winters, and cool summers. Primary production there is very low. In deserts, the lack of water severely limits primary production even though light and temperature are otherwise favorable.

In aquatic habitats, rates of primary production by algae, such as phytoplankton, are determined by nutrient concentration and light intensity. As sunlight penetrates water, it is quickly absorbed by the water molecules and by small suspended particles. Thus, all primary production occurs near the surface, as long as nutrients are available. Although the waters of the open ocean are very clear, and sunlight can penetrate to great depths, the scarcity of nutrients reduces the rate of primary production to less than one-tenth that of coastal bays.

Secondary Production

The energy and material needs of some organisms are met by consuming the organic materials produced by others. These consumer organisms are called *heterotrophs*; there are two types. Those that obtain their food from other living organisms are called *consumers* and include all animals. Those that obtain their energy from dead organisms are called *decomposers* and include mostly the fungi and bacteria.



NASA

This composite image of the earth's biosphere shows the planet's heaviest vegetative biomass in the dark sections, known to be rain forests. The combination of intense sunlight for twelve hours per day, warm temperatures throughout the year, and considerable rainfall makes tropical rain forests the most productive ecosystems on land.

The energy available to each type of consumer becomes progressively less at each level of the *food chain*. Each consumer level uses most of its food energy, about 90 percent, to fuel its respiratory activities. In this energy-releasing process, most of the food energy is actually converted to heat and is lost to the environment. Only 10 percent or less of the original food energy is used to form new biomass. It is only this small amount of energy that is available for the next consumer level. The result is that food chains are limited in their number of links or levels by the reduced amount of energy available at each higher level.

Generally, the greater the amount of primary production, the larger the number of consumer organisms and the longer the food chain. Most food chains consist of three levels; rarely are there examples of up to five levels. It should be noted that the food chain concept is a simplified view of a more complex network of energy pathways, known as *food webs*, that occur in nature. Another outcome of the reduction in energy flow up the food chain is a progressive decrease in production and biomass. The most productive level, and the one with the greatest biomass, is therefore the primary producers, or plants.

Human Threats to Primary Production

The total natural primary production of the earth is limited, and human efforts to increase total world primary production much beyond its present levels may be futile. One reason for this is that much of the earth's surface lacks optimal conditions for plant growth. The open ocean, which covers about 71 percent of the earth's surface, has very little plant growth. On land, the Arctic, subarctic, and Antarctic regions are very unproductive most of the year. Human attempts to increase primary production in the form of food or fuel crops usually involve changing the characteristics of the land, converting forests into croplands, for example, and adding large quantities of nutrients and water. It has been estimated that humans are currently utilizing most of the easily workable croplands and that the development of additional lands for agriculture would require major changes to currently unworkable habitats, changes that would be expensive and demand much fuel energy.

The study of production processes is vitally important in understanding the ecology of natural ecosystems. Such information is necessary to manage and conserve *habitats* and their organisms in the face of human pressures. These processes provide insight into the general health of ecosystems. Pollutants, such as acid rain or industrial toxic wastes, are known to reduce the primary and secondary productivity of forests and lakes.

Throughout the world, humans are reducing the biomass of the world's primary producers through *deforestation*. This is particularly true in the tropics, where high population pressures have necessitated that land be cleared for agriculture and development. There is a worldwide demand for lumber. One obvious consequence is the dramatic reduction in the primary and secondary production of these areas. The *clear-cutting* (removal of all the trees) of tropical forests allows unprotected soils to wash away quickly during the heavy tropical rains. It will take hundreds of years for new soils to develop and for the forest to return—if it can return at all.

Deforestation is also harmful in that tropical forests form a major part of the world's life-support system. For millions of years these forests have buffered the earth's atmosphere by producing the oxygen gas needed by animals and by removing carbon dioxide and other toxic gases. The low level of carbon dioxide in the atmosphere is believed to have moderated the earth's temperature, counteracting the so-called *greenhouse effect*. It is therefore of great importance to understand and preserve these forests and other primary producers of the world.

Smith, Robert L. *Ecology and Field Biology*. 5th ed. Menlo Park, Calif.: Addison Wesley Longman, 1996. This college-level text is easily readable by senior-level high school students. It has many illustrations with high information content, and the extensive appendices make the book a useful source. Chapters discuss basic concepts of energy flow and production in terms of specific ecosystems. Excellent glossary and index.

BIOMES: DEFINITIONS AND DETERMINANTS

Categories: Biomes; ecology; ecosystems

The concept of biomes is similar to plant ecologists' classification of plant formations and classification of life zones. However, the biomes usually refer to ecological communities of both plants and animals, whereas plant formations concern plant communities only. Worldwide, there are six major types of biomes on land: forest, grassland, woodland, shrubland, semidesert scrub, and desert.

One who travels latitudinally from the equator to the Arctic will cross tropical forests, deserts, grasslands, temperate forests, coniferous forest, tundra, and ice fields. Those major types of natural vegetation at regional scales are called biomes. A biome occurs wherever a particular set of climatic and edaphic (soil-related) conditions prevail with similar physiognomy. For example, prairies and other grasslands in the North American Middle West and West form a biome of temperate grasslands, where moderately dry climate prevails. Tropical rain forests in the humid tropical areas of South and Central America, Africa, and Southeast Asia create a biome where rainfall is abundant and well-distributed through the year.

In general, biomes are delineated by both physiognomy and environment. There are six major physiognomic types on land: *forest*, *grassland*, *woodland*, *shrubland*, *semidesert scrub*, and *desert*. Each of the six types occurs in a wide range of environments. Therefore, more than one biome may be defined within each physiognomic type according to major differences in climate. Tropical forests, temperate deciduous forests, and coniferous forests are, for example, separate biomes, although forests dominate all of them. On the other hand, some

Biomes and Their Features

Biome	*Annual Mean Rainfall*[1]	*Climate and Temperature*[2]
Desert	250 mm or less	Arid, with extremes of heat and cold
Grasslands	250-750 mm	Cold winters, warm summers; dry periods
Mediterranean scrub	Low to moderate	Cool winters, hot summers; latitudes 30° to 45°; includes chaparral, maquis
Rain forest (tropical)	2,500-4,500 mm	20-30°
Savanna, deciduous tropics	1,500-2,500 mm	Hot summers; 3-6 months dry; seasonal fires
Taiga (boreal forest)	1,000 mm	Cold, long winters; mild, short summers; seasonal fires
Tundra	Very low year-round	Very cold (3° or less); soil characterized by permafrost; Arctic tundra occurs in Arctic Circle; alpine tundra in other high elevations

1. In millimeters
2. Degrees Celsius

biome types, such as the tundra, are dominated by a range of physiognomic types and are in one prevailing environmental region.

Classification of Biomes

There are many ways to classify biomes. One system, which designates a small number of broadly defined biomes, divides global vegetation into nine major terrestrial biomes: tundra, taiga, temperate forest, temperate rain forest, tropical rain forest, savanna, temperate grasslands, chaparral, and desert. Other systems more narrowly define biomes, designating a larger total number. In those cases, some of the broadly defined biomes are divided into two or more biomes. For example, the biome called temperate forest in a broad classification may be separated into temperature deciduous forest and temperate evergreen forest in a fine classification. The biome of desert in the broad classification may be broken into warm semidesert, cool semidesert, Arctic-alpine semidesert, Arctic-pine desert, and true desert in the fine classification.

Description of Biome Distributions

Naturalists, geographers, and ecologists have tried to correlate world major types of biomes to climatic patterns in both descriptive and quantitative approaches. For example, in northern North America, the tundra and boreal forests are two broad belts of vegetation that stretch from east to west. The distribution of the two biomes is primarily influenced by temperature. South of those two belts are biome types that are mostly controlled by precipitation and evaporation. From east to west in North America, available moisture decreases, influencing biome distribution. Humid regions along the East Coast support forest biomes, including temperate coniferous forests and temperate deciduous forest. West of the eastern forests is a biome type of grasslands, including tall-grass prairie and short-grass steppe. In this zone, there is less precipitation than evaporation. The ratio of precipitation to evaporation is about 0.6 to 0.8 in the land that supports a tall-grass prairie and 0.2 to 0.4 farther west, where a short-grass steppe is supported. Beyond the short-grass steppe are shrubland and the deserts of the West. Western North America is a mountainous country in which vegetation zones reflect climatic changes on an altitudinal gradient. The vegetation in the lowlands is characteristic of the regions (short-grass steppe on the east side of Rocky Mountains, sagebrush cold semideserts in the Great Basin between the Rocky Mountains and the Sierra Nevada, and grasslands in California's Central Valley west of the Sierra Nevada). Above the base regions, the vegetation changes from shrub, woodland, or deciduous forest to montane coniferous forest or alpine tundra. In Central America, from Mexico to Panama where precipitation becomes ample and temperatures are high, tropical rain forests and tropical seasonal forests occur.

Similar distributions of biomes along latitude and altitude can be found in South America, Africa, and Eurasia. In general, the climate-induced patterns of vegetation are influenced by latitude; the location of regions within a continent, which affects the amount of moisture they receive; and altitude, in which mountains modify the climate patterns. In addition, other factors, such as fire and human disturbance, may influence distributions of biomes. For example, most grasslands require periodic fires for maintenance, renewal, and elimination of incoming woody growth. Grasslands at one time covered about 42 percent of the land surface of the world. Humans have converted much of that area into croplands.

Quantitative Relationships

Descriptive relationships can provide pictures of world vegetation distributions along latitudinal and altitudinal gradients of temperature and moisture. Ecologists in the past several decades have also sought quantitative relationships between distributions of biomes and environmental factors. For example, when R. H. Whittaker plotted various types of biomes on gradients of mean annual temperature and mean annual precipitation in 1975, a global pattern emerged relating biomes to climatic variables. It was shown that tropical rain-forest biomes are distributed in regions with annual mean precipitation of 2,500 to 4,500 millimeters and annual mean temperatures of 20 to 30 degrees Celsius. Tropical seasonal forest and savannas also occur in warm regions with precipitation of 1,500-2,500 millimeters and 500-1,500 millimeters per year, respectively. Temperate forests occupy regions with annual temperature of 5 to 20 degrees Celsius and precipitation exceeding 1,000 millimeters per year.

PhotoDisc

Humid regions along the East Coast of North America support forest biomes, including temperate coniferous forests and temperate deciduous forests.

This thermal zone can support temperate rain forest when annual precipitation is more than 2,500 millimeters and temperate grassland when annual precipitation is below 750 millimeters. Temperate woodland occurs between temperate forests and grasslands. Tundra and taiga are distributed in regions with an annual mean temperature below 3 degrees Celsius, whereas deserts occupy areas with annual precipitation below 250 millimeters.

These relationships between climatic variables and biomes provide a reasonable approximation of global vegetation patterns. Many types of biomes intergrade with one another. Soil, exposure to fire, and regional climate can influence distributions of biomes in a given area.

BIOMES: TYPES

Categories: Biomes; ecology; ecosystems

The major recognizable life zones of the continents are divided into biomes, characterized by their plant communities.

Temperature, precipitation, soil, and length of day affect the survival and distribution of biome species. Species diversity within a biome may increase its stability and capability to deliver natural services, including enhancing the quality of the atmosphere, forming and protecting the soil, controlling pests, and providing clean water, fuel, food, and drugs. Major biomes include the *temperate*, *tropical*, and *boreal forests*; *tundra*; *deserts*; *grasslands*; *chaparral*; and *oceans*.

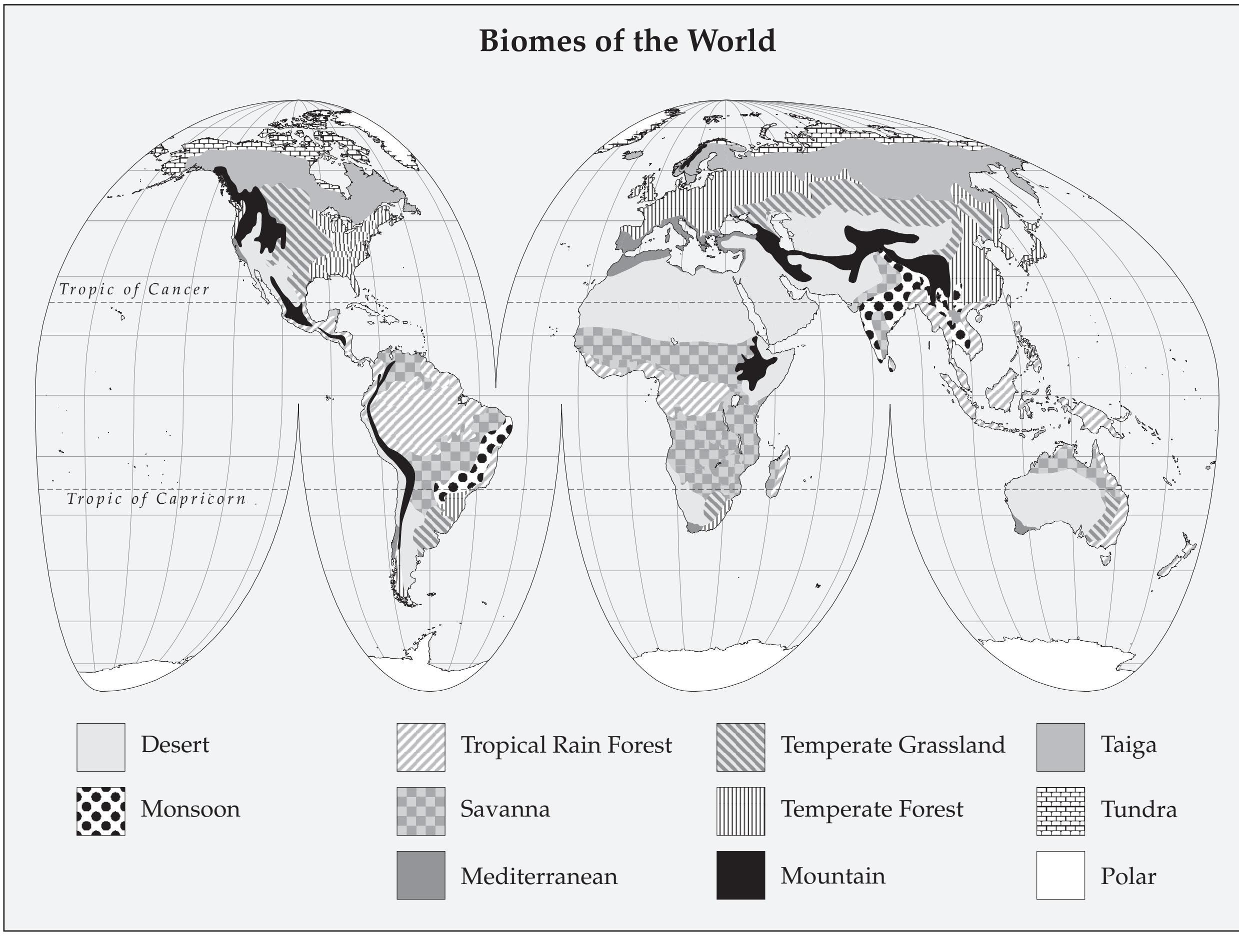
Temperate Forests

The temperate forest biome occupies the so-called temperate zones in the midlatitudes (from about 30 to 60 degrees north and south of the equator). Temperate forests are found mainly in Europe, eastern North America, and eastern China, and in narrow zones on the coasts of Australia, New Zealand, Tasmania, and the Pacific coasts of North and South America. Their climates are characterized by high rainfall and temperatures that vary from cold to mild.

Temperate forests contain primarily *deciduous* trees—including maple, oak, hickory, and beechwood—and, secondarily, *evergreen* trees—including pine, spruce, fir, and hemlock. Evergreen forests in some parts of the Southern Hemisphere contain eucalyptus trees. The root systems of forest trees help keep the soil rich. The soil quality and color are due to the action of earthworms. Where these forests are frequently logged, soil runoff pollutes streams, which reduces spawning habitat for fish. Raccoons, opossums, bats, and squirrels are found in the trees. Deer and black bears roam forest floors. During winter, small animals such as marmots and squirrels burrow in the ground.

Tropical Forests

Tropical forests exist in frost-free areas between the Tropic of Cancer and the Tropic of Capricorn.



Temperatures range from warm to hot year-round. These forests are found in northern Australia, the East Indies, Southeast Asia, equatorial Africa, and parts of Central America and northern South America.

Tropical forests have high biological diversity and contain about 15 percent of the world's plant species. Animal life thrives at each layer of tropical forests. Nuts and fruits on the trees provide food for birds, monkeys, squirrels, and bats. Monkeys and sloths feed on tree leaves. Roots, seeds, leaves, and fruit on the forest floor feed larger animals. Tropical forest trees produce rubber and hardwood, such as mahogany and rosewood. Deforestation for agriculture and pastures has caused reduction in plant and animal diversity in these forests.

Boreal Forests

The boreal forest is a circumpolar Northern Hemisphere biome spread across Russia, Scandinavia, Canada, and Alaska. The region is very cold. Evergreen trees such as white spruce and black spruce dominate this zone, which also contains larch, balsam, pine, fir, and some deciduous hardwoods such as birch and aspen. The acidic needles from the evergreens make the leaf litter that is changed into soil humus. The acidic soil limits the plants that develop.

Animals in boreal forests include deer, bears, and wolves. Birds in this zone include red-tailed hawks, sapsuckers, grouse, and nuthatches. Relatively few animals emigrate from this habitat during winter. Conifer seeds are the basic winter food.

Tundra

About 5 percent of the earth's surface is covered with *Arctic tundra* and 3 percent with *alpine tundra*. The Arctic tundra is the area of Europe, Asia, and North America north of the boreal coniferous forest zone, where the soils remain frozen most of the year. Arctic tundra has a permanent frozen subsoil, called *permafrost*. Deep snow and low temperatures slow the soil-forming process. The area is bounded by a 50 degrees Fahrenheit (122 degrees Celsius) circumpolar *isotherm*, known as the summer isotherm. The cold temperature north of this line prevents normal tree growth.

The tundra landscape is covered by mosses, lichens, and low shrubs, which are eaten by caribou, reindeer, and musk oxen. Wolves eat these herbivores. Bears, foxes, and lemmings also live there. The most common Arctic bird is the old squaw duck. Ptarmigans and eider ducks are also very common. Geese, falcons, and loons are some of the nesting birds of the area.

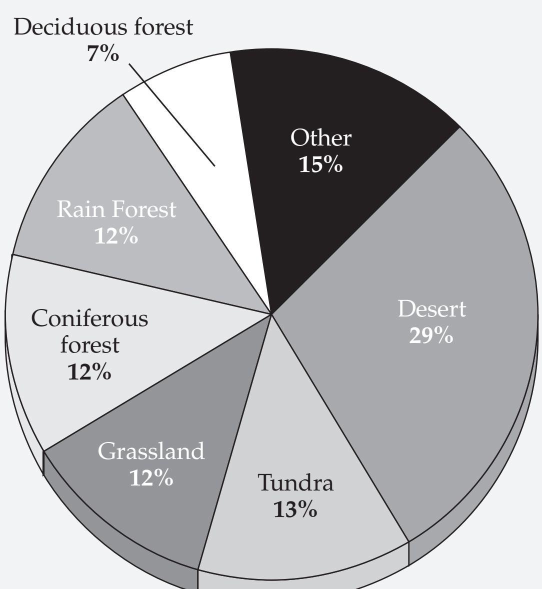
The alpine tundra, which exists at high altitude in all latitudes, is acted upon by winds, cold temperatures, and snow. The plant growth is mostly cushion- and mat-forming plants.

Deserts

The desert biome covers about one-seventh of the earth's surface. Deserts typically receive no more than 10 inches (25 centimeters) of rainfall per year, and evaporation generally exceeds rainfall. Deserts are found around the Tropic of Cancer and the Tropic of Capricorn. As warm air rises over the equator, it cools and loses its water content. The dry air descends in the two subtropical zones on each side of the equator; as it warms, it picks up moisture, resulting in drying the land.

Rainfall is a key agent in shaping the desert. The lack of sufficient plant cover contributes to soil *erosion* during wind- and rainstorms. Some desert plants—for example, the mesquite tree, which has roots that grow 40 feet (13 meters) deep—obtain water from deep below the earth's surface. Other plants, such as the barrel cactus, store large amounts of water in their leaves, roots, or stems. Some plants slow the loss of water by having tiny leaves or shedding their leaves. Desert plants have very short growth periods, because they cannot grow during the long drought periods.

Terrestrial Biomes (percentages)



Grasslands

Grasslands cover about one-quarter of the earth's surface and can be found between forests and deserts. Treeless grasslands exist in parts of central North America, Central America, and eastern South America that have between 10 and 40 inches (250-1,000 millimeters) of erratic rainfall per year. The climate has a high rate of evaporation and periodic major droughts. Grasslands are subject to fire.

Some grassland plants survive droughts by growing deep roots, while others survive by being dormant. Grass seeds feed the lizards and rodents that become the food for hawks and eagles. Large animals in this biome include bison, coyotes, mule deer, and wolves. The grasslands produce more food than any other biome. Overgrazing, inefficient agricultural practices, and mining destroy the natural stability and fertility of these lands, resulting in reduced carrying capacity, water pollution, and soil erosion. Diverse natural grasslands appear to be more capable of surviving drought than are simplified manipulated grass systems. This may be due to slower soil mineralization and nitrogen turnover of plant residues in the simplified system.

Savannas are open grasslands containing deciduous trees and shrubs. They are near the equator and are associated with deserts. Grasses there grow in clumps and do not form a continuous layer.

Chaparral

The chaparral, or *mediterranean*, biome is found in the Mediterranean Basin, California, parts of

Australia, middle Chile, and the Cape Province of South America. This region has a climate of wet winters and summer drought. The plants have tough, leathery leaves and may have thorns. Regional fires clear the area of dense and dead vegetation. The seeds from some plants, such as the California manzanita and South African fire lily, are protected by the soil during a fire and later germinate and rapidly grow to form new plants. Vegetation *dwarfing* occurs as a result of the severe summer drought and extreme climate changes.

Oceans

The ocean biome covers more than 70 percent of the earth's surface and includes 90 percent of its volume. Oceans have four zones. The *intertidal zone* is shallow and lies at the land's edge. The *continental shelf*, which begins where the intertidal zone ends, is a plain that slopes gently seaward. The *neritic zone* (*continental slope*) begins at a depth of about 600 feet (180 meters), where the gradual slant of the continental shelf becomes a sharp tilt toward the ocean floor, plunging about 12,000 feet (3,660 meters) to the ocean bottom, which is known as the abyss. The *abyssal zone* is so deep that it does not have light.

Plankton are animals that float in the ocean. They include algae and copepods, which are microscopic crustaceans. Jellyfish and animal larva are also considered plankton. The nekton are animals that move freely through the water by means of their muscles. These include fish, whales, and squid. The benthos are animals that are attached to or crawl along the ocean's floor. Clams are examples of benthos. Bacteria decompose the dead organic materials on the ocean floor.

The circulation of materials from the ocean's floor to the surface is caused by winds and water temperature. Runoff from the land contains pollutants such as pesticides, nitrogen fertilizers, and animal wastes. Rivers carry loose soil to the ocean, where it builds up the bottom areas. Overfishing has caused fisheries to collapse in every world sector.

Human Impact on Biomes

Human interaction with biomes has increased *biological invasions*, reduced species *biodiversity*, changed the quality of land and water resources, and caused the proliferation of toxic compounds. Managed care of biomes may not be capable of undoing these problems.

BIOPESTICIDES

Categories: Agriculture; bacteria; biotechnology; economic botany and plant uses; environmental issues; microorganisms; pests and pest control

Biopesticides are biological agents, such as viruses, bacteria, fungi, mites, and other organisms used to control insect and weed pests in an environmentally and ecologically friendly manner.

Biopesticides allow biologically based, rather than chemically based, control of pests. A pest is any unwanted animal, plant, or microorganism. When the environment provides no natural resistance to a pest and when no natural antagonists are present, pests can run rampant. For example, spread of the fungus *Endothia parasitica*, which entered New York in 1904, caused the nearly complete destruction of the American chestnut tree because no natural control was present. Viruses, bacteria, fungi, protozoa, mites, insects, and flowers have all been used as biopesticides.

Image Not Available

Advantages of Biopesticides

Many plants and animals are protected from pests by passive means. For example, plant rotation is a traditional method of insect and disease protection that is achieved by removing the host plant long enough to reduce a region's pathogen and pest populations. Biopesticides have several significant advantages over commercial pesticides. They appear to be ecologically safer than commercial pesticides because they do not accumulate in the food chain. Some biopesticides provide persistent control, as more than a single mutation is required to adapt to them and because they can become an integral part of a pest's life cycle. In addition, biopesticides have slight effects on ecological balances because they do not affect nontarget species. Finally, biopesticides are compatible with other control agents. The major drawbacks to using biopesticides are the time required for them to kill their targets and the inefficiency with which they work; also, if the organism being used as a biopesticide is a nonnative species, it may cause unforeseen damage to the local ecosystem.

Viruses and Bacteria

Viruses have been developed against insect pests such as *Lepidoptera* (butterflies and moths), *Hymenoptera* (bees, wasps, and ants), and *Dipterans* (flies). Gypsy moths and tent caterpillars, for example, periodically suffer from epidemic virus infestations, which could be exploited and encouraged.

Many *commensal* microorganisms (microorganisms that live on or in other organisms causing no direct benefit or harm) that occur on plant roots and leaves can passively protect plants against microbial pests by *competitive exclusion* (that is, simply crowding them out). *Bacillus cereus* has been used as an inoculum on soybean seeds to prevent infection by fungal pathogens in the genus *Cercospora*. Some microorganisms used as biopesticides produce antibiotics, but the major mechanism in most cases seems to be competitive exclusion. For example, *Agrobacterium radiobacter* antagonizes *Agrobacterium tumefaciens*, which causes the disease crown gall. Species of two bacterial genera—*Bacillus* and *Streptomyces*—when added as biopesticides to soil help control the damping-off disease of cucumbers, peas, and lettuce caused by *Rhizoctonia solani*. *Bacillus subtilis* added to plant tissue also controls stem rot and wilt rot caused by species of the fungus *Fusarium*. *Mycobacteria* species produce cellulose-degrading enzymes, and their addition to young seedlings helps control fungal infection by species of *Pythium*, *Rhizoctonia*, and *Fusarium*. Species of *Bacillus* and *Pseudomonas* produce enzymes that dissolve fungal cell walls.

Bacillus thuringiensis and *Bacillus popilliae* as Microbial Biocontrol Agents

***Bacillus thuringiensis* Toxins**

The best examples of microbial insecticides are *Bacillus thuringiensis* (*B.t.*) toxins, which were first used in 1901. They have had widespread commercial production and use since the 1960's and have been successfully tested on 140 insects, including mosquitoes. Insecticidal endotoxins are produced by *B.t.* during sporulation, and exotoxins are contained in crystalline parasporal protein bodies. These protein crystals are insoluble in water but readily dissolve in an insect's gut. Once dissolved, the proteolytic enzymes paralyze the gut. Spores that have been consumed germinate and kill the insect. *Bacillus popilliae* is a related bacterium that produces an insecticidal spore that has been used to control Japanese beetles, a corn pest.

The gene for the *B.t.* toxin has also been inserted into the genomes of cotton and corn, producing genetically modified, or GM, plants that produce their own *B.t.* toxin. GM cotton and *B.t.* corn both express the gene in their roots, which provides them with protection from root worms. Ecologists and environmentalists have expressed concern that constantly exposing pests to *B.t.* will cause insects to develop resistance to the toxin. In such a scenario, the effectiveness of traditionally applied *B.t.* would decrease.

Fungi and Protozoa

Saprophytic fungi can compete with pathogenic fungi. There are several examples of fungi used as biopesticides, such as *Gliocladium virens*, *Trichoderma hamatum*, *Trichoderma harzianum*, *Trichoderma viride*, and *Talaromyces flavus*. For example, *Trichoderma* species compete with pathogenic species of *Verticillium* and *Fusarium*. *Peniophora gigantea* antagonizes the pine pathogen *Heterobasidion annosum* by three mechanisms: It prevents the pathogen from colonizing stumps and traveling down into the root zone, it prevents the pathogen from traveling between infected and uninfected trees along interconnected roots, and it prevents the pathogen from growing up to stump surfaces and sporulating.

Nematodes are pests that interfere with commercial button mushroom (*Agaricus bisporus*) production. Several types of nematode-trapping fungi can be used as biopesticides to trap, kill, and digest the nematode pests. The fungi produce constricting and nonconstricting rings, sticky appendages, and spores, which attach to the nematodes. The most common nematode-trapping fungi are *Arthrobotrys oligospora*, *Arthrobotrys conoides*, *Dactylaria candida*, and *Meria coniospora*.

Protozoa have occasionally been used as biopesticide agents, but their use has suffered because of slow growth and the complex culture conditions associated with their commercial production.

Mites, Insects, and Flowers

Well-known "terminator" bugs include praying mantis and ladybugs as well as decollate snails, which eat the common brown garden snail. Fleas, grubs, beetles, and grasshoppers often have natural nematode species that prey on them, which can be used as biocontrol agents. Predaceous mites are used as a biopesticide to protect cotton from other insect pests such as the boll weevil. Parasitic wasps of the genus *Encarsia*, especially *E. formosa*, prey on whiteflies, as does *Delphastus pusillus*, a small, black ladybird beetle.

Dalmatian and Persian insect powders contain pyrethrins, which are a toxic insecticidal compounds produced in *Chrysanthemum* flowers. Synthetic versions of these naturally occurring compounds are found in products used to control head lice.

BIOSPHERE CONCEPT

Categories: Ecology; ecosystems; environmental issues

The term "biosphere" was coined in the nineteenth century by Austrian geologist Eduard Suess in reference to the 20-kilometer-thick zone extending from the floor of the oceans to the top of mountains, within which all life on earth exists. Thought to be more than 3.5 billion years old, the biosphere supports nearly one dozen biomes, regions of climatic conditions within which distinct biotic communities reside.

Compounds of hydrogen, oxygen, carbon, nitrogen, potassium, and sulfur are cycled among the four major spheres, one of which is the biosphere, to make the materials that are essential to the existence of life. The other spheres are the *lithosphere*, the outer part of the earth; the *atmosphere*, the whole mass of air surrounding the earth; and the *hydrosphere*, the aqueous vapor of the atmosphere, sometimes defined as including the earth's bodies of water.

The Water Cycle

The most critical of these compounds is water, and its movement among the spheres is called the *hydrologic cycle*. Dissolved water in the atmosphere condenses to form clouds, rain, and snow. The annual precipitation for any region is one of the major factors in determining the terrestrial biome that can exist. The precipitation takes various paths leading to the formation of lakes and rivers. These flowing waters interact with the lithosphere (the outer part of the earth's crust) to dissolve chemicals as they flow to the oceans. Evaporation of water from the oceans then supplies most of the moisture in the atmosphere. This cycle continually moves water among the various terrestrial and oceanic biomes.

Solar Energy

The biosphere is also dependent upon the energy that is transferred from the various spheres. Solar energy is the basis for almost all life. Light enters the biosphere as the essential energy source for photosynthesis. Plants take in carbon dioxide, water, and light energy, which is converted via *photosynthesis* into chemical energy in the form of sugars and other organic molecules. Oxygen is generated as a by-product. Most animal life reverses this process during *respiration*, as chemical energy is released to do work by the oxidation of organic molecules to produce carbon dioxide and water.

Incoming solar energy also interacts dramatically with the water cycle and the worldwide distribution of biomes. Because of the earth's curvature, the equatorial regions receive a greater amount of solar heat than the polar regions. Convective movements in the atmosphere—such as winds, high- and low-pressure systems, and weather fronts—and the hydrosphere—such as water currents—are generated during the redistribution of this heat. The weather patterns and climates of earth are a response to these energy shifts. Earth's various climates are defined by the mean annual temperature and the mean annual precipitation.

BIOTECHNOLOGY

Categories: Agriculture; bacteria; biotechnology; disciplines; economic botany and plant uses; environmental issues; genetics; history of plant science

Biotechnology is the use of living organisms, or substances obtained from those organisms, to produce processes or products of value to humanity, such as foods, high-yield crops, and medicines.

Modern biotechnological advances have provided the ability to tap into a natural resource, the world gene pool, with such great potential that its full magnitude is only beginning to be appreciated. Theoretically, it should be possible to transfer one or more genes from any organism in the world into any other organism. Because genes ultimately control how any organism functions, gene transfer can have a dramatic impact on agricultural resources and human health in the future.

History of Biotechnology

Although the term "biotechnology" is relatively new, the practice of biotechnology is at least as old as civilization. Civilization did not evolve until humankind learned to produce food crops and domestic livestock through the controlled breeding of selected plants and animals. Eventually humans began to utilize microorganisms in the production of foods such as cheese and alcoholic beverages. During the twentieth century, the pace of modification of various organisms accelerated. Through carefully controlled breeding programs, plant architecture and fruit characteristics of crops have been modified to facilitate mechanical harvesting. Plants have been developed to produce specific drugs or spices, and microorganisms have been selected to produce antibiotics and other medicinal or food products.

Developments in Biotechnology

Since the mid-twentieth century, the ability to utilize artificial media to propagate plants has led to the development of a technology called tissue culture. The earliest form of tissue culture involved using the culture of meristem tissue to produce numerous tiny shoots that can be grown into full-size plants, referred to as clones because each plant is genetically identical. More than one thousand plant species have been propagated by tissue culture techniques. Plants have been propagated via the culture of other tissues, including the stems and roots. In some of these techniques, the plant tissue is treated with hormones to produce callus tissue, masses of undifferentiated cells. The callus tissue can be separated into single cells to establish a cell suspension culture. Callus tissue and cell suspensions can be used to produce specific drugs and other chemicals. Entire plants can also be generated from the callus tissue or from single cells by addition of specific combinations of hormones.

A far more complex method of cloning of plants and animals from the deoxyribonucleic acid (DNA) of a single cell is a more recent development. Proponents of this method of producing copies of organisms have suggested that cloning technology might be used to improve agricultural stock and to regenerate endangered species. These ideas have had their detractors, however, as critics have noted the potential dangers of narrowing a species' gene pool. The July, 1996, birth in Scotland of Dolly, a sheep cloned and raised to adulthood, demonstrated that the cloning of animals had left the realm of science fiction and become a matter of scientific fact.

Recombinant DNA Technology

In practice, recombinant DNA methodology is complex, but in concept, it is fairly easy to comprehend. The genes in all living cells are composed of the same chemical, DNA. The DNA of all cells, whether from bacteria, plants, or animals including humans, is very similar. When DNA from a foreign species is transferred into a different cell, it functions exactly as the native DNA functions; that is, it "codes" for protein.

Image Not Available

The easiest way to manipulate genes is using bacterial cells (most often *Escherichia coli*) and a *vector*, an agent that can be used to pass the gene from one cell to another. *Plasmids*, small extra circular DNA molecules found in many bacterial cells, are commonly used for this purpose. Plasmids are replicated along with the bacterial cell's own DNA every time the cell reproduces. Plasmids can be easily isolated from bacterial cells. When a specific gene has been isolated, it can be fused, using *restriction endonucleases*, with a plasmid to produce a recombinant plasmid. These *recombinant plasmids* can then be put into bacterial cells by a process called *transformation*. Special plasmids called *expression vectors* allow expression of inserted genes once they are inside a bacterial cell.

Although expressing foreign genes in bacterial cells is relatively simple, inserting them into plants and getting them expressed is more complicated. The *Ti plasmid* is a widely used vector that works well in dicots but has never worked for monocots. Consequently, the first successful transgenic plants were dicots, while success with the most important food crops, monocots such as rice and corn, took more time and effort.

Many alternative methods for inserting genes into plant cells have been developed that work on both monocots and dicots. *Microinjection* can be used to insert a gene into individual cells. A less laborious method is called *biolistic*, for biological ballistic, where millions of copies of the gene are attached to tiny projectiles that are then fired into groups of plant cells. Using these and other methods, genetic modification of plants is becoming more routine.

Future of Biotechnology in Agriculture

This new technology could have a tremendous impact on agriculture. As the human population grows, biotechnology will most likely play an important role in producing an increase in food production. Such an increase will require developments such as crop plants that will produce higher yields under normal conditions and crops that will produce higher yields when grown in marginal environments. Biotechnology provides a means of developing higher-yielding crops in much less time than it takes to develop them though traditional plant-breeding programs. Genes for the desired characteristics can be inserted directly into the plant without having to go through repeated controlled selection and breeding cycles to establish the trait.

There are also economic advantages in diversifying agriculture production in a given area. A producer might wish to grow a particular high-value cash crop in an area where soil or climate conditions would prevent such a crop from thriving. Biotechnology can help solve these types of problems. For example, high value crops can be developed to grow in areas that heretofore would not have supported such crops. Plants also can be developed to produce new products such as antibiotics, drugs, hormones, and other pharmaceuticals. Crop plants bioengineered to produce novel products mean that pharmaceuticals and other valuable products could be grown in farm environments rather than in laboratories.

While there will be a growing pressure for agriculture to produce more food in the future, there will also be pressure for crop production to be more friendly to the environment. Biotechnology has the potential to play a major role in the development of a long-term, sustainable, environmentally friendly agricultural system. For example, the development of crop varieties with improved resistance to pests will reduce the reliance on pesticides. Methods of crop production and harvest with less environmental impact will also have to be developed. Because agriculture will continue to have an impact on the environment, the need to remediate polluting agents will continue to exist. Hence biotechnology will play an important role in the development of bioremediation systems for agriculture as well as other industrial pollutants.

Ownership Issues

There will be many difficult ethical and economic issues surrounding the use of this new biotechnology. One of the major questions concerns ownership. Patent laws in the United States read that ownership over an organism can be granted if the organism has been intentionally genetically modified through the use of recombinant DNA techniques. In addition, processes that utilize genetically modified organisms can be patented. Therefore one biotechnology firm may own the patent to an engineered organism, but another firm may own the rights to the process used to produce it.

BOTANY

Categories: Disciplines; history of plant science

Botany is the branch of science that studies plant life.

Botany is a very old branch of science that began with early people's interest in the plants around them. Plant science now extends from that interest to cutting-edge biotechnology. Any topic dealing with plants, from the level of their *cellular biology* to the level of their economic production, is considered part of the field of botany.

History and Subdisciplines

The origins of this branch of biology are rooted in human beings' attempts to improve their lot by raising better food crops around 5000 B.C.E. This practical effort developed into intellectual curiosity about plants in general, and the science of botany was born. Some of the earliest botanical records are included with the writings of Greek philosophers, who were often physicians and who used plant materials as curative agents. In the second century B.C.E. Aristotle had a botanical garden and an associated library.

As more details became known about plants and their functions, particularly after the discovery of the microscope, a number of subdisciplines arose. Plant *anatomy* is concerned chiefly with the internal structure of plants. Plant *physiology* delves into the living functions of plants. Plant *taxonomy* has as its interest the discovery and systematic classification of plants. Plant geography, also known as geobotany or *phytogeography*, deals with the global distribution of plants. Plant *ecology* studies the interactions between plants and their surroundings. Plant *morphology* studies the form and structure of plants. Plant *genetics* attempts to understand and work with the way that plant traits are inherited. Plant *cytology*, often called cell biology, is the science of cell structure and function. *Economic botany*, which traces its interest back to the origins of botany, studies those plants that play important economic roles. These include major crops such as wheat, rice, corn, and cotton.

Ethnobotany is a rapidly developing subarea in which scientists communicate with indigenous peoples to explore the knowledge that exists as a part of their folk medicine. Several new drugs and the promise of others have developed from this search.

At the forefront of botany today is the field of *genetic engineering*, including the *cloning* of organisms. New or better crops have long been developed by the technique of *crossbreeding*, but genetic engineering offers a much more direct course. Using its techniques, scientists can introduce a gene carrying a desirable trait directly from one organism to another. In this way scientists hope to protect crops from frost damage, to inhibit the growth of weeds, to provide insect repulsion as a part of the plant's own system, and to increase the yield of food and fiber crops.

The role that plants play in the energy system of the earth (and may someday play in space stations or other closed systems) is also a major area of study. Plants, through photosynthesis, convert sunlight into other useful forms of energy upon which humans have become dependent. During the same process carbon dioxide is removed from the air, and oxygen is delivered. Optimization of this process and discovering new applications for it are goals for botanists.

BROMELIACEAE

Categories: Angiosperms; economic botany and plant uses; *Plantae*; taxonomic groups

The family Bromeliaceae *comprises a group of perennial, monocotyledon herbs or trees that often age slowly.*

Important ornamentals (called bromeliads) as well as sources of food and medicines, *Bromeliaceae* have substantial economic value and are widely cultivated. The colors of the leaves offer decorative foliage, and the flowers are of astonishing hues due to the rich content of pigment-forming substances known as anthocyanins. Based on ovary position, habit, and floral and pollen morphology, the family *Bromeliaceae* has been split into three subfamilies: subfamily *Pitcairnioideae*, subfamily *Tillandsioideae*, and subfamily *Bromelioideae*. There are fifty-six genera and approximately twenty-six hundred species, growing mostly in the neotropical regions of the world, from Virginia to southern Argentina. One species, *Pitcairnia feliciana*, originated in Africa. This interesting family can nevertheless occupy a variety of ecologically diverse environments, ranging from the dry deserts in Peru to the highest montane forest in the Andes Mountains.

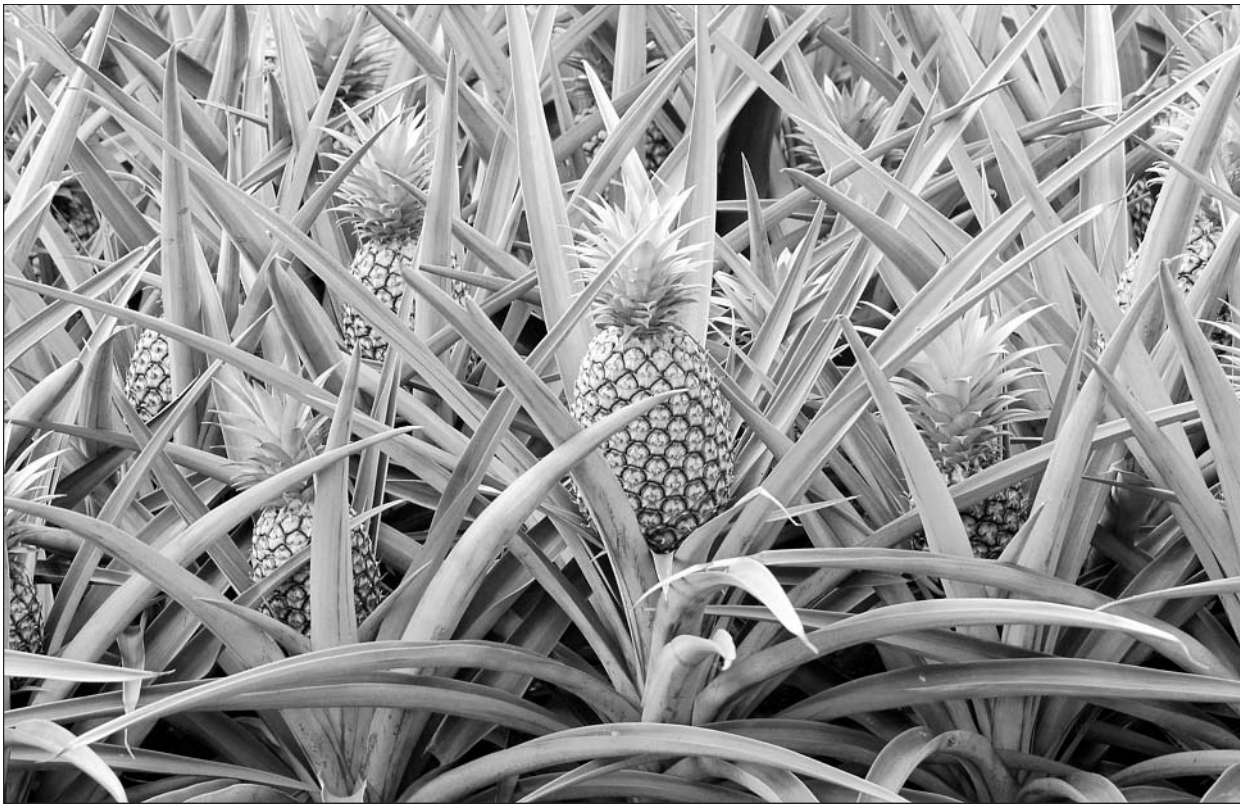
Appearance and Structure

The *Bromeliaceae* family shares a basic ground plan of construction that consists of branches (ramets) and an inflorescence that follows a repetitive pattern when growing. However, modifications, in the form of reductions, of this basic plan have evolved in different subfamilies. The basic pattern consists of sympodial branching, a rhythmic type of growth in which the axis is built up by a linear series of shoot units, each distal unit developing from an axillary bud located on the previous shoot unit. This pattern of development leads to a series of condensed ramets with terminal flowers. Roots, when present, usually emerge from the lower half of each ramet.

Growing Habit

Bromeliaceae range from small plants, such as some miniature *Tillandsia*, to very tall individuals, such as *Puya raimomndii*, reaching up to 32 feet (10 meters) in height. They can be epiphytes, that is, plants that use other species as support without harming them, or terrestrial. Some grow on top of rocks, and some are carnivorous.

Those species whose leaves are born from a common place in the stem (in a rosulate shape) can develop the tank form, also known as *phytotelma*, that is common in genera such as *Aechmea* and *Brocchinia*. These phytotelma harbor a variety of insects and small vertebrates that grow in small pools



The pineapple, Ananas comosus, *is the species of bromeliad most widely used as food.*

of water and old leaves that collect at the bottom of the "tank." The tanks accumulate water and partially dissolved organic matter, creating a nutrient-rich substrate as a continuous supply of moisture. Other *Bromeliaceae* do not form tanks; instead, they have fully functional roots and specialized hairs for water absorption.

Scales

Physiological adaptations to different environments among some species correlate with the presence of a highly evolved type of foliar hair (or trichome) known as a *scale*. The scales may cover the entire surface of the leaf, sometimes appearing in different locations and patterns; they absorb atmospheric water through capillary action, like blotting paper, and the water is later transported to the leaf tissue, where it is stored in the parenchyma. Division of the scale in two parts—known as the shield, or *trichome covering*, and the water absorption cells—is what makes *Bromeliaceae* unique. When water is scarce the scale shrinks, and when water is present the shield cells expand. Scales protect the leaves against transpiration and reduce water evaporation during the dry periods.

Flowers and Pollination

The flowers of *Bromeliaceae* are generally hermaphroditic (functionally unisexual). Their shape can be radial or slightly asymmetric, and the number of floral parts known as sepals and petals is always three. The stamen arrangement is in two whorls, with three stamens in each one. The ovary can be superior or inferior, and the placentation (position of the ovules) is mostly axial. Septal nectaries are always present at the base of the flower. The sepals are distinguished from the petals by their color and size. The petals show bright colors, while the sepals may remain mostly in green hues. Fruits are usually a capsule or a berry, and the seeds are winged.

The bloom of *Bromeliaceae* flowers is usually odorless, although some species may have scented flowers, indicating pollination by nocturnal moths or butterflies. However, their abundant secretion of nectar indicates that the plants are pollinated primarily by birds.

Uses

The main uses of *Bromeliaceae* are as textile fiber, food, medicine, and ornamental plantings. In the food category the pineapple, *Ananas comosus*, is the most widely used species. The medicinal properties of pineapple are based on the presence of bromelain, a proteolitic (protein-breaking) enzyme that is widely used to treat inflammation and pain. Serotonin, a neurotransmitter, is also present, and steroids from the leaves possess estrogenic activity. Thirteen species of *Bromeliaceae* are used as a source of textile fibers; for example, hammocks are made from the fibers of *Aechmea bracteata* and of pineapple.

BROWN ALGAE

Categories: Algae; *Protista*; taxonomic groups; water-related life

Seaweeds that are brown to olive-green in color belong to the phylum Phaeophyta*, or brown algae, which includes between fifteen hundred and two thousand species.*

Brown algae (phylum *Phaeophyta*) are familiar to most people as brown or dark green seaweeds. Some brown algae are microscopic in size, but many are relatively large: One giant kelp measured 710 feet in length. All brown algae are multicellular.

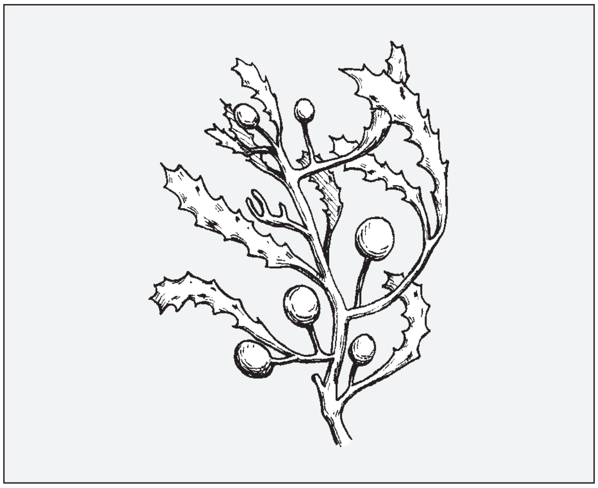
Appearance and Distribution

Brown algae have a body, called a *thallus*, which is a fairly simple, undifferentiated structure. Some thalli consist of simple branched filaments. Some brown algae have more complex structures called *pseudoparenchyma* because they superficially resemble the more complex tissues of higher plants.

Giant kelp have a thallus that is differentiated into a *holdfast*, a *stipe*, and one or more flattened, leaflike *blades*. The holdfast functions as the name implies, and holds the rest of the organism to the substrate. It is a tough, sinewy structure resembling a mass of intertwined roots. The stalk that constitutes the stipe is often hollow, with a meristem (a zone of growing tissue) either at its base or at the blade junctions. Because the meristem produces new tissue at the base, the oldest parts of the blades are at the tips.

The blades, which, like most of the rest of the giant kelp body, are photosynthetic, may have gas-filled floats called bladders toward their bases, which may contain carbon monoxide gas. The function of this particular gas has not yet been determined.

The vast majority of species are marine, living in cold, shallow ocean waters, and may be the dominant plant life on rocky coastlines. The giant kelp can be found in waters around 100 feet deep. Only 4 of the 260 identified genera occur in fresh water. Brown algae of the order *Fucales* are commonly



Brown algae, which range in color from olive green to golden, are among the largest algae, including the giant kelps, and often have a thallus (body) that is differentiated into a holdfast, a stipe (stalk), and one or more flattened, leaflike blades.

called rockweeds; kelp belong to the order *Laminariales*.

Brown algae are less common in tropical and subtropical areas. However, in the Caribbean region, *sargassum* (large masses of brown algae having a branching thallus with lateral outgrowths differentiated into leafy segments, air bladders, or spore-bearing structures) make up large floating mats; they gave their name to the Sargasso Sea.

Pigments and Food Reserves

The color of the brown algae can vary from light yellow-brown to almost black. Its color reflects the presence of varying amounts of the brown xanthophyll pigment fucoxanthin, a carotenoid pigment, in addition to chlorophylls *a* and *c*. The main food reserve is a carbohydrate called laminarin, although giant kelp can also translocate mannitol. Algin (alginic acid) can be found in or on the cell walls and may comprise as much as 40 percent of the dry weight of some kelps.

Reproduction

Reproductive cells of brown algae are unusual in that their two flagella are located laterally, instead of at the ends. The only motile cells in the brown algae are the gametes or reproductive cells. In the common genus *Fucus*, separate male and female thalli are produced. Fertile areas called *receptacles* develop at the tips of the lobes of the thallus. Each receptacle has pores on the surface. These pores open into special spherical, hollow chambers called *conceptacles*, in which the gametes are formed. Eight eggs are produced in the female structure, while sixty-four sperm cells are produced in the male structure. Eventually, both eggs and sperm are released into the water, where fertilization takes place and the resulting zygotes develop into mature thalli.

Economic Uses

Brown algae have several uses and applications for humans. Giant kelp is eaten, and one species found in the Pacific Ocean has been used, in chopped-up form, as a poultice applied to cuts. Algin, a colloidal substance produced by brown algae, is used as a thickener or stabilizer in commercially produced ice cream, salad dressing, beer, jelly beans, latex paint, penicillin suspensions, paper, textiles, toothpastes, and floor polish. Brown algae, with its high concentration of the element iodine, has been used to treat goiter, an iodine-deficiency disease. Kelp, also high in nitrogen and potassium, has been used as fertilizer and as livestock feed.

Some types of brown algae, such as *Fucus*, contain either phenols or terpenes. Botanists believe these substances may discourage herbivory. These substances also have been shown to possess microbe- and cancer-fighting properties. Brown algae is the subject of continuing research in these areas of medicine.

BRYOPHYTES

Categories: Nonvascular plants; paleobotany; *Plantae*; taxonomic groups

Bryophytes comprise three phyla of nonvascular plants, which generally lack the specialized conductive tissues (xylem and phloem) that are found in the vascular plants, are small in size, and are distributed worldwide in moist, shady habitats.

Bryophytes (from the Greek word *bryon*, meaning "moss") were once grouped together into one large phylum. Many botanists today recognize that these organisms belong to at least three distinct phyla: phylum *Hepatophyta* (the liverworts), phylum *Anthocerophyta* (the hornworts), and phylum *Bryophyta* (the mosses).

Origin and Relationships

Bryophytes are thought to have originated more than 430 million years ago, during the Silurian period. Many botanists speculate that bryophytes arose from an ancestor in the green algal order *Charales* or *Coleochaetales* based on biochemical, morphological, and life history comparisons. For example, *Chara* has a flavonoid biosynthesis pathway that is similar to that of higher plants, while *Coleochaete* retains its zygote inside parental tissue, similar to higher plants. These characteristics, along with similarities in cell division patterns, photosynthetic pigment contents, and the use of starch as a storage material, all suggest ancestry in the *Charales* or *Coleochaetales* orders.

Historically, bryophytes were thought to represent a group that formed a separate lineage from that of vascular plants. By the late 1990's a growing body of evidence suggested that bryophytes and vascular plants were derived from a common green algal ancestor. Some botanists suggest that the earliest land plants may have been members of the phylum *Anthocerophyta*. One of the key arguments in this theory is that the structure of some hornwort chloroplasts is virtually identical to the chloroplast structure of the presumed algal ancestors.

Studies conducted in the 1990's involving the presence or absence of certain portions of noncoding deoxyribonucleic acid (DNA) called *introns* in the genetic information of several groups of algae, bryophytes, and vascular plants revealed that members of the *Hepatophyta*, the liverworts, were likely among the first land plants. Like the algae, they lack the introns that are found in groups that are presumed to be more derived. Thus, based on the assumption that introns are derived characters, ancestors of modern liverworts may have given rise to vascular plants.

Anatomy

The dominant phase of the bryophyte life cycle is the haploid gametophyte phase. The gametophyte is photosynthetic and is usually small because of the lack of efficient vascular tissues.

Bryophytes possess rootlike *rhizoids* that anchor the plant to the soil and aid in nutrient uptake. A waxy *cuticle*, which helps prevent water loss, covers the body. Liverworts have pores for gas exchange, while hornworts and mosses have stomata to regulate gas movement. Some liverworts and hornworts have a thalloid body type, which is not differentiated into leaf and stem. The *thallus* may be simple, composed of a ribbonlike, flattened body of relatively undifferentiated tissues, or complex, in which there is a distinct differentiation of tissues. The flat body may aid in the uptake of water and minerals and in gas exchange. The bodies of some liverworts and the mosses are divided into leaf and stem. These terms are used for convenience even though xylem and phloem are not present.

Some mosses possess tissues that have functions similar to xylem and phloem. *Hydroids* are water-conducting cells that make up a tissue called hadrom. *Leptoids* are food-conducting cells that make up a tissue called leptom. These tissues appear similar to the conducting tissues in a group of fossil plants called *protracheophytes*, which are thought to be an intermediate group between the bryophytes and the vascular plants.

The diploid sporophyte of liverworts and mosses consists of a *foot*, which is attached to a stalklike *seta*. The seta connects the foot to the spore-producing organ called the *sporangium*, or *capsule*. The hornwort sporophyte, however, lacks a seta and possesses a long, cylindrical sporangium. The foot of the bryophyte sporophyte contains specialized transfer cells, which bring materials from the maternal gametophyte to the sporophyte. The sporophyte is totally dependent on the maternal gametophyte for its survival. A layer of sterile tissue called the *calyptra* covers the capsules of liverworts and mosses. When the spores are mature, the sporophyte may die, allowing the release of spores as the capsule decays (as in some thalloid liverworts). Alternatively, the capsule may rupture, allowing spores to be released through pores (as in mosses and leafy liverworts), or the capsule may split along the side to release the spores (as in the hornworts). Liverworts and hornworts often have specialized structures in the capsules called *elaters* that aid in dispersing spores from the capsules.

Reproduction and Life Cycle

Bryophytes may reproduce either asexually or sexually. Asexual reproduction primarily occurs by *fragmentation*. Some of the liverworts also repro-

Image Not Available

duce asexually by the production of small masses of vegetative tissue called *gemmae* in special structures called *gemma cups*. Water drops disperse the gemmae.

Bryophytes exhibit a typical plant life-cycle pattern called *alternation of generations*. There are distinct male and female gametophytes in some species, while other species produce both male and female organs in one plant. The reproductive organs are all multicellular. Male organs are called *antheridia*. Special cells within an antheridium undergo mitotic cell division to produce flagellated haploid sperm cells. The sperm cells are the only flagellated cells produced by bryophytes. As with many other plant groups, the presence of flagella on the sperm indicates that these cells require liquid water to swim to the egg.

The female organs are called *archegonia*. The archegonium is composed of a slender neck, within which is a canal. The base of the archegonium has a swollen region called the venter, which contains the egg. Special cells within an archegonium undergo mitotic cell division to produce a haploid egg.

If one gametophyte produces both antheridia and archegonia, the organs usually develop at different times, to reduce to likelihood of self-fertilization. When the sperm and eggs are mature, sperm are released from the antheridia in the presence of liquid water. Water drops transfer sperm from an antheridium to an archegonium. Sperm cells swim through the neck canal of the archegonium where fertilization occurs in the venter. The resulting zygote develops into an embryo, which then grows into the diploid sporophyte.

Sporogenous tissues in the sporangium undergo meiosis to produce haploid *spores*. The spore walls contain a substance called *sporopollenin*, which is resistant to chemicals and decay. After release, spores germinate and grow into new haploid gametophytes. The early threadlike stage of mosses and some liverworts is called the *protonema*. Protonemata are very similar to the body form of some algae.

Phylum *Hepatophyta*

There are between six thousand and eight thousand species of *hepatophytes* (from the Greek word *hepar*, meaning "liver"), which are commonly called liverworts. Hepatophytes are divided into three general groups: the simple thalloid liverworts, the complex thalloid liverworts, and the leafy liverworts. More than 85 percent of all hepatophyte species are leafy. Liverworts are usually terrestrial, although some species may be semiaquatic. Thalloid types are found worldwide. Leafy liverworts, which are often similar in appearance to mosses, are abundant in tropical jungles and fog belts. However, they are typically found in habitats that are more moist than those preferred by mosses.

Phylum *Anthocerophyta*

This phylum, the hornworts, consists of some one hundred species and represents the smallest group of bryophytes. The best-known genus, *Anthoceros* (from the Greek words *anthos*, meaning "flower" and *keras*, meaning "horn"), is found in temperate regions. The gametophyte is similar to thalloid liverworts. The cavities of the gametophyte body are filled with *mucilage*, a slimy secretion, in which grow nitrogen-fixing cyanobacteria, such as the genus *Nostoc*.

Phylum *Bryophyta*

Phylum *Bryophyta*, the mosses, consists of more than ninety-five hundred species. There are three important classes: class *Sphagnidae*, which includes the globally distributed, and economically as well as ecologically important genus *Sphagnum*; class *Andreaeidae*, which consists of a small group of blackish green to reddish brown tufted rock mosses growing on granitic or calcareous rocks in northern latitudes; and the class *Bryidae*, which consists of true mosses.

Economic Uses

Bryophytes are ecologically important members of terrestrial ecosystems. They are primary producers, providing food and habitat for animals. Humans have used bryophytes for many purposes. For example, *Sphagnum* deposits in peat bogs have been used for centuries as fuel for heating and cooking. Dried *Sphagnum* also has the ability to absorb large amounts of liquid, which makes it ideal to act as a soil conditioner for planting. American Indians used mosses as compresses to dress wounds. The antiseptic quality of *Sphagnum*, along with its absorptive properties, made its use attractive as bandage material for the British when cotton supplies were low during World War I.

BULBS AND RHIZOMES

Categories: Anatomy; physiology; reproduction and life cycles

Bulbs and rhizomes are modified stems, stem bases, or other underground organs used by plants for food (or energy) storage and in asexual reproduction.

Plants reproduce both sexually and asexually. Although sexual reproduction is part of the typical life cycle of plants, for a variety of reasons a plant may reproduce asexually. Exact duplicates of a plant, called *clones*, are formed by asexual reproduction.

Asexual Reproduction

Asexual reproduction involves the production of offspring through the formation of *propagules* by mitosis (the process of nuclear cell division). Because genetic recombination does not occur in mitosis, the offspring are genetically identical to the parent plant. Asexual reproduction does not occur in all plants; some reproduce asexually only when humans intervene. Asexual reproduction occurs when a single plant produces a vegetative propagule that develops into a separate free-living plant. Many of the propagules that support asexual reproduction are actually highly modified branches. Others are modified roots. In rare instances, the tissues of leaves may be modified by nature to support asexual reproduction. The propagules of asexual reproduction vary enormously. They are often found in catalogs describing "bulbs," but technically they include *true bulbs*, *corms*, *stolons*, *tubers*, *rhizomes*, *turions*, *pseudobulbs*, and *fleshy roots*.

True Bulbs

Bulbs, corms, stolons, tubers, rhizomes, and turions are all modified stems. Bulbs are modified stem bases that develop underground. The stem is shortened and thickened to produce a mass of tissue shaped like a coin or like a child's toy top. Scalelike leaves with thickened bases are attached to the base of the bulb. Starch is stored in the thickened bases, a food supply that allows the bulb to survive through a dormant season and to produce adventitious roots. Roots are often absent when the bulb is dormant. The starch can also support a period of rapid stem and leaf growth in the growing season and may support the flowering and fruiting of the plant.

In *tunicate* bulbs, a cloak of dried leaves surrounds the outside of the bulb. These dried leaves provide a barrier to desiccation and allow the tunicate bulbs to be stored aboveground for weeks or even months. Onions (*Allium cepa*) and daffodils (*Narcissus*) are examples of tunicate bulbs. Other bulbs have no cloak and usually have shorter, less cylindrical leaves. These scaly bulbs dry quickly when kept aboveground and usually develop flowers only after a more normal, aerial branch system forms. Lilies (*Lilium*) have scaly bulbs.

Stems of both tunicate and scaly bulbs can branch. Belowground, branches appear at first as

Image Not Available

miniature bulbs (*bulbils* or *bulblets*). Bulblets take their energy from the parent bulb but eventually produce aerial stems or leaves and can be separated from the parent. Profuse branching can be stimulated by wounding the stem of the parent bulb. All the bulbs produced by this technique are clones, identical to the parent in their genetic makeup and physical characteristics.

Corms and Tubers

Corms are similar to bulbs in many ways. They have a disk-shaped or top-shaped stem mass that is shorter and wider than most typical stems. They are often cloaked in a tunic of dried leaves that are thinner and smaller than those on bulbs. Corms do not store significant amounts of starch; it is instead stored primarily in the basal plate of the stem. Branches of the corm stem produce new, miniature corms (*cormels*). Wounding the parent stem stimulates greater branching. Gladiolus and crocus are two common garden plants that produce corms.

Tubers are thick, starchy stems that form usually at the tip of a stolon, runner, or tiller. Tubers may form on the soil surface or belowground. A familiar example is the white or Irish potato (*Solanum tuberosum*). The leaves on most tubers are much smaller than the leaves on other parts of the stem, but above each leaf on the tuber is a well-developed axillary bud, commonly called an *eye*. The axillary bud has the potential to elongate, forming a complete and fully developed branch. If the stolon connecting the tuber to the parent plant dies, the branch from the eye of the tuber becomes an independent clone of the parent plant.

Most tubers contain many eyes. If the tuber is cut into smaller pieces, each containing an eye, each piece develops a rhizome, which in turn develops a new tuber. By this technique, a significant increase in the number of plants can be obtained. The cut pieces of tuber are initially prone to decay, but after they have dried for a few days, they heal over with a layer of callus which protects them like a skin. Cutting tubers into small “seed” pieces is a common method for propagating tuber-forming species.

Rhizomes, Stolons, and Fleshy Roots

Rhizomes are specialized, underground stems. Unlike most areal stems, the rhizomes are normally oriented horizontally. Just as pieces of tuber can provide the tissue and energy source for the formation of a new plant, so too can pieces of a rhizome. Many ferns and fern allies propagate naturally by rhizomes. Large stands of these plants can form from a single individual as the rhizomes grow and branch. Eventually, older pieces of the rhizome die, leaving a population of individuals that all have identical genetic characteristics.

Stolons are long, thin, horizontal stems, also called *runners* or *tillers*, which grow along the surface of the ground. When the stolon has grown far enough from the parent plant, the growth pattern changes, and a *crown*, or tuber, forms. A crown is a compressed stem mass with leaves arranged close to one another, also called a *rosette*. Within the crown, roots form at the points of attachment of the leaves to the stems. If the stolon is broken or dies, the crown becomes an independent clone of the parent plant. In this way, a large number of offspring can be produced from a single plant. This is a mechanism of reproduction of the strawberry (*Fragaria*) and is also a common reproductive mechanism for grasses, including crab grass (*Digitaria sanguinalis*) and quack grass (*Agropyron repens*).

Fleshy roots store energy that can be useful for asexual propagation. Most require at least a small amount of stem tissue to support cell growth and differentiation. The true yam (*Dioscorea*) is a tuber, but the sweet potato (*Ipomoea batatas*) is a fleshy root which can easily be propagated asexually. Many buttercups (*Ranunculus*) are also propagated by breaking up the clumps of their fleshy roots.

C_4 AND CAM PHOTOSYNTHESIS

Categories: Photosynthesis and respiration; physiology

Alternative forms of photosynthesis are used by specific types of plants, called C_4 and CAM plants, to alleviate problems of photorespiration and excess water loss.

Photosynthesis is the physiological process whereby plants use the sun's radiant energy to produce organic molecules. The backbone of all such organic compounds is a skeleton composed of carbon atoms. Plants use carbon dioxide from the atmosphere as their carbon source.

The overwhelming majority of plants use a single chemical reaction to attach carbon dioxide from the atmosphere onto an organic compound, a process referred to as *carbon fixation*. This process takes place inside specialized structures within the cells of green plants known as *chloroplasts*. The enzyme that catalyzes this fixation is ribulose bisphosphate carboxylase (Rubisco), and the first stable organic product is a three-carbon molecule. This three-carbon compound is involved in the biochemical pathway known as the *Calvin cycle*. Plants using carbon fixation are referred to as *C_3* plants because the first product made with carbon dioxide is a three-carbon molecule.

C_4 Photosynthesis

For many years scientists thought that the only way photosynthesis occurred was through C_3 photosynthesis. In the early 1960's, however, researchers studying the sugarcane plant discovered a biochemical pathway that involved incorporation of carbon dioxide into organic products at two different stages. First, carbon dioxide from the atmosphere enters the sugarcane leaf, and fixation is accomplished by the enzyme phosphoenolpyruvate carboxylase (PEP carboxylase). This step takes place within the cytoplasm, not inside the chloroplasts. The first stable product is a four-carbon organic compound that is an acid, usually malate. Sugarcane and other plants with this photosynthetic pathway are known as *C_4* plants.

In C_4 plants, this photosynthetic pathway is tied to a unique leaf anatomy known as *Kranz anatomy*. This term refers to the fact that in C_4 plants the cells that surround the water- and carbohydrate-conducting system (known as the *vascular system*) are packed very tightly together and are called *bundle sheath cells*. Surrounding the bundle sheath is a densely packed layer of *mesophyll* cells. The densely packed mesophyll cells are in contact with air spaces in the leaf, and because of their dense packing they keep the bundle sheath cells from contact with air. This Kranz anatomy plays a major role in C_4 photosynthesis.

In C_4 plants the initial fixation of carbon dioxide from the atmosphere takes place in the densely packed mesophyll cells. After the carbon dioxide is fixed into a four-carbon organic acid, the malate is transferred through tiny tubes from these cells to the specialized bundle sheath cells. Inside the bundle sheath cells, the malate is chemically broken down into a smaller organic molecule, and carbon dioxide is released. This carbon dioxide then enters the chloroplast of the bundle sheath cell and is fixed a second time with the enzyme Rubisco and continues through the C_3 pathway.

Advantages of Double-Carbon Fixation

The double-carbon fixation pathway confers a greater photosynthetic efficiency on C_4 plants over C_3 plants, because the C_3 enzyme Rubisco is highly inefficient in the presence of elevated levels of oxygen. In order for the enzyme to operate, carbon dioxide must first attach to the enzyme at a particular location known as the *active site*. However, oxygen is also able to attach to this active site and prevent carbon dioxide from attaching, a process known as *photorespiration*. As a consequence, there is an ongoing competition between these two gases for attachment at the active site of the Rubisco enzyme. Not only does the oxygen outcompete carbon dioxide; when oxygen binds to Rubisco, it also destroys some of the molecules in the Calvin cycle.

At any given time, the winner of this competition is largely dictated by the relative concentrations of these two gases. When a plant opens its *stomata* (the pores in its leaves), the air that diffuses in will be at equilibrium with the atmosphere, which is 21 percent oxygen and 0.04 percent carbon dioxide. During hot, dry weather, excess water vapor diffuses out, and under these conditions plants face certain desiccation if the stomata are left open continuously. When these pores are closed, the concentration of gases will change. As photosynthesis proceeds, carbon dioxide will be consumed and oxygen generated.

When the concentration of carbon dioxide drops below 0.01 percent, oxygen will outcompete carbon dioxide at the active site, and no net photosynthesis occurs. C_4 plants, however, are able to prevent photorespiration, because the PEP carboxylase enzyme is not inhibited by oxygen. Thus, when the stomata are closed, this enzyme continues to fix carbon inside the leaf until it is consumed. Because the bundle sheath is isolated from the leaf's air spaces, it is not affected by the rising oxygen levels, and the C_3 cycle functions without interference. C_4 photosynthesis is found in at least nineteen families of flowering plants. No family is exclusively composed of C_4 plants. Because C_4 photosynthesis is an adaptation to hot, dry environments, especially climates found in tropical regions, C_4 plants are often able to outcompete C_3 plants in those areas. In more temperate regions, they have less of an advantage and are therefore less common.

CAM Photosynthesis

A second alternative photosynthetic pathway, known as *crassulacean acid metabolism* (CAM), exists in succulents such as cacti and other desert plants. These plants have the same two carbon-fixing steps as are present in C_4 plants, but rather than being spatially separated between the mesophyll and bundle sheath cells, CAM plants have both carbon dioxide-fixing enzymes within the same cell. These enzymes are active at different times, PEP carboxylase during the day and Rubisco at night. Just as Kranz anatomy is unique to C_4 plants, CAM plants are unique in that the stomata are open at night and largely closed during the day.

The biochemical pathway of photosynthesis in CAM plants begins at night. With the stomata open, carbon dioxide diffuses into the leaf and into mesophyll cells, where it is fixed by the C_4 enzyme PEP carboxylase. The product is malate, as in C_4 photosynthesis, but it is transformed into malic acid (a nonionic form of malate) and is stored in the cell's *vacuoles* (cavities within the cytoplasm) until the next day.

Image Not Available

Although the malic acid will be used as a carbon dioxide source for the C_3 cycle, just as in C_4 photosynthesis, it is stored until daylight because the C_3 cycle requires light as an energy source. The vacuoles will accumulate malic acid through most of the night. A few hours before daylight, the vacuole will fill up, and malic acid will begin to accumulate in the cytoplasm outside the vacuole. As it does, the pH of the cytoplasm will become acidic, causing the enzyme to stop functioning for the rest of the night.

When the sun rises the stomata will close, and photosynthesis by the C_3 cycle will quickly deplete the atmosphere within the leaf of all carbon dioxide. At this time, the malic acid will be transported out of the vacuole to the cytoplasm of the cell. There it will be broken down, and the carbon dioxide will enter the chloroplast and be used by the C_3 cycle; thus, photosynthesis is able to continue with closed stomata.

Crassulacean acid metabolism derives its name from the fact that it involves a daily fluctuation in the level of acid within the plant and that it was first discovered to be common in species within the stonecrop family, *Crassulaceae*. The discovery of this photosynthetic pathway dates back to the 1960's. The observation that succulent plants become very acidic at night, however, dates back to at least the seventeenth century, when it was noted that cactus tastes sour in the morning and bitter in the afternoon.

CAM Plant Ecosystems

There are two distinctly different ecological environments where CAM plants may be found. Most are terrestrial plants typical of deserts or other harsh, dry sites. In these environments, the pattern of stomatal opening and closing provides an important advantage for surviving arid conditions: When the stomata are open, water is lost; however, the rate of loss decreases as the air temperature decreases. By restricting the time period of stomatal opening to the nighttime, CAM plants are extremely good at conserving water.

The other ecological setting where CAM plants are found is in certain aquatic habitats. When this environment was first discovered, it seemed quite odd, because in these environments conserving water would be of little value to a plant. It was found, however, that there are aspects of the aquatic environment which make CAM photosynthesis advantageous. In shallow bodies of water, the photosynthetic consumption of carbon dioxide may proceed at a rate in excess of the rate of diffusion of carbon dioxide from the atmosphere into the water, largely because gases diffuse several times more slowly in water than in air. Consequently, pools of water may be completely without carbon dioxide for large parts of the day. Overnight, carbon dioxide is replenished, and aquatic CAM plants take advantage of this condition to fix the plentiful supply of carbon dioxide available at night and store it as malic acid. Hence, during the day, when the ambient carbon dioxide concentration is zero, these plants have their own internal supply of carbon dioxide for photosynthesis. Thus, two very different ecological conditions have selected for the identical biochemical pathway.

These two modified photosynthetic pathways adequately describe what happens in most terrestrial plants, although there is much variation. For example, there are species that appear in many respects to have photosynthetic characteristics intermediate to C_3 and C_4 plants. Other plants are capable of switching from exclusively C_3 photosynthesis to CAM photosynthesis at different times of the year. Photosynthesis by aquatic plants appears to present even more variation. C_3-C_4 intermediate plants seem to be relatively common compared to the terrestrial flora, and several species have C_4 photosynthesis but lack Kranz anatomy.

CACTI AND SUCCULENTS

Categories: Angiosperms; *Plantae*

Succulents are fleshy plants that store water in natural reservoirs such as stems or leaves. Cacti are a group of flowering plants; all cacti are succulents.

The *Cactaceae* family includes about 1,650 to 3,500 species of *cacti* and *succulents* classified in 130 genera. Because they live in harsh, arid environments, these fleshy, spiny perennial plants have developed a variety of unique characteristics for protection and to retain water, reduce evaporation, and resist heat.

Cacti

The word "succulent" is derived from the Latin term *sucus*, meaning sap. All cacti are succulents. The word "cactus" is derived from the Greek term *kaktos*, describing thistles. Botanists estimate cacti first existed during the Mesozoic era, about 130 million years ago. Limited cacti fossil evidence exists (the earliest known specimen is about forty thousand years old).

Cacti vary in size. The *Copiapoa laui* is a spherical plant several millimeters in diameter, while the *Pachycereus weberi* is cylindrical, stands more than 20 meters tall, and can weigh more than 25 tons. Cacti often develop bizarre shapes to cope with arid conditions. Some stems are flat, and others are puffy. Many consist of jointed segments, while others have one round stem. Cacti stems swell when storing water. Surface ridges and grooves gather water. Roots extend in a wide area near the soil surface, to capture any moisture. The pincushion, barrel, saguaro, prickly pear, night-blooming cereus, and Christmas cactus are some of the most familiar cacti.

Unlike other plants, cacti have *areolas* on stems where branches, spines, *glochids* (bristles), leaves, and flowers grow. Spines protect and shade the plant and its seedlings from predators and ultraviolet radiation and serve as condensation sites. Known as *crassulacean acid metabolism* (CAM), photosynthesis in cacti is reversed from the process in other plants. Stems have chlorophyll because leaves are either absent or tiny. At night, instead of day, cacti open the stomata on their stems to collect carbon dioxide and expel oxygen. The carbon diox-

Cacti often develop bizarre shapes to cope with arid conditions. Stems of these plants swell when storing water, surface ridges and grooves gather water, and roots extend in a wide area near the soil surface to capture any available moisture.

ide is stored as organic acids for conversion to sugar during the day. Because the temperature is cooler when the stomata are opened, less water is lost. During the day, the closed stomata prevent evaporation from occurring.

Life Cycles of Cacti

Cacti grow slowly and can live more than a century. Flowers usually bloom in late spring and vary in color, size, and shape. Seeds are inside the fruits that blossoms produce. Some cacti grow from seeds if they are shaded and not consumed by predators. Other cacti emerge from stems and take root where they fall. Artificially, cacti can also take root from cuttings. Diverse insects and animals are attracted to the flowers and assist in their pollination. Some birds nest in holes in cacti stems.

Distribution of Cacti

Cacti grow in deserts, prairies, mountains, and tropical climates and have developed a tolerance for extreme conditions. Cacti are indigenous to North, Central, and South America. The *Epiphyllum* species live in tropical trees. Other cacti grow in rocky places. Some Chilean cacti in the Atacama Desert secure water from sea fog. The largest and most diverse population of cacti is in Mexico. The prickly pear is the most widely distributed cactus, ranging from near the Arctic circle to southern South America.

Uses of Cacti

Cactus fruits are edible by humans and animals and used as livestock forage, as a water source, for fuel, and to erect organic barriers. Spines are used as needles and fishhooks, and fibers are twisted into rope. Historically, peyote is a ceremonial hallucinogenic, and other cacti have medicinal purposes. While no cacti are poisonous, some species have unpleasant chemicals that discourage predators.

Some hybrids have naturally occurred, and cactus segments can be detached at joints to graft to artificially unique plants. Because of poaching, cacti are considered endangered plants, with some species threatened by extinction, and are federally protected at Saguaro National Park (in Arizona's Tucson Basin) and Organ Pipe Cactus National Monument (in Arizona's Sonoran Desert).

Succulents

Although they share many traits with their close relatives the cacti, other succulents do not have areolas. Succulents vary in shape and size. Some are as tiny as peas, while others are large as livestock. Succulents take many forms, including that of the string of beads (*Senecio rowleyanus*). Yucca and jade plants are two of the most familiar succulents.

Because of evolutionary adaptation to endure climatic extremes, succulents have small leaves and spongy tissues that keep water for prolonged durations. Succulents retain water to withstand such environmental stresses as drought, scorching wind, shallow or salty topsoil, steep locations, and overcrowding by other plants. Succulents keep flower stalks and fruit until all the water is depleted from them. They have a thick skin, which is waxy, and sometimes alter their shape while adjusting to differences of light and moisture. Most succulents are gray, although a few are colored lilac, pink, light green, beige, or ivory, often in patterns that may serve as camouflage.

The greatest quantity and most diverse succulents can be found in Mexico and South Africa, which have thousands of species. New species are still being discovered because of variations arising from environmentally triggered adaptations. Some succulents, such as the *Argyroderma*, are abundant, growing in thick clumps. The rarer succulents include *Conophytum burgeri*, which lives on only one South African hill. Succulents are threatened by overgrazing and industrial and agricultural development of habitats. Some succulents, particularly aloe, have healing juices to soothe burns.

CALVIN CYCLE

Categories: Biogeochemical cycles; photosynthesis and respiration; physiology

The Calvin cycle is the principal mechanism that leads to the conversion of carbon dioxide into sugars by plants, algae, photosynthetic bacteria, and certain other bacteria that use chemicals as an energy source instead of light.

The Calvin cycle, also known as the Calvin-Benson cycle, is an integral part of the process of *photosynthesis* in plants, algae, and photosynthetic bacteria. Named after its discoverer, Melvin Calvin of the University of California at Berkeley, its principal product is a three-carbon compound called *glyceraldehyde 3-phosphate*, or PGAL. Sugars are synthesized using PGAL as a starting material. Light, absorbed by *chlorophyll*, is used to synthesize the high-energy compounds *adenosine triphosphate* (ATP) and reduced *nicotinamide adenine dinucleotide phosphate* (NADPH). Chlorophyll and the enzymes that are used for synthesis of ATP and NADPH are associated with internal membranes in all photosynthetic cells. The ATP and NADPH, once formed, are released from the membrane-bound enzymes and diffuse into the surrounding solution inside the cell. The Calvin cycle takes place in this solution, using the ATP and NADPH molecules as a source of energy to drive the conversion of carbon dioxide into PGAL.

Enzymes

All the steps in the Calvin cycle and sugar biosynthesis are catalyzed by specific enzyme molecules. The carbon dioxide molecules react with a five-carbon sugar-phosphate molecule called *ribulose bisphosphate* (RuBP) to form a six-carbon intermediate. The reaction is catalyzed by the enzyme *ribulose bisphosphate carboxylase/oxygenase* (Rubisco). The six-carbon intermediate reacts with water and decomposes into two identical three-carbon molecules called phosphoglycerate. These, in turn, react with ATP and NADPH to produce PGAL molecules. Some of these leave the Calvin cycle and are used for the formation of sugars. The ADP and NADP molecules, produced when PGAL is formed, diffuse back to the chlorophyll-containing membranes, where they can be used to regenerate a supply of ATP and NADPH for the next round of the Calvin cycle. The remaining PGAL molecules are used for the regeneration of sufficient amounts of RuBP to permit the reactions of the Calvin cycle to be repeated.

The regeneration of RuBP from PGAL involves the rearrangement of the carbon atoms in three-carbon containing molecules to form five-carbon molecules. For example, if there are ten three-carbon molecules remaining after two three-carbon molecules have been removed from the cycle, then six five-carbon molecules are synthesized by the Calvin cycle. This is accomplished by no less than nine separate enzyme-catalyzed steps, involving intermediate compounds containing two, three, four, five, or seven carbon atoms derived from the PGAL molecules. At the end of this complex process, ATP is used to add another phosphate group to each five-carbon molecule, thus regenerating the required amount of RuBP, the original organic starting material for the cycle. A continuous supply of phosphate must be made available in order to continue running the Calvin cycle. Ultimately, all this phosphate must be supplied to the organism from the environment; in the short term, however, it is gleaned from other biochemical reactions, such as sugar biosynthesis.

PGAL

The principal product of the Calvin cycle is not sugar but PGAL. In higher plants, the Calvin cycle takes place inside *chloroplasts*, and the PGAL molecules are transported across the membranes of the chloroplasts and released into the solution between the chloroplast membranes and the cell's outer membrane. In this solution, called the *cytosol*, the PGAL molecules react to form six-carbon sugar phosphates. These six-carbon sugar phosphates then react to form *sucrose*, a twelve-carbon molecule (ordinary table sugar).

A sucrose molecule consists of one molecule each of the six-carbon sugars *fructose* and *glucose*.

Phosphate is released from the sugar phosphates during the formation of sucrose. The phosphate can then be returned to the chloroplast, where it is needed for the formation of ATP. Most of the sucrose is transported out of the cell and flows to various parts of the plant, such as the fruits or the roots. The transport of sucrose out of the cell requires energy derived from ATP. The accumulation of sucrose in the water outside the cell causes the hydrostatic pressure to rise. This pressure drives the flow of the water and sucrose (sap) through the phloem away from the leaves and toward the fruit or roots. The accumulation of sucrose in the fruit accounts for a large part of the nutritional value of plants.

When conditions do not favor the formation of sucrose, the triose phosphates may remain inside the chloroplast. These can react to form six-carbon sugar bisphosphates that, in turn, can react in several steps to form an insoluble carbohydrate storage compound called *starch*. The conversion of six-carbon sugar bisphosphate into starch releases phosphate. The phosphate released can then participate in the synthesis of more ATP, permitting continued operation of the Calvin cycle even when sucrose is not being formed. The accumulation of starch is another major source of nutritional value in plants.

In the morning, when plants begin receiving light, the amounts of phosphoglycerate and six-carbon sugar phosphates increase dramatically. The amounts of other intermediates in the cycle do not change as much. This suggests that some (but not all) steps in the Calvin cycle shut down in the dark and are activated in the light. The Calvin cycle also operates in nonphotosynthetic bacteria that use environmental chemicals as an energy source for the synthesis of ATP and other high-energy molecules. Although these organisms are responsible only for a minor proportion of the total carbon dioxide converted to organic form every year, their existence is interesting because it suggests that the Calvin cycle evolved before the origin of photosynthesis. The starch that builds up in the chloroplasts during the day is converted to sucrose at night and is then exported from the leaf.

Photorespiration

A significant complication must be taken into account when discussing the Calvin cycle: Oxygen can also react with RuBP, because the active site of Rubisco has affinity for both oxygen and carbon dioxide. Under normal conditions in many higher plants, three out of ten RuBP molecules react with oxygen instead of reacting with carbon dioxide. Under conditions where carbon dioxide levels are lower than normal and oxygen levels are higher than normal, oxygen may even react more frequently than carbon dioxide. This has deleterious consequences, because each RuBP molecule that reacts with oxygen is cleaved into two parts. One part is PGA, identical to that produced by the reaction of RuBP with carbon dioxide. The other part, however, is a two-carbon compound called phosphoglycolate. The latter molecule subsequently is cleaved to produce carbon dioxide; only one of the two carbons in phosphoglycolate is salvaged by the cell in a complex series of reactions called *photorespiration*. Because the photorespiratory reactions use energy, the chlorophyll-containing membranes must produce more ATP and NADPH than would otherwise be needed for the Calvin cycle.

Evolution of the Cycle

The Calvin cycle is believed to have originated more than 3.5 billion years ago in marine bacteria that were using very simple carbon compounds as an energy source. Some of the descendants of these bacteria later acquired the ability to synthesize ATP and NADPH (or their equivalents), using light as an energy source. As long as one billion years ago, some of these photosynthetic bacteria are believed to have established mutually beneficial, or *symbiotic*, relationships with other cells. These symbiotic relationships became stabilized and led to the evolution of algae and higher plants. The photosynthetic organelles of plants and algae, the chloroplasts, are thought to be the direct descendants of the symbiotic photosynthetic bacteria.

The early atmosphere of the earth probably had significantly less oxygen than it does now, so the existence of the oxygenase activity of Rubisco would not have been a problem. When the oxygen concentration in the atmosphere rose to its present level about 1.7 billion years ago, however, the losses of energy caused by the oxygenase reaction became significant. Some organisms evolved mechanisms to prevent these losses: In algae, for example, there are molecular pumps which, in effect, concentrate carbon dioxide in the cell so that the oxygenase reaction is inhibited. In sugarcane, corn, and certain other plants that are specialized to live in hot, dry climates, a similar effect is achieved by C_4 photosynthesis.

Not content with the results of evolution, biotechnologists are interested in altering Rubisco. They reason that if this enzyme can be genetically engineered to lower its oxygenase activity, the net photosynthetic rates of some plants could be improved. Possibly a 30 percent increase in plant productivity could be expected if such strategies prove successful, provided other materials (nitrogen, phosphorus, and other nutrients) are present in sufficient supply to permit the extra growth. Thus, although the Calvin cycle is the major route of entry of inorganic carbon into the biosphere, it is also something of a bottleneck. It remains to be seen whether the Calvin cycle can be made to function more efficiently.

CARBOHYDRATES

Categories: Cellular biology; nutrients and nutrition

Common organic chemicals found in all living organisms, important in energy metabolism and structural polymers, carbohydrate molecules are made up of carbon, hydrogen, and oxygen.

Carbohydrates are made of carbon, hydrogen, and oxygen molecules in a 1:2:1 ratio, respectively. This is often simplified using the formula nCH_2O, where n represents the number of CH_2O subunits in a carbohydrate. This formula should make it clear how the name carbohydrate was derived, as nCH_2O is essentially carbon and water. The simplest carbohydrates are the *monosaccharides*, or simple sugars. Individual monosaccharides can be joined together to make *disaccharides* (composed of two monosaccharides), *oligosaccharides* (short polymers composed of two to several monosaccharides), and *polysaccharides* (longer polymers composed of numerous monosaccharides).

Monosaccharides

The common monosaccharides found in plants have from three to six carbon atoms in a straight chain with one oxygen atom. Most of the oxygen atoms also have a hydrogen atom attached, making them hydroxyl groups (^{-}OH). One of the oxygen atoms is connected to a carbon by a double covalent bond, while the hydroxyl groups are attached to carbon atoms by single covalent bonds. If the double-bonded oxygen is on a terminal carbon (as an aldehyde group), the monosaccharide is called an *aldose*. If the double-bonded oxygen is on an internal carbon, the monosaccharide is called a *ketose*.

The simplest monosaccharides are the three-carbon sugars, or *trioses*. *Pentoses*, with five carbons, are also important in plants. *Ribose* and *deoxyribose* are found in RNA (ribonucleic acid) and DNA (deoxyribonucleic acid), respectively. *Ribulose bisphosphate* is an important intermediate in the incorporation of carbon dioxide into carbohydrates during photosynthesis. *Xylose* and *arabinose* are found as components of some plant polysaccharides.

Hexoses, six-carbon monosaccharides such as *glucose*, *fructose*, and *galactose*, are the most common monosaccharides in plants. These sugars all have the same formula, $C_6H_{12}O_6$ (note the 1:2:1 ratio of C:H:O), but their atoms are arranged differently. Glucose is the primary carbon-containing product of photosynthesis and reverse glycolysis and later can be metabolized through glycolysis and the Krebs cycle to release energy or can be converted to other carbohydrates needed by the plant.

Oligosaccharides

Oligosaccharides are made by joining two or more monosaccharides. The smallest are the disaccharides, formed from two monosaccharides that are joined together by a condensation reaction. Condensation reactions get their name from the fact that when the two monosaccharides are joined together, a molecule of water is released. *Sucrose* (glucose-fructose) is the most common plant disaccharide and is the principal molecule of short-term energy storage and of translocation (transport) in the phloem. Many plants, including sugarcane (*Saccharum officinarum*) and sugar beets (*Beta saccharifera*), have high concentrations of sucrose, which can be extracted and refined for use as table sugar.

Other disaccharides found in plants are *maltose*, which is a glucose disaccharide formed from the hydrolysis (the reverse of a condensation reaction, wherein water is used to "split" the bond between the monosaccharides) of starch, and *trehalose*, also a glucose disaccharide, which is the primary molecule of translocation in species of *Selaginella* and is seen in cyanobacteria (blue-green algae or blue-green bacteria), red algae, and fungi. *Cellobiose*, another glucose disaccharide, is formed by the hydrolysis of cellulose.

The trisaccharide *raffinose* (galactose-glucose-fructose) is a storage molecule in sugar beets and in cotton and legume seeds. *Stachyose* (galactose-galactose-glucose-fructose) and *verbascose* (galactose-galactose-galactose-glucose-fructose) are also storage oligosaccharides, seen mainly in *Fabaceae* (the legume or pea family).

Polysaccharides

The two main functions of polysaccharides in plants are long-term energy storage and structure. Glucose is the most common subunit in plant polysaccharides. The glucose molecules in these polymers are joined together in different ways. The carbon atoms in glucose molecules are numbered from one to six. In some, the 1-carbon of a glucose is attached to the 4-carbon of the next, and this linkage is repeated throughout the molecule. At other times, an additional bond is formed between the 1-carbon and the 6-carbon of adjacent glucoses, which results in a branched polysaccharide.

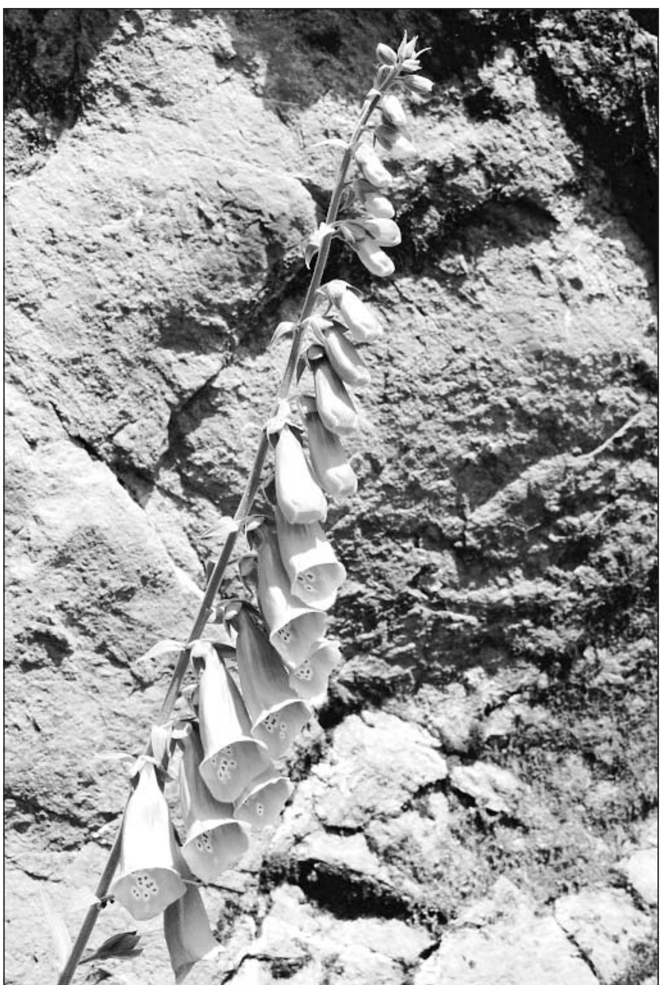
Starch is the most common storage polysaccharide of plants. Two forms of this glucose polymer exist. *Amylose* is a linear polymer made up of between one hundred and several thousand glucose units. *Amylopectin* is very similar, but it is a branched polymer. In most plants, starch is 15-25 percent amylose and 75-85 percent amylopectin. However, starch in some waxy varieties of corn is nearly 100 percent amylopectin and in some wrinkled varieties of peas is as high as 80 percent amylose. Phytoglycogen found on corn (*Zea mays*) is an even more branched glucose polymer.

Fructosans are another type of storage polysaccharide in plants. They are branched or unbranched fructose polymers with a terminal glucose subunit. *Inulin* is found in the tubers or rhizomes of plants in *Campanulaceae* (the bellflower family) and *Asteraceae* (the sunflower or aster family) and usually has thirty to fifty fructose subunits. *Levans*, used for temporary storage by several monocots, especially in *Poaceae* (the grass family), range from seven to eight fructose subunits in the unbranched levans to seventy-two fructose subunits in some highly branched ones.

Structural Polysaccharides

Structural polysaccharides form the fibrous material in plant cell walls. *Cellulose*, an unbranched glucose polymer that averages about eight thousand glucose subunits per molecule, is the main cell wall component of plants, a few fungi, and some algae. Cellulose molecules form microfibrils, many individual cellulose molecules held together by hydrogen bonds. Other microfibrillar cell wall polysaccharides are sometimes called the hemicelluloses. Examples are *mannans* and *glucomannans*, found in the primary cell walls of several green algae and simple vascular plants and in the secondary cell walls of some conifers; *xylans* are found in other algae and in the secondary cell walls of many hardwoods. *Chitin*, a polymer of N-acetylglucosamine, is the main substance forming the cell walls of fungi. (Chitin is the same substance that forms the exoskeletons of most insects.)

Pectins are matrix polysaccharides found in plant cell walls. The most common pectin in higher plants is unbranched polygalacturonic acid (galacturan). Branched and unbranched rhamnogalacturans and arabinans are also present in smaller quantities. Pectin is commercially important as a gelling agent in the production of jams and jellies. A similar pectinlike polysaccharide found in brown algae is alginic acid, a mixture of mannuronic and guluronic acids. It is used as a thickener and a stabilizer in many prepared foods.



PhotoDisc

*Glycosides are formed when carbohydrates are attached to various plant chemicals and include the cardiac glycosides of the foxglove plant (*Digitalis purpurea*), which has strong physiological effects on heart muscle.*

Other Plant Carbohydrates

Carbohydrates are often found attached to other cell components. In both cell membranes and cell walls, there are many glycoproteins, proteins with short oligosaccharides attached. *Glycosides* are interesting carbohydrate-containing secondary metabolites found in many plants. Glycosides are formed when carbohydrates are attached to various plant chemicals. Anthocyanins, which give red to blue color to flowers, fruits, and autumn leaves, are glycosides. Other glycosides include the cardiac glycosides of the foxglove (*Digitalis purpurea*) and milkweed (*Asclepias*) species, which have strong physiological effects on heart muscle, and the cyanogenic glycosides of the almond (*Prunus amygdalus*), which liberate cyanide.

CARBON CYCLE

Categories: Biogeochemical cycles; ecology; environmental issues; photosynthesis and respiration

The carbon cycle is the movement of the element carbon through the earth's rock and sediment, the aquatic environment, land environments, and the atmosphere. Large amounts of organic carbon can be found in both living organisms and dead organic material.

An enormous reservoir of carbon, on the order of 20×10^{15} tons, may be found on the surface of the earth. Most of this reservoir is found in rock and sediment. The carbon cycle therefore represents the movement of this element through the biosphere in a process mediated by photosynthetic plants on land and in the sea. The process involves the fixation of carbon dioxide (CO_2) into organic molecules, a process called *photosynthesis*. Energy used in the process is stored in chemical form, such as that in carbohydrates (sugars such as glucose). The organic material is eventually oxidized, as occurs when a photosynthetic organism dies. Through the process of respiration, the carbon is returned to the atmosphere in the form of carbon dioxide. Because the "turnover" time of such forms of carbon is so slow (on the order of thousands of years), the entrance of this material into the carbon cycle is insignificant on the human scale.

Photosynthesis

Organisms that use carbon dioxide as their source of carbon are known as *autotrophs*. Many of these organisms also use sunlight as the source of energy for reduction of carbon dioxide; hence, they are frequently referred to as *photoautotrophs*. This process of carbon dioxide fixation is carried out by phytoplankton in the seas, by land plants (particularly trees), and by many microorganisms. Most of the process is carried out by the land plants.

The process of photosynthesis can be summarized by the following equation:

$$CO_2 + \text{water} + \text{energy} \rightarrow \text{carbohydrates} + \text{oxygen}$$

The process requires energy from sunlight, which is stored in the form of the chemical energy in carbohydrates. While most plants produce oxygen in the process—the source of the oxygen in the earth's atmosphere—some bacteria may produce products other than oxygen. Organisms that carry out carbon dioxide fixation, using photosynthesis to synthesize carbohydrates, are often referred to as *producers*. Approximately 20 billion to 30 billion tons of carbon are fixed each year by the process—clearly a large amount but only a small proportion of the total carbon found on the earth. Approximately 450 billion tons of carbon are contained within the earth's forests; some 700 billion tons exist in the form of atmospheric carbon dioxide.

Much of the organic carbon on the earth is found in the form of land plants, including forests and grasslands. When these plants or plant materials die, as when leaves fall to the earth in autumn, the dead organic material becomes *humus*. Much of the carbon initially bound during photosynthesis is in the form of humus. Degradation of humus is a slow process, on the order of decades. However, it is the decomposition of humus, particularly through the process called respiration, that returns much of the carbon dioxide to the atmosphere. Thus, the carbon cycle represents a dynamic equilibrium between the carbon in the atmosphere and carbon fixed in the form of organic material.

Respiration

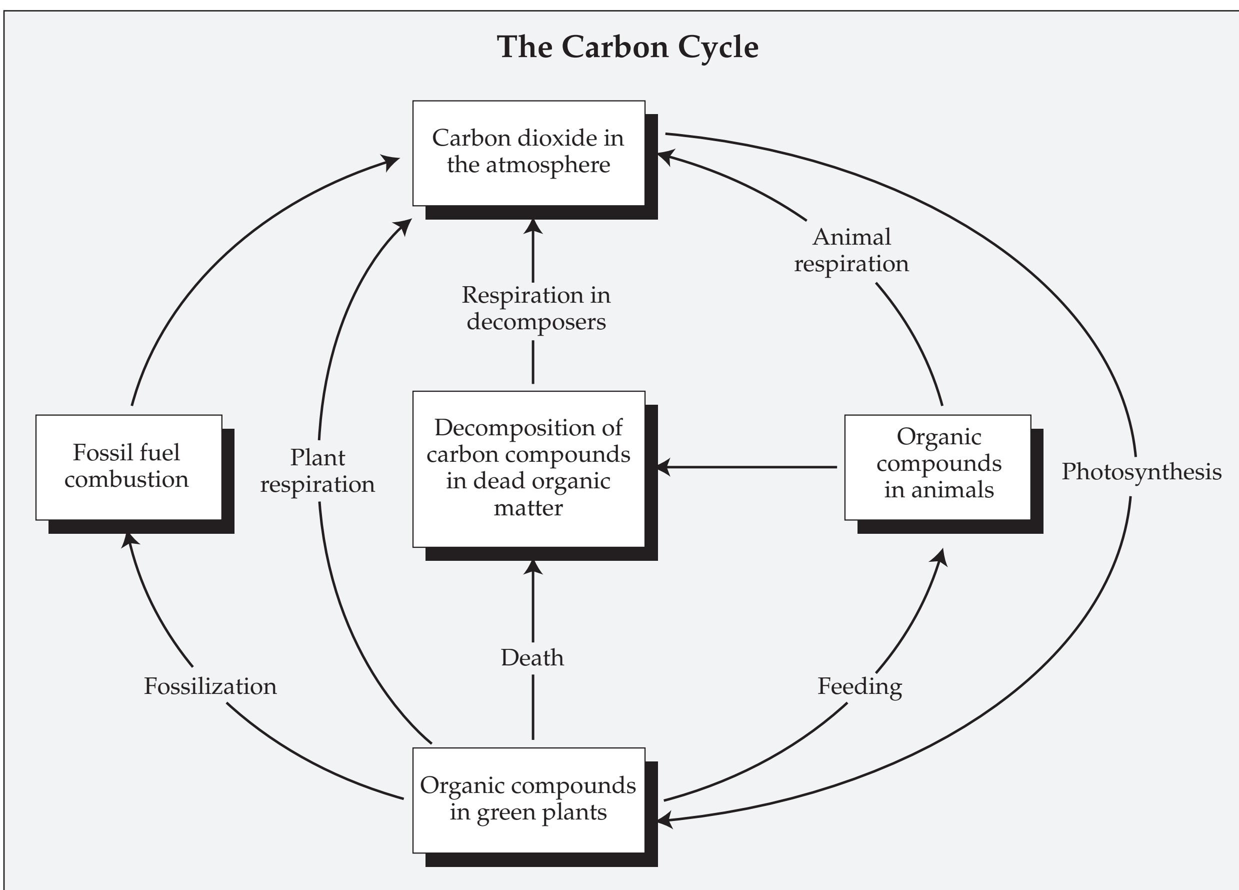
Respiration represents the reverse of photosynthesis. All organisms that use oxygen, including humans, carry out the process. However, it is primarily humic decomposition by microorganisms that returns most of the carbon to the atmosphere. Depending on the particular microorganism, the carbon is in the form of either carbon dioxide or methane (CH_4). Respiration is generally represented by the equation:

$$\text{Carbohydrate} + \text{oxygen} \rightarrow \text{carbon dioxide} + \text{water} + \text{energy}$$

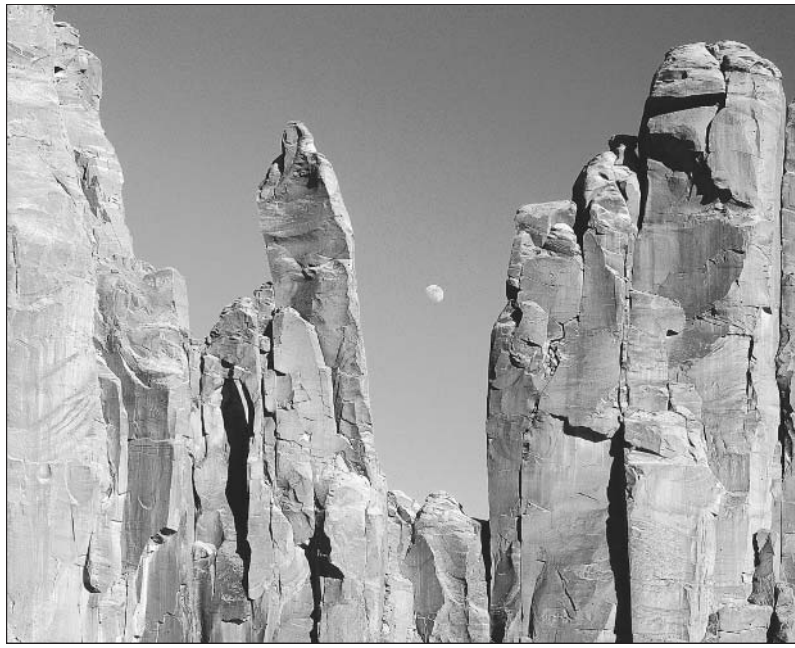
Energy released by the reaction is used by the organism (that is, the consumer) to carry out its own metabolic processes.

Carbon Sediment

Despite the enormous levels of carbon cycled between the atmosphere and living organisms, most carbon is found within carbonate deposits on land and in ocean sediments. Some of this originates in marine ecosystems, where organisms use dissolved carbon dioxide to produce carbonate shells (calcium carbonate). As these organisms die, the shells sink and become part of the ocean sediment. Other organic deposits, such as oil and coal, originate from



fossil deposits of dead organic material. The recycling time for such sediments and deposits is generally on the order of thousands of years; hence their contribution to the carbon cycle is negligible on a human time scale. Some of the sediment is recycled naturally, as when sediment dissolves or when acid rain falls on carbonate rock (limestone), releasing carbon dioxide. However, when such deposits are burned as fossil fuels, the levels of carbon dioxide in the atmosphere may increase at a rapid rate.



PhotoDisc

The biogeochemical carbon cycle is the movement of carbon through the earth's ecosystems. An enormous reservoir of carbon may be found on the surface of the earth, mostly within rock and sediment.

Environmental Impact of Human Activities

Carbon dioxide gas is only a small proportion (0.036 percent) of the volume of the atmosphere. However, because of its ability to trap heat from the earth, carbon dioxide acts much like a thermostat, and even small changes in levels of this gas can significantly alter environmental temperatures. Around 1850, humans began burning large quantities of fossil fuels; the use of such fuels accelerated significantly after the invention of the automobile. By the end of the twentieth century, between 5 billion and 6 billion tons of carbon were being released into the atmosphere every year from the burning of fossil carbon. Some of the released carbon probably returns to the earth through biological carbon fixation, with a possible increase in the land biomass of trees or other plants. (Whether this is so remains a matter of dispute.) Indeed, large-scale deforestation could potentially remove this means by which levels of atmospheric carbon dioxide could be naturally controlled.

CARBON 13/CARBON 12 RATIOS

Categories: Cellular biology; photosynthesis and respiration; physiology

The carbon 13 to carbon 12 ratio is the ratio of two stable carbon isotopes in a given organic sample, often used to determine the photosynthetic pathway being used by a plant.

Although the atom is the smallest unit having the properties of its element, atoms are composed of subatomic particles, of which protons, neutrons, and electrons are the most important. All atoms of a given element (in their non-ionic form) have the same number of protons and electrons, but some atoms may have more neutrons than other atoms of the same element. These different atomic forms are called *isotopes* of the element, and in nature there is a mixture of isotopes for most elements.

Carbon Isotopes

Carbon has an atomic number of 6, meaning that it has six protons. Most carbon atoms also have six neutrons. Because the atomic weight is largely determined by the mass of the protons plus neutrons, this isotope is called carbon 12 (^{12}C); it is the most common form of carbon, accounting for about 99 percent of the carbon in nature. Most of the remaining 1 percent of carbon consists of atoms of the isotope carbon 13 (^{13}C), with seven rather than six neutrons; thus, this isotope is heavier than ^{12}C. A third isotope, carbon 14 (^{14}C), is present in the environment in minute quantities but is not very stable. Consequently, ^{14}C decays spontaneously, giving off radiation, and thus it is a *radioactive isotope*. Both ^{12}C and ^{13}C are considered stable isotopes.

Stable isotopes are measured using a mass spectrometer, an instrument that separates atoms on the basis of their mass differences. Initially when plant material is combusted, the carbon dioxide (CO_2) given off is analyzed by the mass spectrometer for the ratio of carbon 13 to carbon 12 isotopes. This ratio is compared to the ratio of carbon 13 to carbon 12 in an internationally accepted standard of known ^{13}C to ^{12}C ratio and is expressed as the difference between the sample and the standard, minus one. This number is multiplied by one thousand and expressed as a "per mil" (per million parts). In plant matter, this number is always negative. The more negative the ratio of carbon 13 to carbon 12, the less carbon 13 there is present.

C_3, C_4, and CAM Plants

There are three biochemical pathways of carbon acquisition used by different plant species, and the ratio of carbon 13 to carbon 12 in plant tissues is often a useful means of distinguishing the *photosynthetic pathway* being used. Most plants photosynthesize by attaching CO_2 obtained from the atmosphere onto an organic compound in a single carbon fixation step that is a part of the Calvin cycle. This reaction is catalyzed by an enzyme known as ribulose bisphosphate carboxylase (Rubisco), and the first stable organic product is a three-carbon molecule. Some of this three-carbon compound enters a biochemical pathway leading to sugar formation, and the remainder is used to maintain the Calvin cycle. Such plants are referred to as *C_3 plants*.

Some plants, such as corn and sugarcane, have two carbon fixation steps. Atmospheric CO_2 is fixed initially by the enzyme phosphoenolpyruvate carboxylase (PEP carboxylase), and the first product is a four-carbon organic acid; these plants are known as *C_4 plants*. This product is moved to the interior of the leaf and broken down, releasing CO_2 into specialized cells known as Kranz-type bundle sheath cells. Within these cells the CO_2 is fixed a second time by the same process used in C_3 plants.

A third group of plants, known as *CAM plants* (for crassulacean acid metabolism), open their stomatal pores (located on the leaf surfaces) primarily at night. CO_2 enters and is fixed with the enzyme PEP carboxylase. The organic acid produced is stored in the cell overnight. During the day, the stomata are closed, and the acid is broken down. The CO_2 released is then fixed by the same method as in C_3 plants.

Discrimination Against Carbon 13

In terrestrial plants, carbon isotope ratios of photosynthetic tissues vary from $^{-}8$ per mil to $^{-}15$ per mil in C_4 plants and from $^{-}20$ per mil to $^{-}35$ per mil in C_3 plants. CAM plants may range from C_4-like to C_3-like in their carbon isotope ratios. For atmospheric carbon dioxide, the ratio of carbon 13 to carbon 12 is about $^{-}8$ per mil, and thus C_4 plant tissues have slightly less carbon 13 than the air. C_3 plants have much less carbon 13 than the air. In other words, during photosynthesis plants tend to discriminate against $^{13}CO_2$ molecules and more readily fix $^{12}CO_2$. This discrimination against carbon 13 is even more pronounced in C_3 plants.

Discrimination against carbon 13 is attributable to the greater mass of this isotope. One consequence is that $^{13}CO_2$ does not diffuse as readily to the site of photosynthesis as does $^{12}CO_2$, which accounts for a small component of discrimination against carbon 13 in all plants. The major difference in carbon isotope ratio between C_3 and C_4 plants, however, results from a difference in discrimination among the initial carbon-fixing enzymes. In C_3 plants, the carbon-fixing enzyme Rubisco results in a $^{-}27$ per mil discrimination against carbon 13. In C_3 plants, this enzyme is present in the cells adjacent to the stomatal pores and thus obtains CO_2 more or less directly from the atmosphere. Because carbon 13 is discriminated against, $^{13}CO_2$ will tend to accumulate, but it readily diffuses out of the leaf when stomatal pores are open.

In C_4 plants, on the other hand, the initial carbon-fixing enzyme, PEP carboxylase, discriminates very little against carbon 13. In C_4 photosynthesis, the secondary carbon-fixing enzyme, Rubisco, is sequestered in the interior of the leaf in the bundle sheath cells, and the CO_2 it fixes is derived from the breakdown of the C_4 fixation product. As Rubisco discriminates against $^{13}CO_2$, this heavier CO_2 accumulates within the bundle sheath cells and diffuses out very slowly. As $^{13}CO_2$ accumulates in the bundle sheath cells, the higher concentration of $^{13}CO_2$ will overcome the discrimination by the enzyme; in effect, the enzyme will be forced to fix $^{13}CO_2$, and thus discrimination is minimal. C_4 plant tissues consequently have less negative $^{13}CO_2/^{12}CO_2$ ratios.

In typical CAM photosynthesis, the atmospheric CO_2 is fixed at night by the enzyme PEP carboxylase, and, as in C_4 plants, this enzyme discriminates very little against $^{13}CO_2$. During the day, the C_4 fixation product is broken down, and the CO_2 that is released is fixed by Rubisco. This enzyme will discriminate against carbon 13, but because the stomata are closed during the day, $^{13}CO_2$ will accumulate within the leaf and eventually be fixed. Consequently, little discrimination occurs. Such CAM plants have ratios similar to those of C_4 plants. Some CAM plants, however, will open their stomatal pores for varying lengths of time during the day or switch to strictly C_3 photosynthesis during certain times of the year. In these plants, the $^{13}CO_2/^{12}CO_2$ ratio will be more similar to that observed for C_3 plants.

In aquatic plants, the $^{13}CO_2/^{12}CO_2$ ratio does not indicate the photosynthetic pathway used. C_3 aquatic plants frequently will have carbon isotope ratios very similar to that of the source carbon from the water: Because the enzyme Rubisco discriminates against carbon 13, $^{13}CO_2$ tends to accumulate in the layer of water around the leaf. Because the diffusion of gases in water is very slow, the plant will eventually be forced to fix the $^{13}CO_2$. Other aspects of the aquatic environment also influence the carbon isotope ratio of aquatic plant tissues.

Each chapter includes an extensive bibliography.

CARIBBEAN AGRICULTURE

Categories: Agriculture; economic botany and plant uses; food; world regions

Agriculture in the Caribbean islands, from the Bahamas to Trinidad, is concentrated in sugarcane, bananas, coffee, tobacco, and some citrus and cacao.

The Caribbean Sea is an extension of the western Atlantic Ocean that is bounded by Central and South America to the west and south and the islands of the Antilles chain on the north and east. At the end of the twentieth century, agriculture was basic to the economies of nearly every island. Two fundamentally different types of agriculture dominate: large-scale commercial, or plantation, agriculture and small-scale semisubsistence, or peasant, farming. Plantation farming provides the most exports, by value, whereas peasant farming involves far more human labor.

Caribbean agriculture operates under various natural and cultural restraints. Most of the islands have rugged terrain, restricting productive agriculture to river valleys and coastal plains. Typically, less than one-third of an island's land area is suitable for crops. The windward portions of islands are commonly very wet, whereas their leeward areas suffer drought, necessitating irrigation. Various hazards also impact agriculture, including the damaging winds of hurricanes, flooding, accelerated erosion, and landslides. In addition, some crops (notably bananas) have suffered from diseases. On the human side, most peasant farms are restricted to steep, unproductive slopes, while plantations control most of the productive lowland soils. Population pressures have led to the loss of some of the best lands and have caused fragmentation of farmland. Farm labor shortages, climbing wages, and foreign competition have added to the burden.

PhotoDisc

Among the Caribbean islands, coffee is raised for export mainly in Haiti, Jamaica, and the Dominican Republic. Its production is largely for European, Japanese, and U.S. markets.

Commercial Agriculture

Modern plantations own large tracts of land and specialize in one crop, commonly sugarcane, bananas, coconuts, coffee, rice, or tobacco. They are more mechanized and better managed than colonial plantations, although they are still largely British-, French-, or American-owned. The largest plantations are found on the largest islands, especially Hispaniola, Jamaica, and Puerto Rico. Cuba also has large-scale farming, but the operations are government-owned. Plantations always have been smaller in the Lesser Antilles, where relatively little land is available.

Sugar dominates the export economies of Cuba, the Dominican Republic, Guadeloupe, and Saint Kitts. Among traditional sugar producers in the Caribbean, notably Jamaica, Puerto Rico, Trinidad, and Barbados, sugar exports are exceeded by those of other commodities. Haiti, a leading sugar producer as a French colony, now produces little. Overall, sugar production in the Caribbean has been on the decline since the 1960's as a result of the variety of problems noted above.

Other commercial export crops grown in the Caribbean region include bananas, coffee, tobacco, and ganja. Bananas, introduced in the sixteenth century by Spanish missionaries, became an important export in the late nineteenth century as markets developed in Europe and the United States. Sweet bananas are significant exports of Guadeloupe, Martinique, the Dominican Republic, Jamaica, Granada, St. Lucia, and St. Vincent. Overall production is not significant on the world scale. Coffee is raised for export mainly in Haiti, Jamaica, and the Dominican Republic. Jamaica's famous Blue Mountain coffee, grown in the Blue Mountains northeast of Kingston, is among the most prized and expensive coffees of the world. Its production and export is largely for European, Japanese, and U.S. markets.

Tobacco was important before the sugar era and has seen a recent resurgence in the Greater Antilles, especially in Cuba, Puerto Rico, Jamaica, and the Dominican Republic, mostly for cigar production. Ganja, marijuana prepared especially for smoking, is illegal throughout the Caribbean region. The product is nevertheless of considerable commercial importance. Its chief producer is Jamaica, and its main destination is the United States. Other significant export crops include cacao (for chocolate) and citrus.

Peasant Farming

Peasant farming in the Caribbean began after emancipation in the nineteenth century, when freed slaves sought out the only land available, in the hills and mountains. Unfortunately, this land is unsuitable for crop agriculture, having thin and erodible soils. Individual peasant farms average less than 5 acres (2 hectares) in area, often in disconnected plots. A variety of crops are raised, including fruits such as mangoes, plantains, akee, and breadfruit; vegetables such as yams, potatoes, and okra; sugarcane; and coffee.

CARIBBEAN FLORA

Category: World regions

The Caribbean region is noted for its diverse and varied vegetation. Flowers thrive in the moist, tropical environment found on many islands. Hibiscus, bougainvillea, and orchids are just a few of the varieties found there. The heavily touristed region faces challenges in balancing development with preserving its flora.

The Caribbean region comprises the islands from the Bahamas to Trinidad and is noted for its tropical vegetation and flowers. This region has been significantly affected by human activities. Deforestation began with the development of sugarcane culture in the seventeenth century. When forests are cut for farmland, soil erosion and depletion often occur. Jamaica, Haiti, and many of the smaller islands have suffered acute ecological degradation. Thorn scrub and grasses have replaced native forests that were cleared for farming. This new vegetation does not protect the ground from the sun and provides little protection against moisture loss during drought. Livestock overgrazing also has contributed to ecological degradation.

However, these complex and fragile island ecosystems are finally being appreciated and protected. Most islands' governments recognize that they must balance development with protection of the natural environment. Many have established active conservation societies and national wildlife trusts for this purpose.

Rain Forest

The only rain forest left in the Caribbean Islands is a small area in Guadeloupe. However, many of the islands still have large stands of good secondary forest that are being harvested selectively by commercial lumber companies. Gommier, balata, and blue mahoe are some of the valuable species of trees cut commercially. Such tropical woods as cedar, mahogany, and palms grow on many islands. Martinique has some of the largest tracts of forest (rain forest, cloud forest, and dry woodland) left in the Caribbean.

While the Caribbean rain forest is not as diverse as those of Central and South America, it supports numerous plant species. Several of these plants are endemic to the region. For example, Jamaica has more than three thousand species with eight hundred endemics. Orchids and bromeliads are stunning examples of climbing and hanging vegetation in the rain forests of the Caribbean. Huge tree ferns, giant elephant ear plants, figs, and balsam trees are also found in these tropical island rain forests.

Plantations of commercial timber (blue mahoe, Caribbean pine, teak, and mahogany) have been established in many locations. These plantations reduce pressure on natural forest, help protect watersheds and soil, and provide valuable wildlife

Image Not Available

habitat. Much of the original forests of the Caribbean have been cut down to make room for sugar plantations and for use as fuel. Haiti, once covered with forests, is now on the verge of total deforestation. Soil erosion and desertification have severely impacted the country.

Saint Kitts, on the other hand, is one of the few places in the world where the forest is actually expanding. It provides abundant habitat for exotic vines, wild orchids, and candlewoods.

Closer to the coasts, dry scrub woodland predominates. Some trees lose their leaves during the dry season. The turpentine tree is common to the dry scrub forests. It is sometimes called the tourist tree because of its red, peeling bark. The trees' bark and leaves are often sold in marketplaces and used for herbal remedies and bush medicine.

Along the marshy coastal waters of many of the islands are dense mangrove swamps. Mangroves grow thick roots that stand above the waterline. These wetlands provide habitat for the endangered manatee, the American crocodile, and for huge numbers of migratory birds and resident birds, such as the egret and heron.

Dominica, one of the windward islands, is known as the "nature island" of the Caribbean. Most of the southern part of the island (17,000 acres, or approximately 7,000 hectares) has been designated the Morne Trois Pitons National Park, which became a World Heritage Site in 1998. Elfin forests of dense vegetation and low-growing plants cover the highest volcanic peaks and receive an abundance of rain. The trees, stunted by the wind, have leaves adapted with drip tips to cope with the excess moisture. Lower down, the slopes are covered with rain forest. Measures are being taken to protect this forest from cutting for farmland or economic gain because it is a valuable water source and a unique laboratory for scientific research.

CARNIVOROUS PLANTS

Categories: Angiosperms; *Plantae*; poisonous, toxic, and invasive plants

Carnivorous plants have the ability to capture and digest insects and other small animals.

Carnivorous plants are a diverse group. All live in nutrient-poor, often boggy or aquatic environments where minerals from digested prey are essential for survival, or at least for good health. None use captured prey as an energy source, as animals do; rather, carnivorous plants are photosynthetic, like other plants. The mechanisms for capturing prey are varied, and carnivory is found in at least nine distinct plant families, having evolved a number of times independently.

Pitchers

One widespread carnivorous mechanism is the formation of *pitchers*, specialized leaves or portions of leaves that have developed into hollow tubular or pitcherlike structures that contain fluid. The fluid is mostly water but may contain digestive enzymes and mild narcotics. The mouth, or entrance, to the pitcher is generally marked with bright colors and may produce droplets of nectar to attract insects. The throat of the pitcher is usually lined with wax or downward-pointing hairs so that insects will slowly slide downward toward the pool of water but will have great difficulty climbing back out.

Pitchers are found in a number of genera, in several unrelated families. *Sarracenia* is the genus of North American pitcher plants found in bogs, seeps, and marshy areas, primarily in the southeastern United States. The pitchers arise directly from an underground rhizome. A related species, *Darlingtonia californica*, is found in cold-water bogs in northern California and southern Oregon. The genus *Heliamphora* includes many species in South America. The Asian pitcher plants are in the unrelated genus *Nepenthes*. These pitchers hang from the ends of leaves on plants that are generally *epiphytic* (growing on tree branches) or grow on rocky surfaces. The genus *Cephalotus* is not related to any of the foregoing but produces pitchers similar to those of *Nepenthes*. The single species of *Cephalotus* is found in seeps and bogs in southwestern Australia. Finally, in South America there are species in two genera of *bromeliads* (pineapple family), *Catopsis* and *Brocchinia*, that form crude pitchers that have been found to be carnivorous.

Digital Stock

Specialized leaves or portions of leaves of the pitcher plant form hollow, tubular structures which contain fluid, mostly water, that traps insects.

Leaf Traps

The most famous of all carnivorous plants is Venus's flytrap, *Dionaea muscipula*, which is native to bogs in the coastal plain of North and South Carolina. In this species, the two sides of the leaf snap together quickly when trigger hairs on its surface are brushed twice within a short span of time. The closing mechanism involves a wave of rapid cell elongation on the outer surface of the leaf trap that pushes the two sides of the leaf together. The edges of the trap leaves are lined with long spikes which serve as bars to prevent quick-responding insects from escaping during closing. A reddish coloration and drops of nectar lure insects to the trap. Digestive enzymes are secreted from the inner surface of the trap. After the meal is digested, slower growth of cells on the inner surface reopens the trap.

Related to the fly traps are the *sundews*, in the genus *Drosera*, and similar plants in the genera *Drosophyllum*, *Byblis*, and *Tripohylophylum*. Leaves of these plants are covered with tiny glandular hairs, each producing a drop of sticky, nectarlike fluid that attracts the insects and then traps them. Once an animal is tangled in the gluey exudate, digestive enzymes are secreted, and in some, the leaf slowly folds around the prey.

There are many species of sundew, nearly two hundred in Australia alone, with many species in South America, southern Africa, North America, and Europe. The species vary in the size and shape of their leaves and also in their flowers, which come in a variety of colors, sizes, and shapes. They in-

Carnivorous Plants

Common Name	*Genus*	*Species*	*Location*
Australian pitcher plant	*Cephalotus*	1	Southwest Australia
Bladderworts	*Utricularia*	220	Worldwide
Butterworts	*Pinguicula*	80	Asia, Europa, North America
Cobra lily	*Darlingtonia*	1	California, Pacific Northwest
Corkscrew or forked trap	*Genlisea*	20	South America
North American pitchers	*Sarracenia*	10	United States, Southeast
Portuguese sundew	*Drosophyllum*	1	Portugal, western Spain
Rainbow plants	*Byblis*	5	Northwest Australia
Sun pitchers	*Heliamphora*	6	South America
Sundews	*Drosera*	150	Worldwide
Tropical pitcher vines	*Nepenthes*	90	Australia, Indonesia, Madagascar
Venus's flytrap	*Dionaea*	1	North Carolina, South Carolina
Waterwheel plant	*Aldrovanda*	1	Eurasia

habit seeps and bogs or are found in sandy soil that is damp for only a short time. Most of them are tiny rosettes of paddle-shaped to linear leaves, but some are erect, herbaceous tufts 1-2 feet high, or even vines.

One genus of the unrelated family *Lentibulariaceae* also employs leaf traps. This is *Pinguicula*, found in North America in moist, nutrient-poor habitats. Its leaves are flat, somewhat curled at the edges, and moderately sticky, without conspicuous glandular hairs. They do not close around prey. The many species of *Pinguicula* have variously colored, snapdragon-like flowers on long stalks.

Underwater and Underground Traps

The final category of carnivorous plants produces traps under water, or sometimes in damp soil, where they capture tiny crustaceans and other invertebrate animals. *Aldrovanda* is a submerged plant related to Venus's flytrap but is native to Australia. Its miniature underwater traps snap shut when animals swim or bump into them. Another genus with tiny underwater traps is *Utricularia*, related to *Pinguicula*. These traps operate by suddenly expanding to suck water and small animals inside when triggered. The traps are borne on specialized leaves that grow downward into the water or damp soil. Often one only sees the brightly colored, snapdragon-like flowers above the surface. There are hundreds of species of *Utricularia*, found all over the world, particularly in Australia and North America. A third carnivorous genus in the *Lentibulariaceae* is *Genlisea*, which grows in Africa and South America, and which has traps similar to those of *Utricularia*.

CELL CYCLE

Categories: Cellular biology; physiology

In plants, as in all eukaryotic life-forms, the cell cycle comprises the processes of cell division, constituted by three preparatory phases (G_1, G_2, and S), followed by mitosis (nuclear division) and cytokinesis (cytoplasm division).

One of the fundamental characteristics of living organisms is their ability to grow and reproduce. At the cellular level, growth is accomplished by a gain of mass, followed by division into two daughter cells. In unicellular species, such as bacteria and green algae, this division results in the production of new organisms. In multicellular organisms, such as plants, cells must divide many times to produce new individuals, and additional processes of differentiation into mature cell types must occur.

Eukaryotic Cell Division

Plant cells are eukaryotic, meaning that they contain a *nucleus* and membrane-bound cellular compartments called *organelles*, such as chloroplasts, the sites of photosynthesis, and the central *vacuole* used for storage. In order for eukaryotic cell division to occur, cells must accomplish several steps. First, a cell must reach a sufficient size to ensure that the daughter cells will be large enough to survive. The cell achieves this status by making needed molecules, using synthetic biochemical reactions, and monitoring the outside environment to ensure continued favorable conditions for reproduction. Next, a cell must replicate all required macromolecules, including the deoxyribonucleic acid (DNA), as well as the organelles. Finally, the cell must be able to distribute appropriately the cellular contents, including the genetic material, to the daughter cells. The cyclical repetition of these steps comprises the eukaryotic cell division cycle or, more simply, the cell cycle.

Cell Cycle Phases

The general arrangement of the cell cycle was first determined through microscopic observations of living cells undergoing cell division. Originally, four stages were identified: G_1 phase, S phase, G_2 phase, and M phase. G_1 and G_2 phases were named as gap phases, because it was presumed that the cell did not appear to accomplish any specific events during these phases. G_1 phase occurs after the previous cell division and is the phase where the cell grows, metabolizes, and prepares to undergo another round of cell division. During G_1 phase, the cell also transcribes and translates the genes required for DNA synthesis. In S phase, the DNA synthetic phase, the cell concentrates its efforts on accurately replicating its genetic material, the DNA genome. In G_2 phase, the cell coordinates both transcription and translation to synthesize proteins that are required specifically for asexual cell division, or mitosis. During M phase, the DNA chromosomes condense and are divided into the two daughter cells. G_1, S, and G_2 phases together are referred to as *interphase*.

Mitosis itself is composed of four phases: (1) *prophase*, in which chromosomes are condensed, homologous chromosomes are paired together, and the spindle apparatus made of microtubules forms; (2) *metaphase*, in which the paired chromosomes are lined up across the center of the cell on the metaphase plate; (3) *anaphase*, in which the homologous chromosomes are pulled to separate poles in the dividing cell by the attached spindle apparatus; and (4) *telophase*, in which the daughter cell chromosomes are collected together at the poles. Mitosis is followed by cytokinesis, or the process by which the two daughter cells are physically separated. Because plant cells have cell walls, the division of one cell into two daughter cells requires the formation of a cell plate to complete cytokinesis. This cell plate grows outward between the two new nuclei. Once the cell plate reaches the walls of the dividing cell, it forms the cell wall that separates the two new cells.

Checkpoints

The cell will die if it goes through any cell cycle phase out of order. Therefore, the cell has evolved sophisticated *checkpoints* to ensure that critical events, such as DNA replication and cell division, occur in the correct order and that each required step is completed prior to movement to the next phase. Additionally, external conditions, such as a change in nutrient availability, can cause a cellular checkpoint response. There are two main points in the cell cycle which are regulated by checkpoints, the G_1-to-S transition and the G_2-to-M transition. The G_1-to-S transition is important because once the cell commits to divide and starts to copy its DNA, it must complete cell division or die. After DNA replication is complete, the G_2-to-M transition is important for the cell to make sure that all of the DNA has been copied correctly, or the daughter cells will not have the full complement of genetic material.

CDKs and Cyclins

Enzymes are proteins that catalyze chemical reactions in the cell. Without enzymes, chemical reactions would occur too slowly to sustain life. Kinases are enzymes that place a chemical group, called a phosphate group, onto other proteins in the cell. Because of the nature of the phosphate chemical group, the addition of these groups causes conformational changes in the three-dimensional structure of the proteins that accept them. The cell cycle is controlled by the actions of kinases called cyclin-dependent kinases, or CDKs. Each CDK has a partner called a cyclin, which is required for the kinase activity to place phosphate groups on target proteins. The CDK/cyclin pairs perform kinase reactions, which activate proteins leading to completion of cell cycle phases. Opposing the action of the CDK and cyclin pairs are cyclin-dependent kinase inhibitors, or CKIs, which act as brakes to prevent CDK/cyclin activity until the cell is ready to go on to the next step in the cell cycle.

Many of the cell cycle control mechanisms have been conserved throughout all eukaryotic cells, including the plant cell. *Arabidopsis* is a genus that has been widely characterized and used as an experimental model for plant growth and differentiation in scientific laboratories worldwide. In plants such as *Arabidopsis*, two major groups of CDKs have been studied, the A-type and B-type CDKs. The A-type CDKs show kinase activity during the S, G_2, and M phases of the cell cycle and regulate the transitions from G_1-to-S and G_2-to-M phases. The B-type CDKs are active during mitosis and regulate only the G_2-to-M transition in plants.

CELL THEORY

Categories: Cellular biology; history of plant science; physiology

The notion that the cell is the smallest division of life and its attendant principles have been developed over the past three centuries and are collectively known as the cell theory.

Before the invention of the microscope, people studying living organisms saw whole and complete organisms and did not imagine that life was subdivided into smaller compartments. It is now known that the cell is the fundamental unit of life and that all living organisms are composed of cells. Because cells are microscopic, their existence was not discovered until the seventeenth century.

Discovery of the Cell

The discovery of the cell did not come about until the last half of the seventeenth century, after the Dutch inventor Antoni van Leeuwenhoek built the first light microscope. When looking at pond water using his light microscope in 1674, Leeuwenhoek saw many tiny creatures which were invisible to the naked eye. Leeuwenhoek assumed that these tiny "animalcules" were alive because he could see them moving.

However, the first description of the cell is attributed to the English scientist Robert Hooke. In 1665 Hooke first published *Micrographia*, a work devoted to observations made with his compound light microscope. Hooke examined the structure of cork, a dead plant tissue, by cutting cork into very thin slices and observing the slices under his light microscope. Hooke saw the dead cells of the cork outlined by the thickened cell walls of that tissue and determined that cork was composed of a pattern of spaces which resembled small rooms, or "cells." Interestingly, Hooke did not recognize the significance of the cells that he described and thought that the cork cells were merely channels for fluid conduction in the plant.

Cells as Globules

Partly because of problems with chromatic aberrations in early microscopes, scientists thought that living organisms were made of "globules." As early as 1682, plant tissues were described as bladders clustered together. In 1771 William Hewson performed one of the first cell biology experiments by confirming Leeuwenhoek's earlier observation of blood and brain globules and by showing that the blood globules swelled and shriveled in different solutions. By 1812 Johann Jacob Paul Moldenhawer had shown that plant tissue was composed of independent cells, and in 1826 Henri Milne-Edwards determined that all animal tissues were formed from globules. Finally, in 1824 Henri Dutrochet proposed that animals and plants had a similar cellular structure. Ironically, Thomas Hodgkin and Joseph Jackson Lister showed in 1827 that many of the previously observed globules were likely to have been optical artifacts that disappeared when the new achromatic microscope was used. However, the idea that life was made of tiny cells remained.

Cells Compose All Organisms

Matthias Schleiden, a German botanist, suggested in 1838 that all of the structural elements found in plant tissues were composed of cells or cellular products. In 1839 Theodor Schwann, a zoologist, reported that animal tissues were also composed of cells and suggested that all living organisms were actually composed of cells. Based on their contributions, Schleiden and Schwann are considered to have established the official "cell theory." Schwann also contributed to the description of the cell by defining a cell as having three essential components: a cell wall, a nucleus, and a fluid content. The Scottish botanist Robert Brown first described the nucleus of the cell as an essential component of living cells in 1831.

The work of both Schleiden and Schwann contested the notion of *vitalism*, the belief that no single part of an organism was alive but that somehow the substances composing the whole organism together shared the characteristics of life. The idea of vitalism made sense prior to the invention of the microscope (because cells cannot be seen with the naked eye) but did not hold up when cells were observed in all plant and animal tissues. Therefore, the idea that living organisms were made of cells was becoming widespread at this time. An 1830 plant anatomy textbook by Franz Julius Ferdinand Meyen contained a chapter on cell structure and discussed the idea that cells unite to form cellular tissues.

Cell Origins in Organisms

Interestingly, while Schleiden and Schwann realized that all living organisms were made of cells, they did not realize that all cells came from preexisting cells. Indeed, Schwann mistakenly thought that cells had an extracellular origin and could arise de novo. Schwann originally observed plant cells in the endosperm of seeds, where the nuclei multiply before the cell walls form, and he generalized from this unusual system. This idea persisted for a time, even though Hugo von Mohl first described cell division in green algae in 1837. Essentially, von Mohl investigated his hypothesis that all cells must start out very small and gradually grow to full size by observing a filamentous green alga. By studying the alga, Mohl discovered cell division as the algal cells divided and formed partitions between the newly formed daughter cells.

By 1858 the pathologist Rudolf Virchow had expressed the idea that all cells arise from preexisting cells. This idea was important because until that time, the idea of *spontaneous generation* was also popular. Spontaneous generation was the mistaken idea that living organisms could arise spontaneously from nonliving material and was thought to explain such phenomena as the fact that frogs are found in ponds and maggots in rotten meat. In contrast, Virchow wrote: "Where a cell exists, there must have been a preexisting cell, just as the animal arises only from an animal and the plant only from a plant."

Modern Cell Theory

The modern cell theory consists of several principles. As stated by Schleiden and Schwann, all living organisms are composed of one or more cells. Because cells are the smallest units of life, cells must be the site of the chemical reactions that sustain living organisms. Finally, it is clear that all cells arise from preexisting cells, as first stated by Virchow. In order for cells to perform this replication, it is now apparent that all cells contain hereditary information and pass this information from parent cell to daughter cell. Additionally, this hereditary information is contained in the deoxyribonucleic acid (DNA) found in the nuclei of all cells, with this DNA being copied for each daughter cell to use.

CELL-TO-CELL COMMUNICATION

Category: Cellular biology

Cell-to-cell communication involves the various stimuli to which plants respond, whether biotic, such as hormones and disease, or abiotic, such as water status, heat, cold, and light.

Throughout their lives, plants and plant cells continually respond to both external and internal signals, which they use to alter their physiology, morphology, and development. The manner in which plants respond to a stimulus is determined by developmental age, previous environmental experience, and internal biological clocks that specify the time of year and time of day.

Chemical Messengers

In complex multicellular eukaryotes, the coordination of responses to environmental and developmental stimuli requires an array of signaling mechanisms. Animals have evolved two systems, the nervous system and the endocrine (hormone) system, for responding to stimuli. While plants lack a nervous system, they did evolve *hormones* and other chemicals, such as phytochrome, as chemical messengers.

The major groups of plant hormones include the auxins, gibberellins, cytokinins, ethylene, and abscisic acid. These hormones serve as signals for a wide range of physiological, biochemical, and developmental responses. These signals may impact different cells at different times, or they may impact the same cells at different sites. A variety of pathways are available for information flow from any one signal. Information from the same signal may travel to different areas of the cell under different environmental conditions. Alternatively, information might travel to the same site after traveling by different pathways. Most signals appear to induce changes in gene expression, and this altered gene expression is responsible for the observed response.

There are two classes of chemical messengers, based on their ability to cross cellular membranes. *Lipophilic messengers* readily diffuse across membranes and combine with intracellular receptor proteins. When activated by the messenger, these proteins function as transcription factors, thereby inducing the transcription of new proteins. In other words, the messenger-receptor complex signals the activation of genes which encode the proteins that produce the response to the stimulus. While animals have numerous lipophilic messengers, such as the steroid hormones in animals, only one, brassosteroid, has been demonstrated in plants.

Most plant messengers are *hydrophilic*, or water-soluble (rather than lipophilic) and are unable to enter the target cell because they cannot diffuse across the hydrophobic ("water-hating") interior of the membrane. These messengers must first bind with a membrane receptor molecule. This messenger-receptor complex then communicates with other molecules inside the cell to initiate a cascade of events referred to as a *signal transduction pathway*. Most signal transduction pathways cause the activation of other chemicals, referred to as second messengers.

Second Messengers

Signal transduction pathways using a variety of second messengers have been well documented in animal systems. Some of the most common second messengers are 3′,5′-cyclic AMP (cAMP), G-proteins, 1,2 diacylglycerol (DAG), inositol 1,4,5-triphosphate (IP_3), and Ca^{2+}, and many of these have been shown to be active in plants. When a chemical messenger such as a hormone binds to a membrane receptor, one or more of these second messengers are elevated. The elevated level of the second messengers results in the activation of regulatory proteins such as protein kinases or phosphatases. Activated protein kinases will *phosphorylate* transcription factors (that is, add a phosphate group), and activated phosphatases will dephosphorylate (remove a phosphate group from) transcription factors.

A typical signal transduction cascade is presented in the following scenario. An environmental stress causes an elevation in the level of the hormone abscisic acid (ABA), which is responsible for leaf fall. ABA binds to receptors in the membranes of the target cells. The ABA-receptor complex activates a G-protein, which then activates the enzyme phospholipase C. This enzyme catalyzes the conversion of a substrate to DAG and IP_3. The IP_3 stimulates the opening of Ca^{2+} channels in the endoplasmic reticulum or tonoplasts (the membranes surrounding vacuoles). The release of Ca^{2+} from these organelles activates protein kinases, which then activate transcription factors by phosphorylation. The activated transcription factors induce transcription of genes, which encode the proteins necessary for the plant to respond to the environmental stress.

Transport of Messengers

As discussed above, cells communicate primarily via chemical messengers. In most instances, particularly in the case of plant hormones, the messengers are produced in one cell and transported to other cells. Plant cells are usually in contact with others around them, and cell communication (transport of messengers) can occur by transport through either the *apoplast* or the *symplast*. The apoplast refers to the free space between cells and cell wall materials. Water moves freely through the apoplast, and certain chemicals can be found moving with the water. Some important developmental molecules, such as the auxins, have been shown to move through the apoplast. The symplast is composed of the living cytoplasm of the cells, and many substances are transported symplastically.

Rapid transport through the symplast is possible because most living plant cells are connected to neighboring cells by *plasmodesmata* that pass through the adjoining cell walls and provide some degree of cytosolic continuity between them. Plasmodesmata are tubelike cytoplasmic extensions that are divided into eight to ten micro-channels. Although the exact pathway of communication has not been determined, some molecules can pass from cell to cell through plasmodesmata, probably by flowing through the micro-channels. Plasmodesmata appear to be gated, which means that they allow the passage of some molecules and restrict the passage of others.

CELL WALL

Categories: Anatomy; cellular biology; physiology

The cell wall is the outer, rigid wall of a cell, dividing the protoplast (the interior, including the cytoplasm and nucleus) from the cell's external environment. The plant cell wall is both unique to and a major feature of plants, perhaps second only to the plant's photosynthetic ability.

The primary functions of the cell wall in plant cells include are to provide protection for the enclosed *cytoplasm* and give mechanical support to the entire plant structure. Plant cell walls are part of the *extracellular matrix*, a complex mixture of extracellular materials found between cells. These materials are synthesized by the intracellular contents and transported through the plasma membrane. All plant cell types consist of at least a *primary cell wall*, and many also produce a *secondary cell wall*. In addition, certain cells also secrete specialized substances into the extracellular matrix.

Primary Cell Wall

The primary cell wall is first synthesized by young, actively growing cells. It is thin and is composed of *cellulose* embedded within a *noncellulose matrix*. Cellulose is a polysaccharide polymer composed entirely of glucose molecules joined together end on end to form long, unbranched chains. These chains may consist of up to several thousand glucose molecules. The chemical bond joining the glucose molecules in cellulose is slightly different from that found in starch, another polysaccharide composed entirely of glucose. It is this difference in bonds that makes cellulose a structural polysaccharide.

Microfibrils are groupings of about 50 to 60 cellulose chains that are parallel to one another and held together by hydrogen bonds. The tensile strength of microfibrils is comparable to steel wire of the same thickness. The cellulose microfibrils make up approximately 25 percent of the primary cell wall and are arranged somewhat randomly (more parallel in fast growing cells) within the noncellulose matrix.

Noncellulose Matrix

The noncellulose matrix of the primary cell well accounts for about 60 percent to 80 percent of the primary cell wall and is composed of *hemicelluloses*, *pectins*, and *extensins*. Hemicelluloses are highly branched polysaccharide structures composed of heterogeneous mixtures of sugars, some of which are chemically modified. Pectins are also heterogeneous mixtures of sugars but are particularly rich in galacturonic acid. Pectic substances are also a major component of the outermost *middle lamella*, which can be thought of as the cement that holds adjacent cells together. Pectins, extracted from unripe fruits, have been used commercially as thickening agents for jellies and jams. The softness of ripe fruits is due to the enzymatic breakdown of pectins within the middle lamella. The hemicelluloses and various pectins are thought to coat and reinforce the cellulose microfibrils. Extensins are protein components of the matrix. They are glycoproteins that contain a high amount of a modified amino acid called hydroxyproline. Extensins make up about 10 percent of the matrix material, add strength to the cell wall, and are involved in cell growth.

Secondary Cell Wall

Cell types that are directly involved in support of the plant body, such as *sclerechyma* and particularly the *tracheids* and *vessels* of the xylem, undergo secondary wall formation. This wall is typically much thicker and is synthesized by the intracellular contents to the inside of the primary cell wall. Secondary cell wall formation occurs as the cell reaches its mature size. In some cell types there may even be two or more distinct layers of secondary cell wall deposition. Its composition is somewhat similar to the primary cell wall but also differs significantly.

Cellulose microfibrils can make up to 45 percent of this wall, while hemicelluloses and pectins can make up to about 20 percent.

However, what most distinguishes the secondary cell wall is the deposition of *lignin*. Lignin is an extremely tough and durable complex compound characterized by interlocking phenolic groups. Lignin is stronger than cellulose microfibrils, and together they are responsible for the superior strength of many types of wood. In cells that undergo secondary cell wall formation, lignin may also be deposited in the preexisting middle lamella and primary cell wall areas.

Specialized Cell Wall Substances

Certain cell types, especially the epidermis, which is exposed directly to the outer environment, secrete a variety of highly waterproof and protective substances, such as *cutin*, *suberin*, and a variety of *waxes*. These substances are deposited on the outside of the primary cell wall. Cutin and suberin are polymers composed of long-chain fatty acids that are linked or esterified at the acid ends. Suberin differs in that it contains dicarboxylic fatty acids and various phenolic compounds. For the most part, cutin is associated with and is the main constituent of the *cuticle* of the aboveground epidermis, while suberin is mostly associated with the belowground epidermis.

Suberin is also the major component of the *Casparian strip* found in the *endodermis* of the root. This important root tissue forces water and dissolved minerals to move intracellularly into the vascular tissue. Additionally, suberin constitutes scar tissue that is formed when cells are injured or otherwise wounded. Waxes are a family of extremely waterproof substances characterized by long-chain alcohols linked with long-chain fatty acids or hydrocarbons. They are typically secreted as droplets on the exterior of the cuticle and crystallize in a variety of geometric patterns.

Plasmodesmata

Plant cells contain cytoplasmic channels called *plasmodesmata* that connect adjacent cells. As cells divide and the *cell plate* is formed, there are areas where new cell wall material is not deposited because of the extension of the endoplasmic reticulum (ER) from the mother cell to the daughter cell. This ER channel is referred to as the *desmotubule*. Thus, each plasmodesma contains an inner desmotubule. Some cells contain areas called *primary pit fields*, in which numerous plasmodesmata are found.

The purpose of plasmodesmata involves cell-to-cell communication via transport of small molecules. Movement is not thought to occur inside the desmotubule, as it is too narrow, but rather through the cytoplasmic channel between the desmotubule and the plasmodesma itself. The presence of plasmodesmata allows for a continuous cytoplasmic connection within plant tissues called the *symplast*.

In cells which form thick secondary cell walls, particularly the xylem vessels and tracheids, which contain no living protoplast at maturity, numerous pit pairs among adjacent cells are found that allow multiple pathways for the flow of water.

CELLS AND DIFFUSION

Categories: Cellular biology; transport mechanisms

Plant cells, like all other living cells, are surrounded by a semipermeable membrane, and any particle moving into or out of the cell must cross this membrane. There are three basic processes by which particles move across plant cell membranes: diffusion, facilitated diffusion, and active transport.

The process of *active transport* requires the direct input of energy to move particles across the cell membrane. Diffusion and *facilitated diffusion* can occur without the direct expenditure of cellular energy.

Diffusion

If one were to drop a sugar cube into glass of water and immediately use a straw to sip a little water from the top of the glass, the water would not have a sweet taste. However, after a few hours, a sip of water from the top would taste sweet. The reason for the change in the taste of the water is diffusion, the net movement of particles down a *concentration gradient* (that is, from an area of higher concentration to an area of lower concentration). Concentration is the number of particles or amount of substance per unit volume, and a gradient occurs when some factor such as concentration changes from one volume of space to another. Hence, the sugar molecules move more frequently from around the cube where they were highly concentrated to other parts of the glass where they were less concentrated. There is always some movement in both directions, but the net movement is down the concentration gradient.

Diffusion is possible because molecules in a liquid or gaseous phase are not static; they are in constant motion as a result of kinetic energy, which exists at temperatures above absolute zero ($^{-}$273.16 degrees Celsius, or $^{-}$459.69 degrees Fahrenheit). As the concentration of a substance increases, its free energy also increases. When molecules move, they collide with one another and exchange kinetic energy, and there is a random but progressive movement from regions of high free energy (high concentration) to regions of low free energy (low concentration). Diffusion can occur quite rapidly over short distances but can be extremely slow over long distances. For example, a molecule of glucose can diffuse across a typical 50-micrometer diameter cell in 2.5 seconds, but it takes thirty-two years for it to diffuse a distance of 1 meter.

Role in Plants

Diffusion is an important process in the lives of plants. Water is an important component of all cells, and water moves into plant cells by the process of *osmosis*. Osmosis is the diffusion of water across a semipermeable membrane. Many plant nutrients reach the root surface via diffusion through the soil solution. Some nutrient molecules diffuse across root cell membranes into the *cytosol* (cell sap or cytoplasm) or from the cytosol of the endodermal cells into the xylem tissue. Carbon dioxide diffuses from the atmosphere through the stomata and into the air spaces of leaves. Water vapor evaporates from the surface of a leaf by diffusion through the open stomata.

Diffusion also plays a role in the movement of photosynthetic products such as sugars into the phloem for transport throughout the plant. Because cellular membranes are composed of a lipid bilayer, lipid-soluble materials use simple diffusion to cross the membrane surface. Substances with low lipid solubility can move across membranes via facilitated diffusion. In this process, the substance binds to a transporter molecule, generally called an ionophore, which transports the substance across the membrane and down its concentration gradient.

Bulk Flow

As previously mentioned, diffusion occurs rapidly over short distances. In order to move substances such as water over long distances—for example from the roots to the leaves, plants use a process referred to as *bulk flow*. Bulk flow is the concerted *en masse* movement of groups of molecules, usually in response to a pressure gradient. A moving stream, water flowing through a garden hose, and wind currents are examples of bulk flow. Pressure-driven bulk flow is the major mechanism behind the movement of water over long distances through the xylem. This process is different from diffusion because it is independent of solute concentration.

Active Transport

Whereas diffusion and facilitated diffusion do not require the direct input of cellular energy because they involve transport down a concentration gradient, moving substances against their concentration gradient requires the expenditure of energy. This "uphill" movement across membranes is called active transport.

The most common source of energy for active transport comes from adenosine triphosphate (ATP). When this high-energy phosphate is hydrolyzed, the stored energy is released to drive cellular reactions such as active transport. More specifically, the substance is moved across the membrane by a carrier protein embedded in the membrane. The carrier protein uses energy from the hydrolysis of ATP (that is, the removal of one phosphate group). Although active transport is primarily for movement against a concentration gradient, it can also be used to move substance down their concentration gradient.

There are two important modifications of the active transport process: *cotransport* and *countertransport*, both of which involve the movement of one substance down its concentration gradient while simultaneously transporting another substance against its specialized membrane proteins. Although these proteins do not require an energy source to operate, ATP is still indirectly consumed. The substance being moved down its concentration gradient would eventually be at equal concentrations on each side of the membrane. To counteract this, active transport, with hydrolysis of ATP as the energy source, is used to pump the substance across the membrane to maintain the gradient.

CELLULAR SLIME MOLDS

Categories: Microorganisms; molds; *Protista*; taxonomic groups; water-related life

Cellular slime molds, or dictyostelids, were originally considered to be fungi. These microscopic, multicellular organisms are easily mistaken for some of the microfungi that commonly occur as contaminants in laboratory cultures. However, cellular slime molds are more closely related to the protozoans than to fungi.

Although once thought to be fungi, the protists of the phylum *Dictyosteliomycota* actually have more in common with the *paramecium* or *amoeba* that can be observed in a drop of pond water when viewed under the microscope than they do with mushrooms and toadstools. Cellular slime molds are essentially microscopic throughout their entire life cycle, and only rarely can they be observed directly in nature, as is the case for the plasmodial slime molds. Cellular slime molds must therefore be grown under controlled laboratory conditions in order to be studied.

Life Cycle

Since their discovery in the late nineteenth century, cellular slime molds have intrigued biologists. Their life cycle exhibits a curious alternative to the way in which most other creatures on earth grow, develop, and become multicellular, with different specialized tissues produced as a result of the process. Most plants and animals begin life as a single cell (called a zygote) that is the product of the fusion of an egg cell and sperm cell. Shortly after the two cells fuse (through a process termed fertilization), the zygote divides into two cells that stick together. These cells soon divide again to produce a cluster of four cells that in turn divide, and so on. Within hours or days (depending upon the particular plant or animal), clusters of dozens to thousands of cells form an embryo. Specialized cells begin to take form, and the basic shape of the body of the organism begins to become apparent.

Cellular slime molds approach reproduction differently. Like fungi and plasmodial slime molds, they produce *spores* as reproductive structures. When a spore germinates (no fusion of cells is required), it releases a single *amoeboid cell* that begins to engulf and digest bacteria in soil and decaying plant debris, the usual habitats for cellular slime molds. When the amoeboid cell divides, the two cells produced separate and become completely independent of each other, with each continuing to feed and undergo additional divisions for a number of hours or days. Only after the growing population of amoeboid cells depletes the local supply of bacteria is there any indication that a multicellular structure will be produced.

In response to the production of chemical attractants, thousands of amoeboid cells that have been operating as individual single-celled organisms begin to move, either singly or in streaming masses, to form multicellular clumps, or *aggregations*. Shortly thereafter, one or more cigar-shaped structures called *pseudoplasmodia* emerge from each aggregation. A pseudoplasmodium is a unified collection of thousands of what had once been separate, independent amoeboid cells. The cells remain distinct in the pseudoplasmodium but no longer act independently. Instead, they cooperate as parts of a multicellular entity. Remarkably, when amoeboid cells of two or more different species of cellular slime molds are grown together, the amoeboid cells of the different species can recognize each other, so that the cells that form any one aggregation are all of a single species rather than a mixture.

Immediately, or perhaps after the entire structure has migrated a short distance toward a light source, cells of the pseudoplasmodium begin to display different patterns of specialization. Cells that happen to have been positioned near the anterior end of the moving "cigar" begin to secrete a wall consisting of *cellulose*. These cells bind together to form a slender stalk that grows upward from the surface of the substrate upon which the pseudoplasmodium occurs. Other cells, those that happened to have been nearer the posterior end of the pseudoplasmodium, are lifted off the surface on the end of the extending stalk. These cells begin to become encapsulated and specialized as spores. Only the latter live on and produce another generation of amoeboid cells to feed on soil bacteria. The cells that produced the stalk in order to elevate the spore cluster above the substrate eventually die, dry up, and decay.

Reproduction

It appears that cellular slime molds reproduce asexually most of the time, at least under laboratory conditions. All of the cells that originate from the same spore are basically genetically identical to one another and collectively represent a genetic clone. As is the case for asexual reproduction in other life-forms, finding a "mate" is not necessary to perpetuate the species. If amoeboid cells are equipped with the genetic characteristics necessary to survive long enough to produce spores, the same gene combinations will be passed faithfully to all offspring, thus providing the same qualities for survival.

However, a method of sexual reproduction, with its potential of introducing genetic variability, also seems to exist in cellular slime molds. Occasionally in laboratory cultures, a number of large, thick-walled cells are found that are quite different from spores or encysted amoeboid cells. These giant cells are called *macrocysts*. Macrocysts appear to form when several amoeboid cells (sometimes described as being of compatible "mating types") fuse together and rearrange their genetic libraries and those of other amoeboid cells that may be engulfed. When macrocysts germinate, the amoeboid cells that emerge seem to have different combinations of genetic information than the cells that initially formed the macrocysts. This mixing up of genetic information, along with the genetic changes resulting from mutations, provides cellular slime molds with an ability to cope with changing environments.

Distribution and Ecology

Most of what is known about cellular slime molds has been acquired from studying these organisms in laboratory culture. What about the biology of "wild" slime molds in nature? In natural ecosystems, it is quite likely that cellular slime molds play a significant role in controlling the size of bacterial populations in soil and decaying litter. Nutrients that are taken up from decaying plants and animals by bacteria are transferred to cellular slime cells when the latter feed upon these bacteria. The cellular slime molds, in turn, become food for soil protozoans, nematode worms, microscopic arthropods such as mites, and other small invertebrate animals. Because of this, cellular slime molds play an essential role in patterns of energy flow and nutrient cycles within terrestrial ecosystems.

There are about seventy-five described species of cellular slime molds. These have been assigned to one of three genera: *Dictyostelium*, *Polysphondylium*, and *Acytostelium*. Some species of cellular slime molds have been found in almost all parts of the world. Two good examples are *Dictyostelium mucoroides* and *Polysphondylium pallidum*. Numbers of species of cellular slime molds appear to be highest in the American tropics, which suggests that this region represents a center of evolutionary diversification of the group. More than thirty-five different species have been found in the small area around the Mayan ruins at Tikal in Guatemala. In general, numbers of species of cellular slime molds decrease with increasing elevation and with increasing latitude.

Some species have restricted habitat associations. One species (*Dictyostelium caveatum*) has been found only in a single cave system in Arkansas. Another species (*Dictyostelium rosarium*), known from a number of localities worldwide but rarely aboveground, also seems to have an affinity for the type of conditions found in caves. Of the thirty-five species that occur at Tikal, many appear to be restricted to tropical or subtropical locations. *Dictyostelium discoideum* is the most intensively studied cellular slime mold and the one most widely used in research on developmental biology and genetics. Any search for information about cellular slime molds would probably turn up numerous references to this particular form.

Dispersal of Spores

Unlike most spore-producing organisms (including plasmodial slime molds), cellular slime molds produce spores that do not seem to be carried appreciable distances by wind. Instead, dispersal of cellular slime mold spores seems to depend more upon their accidental transport on the body surface or within the digestive tract of some animal. Viable spores of cellular slime molds have been recovered from the droppings of a number of animals, including rodents, amphibians, bats, and even migratory birds that travel great distances between winter and summer homes. In tropical forests, many living plants and considerable amounts of organic material are found high above the ground in the forest canopy. Cellular slime molds have been isolated from the mass of organic material (literally a "canopy soil") found at the bases of epiphytic plants growing on the trunks and branches of trees in these forests. It seems likely that they are introduced to such habitats by being carried up from the ground by birds, insects, or other animals that move between the forest floor and the canopy above it.

CENTRAL AMERICAN AGRICULTURE

Categories: Agriculture; economic botany and plant uses; food; world regions

Agriculture is generally understood to be concerned with the production of food; however, in Central America, ornamental plants and flowers, forest products, and fibers are also important agricultural commodities.

The nations of Central America are generally considered to be Belize, Costa Rica, El Salvador, Guatemala, Honduras, Nicaragua, and Panama. At the end of the twentieth century, the agricultural sector employed about 46 percent of the available labor force in Central America, most of which was engaged in subsistence agriculture. This percentage is higher than that of the neighboring developing countries of Mexico (28 percent) and Colombia (30 percent). The Central American percentage is higher than those in more developed countries, such as the United States and Canada, each of which is below 4 percent. The percentage of suitable land in Central America is about equal to that in Mexico (12 percent) but significantly more than in Colombia (4 percent). Arable land in the United States is about 19 percent.

Early Agriculture

Considerable archaeological evidence supports the existence of sedentary agriculture in the region for more than two thousand years. The early Maya farmed raised fields in lowland swamp areas and constructed irrigation systems in areas with a dry season. In highland areas, steep slopes were terraced. The most prominent terrace agriculture in the Americas was in the Andean cultures, but Central Americans also used this practice. Agriculture was based mainly on corn, but other crops were widely grown, including squash, beans, and chile peppers. Nonfood crops such as cotton and tobacco were grown for both domestic use and trade. These two crops continue to be important.

Exactly what group of Central Americans established the various agricultural practices, or when, is debatable. However, it is known that agriculture supported large communities of people early in the first millennium. The cities of Tikal, Copán, Caracol, and others had populations of thirty-five thousand or more.

Raised field agriculture had several benefits. Sediment dredged from channel bottoms was added to the fields, raising the surface above the surrounding swamp, creating dry land. This mate-

rial was rich in nutrients from decaying plant matter and wastes from aquatic creatures. Channels of water dividing the dry land provided habitat for fish and turtles, which were a protein-rich food source for people.

Slash-and-burn agriculture was practiced. The process involved stripping forests and burning the debris in place. Trees too large to be cut with primitive stone implements were *girded*; that is, a circle of bark was removed from around the tree, and the tree died afterward. Burned debris added nutrients to the topsoil. Because the soil was generally poor, the fields, usually known as *milpas*, or cornfields, but sometimes referred to as *swidden*, were abandoned after two or three years of production and left *fallow* for up to twenty years. This process is still practiced.

Intercropping, or *polyculture*, was a practice that helped ensure a harvest. The planting of several crops and different varieties provided a harvest even if one crop failed. This practice is also in use today.

Traditional Crops

Since the nineteenth century, certain crops have been raised in Central America as export crops and others principally for domestic consumption. Many of the traditional crops grown are not native to the region. Many of the most widely grown crops are termed *exotics*, that is, plants not native to the region that were introduced by European settlers. Bananas, coffee, and sugarcane are three principal exotic crops, with corn being a fourth. Most of the production of introduced plants is grown for export, although native corn is for local use.

Bananas are grown extensively in the Caribbean and Pacific lowlands but most prominently in the Sula Valley of Honduras, a leading world exporter of this crop. The banana industry flourished under the control of North American growers, especially the United Fruit Company. In the later part of the nineteenth century, the banana export business grew and enjoyed large markets in the United States and Europe. The United Fruit Company also exerted strong influence over governmental policies in the region.

Coffee is grown extensively in the highland areas of all seven Central American countries. A slow-ripening crop, coffee requires as much as two months to harvest. Small-scale growers who sell their product through cooperatives produce much of the area's coffee. The best-quality coffee is shade-grown, and so banana trees often are planted throughout the small fields.

Sugarcane, first introduced by Christopher Columbus to the island of Cuba, is another plant grown throughout a wide area. Sugarcane is labor-intensive during harvest but requires little attention at other times. The harvest of sugarcane begins with the burning of the fields. This practice reduces the volume of foliage and leaves only the stalks, or canes, which are the source of sugar. After the burning—which has the side benefit of chasing out the snakes that inhabit the cane fields—teams of workers with machetes march through the fields cutting the cane.

Corn (maize) is not grown for export. Along with regionally grown rice, it is for domestic consumption. Corn meal is used in the preparation of tortillas, which are eaten at nearly every meal. Rice is commonly served with red or black beans.

Leading Agricultural Crops of Central American Countries

Country	*Products*
Belize	Bananas, cacao, citrus, sugarcane, lumber
Costa Rica	Coffee, bananas, sugar, corn, rice, beans, potatoes, timber
El Salvador	Coffee, sugarcane, corn, rice, beans, oilseed, cotton, sorghum
Guatemala	Sugarcane, corn, bananas, coffee, beans, cardamom
Honduras	Bananas, coffee, citrus, timber
Nicaragua	Coffee, bananas, sugarcane, cotton, rice, corn, cassava, citrus, beans
Panama	Bananas, corn, sugarcane, rice, coffee, vegetables

Source: Data are from *The Time Almanac 2000*. Boston: Infoplease, 1999.

Image Not Available

Export crops have varied in their economic value to the region. A banana disease nearly ruined the industry in the 1930's. The Great Depression in those same years sharply reduced exports to North America. Import quotas imposed by the United States on sugar and the U.S. trade embargo on all Cuban products imposed in the early 1960's provided both a low and a high for Central American sugar producers. Overproduction of coffee by South American producers has led to depressed prices several times. During the late 1990's, the European Union's agricultural import practice of favoring former colonies reduced the value of bananas to growers. In Central America, only Belize (formerly British Honduras) benefits from European tariff regulations.

Nontraditional Crops

Vegetables, high-value crops, and ornamental plants and flowers are being grown at an increased rate. The leading crops are broccoli, cauliflower, snow peas, melons, strawberries, and pineapples.

Palm oil from a nonnative tree is another high-value farm product. Nontraditional crops are labor-intensive and affect the environment because of the heavy requirements for chemical pesticides. Workers face health risks due to these chemical applications, but employment is high. In Costa Rica, the government encourages investment in reforestation using teak from Southeast Asia.

CENTRAL AMERICAN FLORA

Category: World regions

Central America—comprising the nations Belize, Costa Rica, El Salvador, Guatemala, Honduras, Nicaragua, and Panama—is a land bridge that connects North America and South America, and many of its plants are similar to plants found on both those continents.

Lowlands

Tropical *rain forests* lie on the eastern half of Central America and typically have many tall, broad-leaved evergreen trees 130 feet (40 meters) or more in height, and 4-5 feet (1.2-1.5 meters) in diameter that form a dense canopy. Shade-seeking plants, such as palms, figs, ferns, vines, philodendrons, and orchids, form the forest undergrowth beneath the trees.

Epiphytes, such as orchids, ferns, bromeliads, and mosses, cling to the branches of the trees in a dense mat of vegetation—these plants have no roots but grow by clinging to the trunks of trees and drawing moisture and nourishment from the air. Rain-forest trees that are harvested for their commercial value include mahogany, kapok, cedarwood, tagua, ebony, and rosewood for making furniture; breadfruit, palm, and cashew; sapodilla, used to make latex; and the rubber tree. Many brilliantly colored flowers also grow in Central America. The most common of these are orchids (with close to a thousand species), heliconias, hibiscus, and bromeliads.

In the Caribbean lowlands, where the soil is porous and dry, extensive savanna *grasslands* with sparse forests of pines, palmettos, guanacastes, cedars, and oaks are found. Along the Caribbean coast (called the Mosquito Coast), mangroves and coconut palms flourish in swamps and lagoons.

Highlands

The central mountains and highlands of Central America are cooler than the coastal lowlands, and

Cacao: The Chocolate Bean

Cacao (cocoa) beans (*Theobroma cacao*), from which chocolate is made, have been cultivated in Central America for centuries. Although now a major African crop as well, cacao originated in the Americas. Once considered the drink of the gods, chocolate was reserved for royalty. Today, millions around the world enjoy chocolate, especially mixed with sugar and milk.

The beans are actually the berries of the small cacao tree, which grows in shade and is rarely more than 20 feet (6 meters) tall. The tree's football-shaped pods are 6-8 inches (15-20 centimeters) in length. When ripe, the pods can be red, yellow, or orange, depending on the variety. The tree's flowers are tiny, inconspicuous white blossoms that emerge singularly from the lower branches or trunk, not from stem ends. The cacao seeds, or beans, are surrounded by a whitish, gelatinous mass. Cacao beans must be fermented, dried, and cleaned before the chocolate aroma and taste develop.

the vegetation there is mainly deciduous hardwood trees such as walnut, pine, and oak. The eastern slopes of the mountains have abundant rainfall. "Cloud forests" that are 5,000 feet (1,525 meters) above sea level are thick with evergreen oak, sweet gum, pine, and laurel, which grow to a height of about 65 feet (20 meters) and are festooned with ferns, bromeliads, mosses, and orchids.

On the western side of the mountains, facing away from the moist Caribbean winds and receiving rain only seasonally, vegetation is sparse and semiarid, and soils are poor and unproductive. Deciduous tropical forests dominate there, and vegetation is characterized by evergreen herbs and shrubs, plumeria (frangipani), eupatorium pines, myrtles, and sphagnum mosses.

CHAROPHYCEAE

Categories: Algae; microorganisms; *Protista*; taxonomic groups; water-related life

It is almost impossible not to see Spirogyra *floating on the surface of a pond on a hot summer day, but most people dismiss it as pond scum. Few realize that what they are looking at is a member of the* Charophyceae, *a class in the phylum Chlorophyta, or green algae, and a cousin of the ancestor of the* Embryophyta, *or bryophytes and vascular plants.*

Most *Charophyceae*, like *Spirogyra*, live in freshwater habitats, but some also occur in moist soil in terrestrial habitats. *Charophyceae* can live as single cells, colonies, or branched and unbranched filaments and come in a variety of shapes. The characteristics that unite members of the class—and which link them with the embryophytes—include flagellated cells (similar to sperm cells in vascular plants), a nuclear envelope that breaks down during mitosis, mitotic spindles that persist as phragmoplasts (a type of cytoskeletal scaffolding) through cell division either by furrowing or by forming a cell plate, the presence of chlorophylls *a* and *b* and phytochrome, and the storage of starch inside plastids.

Charophytes possess decay-resistant cell walls made of phenolic compounds as well as lignins or ligninlike compounds. Cell walls made of similar compounds are found in bryophytes and vascular plants as well. Likewise, all three groups of plants also contain sporopollenin, the substance in the walls of spores and pollen grains that makes them virtually indestructible. Communication channels between cells are similar, too. Plasmodesmata similar to that seen in embryophyte cells allow between-cell communications in charophytes and embryophytes.

Life Cycle

Charophytes have a two-stage life cycle involving a dominant haploid stage, upon which develops the sex organs; antheridia, which produce sperm cells; and oogonia, which produce egg cells. Typically, individual charophytes produce both antheridia and oogonia, but in some species an individual will produce only one or the other. Fertilization—which in one group, the *Zygnematales*, takes place via conjugation—produces a diploid zygote, which quickly undergoes meiosis. If the environment is unfavorable, the zygote will go dormant and remain so for a long period of time. Dormancy ends when the environment improves.

Classification

Genetic analysis supports the recognition of six orders within the *Charophyceae*: the *Mesostigmatales*, *Chlorokybales*, *Klebsormidiales*, *Zygnematales*, *Coleochaetales*, and *Charales*.

Of these, the most abundant group is the *Zygnematales*, a large order which consists of more than three thousand species, including *Spirogyra* and the desmids, a group of mostly single-celled organisms with a constriction across the middle which nearly divides the cells in two. *Zygnematales* live primarily in freshwater habitats as phytoplankton, as benthic dwellers, or attached to other aquatic plants. Some species live on snow and ice.

The *Charales*, commonly called stoneworts or brittleworts, are a large group of filamentous charophytes that feature complex branching patterns. Some can reach lengths of more than a meter. The branching pattern—branches reach out from nodes along the filament—is similar to that of higher plants. *Charales* reside primarily in freshwater habitats, but some can be found in brackish water as well as on land. The stems of stoneworts and brittleworts can be encrusted with calcium and magnesium carbonates. As a result, their hard bodies are well known from the fossil record. The lineage extends back to more than 400 million years ago. Two current genera, *Chara* and *Nitella*, date back about 200 million years.

The *Coleochaetales* are a small group of complex, microscopic filamentous algae that can be found only in freshwater habitats. *Klebsormidiales* are a small group of unbranched, filamentous charophytes that occur in both freshwater and terrestrial environments. *Mesostigmatales* and *Chlorokybales* are two groups of rare algae. The *Coleochaetales* and *Charales* are more closely related to bryophytes and vascular plants than the other groups.

Evolutionary Significance

For decades, structural similarities led plant biologists to suspect that the *Embryophyta* evolved from charophytes. Recently, cladistic analyses of chemical, structural, and genetic characteristics have opened up research on the topic. In cladistics, characteristics among a number of organisms are analyzed statistically in the hopes of developing a classification system for the group which will reveal evolutionary relationships. Cladistic analyses support the notion that embryophytes are monophyletic; in other words, bryophytes and vascular plants descend from a common ancestor.

Furthermore, several recent analyses support the notion that a member of the *Charophyceae* gave rise to embryophytes. Cladistic analyses were somewhat unclear, however, about the relationships of the charophyte orders with one another and with other green algae (*Chlorophyta*), bryophytes, and land plants.

One of the latest analyses of mitochondrial, chloroplast, and nuclear genes helps resolve some of the confusion. The research indicates that the *Mesostigmatales* were probably the most ancient group of charophytes, followed by the *Chlorokybales*, *Klebsormidiales*, *Zygnematales*, *Coleochaetales*, and *Charales*.

The work also supports earlier suggestions that the *Charales* are the closest living relatives to extant embryophytes and that the charophytes descended from other green algae.

CHEMOTAXIS

Categories: Cellular biology; microorganisms; movement; physiology

Chemotaxis is the ability of a cell to detect certain chemicals and to respond by movement, such as microbial movement toward nutrients in the environment.

Many microorganisms possess the ability to move toward a chemical environment favorable for growth. They will move toward a region that is rich in nutrients and other growth factors and away from chemical irritants that might damage them. Among the organisms that display this *chemotactic behavior*, none is simpler than bacteria. Bacteria are single-celled *prokaryotic* microorganisms, which means that their deoxyribonucleic acid (DNA) is not contained within a well-defined nucleus surrounded by a nuclear membrane, as in *eukaryotic* (plant and animal) cells. *Prokaryotes* lack many of the cellular structures associated with more complex eukaryotic cells; nevertheless, many species of bacteria are capable of sensing chemicals in their environment and responding by movement.

Bacterial Flagella

Bacteria capable of movement are called *motile bacteria*. Not all bacteria are motile, but most species possess some form of motility. Although there are three different ways in which bacteria can move, the most common means is by long, whiplike structures called *flagella*.

Bacterial flagella are attached to cell surfaces and rotate like propellers to push the cells forward. A bacterial cell must overcome much resistance from the water through which it swims. In spite of this, some bacteria can move at a velocity of almost 90 micrometers per second, equivalent to more than one hundred bacterial cell lengths per second.

A flagellum is composed of three major structural components: the *filament*, the *hook*, and the *basal body*. The filament is a hollow cylinder composed of a protein called *flagellin*. A single filament contains several thousand spherically shaped flagellin molecules bound in a spiral pattern, forming a long, thin cylinder. A typical filament is between 15 and 20 micrometers long but only 0.02 micrometer thick. The filament is attached to the cell by means of the hook and basal body. The hook is an L-shaped structure composed of protein and slightly wider than the filament. One end of the hook is connected to the filament, and the other end is attached to the basal body. The basal body, also known as the *rotor*, consists of a set of protein rings embedded in the cell wall and plasma membrane. Inside these rings is a central rod attached to the hook. The central rod of the basal body rotates inside the rings, much like the shaft of a motor. As it rotates, it causes the hook and the filament to turn.

Bacteria in Motion

While they are moving, bacteria change direction by reversing the rotation of their flagella. As a bacterium swims forward in a straight line, its flagella spin in a counterclockwise direction. Because of their structure, the flagella twist together when they rotate counterclockwise and act cooperatively to push the cell forward. The forward movement is referred to as a *run*. Every few seconds, a chemical change in the basal body of each flagellum causes it to reverse its spin from counterclockwise to clockwise. When the flagella spin clockwise, they fly apart and can no longer work together to move the cell forward. The cell stops and tumbles randomly until the flagella reverse again, returning to counterclockwise spin and a forward run. This type of movement, in which the cell swims forward for a short distance and then randomly changes its direction, is called *run and tumble* movement.

Certain eukaryotic microorganisms, such as *Euglena* and some other protozoa, are also motile by means of flagella. The structure and activity of eukaryotic flagella are, however, completely different from those of bacteria. Eukaryotic flagella are composed of protein fibers called *microtubules*, which move back and forth in a wavelike fashion to achieve movement. The rotation of bacterial flagella and the run and tumble movement they produce are unique to bacteria.

Attractants and Repellants

Bacteria respond by chemotaxis to two broad classes of substances, *attractants* and *repellants*. They move toward high concentrations of attractants (*positive chemotaxis*) and away from high concentrations of repellants (*negative chemotaxis*). Attractants are most often nutrients and growth factors, such as monosaccharides (simple sugars), amino acids (the building blocks of protein), and certain vitamins required for bacterial metabolism. Repellants include waste products given off by the bacteria as well as other toxic substances found in the environment.

Bacteria respond to attractants and repellants by altering the time between tumbles in their run and tumble movement. When a bacterial cell detects an attractant, the time between tumbles and the time of the runs increase. As long as the cell is moving toward a higher concentration of attractant, its runs will be longer. The opposite effect occurs when a cell encounters a repellant. A repellant causes the time between tumbles to decrease, resulting in shorter runs as the cell changes direction more frequently while trying to avoid the repellant. The net result is that the cell tends to move toward a lower concentration of the repellant.

Chemotactic Receptors

Bacteria recognize attractants and repellants through specialized proteins called *chemotactic receptors*, also called *methyl-accepting chemotactic proteins* (MCPs), which are embedded in their plasma membranes just inside the cell wall. Biologists have identified roughly twenty different receptors for attractants and some ten for repellants. Each receptor protein is believed to respond to only a single type of attractant or repellant.

When an attractant molecule binds to its chemotactic receptor, two separate events occur. First, there is a rapid activation of the receptor. The attractant molecule binds to a special site on the receptor protein to form an activated receptor. This binding is not permanent, however, so a cell must remain in an area with attractant molecules for its receptors to remain activated. The activated receptor sends a chemical signal to the basal bodies of flagella, which causes them to spin in a counterclockwise direction, producing continuous swimming in one direction.

At the same time, there is adaptation of the activated receptors to the attractant. Adaptation is important because it keeps the cell from swimming too long in one direction. It is accomplished by *methylation* of the receptors, a process in which methyl groups are attached to the protein by an enzyme in the cell. (A methyl group consists of an atom of carbon attached to three atoms of hydrogen.) Methylated receptors do not stimulate the basal bodies for counterclockwise rotation as effectively as nonmethylated receptors. After a cell has been in the presence of an attractant for a short while, its receptors adapt to the attractant, and it returns to the original pattern of run and tumble movement. Adaptation is reversed by *demethylation*, the removal of methyl groups from the receptor by a separate enzyme. Together, the balance between methylation and demethylation makes the receptors very sensitive to small changes in attractant concentration, so that cells remain in the region with the greatest concentration of attractant.

The action of repellants appears to be similar to that of attractants. Repellant molecules bind to sites on their chemotactic receptors, activating the receptors. The activated receptors signal the flagella to spin clockwise instead of counterclockwise, causing the cell to tumble and to change direction. Repellant receptors also adapt through methylation and demethylation, much like attractant receptors.

It is not entirely understood how an activated chemotactic receptor can signal flagella to rotate. Four different proteins inside the bacterial cell have been identified as a possible link between the chemotactic receptors and the basal bodies of flagella. These proteins are believed to regulate flagellar rotation using a process called *phosphorylation*. Phosphorylation, the attachment of phosphate molecules to a protein, is used in all types of cells as a kind of "on and off" switch to regulate protein activity.

CHLOROPHYCEAE

Categories: Algae; microorganisms; *Protista*; taxonomic groups; water-related life

Chlorophyceae *(from the Greek word* chloros, *meaning "green") make up an extremely large and important class of green algae. Members may be unicellular, colonial, or filamentous. Cells of unicellular and colonial chlorophyceans may have two or more flagella.*

There are about 2,650 living species of chlorophyceans. The main features of the class (and most plants) are the use of starch as the principal food reserve and the green chloroplasts with chlorophylls *a* and *b*. In spite of plant characteristics, this algal group is not directly related to early land plants. Chlorophyceans are almost entirely restricted to freshwater and terrestrial habitats. Some members of this class have adapted to life on snow as *snow algae*. Snow algae cause snow to appear red-burgundy or orange in color because of high levels of unusual carotenoid pigments within the algal cells.

There are a variety of asexual and sexual reproduction modes among members of this class. Sexual reproduction is characterized by the formation of a zygote produced by gametic fusion. Chlorophyceans show differences during cell division compared to other green algal groups. For example, they produce a set of microtubules, the *phycoplast*, that is parallel to the plane of cell division.

Diversity

The *Chlorophyceae* include some familiar green algae. Perhaps the most famous chlorophyceans are *Chlamydomonas* (from the Greek word *chlamys*, meaning "cloth") and *Volvox* (from the Latin *volvo*, meaning "to roll"). Both are important research models in laboratories. Chlorophyceans fall into several orders, including *Volvocales*, *Chlorococcales*, *Chaetophorales*, and *Oedogoniales*.

Volvocales

Members of the order *Volvocales* include both unicellular organisms, such as those in the genus *Chlamydomonas* with their two equal flagella, and colonial forms. The *Chlamydomonas* are a large genus of chlorophyceans. More than six hundred species have been described worldwide. The *Chlamydomonas* probably represent the most primitive structure among chlorophyceans. Nevertheless, their basic cell features may be found among other representatives of this order.

A cell wall made of glycoproteins, rather than cellulose, surrounds each *Chlamydomonas* cell. Inside the cell, there is a single large chloroplast and a pyrenoid, which forms starch.

Other cytoplasmic structures include the contractile vacuole rather than a central vacuole. The contractile vacuole is responsible for the removal of water from the cell. Cells of *Chlamydomonas* are capable of phototaxis: They swim toward moderate light but away from high-intensity light. Rhodopsin-like pigment is their primary light-sensing photoreceptor. Under dry conditions, *Chlamydomonas* form a palmelloid stage, in which nonflagellate cells are held together by common mucilage.

Chlamydomonas reproduce asexually via cell division. Also, cells of this alga can become gametes. In most species of *Chlamydomonas*, the male and female gametes appear the same; they are designated (+) and (–). Colonial flagellates of the order *Volvocales* range from simple colonies of *Gonium* to visible-without-magnification spheres of *Volvox* with up to several thousands of cells and some sort of cellular specialization.

Volvox are one of the most structurally advanced colonial forms of green algae. Only specialized cells participate in reproduction. During asexual reproduction, some cells of *Volvox* divide and bulge inward, forming new daughter colonies, which are held for some time within the parent colony. *Volvox* are also capable of sexual reproduction.

They produce gametes that differentiate into sperm and eggs.

Chlorococcales

Members of the order *Chlorococcales* include nonmotile unicellular and colonial algae. Typical representatives of the unicellular nonmotile form are found in *Chlorococcum*. They occur as spherical single cells or cell aggregates and produce flagellated zoospores. Examples of colonial representatives of *Chlorococcales* are *Hydrodictyon*, commonly known as the "water net"; *Pediastrum*, famous for their distinctive, starlike shape; and *Scenedesmus*, widespread inhabitants of the freshwater phytoplankton. The order *Chlorococcales* has now been divided on the basis of small subunit ribosomal ribonucleic acid (RNA) sequence data into several groups, including the *Sphaeropleales*, *Tetracystis* clade, and *Dunaliella* clade.

Chaetophorales* and *Oedogoniales

The most complex of the class *Chlorophyceae* are the filamentous members in orders *Chaetophorales* and *Oedogoniales*, some of which exhibit features that are observed primarily in plants. The chaetophoralean green algae have plantlike bodies with a system of primary and secondary branches. The *Draparnaldia* (named for Jacques Phillipe Raymond Draparnaud, a French naturalist) from order *Chaetophorales* have a main filamentous axis with relatively large cells, primary branches with smaller cells, and secondary branches with even smaller cells. One representative of *Oedogoniales*, the green alga *Oedogonium* (from the Greek *oidos*, meaning "swelling"), has been a subject of intense study for its unusual cell division technique. The entire contents of an *Oedogonium* cell may be used in the formation of one large zoospore with multiple flagella. Members of *Bulbochaete* (from the Greek *bolbos*, meaning "bulb") resemble *Oedogonium* in cell division but differ in being branched and having a distinctive hair cell at the end of each branch.

Technological Uses

A few chlorophycean green algae have commercial value. These algae are good candidates for the industrial production of hydrogen gas because they are able to release the gas from water using solar energy. Hydrogen gas is an environmentally desirable fuel because the burning of hydrogen produces water, and it can be converted effectively to electricity.

Another "commercial" organism is *Dunaliella salina*, a saltwater alga that accumulates massive amounts of beta-carotene, a vital antioxidant also used in food coloring and in pharmaceuticals. *Selenastrum capricornutum* are the most widely used algal biomonitors in the detection of water pollution. Chlorophyceans are used in freshwater aquaculture systems as food for fish. One alga with possible potential for salmon feeds is *Haematococcus*. Algae contain large amounts of the pigment astaxanthin, which is responsible for the red coloration typical of salmon flesh. *Chlorella* (formerly classified in the order *Chlorococcales*) are famous both as the experimental systems in the discovery of the photosynthetic Calvin cycle and as health food in Asia.

CHLOROPLAST DNA

Categories: Cellular biology; genetics; photosynthesis and respiration; reproduction and life cycles

Plants are unique among higher organisms in that they meet their energy needs through photosynthesis. The specific location for photosynthesis in plant cells is the chloroplast, which also contains a single, circular chromosome composed of DNA. Chloroplast DNA contains many of the genes necessary for proper chloroplast functioning.

A better understanding of the genes in chloroplast deoxyribonucleic acid (cpDNA) has improved the understanding of photosynthesis, and analysis of the deoxyribonucleic acid (DNA) sequence of these genes has been useful in studying the evolutionary history of plants.

Discovery of Chloroplast Genes

The work of nineteenth century Austrian botanist Gregor Mendel showed that the inheritance of genetic traits follows a predictable pattern and that the traits of offspring are determined by the traits of the parents. For example, if the pollen from a tall pea plant is used to pollinate the flowers of a short pea plant, all the offspring are tall. If one of these tall offspring is allowed to self-pollinate, it produces a mixture of tall and short offspring, three-quarters of them tall and one-quarter of them short. Similar patterns are observed for large numbers of traits from pea plants to oak trees. Because of the widespread application of Mendel's work, the study of genetic traits by controlled mating is often referred to as Mendelian genetics.

In 1909 German botanist Karl Erich Correns discovered a trait in the four-o'clock plants (*Mirabilis jalapa*) that appeared to be inconsistent with Mendelian inheritance patterns. He discovered that four-o'clock plants had a mixture of leaf colors on the same plant: Some were all green, many were partly green and partly white (variegated), and some were all white. If he took pollen from a flower on a branch with all-green leaves and used it to pollinate a flower on a branch with all-white leaves, all the resulting seeds developed into plants with white leaves. Likewise, if he took pollen from a flower on a branch with all-white leaves and used it to pollinate a flower on a branch with all-green leaves, all the resulting seeds developed into plants with green leaves. Repeated pollen transfers in any combination always resulted in offspring whose leaves resembled those on the branch containing the flower that received the pollen, that is, the maternal parent. These results could not be explained by Mendelian genetics.

Since Correns's discovery, many other such traits have been discovered. It is now known that the reason these traits do not follow Mendelian inheritance patterns is that their genes are not on the chromosomes in the nucleus of the cell where most genes are located. Instead, the gene for the four-o'clock leaf color trait is located on the single, circular chromosome found in chloroplasts. Because chloroplasts are specialized for photosynthesis, many of the genes on the single chromosome produce proteins or ribonucleic acid (RNA) that either directly or indirectly affect synthesis of chlorophyll, the pigment primarily responsible for trapping energy from light. Because chlorophyll is green and because mutations in many chloroplast genes cause chloroplasts to be unable to make chlorophyll, most mutations result in partially or completely white or yellow leaves.

Identity of Chloroplast Genes

Advances in molecular genetics have allowed scientists to take a much closer look at the chloroplast genome. The size of the genome has been determined for a number of plants and algae and ranges from 85 to 292 kilobase pairs (one kb equals one thousand base pairs), with most being between 120 kb and 160 kb. The complete DNA sequences for several different chloroplast genomes of plants and algae have been determined. Although a simple sequence does not necessarily identify the role of each gene, it has allowed the identity of a number of genes to be determined, and it has allowed scientists to estimate the total number of genes. In terms of genome size, chloroplast genomes are relatively small and contain slightly more than one hundred genes.

Roughly half of the chloroplast genes produce either RNA molecules or polypeptides that are important for protein synthesis. Some of the RNA genes occur twice in the chloroplast genomes of almost all land plants and some groups of algae. The products of these genes represent all the ingredients needed for chloroplasts to carry out transcription and translation of their own genes. Half of the remaining genes produce polypeptides directly required for the biochemical reactions of photosynthesis. What is unusual about these genes is that their products represent only a portion of the polypeptides required for photosynthesis. For example, the very important enzyme ATPase, the enzyme that uses proton gradient energy to produce the important energy molecule adenosine triphosphate (ATP), comprises nine different polypeptides. Six of these polypeptides are products of chloroplast genes, but the other three are products of nuclear genes that must be transported into the chloroplast to join with the other six polypeptides to make active ATPase. Another notable example is the enzyme ribulose biphosphate carboxylase (RuBP carboxylase), which is composed of two polypeptides. The larger polypeptide, called rbcL, is a product of a chloroplast gene, whereas the smaller polypeptide is the product of a nuclear gene.

Image Not Available

The last thirty or so genes remain unidentified. Their presence is inferred because they have DNA sequences that contain all the components found in active genes. These kinds of genes are often called "open reading frames" (ORFs) until the functions of their polypeptide products are identified.

Impact and Applications

The discovery that chloroplasts have their own DNA and the further elucidation of their genes have had some impact on horticulture and agriculture. Several unusual, variegated leaf patterns and certain mysterious genetic diseases of plants are now better understood. The discovery of some of the genes that code for polypeptides required for photosynthesis has helped increase understanding of the biochemistry of photosynthesis. The discovery that certain key chloroplast proteins, such as ATPase and RuBP carboxylase, are composed of a combination of polypeptides coded by chloroplast and nuclear genes also raises some as yet unanswered questions. For example, why would an important plant structure like the chloroplast have only part of the genes it needs to function? Moreover, if chloroplasts, as evolutionary theory suggests, were once free-living bacteria-like cells, which must have had all the genes needed for photosynthesis, why and how did they transfer some of their genes into the nuclei of the cells in which they are now found?

Of greater importance has been the discovery that the DNA sequences of many chloroplast genes are highly conserved; that is, they have changed very little during their evolutionary history. This fact has led to the use of chloroplast gene DNA sequences for reconstructing the evolutionary history of various groups of plants. Traditionally, plant systematists (scientists who study the classification and evolutionary history of plants) have used structural traits of plants, such as leaf shape and flower anatomy, to try to trace the evolutionary history of plants. Unfortunately, there are a limited number of structural traits, and many of them are uninformative or even misleading when used in evolutionary studies. These limitations are overcome when gene DNA sequences are used.

A DNA sequence of a few hundred base pairs in length provides the equivalent of several hundred traits, many more than the limited number of structural traits available (typically much fewer than one hundred). One of the most widely used sequences is the rbcL gene. It is one of the most conserved genes in the chloroplast genome, which in evolutionary terms means that even distantly related plants will have a similar base sequence. Therefore, rbcL can be used to retrace the evolutionary history of groups of plants that are very divergent from one another. The rbcL gene, along with a few other very conservative chloroplast genes, has already been used in attempts to answer some basic plant evolution questions about the origins of some of the major flowering plant groups. Less conservative genes and ORFs show too much evolutionary change to be used at higher classification levels but are extremely useful in answering questions about the origins of closely related species, genera, or even families. As analytical techniques are improved, chloroplast genes show promise of providing even better insights into plant evolution.

CHLOROPLASTS AND OTHER PLASTIDS

Categories: Cellular biology; photosynthesis and respiration; physiology

Plastids are highly specialized, double membrane-bound organelles found within the cells of all plants and algae. A type of plastid called the chloroplast is the cellular location of the process of photosynthesis.

Plastids exhibit remarkable diversity with respect to their development, morphology, function, and physiological and genetic regulation. Chloroplasts, a type of plastid, are arguably largely responsible for the maintenance and perpetuation of most of the major life-forms on earth through *photosynthesis*. The process of photosynthesis uses visible light as an energy source to power the conversion of atmospheric carbon dioxide into organic molecules that can be used by living organisms. As a by-product of photosynthesis, oxygen is released into the atmosphere and is used by living organisms in the energy-obtaining process of cellular respiration. Other plastid types are specialized for synthesis and storage of pigments, starch, and other secondary metabolites.

Plastid Structure

The typical plastid from the cell of a flowering plant is surrounded by a double membrane system consisting of an inner and outer membrane, with an intermembrane space between the two. In chloroplasts, the photosynthetic pigments that are responsible for absorbing sunlight are located in the *thylakoid* membrane system. This continuous internal membrane system is found throughout the chloroplast *stroma*, an internal fluid matrix analogous to the cellular cytosol. *Granal thylakoids* are organized into stacks, and the *stromal thylakoids* are unstacked and exposed to the stromal matrix. The internal space within the thylakoid membrane system is called the *lumen*. The pigments and proteins involved in the light reactions of photosynthesis, the processes whereby light energy is converted into chemical energy, are embedded in the thylakoid membrane system. The *dark reactions*, or *Calvin cycle*, which is the carbon fixation pathway that leads to the formation of simple carbohydrates, occurs in the stroma. Small starch granules and oil bodies, termed *plastoglobuli*, are often found in chloroplasts. These serve as energy storage reserves for the plant cell. Plastids other than chloroplasts typically lack thykaloids.

Proplastids

The developmental precursor to all plastid types is the *proplastid*. Proplastids are relatively undifferentiated plastids typically found in young, undifferentiated meristematic cells and tissues. Under the appropriate cellular and environmental conditions, proplastids can undergo development and differentiation to any of three main plastid types: chloroplasts, *chromoplasts*, or *leucoplasts*.

Chloroplasts

Chloroplasts typically contain one or more of the three types of plastid chlorophylls (chlorophyll *a*, *b*, or *c*) and, often, members of the two classes of photosynthetic accessory pigments: *carotenoids* and *phycobilins*. The most obvious and essential physiological process unique to chloroplasts is photosynthesis. In the energy transduction reactions (the light reactions), radiant energy in the form of visible light (mostly of the violet, blue, and red wavelengths) is harnessed primarily by the green pigment chlorophyll. The harnessed energy is then used to phosphorylate adenosine diphosphate (ADP) to produce adenosine triphosphate (ATP) in a process termed *noncyclic photophosphorylation* and reduce the electron carrier nicotinamide adenine dinucleotide phosphate (NADP) to NADPH. Oxygen is liberated through the light-dependent oxidative splitting of water.

In the carbon-fixation reactions (often called the dark reactions, although they can occur in the presence of light) the ATP is used as an energy source for the attachment of atmospheric carbon dioxide to the simple sugar ribulose 1,5-bisphosphate (RuBP). The NADPH is used to facilitate the reduction of RuBP through a series of simple sugars in a biochemical set of reactions known as the Calvin cycle. One of the products of this cycle, glyceraldehydes-3-phosphate (G3P), is used by the chloroplast to make glucose and other carbohydrates. G3P is also needed to perpetuate the Calvin cycle, so only one of every three produced is used for carbohydrate synthesis.

Chloroplasts are also the site of synthesis for the three aromatic amino acids: phenylalanine, tyrosine, and tryptophan. The precursor compound aspartate is imported into chloroplasts from the cell cytosol and is used for the synthesis of the amino acids lysine, threonine, and isoleucine. An intermediate in the synthesis of threonine, called homoserine 4-phosphate, is exported from the chloroplast into the cytosol as a precursor for methionine. Thus, there is a strong integration of function among the chloroplast, cytosol, and nucleus, in that the enzymes involved in these amino acid biosynthetic pathways are nuclear-encoded, their mRNAs are translated using cytosolic ribosomes, and most of the biosynthetic enzymes are imported into the chloroplast.

Fatty acid biosynthesis is another biochemical function that occurs in chloroplasts. Fatty acids, as lipid precursors, might be either incorporated directly into chloroplast lipids via a plastid-localized biochemical pathway or exported into the cytoplasm for conversion into endoplasmic reticulum lipids. Lipids found in the inner plastid membrane are plastid-synthesized, whereas those of the outer plastid membrane are synthesized in the endoplasmic reticulum.

Other Plastids

Other plastid types include *chromoplasts*, which typically contain carotene or xanthophyll pigments and are responsible for the colors of many fruits, flowers, and roots. Under some conditions chromoplasts can differentiate into chloroplasts. Leucoplasts are colorless and lack complex inner membranes. One type of leucoplast, the *amyloplast*, synthesizes and stores starch. Other leucoplasts synthesize a wide range of products, including oils and proteins. Proplastids that are arrested during their normal development into chloroplasts are termed *etioplasts*. These typically are formed when developing plant tissues are deprived of light.

Evolutionary History

Plastids possess a number of features that provide insights into their remarkable evolutionary history. The chloroplasts of eukaryotic cells photosynthesize in a manner similar to the more ancient prokaryotic cyanobacteria by using membrane-bound chlorophyll to capture radiant energy. Some plastids even bear a strong morphological similarity to cyanobacteria, being similar in size and having similar internal structures. Plastids divide by binary fission in a manner similar to bacterial reproduction.

Plastids also have a certain degree of autonomy in terms of their genetic system. Typically, the majority of flowering plant plastids contain multiple copies (50-100) of a circular chromosome, ranging in size from 130 to 180 kilobase pairs (kb) in higher plants. Chromosome size in algae is much more variable, ranging all the way from 57 kb to 1,500 kb. The plastid chromosome contains genes for RNAs, such as rRNA (ribosomal RNA) and tRNA (transfer RNA), and structural genes that code for polypeptides involved in photosynthesis, transcription, protein synthesis, energy transduction, and several other functions. Many of the genes on the chloroplast chromosome are organized into clusters termed *operons* in a manner similar to that found in eubacteria.

The nucleotide sequences of many plastid genes, especially the ribosomal RNA genes, are highly similar to those in eubacteria, and the ribosomes found within plastids have a similar composition and size to eubacterial ribosomes. The plastid-encoded genes are transcribed either by a nuclear-encoded or plastid-encoded RNA polymerase, and the resultant mRNAs are translated by plastid ribosomes found within the stroma. The majority of plastid biochemical processes rely on both nuclear- and plastid-encoded genes. Some proteins, such as RuBP carboxylase/oxygenase (Rubisco), are composed of both nuclear- and plastid-encoded protein subunits, again demonstrating the remarkable coordination of biogenesis and development between organelle and cytosol.

This evidence lends strong support to the *endosymbiotic theory* of the origin of plastids. This theory, in essence, states that plastids were once free-living, *autotrophic* (having the ability to obtain carbon from carbon dioxide), prokaryotic cells that were engulfed through *phagocytosis* by an ancestral *heterotrophic* nucleated cell (a cell having a metabolism where carbon must be obtained from organic molecules) termed a *protoeukaryote*. Typically this engulfment would result in the ingestion and subsequent destruction of the engulfed prokaryotic cell. However, in one—or perhaps several—independent incidents, a symbiotic relationship was gradually established between the engulfed photosynthetic bacterium and the protoeukaryote. The captured bacterium provided an internal source of food production for the heterotrophic eukaryotic cell through photosynthesis. The bacterium, in turn, was provided with protection and a stable external environment in the cytosol of the eukaryotic cell.

To coordinate further the physiological and genetic interactions between the two, massive transfer of genes took place over time from the genome of the photosynthetic bacterium to the nuclear genome of the protoeukaryote, leading to the genetic capture and control of the photosynthetic endosymbiont. Recent investigations have shown that this gene transfer event is an ongoing process, with examples of transfer documented in recent evolutionary time for both plastids and mitochondria in several different evolutionary lineages of flowering plants.

CHROMATIN

Categories: Cellular biology; genetics; reproduction and life cycles

Chromatin is an inclusive term referring to DNA and the proteins that bind to it, located in the nuclei of eukaryotic cells. The huge quantity of DNA present in each cell must be organized and highly condensed in order to fit into the discrete units of genetic material known as chromosomes. Gene expression can be regulated by the nature and extent of this DNA packaging in the chromosome, and errors in the packaging process can lead to genetic disease.

Scientists have known for many years that the hereditary information within plants and other organisms is encrypted in molecules of *deoxyribonucleic acid* (DNA) that are themselves organized into discrete hereditary units called *genes* and that these genes are organized into larger subcellular structures called *chromosomes*. James Watson and Francis Crick elucidated the basic chemical structure of the DNA molecule in 1952, and much has been learned since that time concerning its replication and expression. At the molecular level, DNA is composed of two parallel chains of building blocks called *nucleotides*, and these chains are coiled around a central axis to form the well-known *double helix*.

Each nucleotide on each chain attracts and pairs with a complementary nucleotide on the opposite chain, so a DNA molecule can be described as consisting of a certain number of these nucleotide base pairs.

The entire human genome consists of more than six billion base pairs of DNA, which, if completely unraveled, would extend for more than 2 meters. It is a remarkable feat of engineering that in each human cell this much DNA is condensed, compacted, and tightly packaged into chromosomes within a nucleus that is less than 10^{-5} meters in diameter. Plants typically have larger genomes than humans; for example, wheat has fifteen billion base pairs of DNA. By contrast, the most widely studied plant among current scientists is *Arabidopsis*. The species *Arabidopsis thaliana* was selected as a model organism in plant research because of its comparatively simple structure: Its 26,000 genes make up "only" 125 million base pairs.

What is even more astounding is the frequency and fidelity with which this DNA must be condensed and relaxed, packaged and unpackaged, for replication and expression in each individual cell at the appropriate time and place during both development and adult life. The essential processes of DNA replication or gene expression (*transcription*) cannot occur unless the DNA is in an open or relaxed configuration.

Chemical analysis of mammalian chromosomes reveals that they consist of DNA and two distinct classes of proteins, known as *histone* and *nonhistone* proteins. This nucleoprotein complex is called chromatin, and each chromosome consists of one linear, unbroken, double-stranded DNA molecule that is surrounded in predictable ways by these histone and nonhistone proteins. The histones are relatively small, basic proteins (having a net positive charge), and their function is to bind directly to the negatively charged DNA molecule in the chromosome. Five major varieties of histone proteins are found in chromosomes, and these are known as H1, H2A, H2B, H3, and H4. Chromatin contains about equal amounts of histones and DNA, and the amount and proportion of histone proteins are constant from cell to cell in all higher organisms, including the higher plants. In fact, the histones as a class are among the most highly conserved of all known proteins. For example, for histone H3, which is a protein consisting of 135 amino acid "building blocks," there is only a single amino acid difference in the protein found in sea urchins as compared with the one found in cattle. This is compelling evidence that histones play the same essential role in chromatin packaging in all higher organisms and that evolution has been quite intolerant of even minor sequence variations between vastly different species.

Nonhistones as a class of proteins are much more heterogeneous than the histones. They are usually acidic (carrying a net negative charge), so they will most readily attract and bind with the positively charged histones rather than the negatively charged DNA. Each cell has many different kinds of nonhistone proteins, some of which play a structural role in chromosome organization and some of which are more directly involved with the regulation of gene expression. Weight for weight, there is often as much nonhistone protein present in chromatin as histone protein and DNA combined.

Nucleosomes and Solenoids

The fundamental structural subunit of chromatin is an association of DNA and histone proteins called a *nucleosome*. First discovered in the 1970's, each nucleosome consists of a core of eight histone proteins: two each of the histones H2A, H2B, H3, and H4. Around this histone octamer is wound 146 base pairs of DNA in one and three-quarters turns (approximately eighty base pairs per turn). The overall shape of each nucleosome is similar to that of a lemon or a football. Each nucleosome is separated from its adjacent neighbor by about fifty-five base pairs of *linker DNA*, so that in its most unraveled state they appear under the electron microscope to look like tiny beads on a string. Portions of each core histone protein protrude outside the wound DNA and interact with the DNA that links adjacent nucleosomes.

The next level of chromatin packaging involves a coiling and stacking of nucleosomes into a ribbonlike arrangement, which is twisted to form a chromatin fiber about 30 nanometers in diameter, commonly called a *solenoid*. Formation of solenoid fibers requires the interaction of histone H1, which binds to the linker DNA between nucleosomes. Each turn of the chromatin fiber contains about twelve hundred base pairs (six nucleosomes), and the DNA has now been compacted by about a factor of fifty. The coiled solenoid fiber is organized into large domains of 40,000 to 100,000 base pairs, and these domains are separated by attached nonhistone proteins that serve both to organize and to control their packaging and unpackaging.

Loops and Scaffolding

Physical studies using the techniques of X-ray crystallography and neutron diffraction have suggested that solenoid fibers may be further organized into giant supercoiled *loops*. The extent of this additional looping, coiling, and stacking of solenoid fibers varies, depending on the cell cycle. The most relaxed and extended chromosomes are found at *interphase*, the period of time between cell divisions. Interphase chromosomes typically have a diameter of about 300 nanometers. Chromosomes that are getting ready to divide (*metaphase* chromosomes) have the most highly condensed chromatin, and these structures may have a diameter of up to 700 nanometers. One major study on the structure of metaphase chromosomes has shown that a skeleton of nonhistone proteins in the shape of the metaphase chromosome remains even after all of the histone proteins and the DNA have been removed by enzymatic digestion. If the DNA is not digested, it remains in long loops (10 to 90 kilobase pairs) anchored to this nonhistone protein scaffolding.

Impact and Applications

Studies on chromatin packaging continue to reveal the details of the precise chromosomal architecture that results from the progressive coiling of the single DNA molecule into increasingly compact structures. Evidence suggests that the regulation of this coiling and packaging within the chromosome has a significant effect on the properties of the genes themselves. In fact, errors in DNA packaging can lead to inappropriate gene expression and developmental abnormalities. In humans, the blood disease thalassemia, several neuromuscular diseases, and even male sex determination can all be explained by the altered assembly of chromosomal structures.

The unifying lesson to be learned from these examples of DNA packaging and disease is that DNA sequencing studies and the construction of genetic maps will not by themselves provide all the answers to questions concerning genetic variation and genetic disease. An understanding of genetics at the molecular level depends not only on the primary DNA sequence but also on the three-dimensional organization of that DNA within the chromosome. Compelling genetic and biochemical evidence has left no doubt that the packaging process is an essential component of regulated gene expression.

CHROMATOGRAPHY

Category: Methods and techniques

Chromatography is a method of separating the components of a mixture over time. Chromatography has allowed for the discovery of many specialized pigments, including at least five forms of chlorophyll.

Chromatography was first described in 1850 by a German chemist, Friedlieb Ferdinand Runge. It was not until the early twentieth century, however, that Mikhail Semenovich Tsvet became the first to explain the phenomenon and methods of this analytical tool.

Chromatography and Photosynthesis

Tsvet's chromatography of plant leaf pigments prompted scientific investigations of photosynthesis—the all-important biochemical reaction that transforms inorganic to organic energy and therefore is at the base of most life. Chromatography has revealed that many different *pigments*, not only green ones, are simultaneously present in leaves. Each pigment absorbs only certain colors of light from sunlight, rather than absorbing all the incident light energy that falls upon it. Each pigment behaves as though it has a tiny "window" that allows the energy of certain wavelengths of light to be harvested. These little bundles of energy are *quantized*, or set, amounts of energy, and they are unique for each different type of pigment. (White sunlight is actually composed of a broad range of wavelengths, with the visible wavelengths appearing as a rainbow of colors when passed through a prism.)

Paper chromatography has allowed for the discovery of many specialized pigments, including at least five forms of *chlorophyll*. Chlorophyll pigments are now known to include chlorophylls *a* through *e*. Also, many different forms of *carotenes* and *xanthophylls* exist. Paper chromatography reveals that red and yellow pigments are always present in the leaves of deciduous trees and shrubs and not just during the fall color change. Because of the high abundance of the green chlorophyll pigments, as compared with the bright reds of carotenes or yellows of xanthophyll, only the dominant green hues are generally seen. In the fall, deciduous trees show a loss of chlorophyll pigments, thereby revealing the brilliant foliage associated with an autumn forest.

Once pigments are separated from one another, they can be chemically characterized and further studied. Carotenes and xanthophylls have been discovered to be of similar chemical composition, with each being made of forty carbon atoms covalently bonded to one another. Different arrangements of these covalent bonds produce the different colors of red and orange.

Chromatography has allowed scientists the opportunity to trace the path that carbon atoms follow through every tiny increment of the photosynthetic process. Paper chromatography, coupled with radioisotopic studies of carbon-labeled (with radioactive carbon 14) compounds, eventually led to the ability to describe the carbon-containing products of each step in the series of reactions of photosynthesis. Today this pathway is called the *Calvin cycle*.

Methodology

A classical demonstration of chromatographic principles utilizes techniques that allow plant pigments to be isolated. Spinach leaves are an excellent tool for the identification of four pigments: chlorophyll *a*, chlorophyll *b*, carotene, and xanthophyll. The stationary phase is a piece of chromatography paper with a dried spot of the plant extract near one end. The mobile phase is an acetone-ligroin mixture, a nonpolar (hydrophobic) solvent mixture. The paper is placed with a small portion of the end with the pigment spot in the solvent, the mobile phase. As the acetone-ligroin mobile phase comes into contact with the paper, *capillary action* allows the liquid to travel upward, against gravity.

The mobile phase has a migrating moisture line, or leading line of wetness, which is called the solvent front. As the solvent travels over the spot, each of the pigments will travel with the mobile phase at different rates from the original spot. Some pigments will adhere to the paper more strongly than others, and thus travel shorter distances along the paper. Yellow-green chlorophyll *b* travels the least distance with the mobile phase. Chlorophyll *b* is a more polar (water-loving) pigment than the other pigments found in spinach extracts and is therefore more strongly attracted to the polar surface of the paper than to the nonpolar solvent.

The remaining pigments travel increasing distances with respect to chlorophyll *b*, beginning with blue-green chlorophyll *a*, followed by yellow-orange xanthophyll and, finally, the orange pigment of carotene. Carotene moves the farthest because it is the most nonpolar of the pigments and it is attracted more strongly to the acetone-ligroin mixture (mobile phase) than to the paper. This stronger, nonbonded interaction with the mobile phase indicates that carotene is the most nonpolar pigment found in spinach chloroplasts.

Once the solvent front is about half an inch from the top of the paper strip, the strip is removed from the chamber. A pencil line must be drawn immediately across the top of the strip to indicate how far up the paper the mobile phase traveled. The paper strip is then referred to as a *chromatogram*.

The *Rf value* is a numerical constant that is unique for each of the four pigments identified in spinach. The ratio of the distance each pigment travels, as compared with the distance traveled by the mobile phase (from the start to finish lines), will be unique to that pigment alone. Thus, chlorophyll *b* will not switch places with carotene on the chromatogram because of the unique interactions it has with the stationary and mobile phases. For this reason, the Rf values determined by the method described above can be generated repeatedly by anyone using this method.

Types of Chromatography

As performed by Runge and Tsvet, chromatography has evolved from the days of paper, chalk, and dyes into a computerized and versatile instrumentation requiring expert training and a significantly larger budget. *Thin-layer chromatography* (TLC) is useful in protein chemistry. The stationary phase of this method consists of thin gel applied to a plastic or glass plate (strip). Various gels can be used to coat the plate. Some coatings may be polar, while others may be nonpolar.

Column chromatography can look for the amounts and types of vitamins in food or diet supplement tablets. Pigments, steroids, alkaloids, and carbohydrates all can be identified and measured using an appropriate column-chromatographic system. Many recent advances in column chromatography now allow for isolation and purification of proteins, DNA, RNA, and many other biological molecules.

High-pressure liquid chromatography (HPLC) can purify biologically important enzymes from living systems without destroying the biological activity of the enzyme. In *gas chromatography* (GC), an inert gas such as helium or nitrogen flows through several feet of a packed and coiled column. The gas acts as the mobile phase by sweeping the sample through the column. The packing is often a solid material, but liquid-coated solid particles are also used. Paper chromatography continues be a popular method for analysis of plant pigments, dyes, inks, and food colorings. It is largely used, however, in academic settings to demonstrate the principles of chromatography.

Bassham, J. A. "The Path of Carbon in Photosynthesis." *Scientific American* 206 (June, 1962): 40, 88-100. Describes the paper chromatography method as coupled with radioisotope tracers. It is an excellent article of historical significance, as it gives an account of the surprise intermediate products, such as amino acids, fats, carbohydrates, and other compounds, made during photosynthesis. The photographs of the chromatograms are worth scrutiny.

Braithwaite, A., and F. J. Smith. *Chromatographic Methods*. 5th ed. London: Blackie Academic & Professional, 1996. An excellent book that describes the many types of chromatography available today. Specific chapters deal with column chromatography, TLC, GC, HPLC, and combined techniques, such as mass spectroscopy and gas chromatography. The final chapter of the book provides model experiments in a cookbook style. This book is not overly technical, but it is more sophisticated than some references geared specifically to the beginner.

Clevenger, Sarah. "Flower Pigments." *Scientific American* 210 (June, 1964): 84-88. This article is a great resource to teachers because it offers options for pigments from nature that can be investigated. Technical in sections, but the introduction is quite accessible. The photographs show both one-dimensional and two-dimensional paper chromatograms, using methods that can be applied to the analysis of either plant leaf or petal extracts.

Hamilton, R. J., Sheila Hamilton, and David Kealey. *Thin Layer Chromatography: Analytical Chemistry by Open Learning*. New York: John Wiley & Sons, 1987. An excellent self-teaching approach to TLC theory and methods. This book is not as difficult to read as the title may imply; much of the material is very clearly written.

Kost, Hans-Peter, ed. *Plant Pigments*. Boca Raton, Fla.: CRC Press, 1988. A handbook that gathers together data tables on plant pigments chromatography, giving not only the results of modern separation methods but also older sources that are often difficult to access. A workbench reference book for researchers.

Morholt, E., P. Brandwein, and A. Joseph. *A Sourcebook for the Biological Sciences*. 3d ed. San Diego: Harcourt Brace Jovanovich, 1986. This reference was designed as a resource for high school science teachers and is still very useful. The diagrams of paper chromatography (which in this case is applied to amino acid analysis) and column chromatograpy are accurate and clear. Contacts and sources of audiovisual support materials can be found toward the end of the text. The best features of the book, however, are its well-written presentations and step-by-step approach.

Tocci, Salvatore. *Biology for Young Scientists*. Rev. ed. New York: Franklin Watts, 2000. This book contains excellent, brief descriptions of paper chromatography and photosynthesis. The chapter on photosynthesis and respiration makes particularly good reading for high school students.

CHROMOSOMES

Categories: Cellular biology; genetics; reproduction and life cycles

Chromosomes contain the genetic information of cells. Replication of chromosomes assures that genetic information is correctly maintained as cells divide.

The *genome* of an organism is the sum total of all the genetic information of that organism. In eukaryotic cells, this information is contained in the cell's nucleus and organelles, such as mitochondria and plastids. In prokaryotic organisms (bacteria and archaea), which have no nucleus, the genomic information resides in a region of the cell called the *nucleoid*. A chromosome is a discrete unit of the genome that carries many *genes*, or sets of instructions for inherited traits. Genes, the blueprints of cells, are specific sequences of deoxyribonucleic acid (DNA) that code for messenger ribonucleic acids (monas), which in turn direct the synthesis of proteins.

Each eukaryotic chromosome contains a single long DNA molecule that is coiled, folded, and compacted by its interaction with chromosomal proteins called *histone*. This complex of DNA with chromosomal proteins and chromosomal RNAs is *chromatin*. DNA of higher eukaryotes is organized into loops of chromatin by attachment to a *nuclear scaffold*. The loops function in the structural organization of DNA and may increase transcription of certain genes by making the chromatin more accessible.

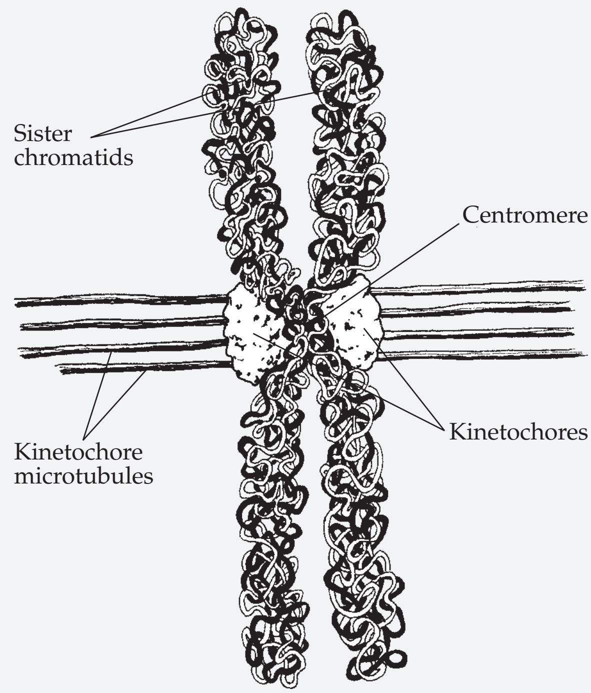
To maintain the genetic information of a cell, it is essential that chromosomes correctly replicate and divide as a cell divides. After DNA replication, chromosomes separate in a process called mitosis. During this process, the nuclear envelope breaks down and chromosomes condense into compact structures. A cellular structure known as the mitotic spindle forms, pulling pairs of replicated chromosomes apart so that the two cells receive identical sets of chromosomes.

Chromosomes are readily visualized when they condense during cell division. All the chromosomes of a cell visualized during mitosis constitute that cell's *karyotype*. Each chromosome has a *centromere*—a constricted area of the condensed chromosome where the mitotic or meiotic spindle attaches to assure correct distribution of chromosomes during cell division—and a *telomere*, the end or tip of a chromosome, which contains tandem repeats of a short DNA sequence.

The number of chromosomes in a gamete (either egg or sperm) is the *haploid* number, n. The haploid number of chromosomes in humans is 23; in corn, 10; in peas, 7; in *Arabidopsis* (the model organism used in much botanical research), 4. Some carp and some ferns have more than 50 chromosomes in the haploid genome. Pollen grains of some plants, such as pear, contain three haploid cells: One directs the growth of the pollen tube down the style to the ovary; the other two are sperm. In flowering plants (angiosperms), there is a unique double fertilization whereby one sperm nucleus fuses with the egg nucleus to form the diploid ($2n$) zygote, and the other sperm nucleus fuses with two polar nuclei to form the triploid nutritive tissue, or *endosperm*, which will nourish the embryo in the seed. The zygote then increases in cell number by *mitosis*, a type of cell division during which chromosomes in a nucleus are replicated and then separated to form two genetically identical daughter nuclei. This is followed by *cytokinesis*, the process of cytoplasmic division, which results in two daughter cells, each having the same number of chromosomes and genetic composition as the parent cell. The mature $2n$ plant forms the haploid (n) gametes by *meiosis*, a type of cell division that reduces the number of chromosomes to the haploid number.

A distinctive feature of plant cell division is the plant cell has three genomes (the nuclear, mitochondrial, and plastid genome) to replicate and divide. The chromosomes of eukaryotes consist of unique genes among a complex pattern of repeated DNA sequences. *Arabidopsis* has only 4 chromosomes containing about 120 million base pairs. There are typically between twenty and one hundred copies of the mitochondrial genome per mitochondrion, ranging in size from two hundred to twenty-four hundred kilobase pairs (or kb; one kilobase pair equals one thousand base pairs). Plant mitochondrial genomes are much larger than the mitochondrial genomes of yeast or animals. Chloroplast genomes range in size from 130 to 150 kb, with 50 to 150 copies of that genome per plastid.

Schematic of a Chromosome



Kimberly L. Dawson Kurnizki

In cell division in plant cells, the two daughter nuclei are partitioned to form two separate cells by a cell plate that grows at the equator of the mother cell. In animal cells, this separation involves the constriction of the cell at a central contractile ring. DNA replication is strictly controlled during the cell cycle. DNA synthesis occurs in the synthesis (S) phase, beginning at origins of replication distributed around the genome, occurring on average every 66 kb in dicotyledonous plants and on average every 47 kb in monocotyledonous plants. *Heterochromatin* is the term for regions of chromosomes that are permanently in a highly condensed state, are not transcribed, and are late-replicating. Heterochromatin contains highly repeated DNA sequences. *Euchromatin* is the rest of the chromosomes that is extended, accessible to RNA polymerase, and at least partially transcribed.

Some plants and animals have extra chromosomes that do not seem to be essential. These are called accessory or *supernumerary chromosomes*. They have been most studied in corn where these extra chromosomes are called *B-chromosomes*. B-chromosomes are usually highly condensed heterochromatin that may or may not be present in an individual of that species.

An increase in the copy number of the genome is common in plants and animals, occurring during the development of individuals. *Polyploids* have three or more complete sets of chromosomes in their nuclei instead of the two sets found in *diploids*. For example, in *Arabidopsis*, tissues of increasing age have an increase in polyploidy, reaching up to sixteen duplications.

CHRYSOPHYTES

Categories: Algae; microorganisms; *Protista*; taxonomic groups; water-related life

The Chrysophyceae*, classified within the kingdom* Chromista*, are mostly unicellular or colonial organisms found in fresh and salt water throughout the world.*

The *Chrysophyceae* (in some systems corresponding to the phylum *Chrysophyta*) are related to heterokont algae and include more than eight hundred described species that are classified in approximately one hundred genera. They are most closely related to the *Synurophyceae* and other pigmented heterokont algae, including the *Bacillariophyceae* (diatoms), *Eustigmatophyceae*, *Phaeophyceae* (brown algae), and *Xanthophyceae* (yellow-green algae), among others. The classification of chrysophycean species remains in a state of flux. In one system of classification primary importance is placed upon the number of flagella (zero, one, or two) that are present in the motile cell stage. A second classification organizes species based upon the predominant vegetative state of the organism. For example, in this classification amoeboid, coccoid, palmelloid, and flagellate species are assigned to separate orders.

Ecology and Diversity

Chrysophytes are predominantly found in freshwater environments, although some are marine, and a few are reported from soil or snow. Members of the group are widely distributed but are most common in cold-temperate lakes, ponds, bogs, and ditches. Some species are common members of the phytoplankton, whereas others are epibionts or are neustonic (attached to the surface film of quiet water). Other species are only rarely observed.

Most chrysophytes are free-swimming unicellular or colonial flagellates. Others are coccoid (that is, immobile, walled unicells), amoeboid, or palmelloid (with cells enveloped in a gelatinous matrix). A few species are parenchymatous.

Cell Walls

Most chrysophytes lack a cell wall, but others produce species-specific outer coverings of scales or loricae. For example, complex siliceous scales or spines that are produced in silica deposition vesicles cover the cells of *Paraphysomonas*. The scales of *Chrysolepidomonas* are organic and of two types: those that are dendritic (tree-shaped) and those that are canistrate (cylindrical). The cells of other species may be enclosed within an organic vaselike or flasklike lorica composed of cellulose and proteins or chitin (for example, *Dinobryon*, *Pseudokephyrion*, *Poteriochromonas*, *Lagynion*, and *Stenocalyx*). In such species the lorica is typically composed of fine, interwoven fibrils. In *Dinobryon* these fibrils are helically arranged and secreted as the cell rotates about its longitudinal axis. In contrast, the loricae of *Epipyxis* species are composed of imbricate, overlapping scales. The posterior pole of the cell is typically positioned at the base of the lorica and may be attached by a fine cytoplasmic extension; the flagella protrude externally through the lorica opening.

Flagella

Chrysophytes are heterokont, biflagellate organisms that swim with at least one flagellum forwardly directed. The two flagella of motile cells are anteriorly inserted in an apical or subapical position and are unequal in length. The flagella differ morphologically and are heterodynamic. In most species, the basal bodies from which the flagella arise are either oriented at an acute angle to one another or are perpendicular to one another.

In *Hydrurus*, *Chromphyton*, and *Lagynion*, the basal bodies form an obtuse (oblique) angle with respect to one another. The long (immature) flagellum is anteriorly directed and is ornamented with two rows of mastigonemes and finer lateral filaments. Each mastigoneme is composed of a base, a tubular shaft, and one to three terminal filaments; these are known as tripartite tubular hairs. Mastigonemes are produced in the perinuclear space between the two outer membranes of the chloroplast and the two surrounding membranes of the chloroplast endoplasmic reticulum (see below). The long flagellum beats in an undulatory, sine-wave-like motions that are initiated at the base of the flagellum. The relatively stiff short (mature) flagellum is directed laterally or posteriorly, lacks mastigonemes, and rotates helically. A distinct swelling associated with the eyespot is typically present at the proximal base of the smooth flagellum.

In some taxa (such as *Chromulina*, *Chrysococcus*, and *Sphaleromantis*), the short flagellum is highly reduced and may be nonemergent; it is therefore undetectable by light microscopy. In a handful of species the short flagellum is entirely absent, although the mature basal body may persist within the cell. Naked motile cells bearing two visible flagella are often referred to as *Ochromonas*-like (or ochromonadalean), whereas those with one visible flagellum are typically assigned to the genus *Chromulina*.

The transitional region between the basal body and flagellum contains an electron-dense transitional plate, above which lies a coiled, apparently springlike transitional helix. The functions of the transitional plate and helix, which are also found in other flagellates, are uncertain.

In heterotrophic and mixotrophic species, the flagella play a role in prey capture. Particles actively captured by the flagella that are recognized as food are pushed into a feeding basket; those not recognized as food are released. The feeding basket is formed and closed by movements of underlying microtubules (see below). Water currents produced by the undulation of the long flagellum may passively bring food particles in contact with the cells that, in some species, are collected by pseudopodia.

Cell Organization

Cells possess a single pear-shaped nucleus that is positioned at the anterior end of the cell. The narrow end of the nucleus typically lies close to the basal bodies. A prominent Golgi apparatus with distended cisternae lies against the nucleus. Contractile vacuoles (absent in some marine forms) are also found at the anterior end of the cell.

One or more mitochondria with tubular cristae are present in the cell. Because the mitochondria are usually long and coiled, the actual number of mitochondria present is difficult to discern. Fibrous bands, sometimes referred to as connecting fibers, connect the basal bodies to one another. A cross-striated band of fibers known as the rhizoplast extends from the basal apparatus and forms a connection to the nucleus. Typically four microtubular roots (R1, R2, R3, and R4) originate near the basal bodies, take characteristic paths through the cell, and proliferate beneath the plasmalemma. For example, in most species roots R3 and R4 often form a loop beneath the short flagellum. Other microtubules are nucleated from the four major roots that provide the cytoskeletal elements needed to maintain cell shape.

Muciferous bodies or discobolocysts are present in some species. Muciferous bodies are capable of extruding long threads, whereas discobolocysts forcefully eject discoid projectiles. These functions of these organelles have been little studied but may be involved in prey capture or predator avoidance.

Nutrition

The *Chrysophyceae* employ a variety of means to obtain energy. Most chrysophytes are photosynthetic but require an exogenous source of vitamins (such as vitamin B_{12}, biotin, and thiamin) for growth. It is probable that all chrysophytes are opportunistically or facultatively osmotrophic; that is, they are capable of directly absorbing small inorganic or organic molecules (such as sugars and amino acids) from the surrounding medium. Several species, particularly those with leucoplasts, are obligate heterotrophs that are bactivorous or consume small organic particles. Mixotrophic species are also well represented among the chrysophytes. This category includes photosynthetic species that, routinely or under unfavorable conditions, supplement their nutrition via phagotrophy.

Chloroplasts, Photosynthetic Pigments, and Storage Products

The chloroplasts of chrysophytes are typically golden-brown or yellow-green in color, and there are usually one to two chloroplasts per cell. Chloroplasts are peripherally located, and pyrenoids may be present or absent. Four unit membranes surround each chloroplast; the outer two are derived from the endoplasmic reticulum and are typically continuous with the nuclear envelope. Chloroplast lamellae are typically composed of three adpressed thylakoid membranes, and a girdle lamella, which completely encircles the chloroplast, is usually present. The chloroplast deoxyribonucleic acid (DNA) is ring-shaped and lies just beneath the girdle lamella.

The light-harvesting complex of chrysophytes contains chlorophylls *a* and *c*, beta-carotene, and the xanthophylls fucoxanthin, neoxanthin, violaxanthin, and zeaxanthin. Among these, fucoxanthin is dominant and is therefore responsible for the golden-brown color observed in most chrysophytes.

The major product of photosynthesis is a water-soluble o-1,3-linked glucan (known as chrysolaminarin or leucosin) that is stored in cytoplasmic vacuoles in the posterior region of the cell. Lipids may also be produced and are also stored in the cytoplasm.

Eyespots (or stigmata) are present in many, but not all, species. The eyespot takes the form of a single layer of orange or reddish colored, lipidlike droplets that are located just beneath the chloroplast membrane. These droplets lie near a swelling located at the base of the smooth (short) flagellum; together the eyespot and flagellar swelling form a photoreceptor apparatus.

Several chrysophyte genera are known that contain a vestigial chloroplast (leucoplast) that lacks pigments (including *Anthophysa*, *Monas*, *Oikomonas*, *Paraphysomonas*, and *Spumella*).

Reproduction

Asexual reproduction in amoeboid and flagellate species occurs by longitudinal division of the cell; fragmentation is common among colonial, palmelloid, and parenchymatous species. In coccoid species reproduction may proceed via cell division or the formation of autospores that rupture and exit the parent cell wall. Some taxa, such as the parenchymatous genera *Phaeodermatium* and *Hydrurus* or members of the palmelloid family *Chrysocapsaceae*, reproduce by means of flagellated swarmers (zoospores).

Under certain environmental conditions, silicified resting cysts, or statospores, are produced by many species. Statospores are formed endogenously, are roughly spherical or ellipsoidal, and have walls that may be smooth or ornamented. The stomatocyst opening (porus) may be simple, possess a thickened collar, or take the form of a narrow neck. The cyst wall is formed by the deposition of silicate on an internal membrane, and the porus is preformed or produced by resorption of a portion of the cyst wall. Depending on the species, cytoplasm located outside the cyst wall may or may not be absorbed through the porus, which at maturity is occluded by a pectic plug. During excystment the plug is lost, and one or more amoeboid or free-swimming flagellate cells emerge.

Sexual reproduction is known only in a handful of species. In those cases observed, vegetative cells behave as gametes and fuse apically. The resulting quadriflagellate cell (planozygote) will encyst forming sexually derived binucleate hypnozygotes or stomatocysts. It is presumed that karyogamy (nuclear fusion) and meiosis occur within the cyst, but these processes have yet to be studied. Depending upon the species, sexual stomatocysts may give rise to one, two, or four vegetative cells.

CHYTRIDS

Categories: Fungi; taxonomic groups; water-related life

Chytrids are fungi in the phylum Chytridiomycota. *They have motile spores and are primarily aquatic organisms.*

Like all fungi, chytrids live in their food and have an absorptive mode of nutrition in which they secrete digestive enzymes and absorb the breakdown products. Chytrids also have cell walls made of chitin, make the amino acid lysine via the amino adipic acid (AAA) pathway, and possess a ribosomal DNA (deoxyribonucleic acid) sequence that places them more closely with other fungi than with any other group of organisms. The feature that sets them apart from other fungi is the possession of a motile zoospore. All other fungi produce spores without flagella.

Characteristics

A posteriorly oriented, whiplash-type flagellum is the feature that unites all the organisms in the division *Chytridiomycota* within the kingdom *Fungi*. As absorptive heterotrophs, they live either as *saprophytes*, growing on dead organic matter, or as parasites in living plants, other fungi, insects, or algae. The vegetative organism may take the form of a spherical structure, with or without branching rhizoids, on the surface of substrate or host or may send mycelial threads through the material in which it is living. Asexual reproduction occurs by a variety of means described below. Sexual reproduction is known to exist in several types of chytrids and in some species involves the alternation between a gamete-producing phase and a spore-producing phase.

The sporangia that produce the motile zoospores develop in a variety of ways. Two features are used to characterize development: the fate of the nucleus upon encystment of the zoospore and the number of zoosporangia produced from a single zoospore. The three most common types of thallus development are endogenous-monocentric, exogenous-monocentric, and exogenous-polycentric. Endogenous-monocentric development occurs when the zoospore nucleus stays within the encysted zoospore wall, undergoes mitosis, and produces a single zoosporangium. Exogenous-monocentric development occurs when the zoospore nucleus migrates into the germ tube, undergoes mitosis, and produces a single zoosporangium. Exogenous-polycentric development occurs when the zoospore nucleus migrates into the germ tube, undergoes mitosis, and spreads to many locations for zoosporangium production.

The phylum-defining zoospore may be one of four basic morphological types. Though the types are determined by electron microscope, the morphological type can be recognized using light microscopy with experience. The four morphological types are the basis of classification at the ordinal level as described below.

Ecology and Habitats

Because chytrids are absorptive heterotrophs, they grow in their food, digesting complex food molecules and absorbing the simpler breakdown products. When growing in dead material, these fungi are saprophytes and are decomposing organisms in ecosystems. Because the zoospore requires water for dispersal, these fungi are found in aquatic environments. However, they also can be found in soils that are wet with soil water. Chytrids also can live within living organisms as parasites, causing major declines in populations. The gut chytrids, *Neocallimastigales*, live in the rumina (stomachal cavities) of herbivorous mammals.

Taxonomy

There are approximately eight hundred species of chytrids, arranged in five orders. Taxonomy of the different orders is based on the ultrastructure of the zoospore. Ultrastructure features used in taxonomy include the presence or absence of a connection between the nucleus and the kinetosome by microtubules; whether ribosomes are dispersed or collected into a mass surrounded by membranes; the degree of organization of the microbody-lipid complex (MLC); the location and number of lipid globules; and presence or absence of a rumposome—a honeycomblike organelle of unknown function. The main characteristics of the five orders are described below.

Chytridiales. During examination of the main features of the zoospore—lipid globule, microbody, mitochondria, and nucleus—the nucleus seems to occupy whatever space is left over within the zoospore. Rootlet microtubules are located within the plasma membrane connecting the kinetosome to the rumposome. Ribosomes are gathered in the center of the cell, enclosed within membranes. In the MLC, the posteriorly located lipid globules are in close association with the microbody, mitochondrian, and rumposome.

Spizellomycetales. The nucleus of the zoospore is close to the kinetosome or, if separated, is connected to it via microtubules or a rhizoplast. Rootlet morphology is variable, and ribosomes are scattered throughout the cytoplasm. The MLC has a loose association of the microbody and lipid at the anterior end of the zoospore with the mitochondria located toward the rear. There is no rumposome. Ribosomes are dispersed throughout the zoospore.

Neocallimastigales. *Neocallimastix* and other genera of the order are uniflagellate or multiflagellate and live in the rumen of herbivorous mammals. Because they live in this unique environment, rumen chytrids are obligate anaerobes. The zoospores lack any of the MLC organelles and the rumposome. All these anaerobic fungi are cellulolytic and digest plant cell walls of the food upon which sheep and cattle feed.

Monoblepharidales. The zoospores have a centrally located nucleus that is not connected to the kinetosome. Microtubules extend randomly into the cytoplasm from the kinetosome. The MLC has a rumposome in close association with a microbody and anteriorly located lipid globules. The ribosomes are centrally located, surrounding the nucleus. These fungi have a mycelial growth form and reproduce sexually by producing a motile male cell and a nonmotile egg cell.

Blastocladiales. A nuclear cap consisting of ribosomes encased within a membrane located anteriorly to a cone-shaped nucleus and a single large mitochondrian with a side body complex are the two most distinctive features of these fungi. Some of these fungi produce mycelial growth forms, whereas others produce the saclike zoosporangium with rhizoids.

Evolutionary History

Evolutionary history of the chytrids can be traced back to the Pennsylvanian period through fossil evidence. Sequential analysis of the small subunit ribosomal DNA gene from fifty-four chytrids indicates that the *Chytridiomycota* are related to other fungi and that there are natural groups within the division: *Blastocladiales*, *Monoblepharidales*, and *Neocallimastigales*. Despite the diversity of the data, the monophyletic nature of the *Chytridiales* and *Spizellomycetales* is not rejected. The DNA groupings closely resemble groupings based on zoospore ultrastructure.

Representative Organisms

Allomyces is a mycelial member of the *Blastocladiales*, which is interesting because it has an alternation of generations between a gamete-producing thallus (gametothallus) and a spore-producing thallus (sporothallus). In all organisms with alternation of generations, the gametothallus produces gametes by mitosis in gametangia. The gametes are distinguished by size, the male being smaller than the female. The motile male gamete is chemotactically attracted to the hormone sirenin, which is produced by the female gametes and enables fertilization. Upon fertilization, the zygote nucleus undergoes mitosis as the germ tube develops into mycelia without crosswalls. The dichotomously branched mycelia of the sporothallus produce two types of sporangia. The thin-walled sporangia produce diploid spores by mitosis. These diploid zoospores are responsible for increasing numbers of *Allomyces* in its habitat.

The sporothallus also can produce a thick-walled sporangium capable of withstanding harsh environmental conditions. Zoospores in this sporangium are produced by meiosis. When these haploid zoospores geminate, the nucleus divides by mitosis and spreads throughout the dichotomously branched mycelia. The life cycle of the fungus now is completed.

Batrachochytrium is interesting because it parasitizes frogs. Within the last decade, declines in populations of frogs around the world have been described. *Batrachochytrium dendrobatidis* is responsible for this chytridiomycosis in amphibians, including salamanders.

Blastocladiella is a developmental biology tool. The thallus has the exogenous, monocentric developmental pathway resulting in a rhizoidal system with a single thin-walled, colorless sporangium or a single thick-walled, resistant sporangium. The chemical environment of the developing thallus determines which sporangium is produced. High carbon dioxide levels favor the development of the thick-walled sporangium. This shift from a thin-walled sporangium pathway to a thick-walled sporangium pathway has been traced to a disruption of the Krebs cycle. This organism is one of a few nongreen organisms in which light promotes the growth of the organism.

Coelomomyces is a mycelial member of the *Blastocladiales* that parasitizes invertebrate animals. Coelomomyces alternates between a haploid gametothallus and a diploid sporothallus. The unique feature of *Coelomomyces* is that each phase is specific for a different host. The diploid sporothallus parasitizes mosquitoes and grows as wall-less mycelia within the hemocoel of the mosquito larvae. *Coelomomyces* has been studied as a possible mycoinsecticide against mosquitoes. Difficulty in using *Coelomomyces* as a mycoinsecticide occurred until the discovery of the fact that an alternate host was required to achieve completion of the life cycle. The zoospores produced by the thick-walled sporangium within the mosquito are produced by the process of meiosis and are haploid. The haploid zoopore must infect a microcrustacean copopod or ostracod in order for the gametes to be produced. The haploid zoospore develops into the gametothallus, which produces the motile gametes. The resulting zygote will infect mosquito larvae, completing the life cycle.

CIRCADIAN RHYTHMS

Categories: Movement; physiology

Circadian rhythms in plants are phases of growth and activity that appear in regular, approximately twenty-four-hour, cycles.

Biological activities that cycle in approximately twenty-four-hour intervals are called circadian rhythms (from the Latin *circa*, meaning "about" and *dies*, meaning "a day"). Circadian rhythms allow plants to anticipate environmental cycles and to coordinate their activities with them. Circadian rhythms are not simply responses to changing external conditions, as they continue even when a plant is placed under constant conditions. This continuation indicates that circadian rhythms are controlled by endogenous (internal) timing mechanisms, collectively referred to as the *biological clock*.

Digital Stock

Many plants, such as these California poppies, open their flowers in the morning and close them at night. These cycles are important for timing pollen availability with the activity of insect, bird, and mammal pollinators. It is essential that flowers of the same species be open at the same time of day or night to promote outcrossing that results in increased genetic variation.

Plant circadian rhythms include cycles in gene regulation, enzyme activity, leaf movements, flower opening, and stomatal opening. Circadian rhythms also interact with photoperiodism in the control of major developmental processes, such as dormancy and the induction of flowering.

History

In 1729 the French astronomer Jean-Jacques Dortous de Mairan discovered the endogenous nature of circadian rhythms when he looked at the sleep movements of leaves of the sensitive plant, *Mimosa*, known as *nyctinastic leaf movements*. Mimosa leaves fold closed at night and open during the day. It had been thought that these leaf movements occurred in response to external cycles of light and darkness. De Mairan examined the plants under constant environmental conditions and discovered that the nyctinastic movements of the leaves continued. This was the first description of a biological activity with an endogenous circadian rhythm. Current models for how plants accomplish circadian rhythms are divided into three parts: entrainment, biological clock, and output pathways.

Entrainment

The synchronization of circadian rhythms to the cycles of the outside world is accomplished via input pathways and is referred to as *entrainment*. In nature, circadian rhythms are entrained primarily by light or temperature cycles to have periods of twenty-four hours. It is essential that circadian rhythms be entrained, because without synchronization of the biological clock with environmental cycles, the advantages of circadian rhythms would be lost.

Biological Clock

The biological clock is also referred to as the central oscillator and the pacemaker. It is endogenous and self-sustaining. Although circadian rhythms are entrained by external stimuli, they continue in the absence of external cycles. Under artificially constant conditions, circadian rhythms do not maintain twenty-four-hour periods but revert to free-running periods that are usually between twenty-one and twenty-seven hours. The molecular mechanisms of the biological clock remain unknown, but they are thought to include autoregulatory feedback mechanisms.

An interesting feature of the biological clock is that the free-running period is generally insensitive to changes in temperature. Most chemical and biological processes are affected by temperature changes; higher temperatures make them go faster, and lower temperatures make them go slower. That the biological clock is able to compensate for temperature changes and maintain timekeeping functions is important to plants experiencing extreme changes in temperature.

Output Pathways

The *output pathways*, or "hands" of the biological clock, are the measurable rhythms exhibited by the plant. Known circadian rhythms range from the subcellular level to the cell and tissue level to the developmental level.

Subcellular Level

Subcellular circadian rhythms include cycles in gene regulation (at the levels of transcription, transcript abundance, translation, and post-translational modification), calcium signaling, and enzyme activity. One well-characterized rhythm is the rate of carbon dioxide assimilation in plants with CAM (crassulacean acid metabolism) photosynthesis. Such plants open their stomata at night to allow for gas exchange, fixing carbon dioxide into an organic acid that is stored in the vacuole. During the day, the plants close their stomata (presumably to conserve water) and continue photosynthesis using carbon dioxide released from the organic acids. The circadian rhythm of carbon dioxide assimilation in CAM plants is controlled by rhythmic changes in the activity of the enzyme (PEP carboxylase) that fixes carbon dioxide into the organic acid.

Cell and Tissue Levels

Cell- and tissue-level circadian rhythms include those controlled by cycles in cell expansion and contraction, such as the obvious rhythms of leaf and petal movements and the opening and closing of stomata. Leaf movements are brought about by a cycling in the expansion and contraction of specialized cells in a region at the base of the leaf that is called the pulvinus. Nyctinastic leaf movements presumably allow a plant to maximize light interception for photosynthesis.

Many plants open their flowers in the morning and close them at night. Other plants open their flowers in the afternoon (such as the four o'clocks, *Mirabilis jalapa*), in the evening (evening primrose, *Oenothera biennis*), or even at night (the bat-pollinated cactus *Cereus*). These cycles are important for timing pollen availability with the activity of insect, bird, and mammal pollinators. It is essential that flowers of the same species be open at the same time of day or night to promote outcrossing that results in increased genetic variation.

Circadian cycles of stomatal opening and closing allow a plant to balance carbon dioxide uptake with water loss. Plants with CAM photosynthesis open their stomata at night, in contrast to plants that carry out C_3 and C_4 photosynthesis, which open their stomata during the day. Other known tissue-level circadian rhythms include hypocotyl elongation, nectar secretion, and hormone synthesis.

Developmental Level

Developmental processes that depend on interactions with circadian rhythms and the biological clock include the photoperiodic control of flowering and dormancy. These photoperiodic responses rely on the ability of a plant to measure relative amounts of light and darkness within each twenty-four-hour period. It remains unknown whether one biological clock controls both photoperiodism and circadian rhythms.

CLADISTICS

Categories: Classification and systematics; disciplines; methods and techniques

Cladistics is a quantitative method of classification of plants that attempts to recover evolutionary relationships, based on observable characters.

Since the dawn of history, humans have classified plants. In primitive cultures classifications were by economic use, such as food, clothing, medicine, and shelter. Later the form (morphology) of a plant became important, for example, trees, shrubs, or herbs. Carolus Linneaus considered the similarity of floral parts to be critical, and this formed the basis of his classification system. Each of these systems is said to be "artificial." That is, the classification was solely for a human purpose and did not attempt to indicate genetic relationships between plants. Since Charles Darwin, the goal of plant systematics has been to develop a "natural," phylogenetic classification, one that represents the natural relationships of each species to all others. Cladistics was developed as a method to construct phylogenetic classifications.

A Brief History

Three systems have evolved to aid systematists (scientists who study the phylogenetic relationships of organisms) in their work. Traditional *phylogenetics* was based on intuition and involved the "art and science" of character weighting. The scientist studied a group of plants and decided which characters he or she thought were important. Evolutionary relationships were then based on these characters. Individual bias led to disagreements that could not be resolved objectively.

Computer-assisted numerical approaches permitted systematists to employ a more objective methodology and analyze large quantities of data, gathered from a variety of sources that range from traditional morphology to the most sophisticated molecular techniques. The earliest attempt, *phenetics*, used computers to determine the degree of total similarity between taxa. Unfortunately, this ignored both parallel and convergent evolution.

The methods of cladistics were first formalized in the 1950's and 1960's by Willi Hennig. This approach requires three assumptions to be met: evolution occurs; evolution is monophyletic (that is, lineages derive from a common ancestor); and characteristics passed from generation to generation are either modified or not. Although phylogenetics is concerned with genealogical relationships, the latter cannot be observed; rather, they must be inferred from observable characters (morphological, biochemical, behavioral, and so on) in much the same way as one infers genotypes when constructing a family pedigree. Cladistics is a quantitative method that attempts to recover evolutionary relationships, based on observable characters, and presents the resulting phylogeny in the form of a treelike diagram called a *cladogram*.

When many different organisms are being classified and when many different characters are being analyzed simultaneously, alternative cladograms may result. The most parsimonious tree (the cladogram requiring the fewest evolutionary changes) is generally preferred, because it is assumed that the simplest pathway is the one most likely to reflect the evolutionary history of the plants being examined.

Constructing a Cladogram

The most important decision to make before beginning construction of a cladogram to represent the relationships among a group of plants is the choice of an appropriate *outgroup*. The outgroup cannot belong to the group of plants being analyzed, but it should be closely related. Much of the work of a phylogenetic study is determining an appropriate outgroup to be used for comparisons.

The next step involves construction of a *character matrix*. A character is any feature of a plant. It may be an observable morphological or biochemical feature or an ecological or physiological attribute. Every useful character will have more than one character state. For instance, the character "root type" may have the character states "taproot," "fibrous root," or "adventitious root."

Characters having a common origin are called homologous. Cladistic analysis recognizes two types of homologies: plesiomorphies and apomorphies. *Plesiomorphies* are considered to be the primitive state of a character; that is, the character is unchanged from the ancestral condition. Plesiomorphies are determined by comparison of the character states in the members of the taxa being investigated with the character state in the outgroup. A character state found in both the outgroup and the taxa being examined is considered to be plesiomorphic. Any modification of the character state is considered to be apomorphic; thus, *apomorphies* are derived from plesiomorphies. Apomorphies shared by two or more taxa are called synapomorphies. Identification of *synapomorphies*, assumed to be derived from increasingly recent common ancestors, provides the basis for constructing cladograms.

Qualitative Approach

The first step toward a qualitative approach to constructing a cladogram is to examine the character matrix and list groupings of taxa according to the apomorphic trait for each character. Next, one character to begin the tree is chosen. Any character will do, but it is simplest to begin with a character in which only the outgroup has the plesiomorphic state and all ingroup taxa share the same apomorphy. For instance, a conifer might be the outgroup for classifying flowering trees. The plesiomorphic reproductive structure would be a cone, and the synapomorphy shared by all ingroup members would be flowers. The tree would have the conifer at the base, with a single line extending to the right to a branch point (node) from which all ingroup members diverge. The character state "flower" would be placed on the line between the conifer and the node, indicating that the shared character state, flowers, evolved prior to the divergence of ingroup taxa from one another.

Next, a second character is added to the existing tree. For instance, the conifer and dicot trees would all share the plesiomorphic character of a taproot, but monocot trees, such as palms, would have fibrous roots. The tree should now be extended to the right to form a second node with the character state "fibrous roots" added to the new stem segment and the monocot trees branching off the second node. The monocot taxa diverged from each other after fibrous roots evolved. The dicots do not have fibrous roots, so they are diagramed at the node to the left of "fibrous roots." The tree is continued by the addition of one character at a time until all have been used.

Quantitative Approach

The qualitative approach becomes increasingly difficult as the number of taxa and number of characters are increased. The advantages of the quantitative approach are that the process can be automated and human bias can be minimized. The following example illustrates "by hand" the way computers can be programmed to produce a cladogram. The first step is to code the character matrix to produce a numerical matrix for analysis. Plesiomorphic characters in the data matrix are coded as 0; different apomorphic character states are coded as successive integers, 1, 2, 3, and so on.

The simplest cladogram consists of a Y-shaped diagram representing three taxa, two from the group being studied and a third being the outgroup. The outgroup is placed at the bottom and serves to "root" the tree. The two ingroup species are located at the top of each arm. The point where the two arms diverge is a node and represents the ancestral taxon derived from the outgroup that gave rise to both ingroup taxa—it represents the common ancestor of the ingroup taxa. A numerical algorithm computes what the character states of this ancestral species must have been.

Additional taxa can now be added to the cladogram, one at a time. A series of new trees are constructed in which the new taxon is added between each existing taxon and each existing node. There are three places a fourth taxon could be added to the simple tree: between the root and the node, between the node and the first ingroup taxon, and between the node and the second ingroup taxon. An algorithm computes which of the three possible trees is the most parsimonious, and this tree is used as the basis for adding the fifth taxon (in one of now five possible positions between the four existing taxa and the two nodes). This process is continued until all taxa have been added to the tree and the cladogram is complete.

CLIMATE AND RESOURCES

Category: Environmental issues

Climate is described by the average of weather conditions at a place or in a region, usually recorded as both the mean and the extremes of temperature, precipitation, and other conditions. Resources are the factors and characteristics of the natural environment that people find useful, including climate, land, soil, water, minerals, and wild vegetation. Thus, climate itself is a resource, affecting the character of the plant life and other resources it supports.

The nature and distribution of wild vegetation are to a large degree the products of climate: the temperature, moisture, solar radiation, and other environmental conditions that characterize a region. The major global vegetation types that accompany forest, shrub, grassland, desert, rain forest, tundra, and other biomes reflect climatic controls.

Solar radiation is the basic determinant of climate. The sun's rays are vertical at some time of the year only in the tropics, between the Tropic of Cancer (23.5 degrees north latitude) and the Tropic of Capricorn (23.5 degrees south latitude). These lines determine where the greatest heat supply is found; regions poleward of about 40 degrees north and south latitudes actually have a net loss of reradiation to outer space and depend upon a heat supply from the tropics, which is carried poleward by the general circulation of the atmosphere. The general circulation is the average of wind flow at the surface of the earth and is driven by the surplus of solar radiation in the tropics.

Equatorial Climates

By definition, tropical climates do not experience freezing temperatures, have the least variation in length of day, and consequently experience the least "seasonality" of any latitudes. Seasons in the tropics are characterized more by precipitation contrasts—"dry" and "wet"—than by summer and winter temperatures. The greatest combination of heat and moisture resources on the earth's surface, especially important in creating the conditions under which tropical rain forests flourish, is near the equator.

The depth to which rock and soils are weathered and leached (mineral plant foods dissolved and removed by groundwater flow) is greater near the equator than elsewhere on the earth's surface. Continuous high temperatures work against carbon storage in the soils. Under wild vegetation conditions, where the rain forest canopy protects soils from raindrop impact, erosion rates are not as high as one would expect from the intense rain showers. On sloping land, however, the soils become saturated and flow downslope, often catastrophically in landslides. Where wild vegetation has been removed by human activity, such as farming or development of urban centers, erosion and mass wasting (landslides) are exacerbated during rainy seasons and cause considerable loss of life and property damage.

With increasing distance from the equator, the tropics experience more pronounced seasons, particularly in moisture resources. Precipitation totals decline, and *drought* risk increases. Dry seasons are expected annually because of the shifting of the general circulation of the atmosphere. The timing and extent of this shift determine whether a region experiences drought.

East and South Asia are most affected by shifting atmospheric circulation and the resulting wet and dry seasons. Africa also has pronounced wet and dry seasons. Droughts in this part of the world result in famine: An estimated one million people died in the Sahelian droughts of the late 1960's and 1970's. Thus climate must be defined both in terms of averages and of extremes. Extremes result in hazards that have dire consequences for the inhabitants of the affected region.

The probability of drought increases as precipitation averages decrease. Additionally, most tropical rainfall takes the form of intense thundershowers, which are spatially highly variable. One farm may be drenched by rain while its neighbors con-

The eastern sides of midlatitude landmasses are subject to intense summer storms.

tinue to be tormented by drought. In addition to drought risk on the margins of the tropics, a major climatic hazard is the tropical cyclone, also called a hurricane or typhoon. Cyclones rarely affect the equatorial zone but frequent the tropical transition to the subtropics and midlatitudes. Movement of tropical cyclones is easterly in their early and middle stages, following the general circulation known as the trade winds.

The Subtropics

The climates that exist in the *subtropics*, poleward of the tropics, depend on the side of the continent: West sides are *deserts* or subtropical *drylands*; east sides are the *humid subtropics*, a transition zone with cooler temperatures and more risk of frost with greater distance from the equator. The humid subtropics are subject to occasional easterly flow weather systems, including tropical cyclones. While cyclones represent a serious hazard, claiming both lives and property, these easterly systems also deliver moisture and thus reduce the possibility of drought. The generally warm temperatures and moist conditions make these climates some of the most productive for crop growth, exceeding the potential of the tropics.

In the subtropics, leaching of soils and high erosion rates on cleared fields are nearly as great a problem as in the tropics. The west coast drylands, which include all the world's major deserts—Sahara, Atacoma, Kalahari, Australian, and North American—are a consequence of the general circulation of the atmosphere, which in these locations makes the swing from the prevailing westerlies of the middle latitudes to the easterly trade winds. In the process, high atmospheric pressures prevail, and winds are descending or subsiding, and therefore warming—just the opposite of the conditions required for rainfall. Drylands may extend deep into the continents, as in North America and especially in Africa and Asia. The dryness of the Sahara blankets the Middle East and extends northward into Central Asia. Temperatures along the equatorward flank of these five major dryland zones are tropical, and where irrigation water is available, tropical plants may be grown. Most of the drylands are subtropical or midlatitude, and thus they experience frost as well as drought hazard. Weathering and erosion are appreciably less in the drylands, owing to the absence of moisture. Leaching of the soils is virtually absent. Instead, salts in the soils can build up (*salinization*) to levels that are toxic to most plants—another climate-related hazard.

The Midlatitudes

The *midlatitudes* extend from the subtropics to the polar climates of the Arctic and Antarctic. Temperatures follow a transition from warm on the equatorward flank to too cold for agriculture nearer the poles. This is the realm of the westerlies, with extratropical cyclones delivering most of the weather. It is a zone of contrasting conditions, year by year and day by day, ranging from warmer than average to colder than average, from too humid to too dry on the inland dryland border. The hazards of extreme temperature and precipitation often dominate life, as tropical and polar air masses converge to create the cyclones that march from west to east.

Drought risk is most important on the dryland border and results in the world's great grasslands. Summer heat may be a hazard on occasion. Nearly every winter brings storms with freezing rain, high winds, and heavy snowfalls, particularly on the eastern sides of the continents. The eastern sides are also afflicted with intense summer storms, such as the tornadoes of North America (a winter phenomenon in the adjoining humid subtropics) and the tail ends of hurricanes and typhoons, as these storms become caught up in westerly circulation and curve poleward again. The Arctic fringe of the midlatitudes is too cool for significant agriculture but yields the great subarctic forests of Canada, Scandinavia, and Russia.

CLINES

Categories: Ecology; ecosystems; genetics

A cline is one form of geographic variation in which characteristics of a species change gradually through the species' geographic range.

Many plant and animal species have populations that differ in terms of their morphological, physiological, and biochemical characteristics. A *species* is generally defined as a group of organisms that have the potential to interbreed and produce fertile offspring. A *population* is defined as a group of organisms which are actively interbreeding. The following example will clarify the relationship between species and populations and simultaneously introduce geographic variation.

Geographic Variation

The ponderosa pine (*Pinus ponderosa*) occupies a broad geographic range in western North America. Leaves (needles) of ponderosa pines in the Rocky Mountains are bundled into groups of two or three, and cones of these trees are more than 9 centimeters long. In contrast, leaves of ponderosa pines in southern Arizona and northern Mexico are bundled in groups of five, and their cones are less than 9 centimeters long. These differences constitute geographic variation which has developed because reproduction between Rocky Mountain ponderosa pines and Arizona-Mexican ponderosa pines was restricted because of geographic separation. Despite their differences, the two groups belong to the same species because they could produce fertile offspring if their geographic separation were overcome. However, they are members of different populations because they are not currently interbreeding. They are different populations of the same species.

Such geographic variation occurs in many species with broad geographic ranges and is often due to differences in the environmental conditions under which the separate populations exist. The different environments select for different genetic adaptations, resulting in hereditary variation. If such geographic variation occurs gradually over the range of the species, it is *clinal variation*.

Clinal Geographic Variation

In the foregoing example, the geographic variation is too abrupt to be considered clinal. However, ponderosa pines in the Sierra Nevada of California do show clinal geographic variation. The pines at the base of the mountains grow appreciably larger than the pines growing at the highest elevation on the mountains. The change in size is gradual; ponderosa pine trees become progressively smaller as elevation increases.

By taking seeds from trees at several elevations and planting them at the same elevation, scientists showed this size variation to be hereditary. Although all the trees were grown under the same conditions, the largest trees grew from the seeds collected at the base of the mountains, and tree size decreased as the elevation of seed origin increased. The advantages to being small in the relatively harsh environment of the high mountains and tall at the mountain base were important enough to code tree size into the trees' genes. The yarrow (*Achillea lanulosa*) and a number of other plant species show similar clinal variation with elevation in mountains.

In clinal variation, populations are not completely separated from one another, and individuals from adjacent populations do interbreed. However, reproduction between populations is not as common as reproduction between members of the same population. As a result, slight differences between adjacent populations are maintained.

Interestingly, in some clines members of the two extreme populations (the populations at the two ends of the cline) may not be able to interbreed and produce fertile offspring. They are still considered to be members of the same species because they exchange genes through the intermediate populations. The seaside goldenrod (*Solidago sempervirens*) illustrates this. It grows along the Atlantic coast of North America and displays a cline in flowering time. Canadian plants flower in August, plants in the middle Atlantic states flower in September and October, and those in Florida do so in November. These are genetically controlled flowering times, so even if grown together, the plants from Florida and Canada could not interbreed.

However, because Canadian plant flowering times overlap those in the northern United States (which overlap those in the central United States, which overlap those to their south, which overlap those in Florida), there is interbreeding between all adjacent populations and, indirectly, between the Canadian plants and the Florida plants. If the cline were to be subdivided into two or more species, where would the separations be drawn without separating interbreeding organisms into different species? The simplest solution is to consider all members of the cline to be members of the same species.

Local Clinal Variation

Great distances are not always required to establish clines. White clover (*Trifolium repens*), a European native which has been introduced all over the world, affords an example. Some white clover plants release cyanide when parts of the plant are eaten by grazers, such as snails and slugs. Others do not. The cyanide protects the plant from further grazing because it is toxic to the grazers. However, the cyanide-releasing form of clover suffers more frost damage than clover plants that do not release cyanide. Plants protect themselves from the cyanide by sequestering it into cellular compartments. Frost damage occurs when cyanide is released into the plant cells after those compartments are ruptured by ice crystals. Cyanide-storing plants also grow more slowly than forms that do not store cyanide, because some energy that could otherwise be used for growth is required to sequester the cyanide.

Latitudinal and elevational temperature gradients generate clines in the production of cyanide, with greater cyanide production at lower elevations and latitudes. More frequent freezing results in more frequent cyanide damage, and low temperatures result in less grazing, because grazers are not as active. Plants that do not go to the expense of storing cyanide are favored under those conditions. This is a classic geographic cline. However, changes in grazing pressure over much smaller distances also generate clines in cyanide storage. Grazing pressure changes over meters when white clover grows in a garden protected by pesticides and in an adjacent, unprotected field. The result is a cline in cyanide storage by white clover very similar to the geographic clines discussed above but on a scale of meters.

CLONING OF PLANTS

Categories: Biotechnology; economic botany and plant uses; genetics

Plant cloning is the production of a cell, cell component, or plant that is genetically identical to the unit or individual from which it was derived.

The term "clone" is derived from the Greek word *klon*, meaning a slip or twig. Hence, it is an appropriate choice. Plants have been "cloned" from stem cuttings or whole-plant divisions for many centuries, perhaps dating back as far as the beginnings of agriculture.

Historical Background

In 1838 German scientists Matthias Schleiden and Theodor Schwann presented their *cell theory*, which states, in part, that all life is composed of cells and that all cells arise from preexisting cells. This theory formed the basis for the concept of *totipotency*, which states that since cells must contain all of the genetic information necessary to create an entire, multicellular organism, all of the cells of a multicellular organism retain the potential to recreate, or regenerate, the entire organism. Thus was the basis for plant cell culture research.

The first attempt at culturing isolated plant tissues was by Austrian botanist Gottlieb Haberlandt at the beginning of the twentieth century, but it was unsuccessful. In 1939 Professor R. J. Gautheret and colleagues demonstrated the first successful culture of isolated plant tissues as a continuously dividing callus tissue. The term *callus* is defined as an unorganized mass of dividing cells, such as in a wound response. It was not until 1954, however, that the first whole plant was regenerated, or cloned, from a single adult plant cell by W. H. Muir et al. Thereafter, an increased understanding of plant physiology, especially the role of plant hormones in plant growth and development, contributed to rapid advances in plant cell and tissue culture technologies in the 1970's and 1980's. Many plant species have been successfully cloned from single cells, thus demonstrating and affirming the concept of totipotency.

Image Not Available

Horticulture

By far, the greatest impact of cloning plants *in vitro* (Latin for "in glass," meaning in the laboratory or outside the plant) has been on the horticultural industry. In the 1980's plant tissue culture technologies propagated and produced many millions of plants. Today, many economically important plants are commonly propagated via tissue culture techniques, including vegetable crops (such as the potato), fruit crops (strawberries and dates), floriculture species (orchids, lilies, roses, Boston ferns), and even woody species (pines and grapes).

The advantages of plant cell, tissue, and organ culture technologies include a more rapid production of plants, taking weeks instead of months or years. Much less space is required (square feet instead of field plots). Plants can be produced year-round, and economic, political, and environmental considerations that hamper the propagation of regional or endangered plant species can be reduced. The disadvantages include the high start-up costs for facilities, the skilled labor required, and the need to maintain sterile conditions.

Two other significant considerations must be considered as a result of plant propagation technologies. As illustrated by the Irish Potato Famine of the 1840's, the cultivation of whole fields of genetically identical plants (*monoculture*) leaves the entire crop vulnerable to pest and disease infestations. The second important consideration when generating entire populations of clones, especially using tissue culture technologies, is the potential for introducing genetic abnormalities, which then are present in the entire population of plants produced, a process termed *somaclonal variation*.

Biotechnology

An absolute requirement for genetic engineering of plants is the ability to regenerate an entire plant from a single, genetically transformed cell, thus emphasizing the second major impact of plant cell culture technologies. In 1994 the U.S. Food and Drug Administration (FDA) approved the first genetically modified whole food crop, Calgene's Flavr Savr tomato. This plant was produced using what is termed anti-sense technology. One of the tomato's genes involved in fruit ripening was reversed, thus inactivating it and allowing tomatoes produced from it to have significantly delayed ripening. Although no longer commercially marketed, the Flavr Savr demonstrated the impact of genetic engineering in moving modern agriculture from the Green Revolution into what has been termed the Gene Revolution.

Other examples of agricultural engineering exist today, such as Roundup Ready Soybeans, engineered to resist the herbicide used on weeds where soybeans are grown, and BT Corn, which contains a bacterial gene conveying increased pest resistance. Since 1987, the U.S. Department of Agriculture (USDA) has required field testing of genetically modified crops to demonstrate that their use will not be disruptive to the natural ecosystem. To date, thousands of field trials have been completed or are in progress for genetically modified versions of several crop species, including potatoes, cotton, alfalfa, canola, and cucumbers.

COAL

Category: Economic botany and plant uses

Coal is one of the world's most important natural resources based on plant life. Fuel in the form of coal can be any of a variety of combustible sedimentary and metamorphic rocks containing a specified amount of fossilized plant remains.

Coal is a general term encompassing a variety of combustible sedimentary and metamorphic rocks containing altered and fossilized terrestrial plant remains in excess of 50 percent by weight, and more than 70 percent by volume. Categories of coal differ in relative amounts of moisture, volatile matter, fixed carbon, and degree of compaction of the original carbonaceous material. Coal is therefore commonly termed a *fossil fuel*. This key resource is the product of the carbon from ancient plants that have undergone sedimentary and metamorphic transformation over millions of years.

Formation

After dead land-plant matter has accumulated and slowly begun to compact, biochemical decomposition, rising temperature, and rising pressure all contribute to the lengthy process of altering the plant debris into coal. The more common coals are of vascular vegetable origin, formed from the compaction and induration of accumulated remains of plants that once grew in extensive swamp and coastal marsh areas. These deposits are classed as *humic* coals consisting of organic matter that has passed through the *peat*, or earliest coal formation, stage. A variety of humic coals are known.

The swamp water environment within which humic coals form must be deficient in dissolved oxygen, the presence of which would ordinarily cause decay of the plant tissue. Under such near-stagnant conditions plant remains are preserved, while the presence of hydrogen sulfide inhibits organisms that feed on dead vegetation. Analog environments under which coal is currently forming are found within the Atchafalaya swamp of coastal Louisiana and the many peat-producing regions of Ireland. A layer of peat in excess of 2 meters in thickness and covering more than 5,000 square kilometers is present in the Great Dismal swamp of coastal North Carolina and Virginia.

The *sapropelic* class of coal, relatively uncommon in distribution and composed of fossil algae and spores, is formed through partial decomposition of organic matter by organisms within oxygen-deficient lakes and ponds. Sapropelic coals are subdivided into boghead (algae origin) and cannel (spore origin) deposits.

The vegetable origin of coal has been accepted since 1825 and is convincingly evidenced by the identification of more than three thousand freshwater plant species in coal beds of Carboniferous (360 million to 286 million years ago) age. The common association of root structures and even upright stumps with layers of coal indicate that the parent plant material grew and accumulated in place.

Detailed geologic studies of rock sequences that lie immediately above and below coal deposits indicate that most coals were formed in coastal regions affected by long-term sea level cycles characterized by transgressing (advancing) and regressing (retreating) shorelines. Such a sequence of rock deposited during a single advance and retreat of the shoreline, termed a cyclothem, typically contains nonmarine strata separated from overlying marine strata by a single layer of coal. In sections of the Interior coal province, a minimum of fifty cyclothems have been recognized, some of which can be traced across thousands of square kilometers. Such repetition in a rock sequence is most advantageous to the economics of a coal region, creating a situation in which a vertical mine shaft could penetrate scores of layers of coal.

The formation of coal is a long-term geologic process. Coal cannot therefore be considered a renewable resource, even though it is formed from plant matter. Studies have suggested that 1 meter of low-rank coal requires approximately ten thousand years of plant growth, accumulation, biologic reduction, and compaction to develop. Using these time lines, the 3-meter-thick Pittsburgh coal bed, underlying 39,000 square kilometers of Pennsylvania, developed over a period of thirty thousand years, while the 26-meter-thick bed of coal found at Adaville, Wyoming, required approximately a quarter of a million years to develop.

Coal formation favors sites where plant growth is abundant and conditions for organic preservation are favorable. Such climates range from subtropical to cold, with the ideal being classed as temperate. Tropical swamps produce an abundance of plant matter but have very high bacterial activity, resulting in low production of peat. Modern peats are developing in temperate to cold climate regions, such as Canada and Ireland, where abundant precipitation ensures fast plant growth, while relatively low temperatures diminish the effectiveness of decay-promoting bacteria.

The first coal provinces began to form with the evolution of cellulose-rich land plants. One of the earliest known coal deposits, of Upper Devonian age (approximately 365 million years ago), is found on Buren Island, Norway. Between the Devonian period and today, every geologic period is represented by at least some coal somewhere in the world. Certain periods of time, however, are significant coal-forming ages.

During the Carboniferous and Permian periods (360 to 245 million years ago) widespread development of fern and scale tree growth set the stage for the formation of the Appalachian coal province and the coal districts of Great Britain, Russia, and Manchuria. Coal volumes formed during these periods of geologic time constitute approximately 65 percent of present world reserves. The remaining reserves, developed mainly over the past 200 million years, formed in swamps consisting of *angiosperms* (flowering plants). The reserves of the Rocky Mountain province and those of central Europe are representative of these younger coals.

Classification of Coal

With the advent of the Industrial Revolution there was a need for a system of classification defining in detail the various types of coals. Up to the beginning of the nineteenth century, coal was divided into three rudimentary classes, determined by appearance: bright coal, black coal, and brown coal. Through the decades other schemes involving various parameters were introduced.

In 1937 a classification of coal rank using fixed carbon and Btu content was adopted by the American Standards Association. Adaptations of this scheme are still in use, listing the steps of progressive increase in coal rank as lignite (brown coal), subbituminous, bituminous (soft coal), subanthracite, and anthracite (hard coal). Some classification schemes also list peat as the lowest rank of coal. Technically speaking, peat is not a coal; rather, it is a fuel and a precursor to coal.

Coalification is the geologic process whereby plant material is altered into differing ranks of coal by geochemical and diagenetic change. With an increase in rank, chemical changes involve an increase in carbon content accompanied by a decrease in hydrogen and oxygen. Correspondingly, *diagenesis* involves an increase in density and calorific value and a progressive decrease in moisture. At all ranks, impurities include sulfur, silt and clay particles, and silica.

Peat, an unconsolidated accumulation of partly decomposed plant material, has an approximate carbon content of 20 percent. In many classification schemes, peat is listed as the initial stage of coal formation. Moisture content is quite high, at least at the 75-percent level. When dry, peat has an oxygen content of about 30 percent, is flammable, and will freely but inefficiently burn slowly and steadily for months at a low heat-content value of 5,400 Btu's per pound. (The British thermal unit, or Btu, is the

Image Not Available

quantity of heat required to raise the temperature of one pound of water one degree Fahrenheit.)

Types of Coal

Lignite, or brown coal, is brownish-black in color, banded and jointed, and subject to spontaneous combustion. Carbon content ranges from 25 to 35 percent. With a moisture content around 40 percent, it will readily disintegrate after drying in the open air. Because lignite has a maximum calorific value of 8,300 Btu's, it is classed as a low heating-value coal.

Deeper burial with even higher temperatures and pressures gradually alters lignite to *bituminous coal*, a dense, dusty, brittle, well-jointed, dark brown to black fuel that burns readily with a smoky yellow flame. It is the most abundant form of coal in the United States. Calorific value ranges from 10,500 to 15,500 Btu's per pound, and carbon content varies from 45 to 86 percent. Moisture content is as low as 5 percent, but heating value is high.

The *subbituminous* class of coal is intermediate between lignite and bituminous and has characteristics of both. Little woody matter is visible. It splits parallel to bedding but generally lacks the jointing of bituminous coal. It burns clean but with a relatively low heating value.

Anthracite is jet-black in color, has a high luster, is very hard and dust-free, and breaks with a conchoidal fracture. Carbon content ranges from 86 to 98 percent. It is slow to ignite, burns with a short blue flame without smoke, and, with a calorific value in excess of 14,000 Btu's per pound, is a high heating fuel. U.S. reserves are found mainly in eleven northeastern counties in Pennsylvania. Subanthracite coal has characteristics intermediate between bituminous and anthracite.

Bedded and compacted coal layers are geologically considered to be rocks. Lignite and bituminous ranks are classed as organic sedimentary rocks. Anthracite, formed when bituminous beds of coal are subjected to the folding and regional deformation affiliated with mountain building processes, is listed as a metamorphic rock. Because peat is not consolidated or compacted, it is classed as an organic sediment. *Graphite*, a naturally occurring crystalline form of almost pure carbon, is occasionally associated with anthracite. While it can occur as the result of high-temperature alteration of anthracite, its chemical purity and common association with crystalline rock causes it to be listed as a mineral.

Worldwide Distribution

While coal has been found all over the world, principal mining activity and approximately 95 percent of world reserves lie in the Northern Hemisphere—in Asia, Europe, and North America.

It is estimated that total world coal resources, defined as coal reserves plus other deposits that are not economically recoverable plus inferred future discoveries, are on the order of 10 trillion tons. Of this amount, estimates of world coal reserves, defined as those deposits that have been measured, evaluated, and can be extracted profitably under existing technology and economic conditions, range up to a high of approximately one trillion tons. World reserves can be divided into two categories, with 73 percent composed of anthracite and bituminous coals and 27 percent composed of lignite. Among nations, the United States possesses the greatest amount (approximately 500 billion tons) of total world reserves.

Modern Use

Historically, coal has been industry's fuel of choice. Countries with large coal reserves have risen commercially, while those less endowed with this resource—or lacking it altogether—have turned to agriculture or stagnated in development. Different ranks of coal are employed for different purposes. In the middle of the twentieth century it was common to see separate listings of coking, gas, steam, fuel, and domestic coals. Each had its specific uses. Coal for home use could not yield excessive smoke, while coal for locomotives had to raise steam quickly and not produce too high an ash content. Immediately after World War II fuel coal use, representing 78 percent of annual production, was divided into steam raising, railway transportation, domestic consumption, electric generation, and bunker coal. The remaining 22 percent was employed in the production of pig iron, steel, and gas.

Fifty years later, more than 80 percent of the approximately 1 billion tons of coal produced annually in the United States was used to generate electricity. Industrial consumption of coal, particularly in the production of coke for the steel and iron manufacturing industry, is the second most important use. Other industrial uses of coal are food processing and the manufacture of paper, glass, cement, and stone. Coal produces more energy than any other known fuel, including natural gas, crude oil, nuclear, and renewable fuels.

While expensive to produce, the conversion of intermediate ranks of coal into liquid (coal oil) and gaseous (coal gas) forms of hydrocarbon fuels will become more economically viable, especially during times of increase in the value of crude oil and natural gas reserves. New uses of coal are constantly being explored and tested. Two promising techniques are the mixing of water with powdered coal to make a slurry which can be burned as a liquid fuel and the underground extraction of coal-bed methane (firedamp). Interest in the latter by-product as an accessible and clean-burning fuel is especially high in Appalachian province localities distant from conventional gas resources.

Coal Mining

Coal has been produced by two common methods: underground (deep mining) and surface (strip mining). Underground mining requires digging extensive systems of tunnels and passages within and along the coal layers. These openings are connected to the surface so the coal can be removed. Prior to the development of the gigantic machinery used in open-pit mining, deep mining was the industry norm. This early period was characterized by labor-intensive pick and shovel work in cramped mine passages. Constant dangers to miners included the collapse of ceilings, methane gas explosions, and pneumoconiosis, known as black lung disease.

Today augers and drilling machinery supplement human labor to a large extent. Mine safety and health regulations have greatly reduced a once-high annual death toll. The common method of underground extraction involves initial removal of about 50 percent of the coal, leaving a series of pillars to support the mine roof. As reserves are exhausted, the mine is gradually abandoned after removal of the pillars. Another modern underground mining technique, with a coal removal rate approaching 100 percent, involves the use of an integrated rotary cutting machine and conveyer belt.

Surface mining of coal, accounting for about 61 percent of U.S. production, is a multiple-step process. First the overburden material is removed, allowing exposure of the coal. Coal is then mined using surface machinery ranging from bulldozers to gigantic power shovels. Finally, after removal of all the coal, the overburden is used to fill in the excavated trench, and the area is restored to its natural topography and vegetation. Economics usually determine whether underground or open-pit techniques are preferable in a given situation. Generally, if the ratio of overburden to coal thickness does not exceed twenty to one, surface mining is more profitable.

With increased concern for the environment, and with federal passage of the Coal Mine Health and Safety Act (1969) and the Clean Air Act (1970), the mining of coal in the United States has undergone both geographic and extraction-technology changes. Because the Rocky Mountain province coals, while lower grade than eastern coals, contain lower percentages of sulfur, the center of U.S. production has gradually shifted westward. The burning of high-sulfur coals releases sulfur dioxide into the atmosphere; it is a significant contributor to acid rain.

Western coals are often contained within layers thicker than those found in the East, are shallow in depth, and can be found under large areas—all conditions amenable to surface mining. As a result, the state of Wyoming, with a 1995 production of 265 million tons of low-sulfur coal, became the leading U.S. coal producer. The 1979 version of the U.S. Department of Energy's annual report on the database of minable coal reserves, titled "Demonstrated Reserve Base of Coal in the United States on January 1, 1979," listed reserves at 475 billion tons. At current levels of production it is estimated that the United States has more than 250 years of future production.

COEVOLUTION

Categories: Ecology; ecosystems; evolution

Coevolution is the interactive evolution of two or more species that results in a mutualistic or antagonistic relationship.

When two or more different species evolve in a way that affects one another's evolution, coevolution is taking place. This interactive type of evolution is characterized by the fact that the participant life-forms are acting as a strong selective pressure upon one another over a period of time. The coevolution of plants and animals, whether animals are considered strictly in their plant-eating role or also as pollinators, is abundantly represented in every terrestrial ecosystem throughout the world where flora has established itself. Moreover, the overall history of some of the multitude of present and past plant and animal relationships is displayed (although fragmentally) in the fossil record found in the earth's crust.

Beginnings

The most common coevolutionary relationships between plants and animals surround plants as a food source. Microscopic, unicellular plants were the earth's first *autotrophs* (organisms that can produce their own organic energy through photosynthesis, that is, from basic chemical ingredients derived from the environment). In conjunction with the appearance of autotrophs, microscopic, unicellular *heterotrophs* (organisms, such as animals, that must derive food from other sources, such as autotrophs) evolved to exploit the autotrophs.

Sometime during the later part of the Mesozoic era, angiosperms, the flowering plants, evolved and replaced most of the previously dominant land plants, such as the gymnosperms and the ferns. New species of herbivores evolved to exploit these new food sources. At some point, probably during the Cretaceous period of the late Mesozoic era, animals became unintentional aids in the angiosperm pollination process. As this coevolution proceeded, the first animal pollinators became more and more indispensable as partners to the plants.

Eventually, highly coevolved plants and animals developed relationships of extreme interdependence, exemplified by the honeybees and their coevolved flowers. This angiosperm-insect relationship is thought to have arisen in the Mesozoic era by way of beetle predation, possibly on early, magnolia-like angiosperms. The fossil record gives some support to this theory. Whatever the exact route along which plant-animal pollination partnerships coevolved, the end result was a number of plant and animal species that gained mutual benefit from the new type of relationship.

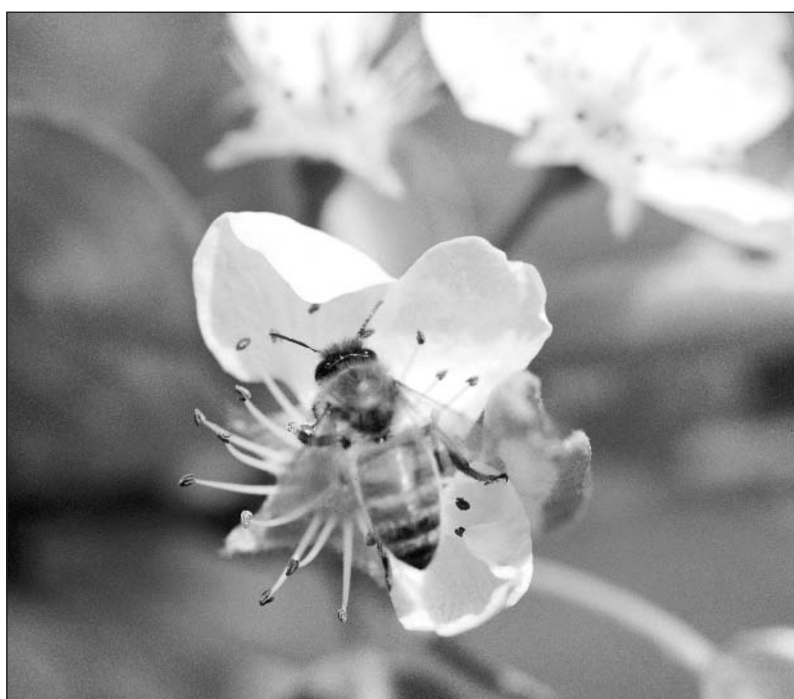
Coevolutionary Relationships

Coevolved relationships include an immense number of relationships between plants and animals, and even between plants and other plants. Among these coevolved situations can be found *commensalisms*, in which different species have coevolved to live intimately with one another without injury to any participant, and *symbioses*, in which species have coevolved to literally "live together."

Such intertwined relationships can take the form of *mutualism*, in which neither partner is harmed and indeed one or both benefit—as in the relationships between fungi and algae in lichens, fungi and roots in mycorrhizae, and ants and acacia trees in a symbiotic mutualism in which the ants protect the acacias from herbivores. In *parasitism*, one partner benefits at the expense of the other; a classic example is the relationship between the mistletoe parasite and the oak tree. Another coevolutionary relationship, *predation*, is restricted primarily to animal-animal relationships (vertebrate carnivores eating other animals, most obviously), although some plants, such as Venus's flytrap, mimic predation in having evolved means of trapping and ingesting insects as a source of food. Some highly evolved fungi, such as the oyster mushroom, have evolved anesthetizing compounds and other means of trapping protozoa, nematodes, and other small animals.

One of the most obvious and complex coevolutionary relationships are the mutualisms that have evolved between plants bearing fleshy fruits and vertebrate animals, which serve to disperse the seeds in these fruits. Over time, plants that produce these fruits have benefited from natural selection because their seeds have enjoyed a high degree of survival and germination: Animals eat the fruits, whose seeds are passed through their digestive system (or regurgitated to feed offspring) unharmed; at times the seeds are even encouraged toward germination as digestion helps break down the seed coat. Furthermore, dispersal through the animals' mobility allows the seeds to enjoy more widely distributed propagation. The coevolutionary process works on the animals as well: Birds and animals that eat the fruits enjoy a higher degree of survival, and so natural selection favors both fleshy-fruit-producing plants and fleshy-fruit-eating animals. Similar selection has favored the coevolution of flowers with colors and smells that attract pollinators such as bees.

Eventually some plant-animal mutualisms became so intertwined that one or both participants reached a point at which they could not exist without the aid of the other. These obligatory mutualisms ultimately involve other types of animal partners besides insects. Vertebrate partners such as birds, reptiles, and mammals became involved in mutualisms with plants. In the southwestern United States, for example, bats and the agave and saguaro cactus have a special coevolutionary relationship: The bats, nectar drinkers and pollen eaters, have evolved specialized feeding structures such as erectile tongues similar to those found among moths and other insects with similar lifestyles. In turn, angiosperms coevolutionarily involved with bats have developed such specializations as bat-attractive scents, flower structures that match the bats' feeding habits and minimize the chance of injuring the animals, and petal openings timed to the nocturnal activity of bats.



PhotoDisc

As coevolution proceeded over time, animal pollinators and highly coevolved plants developed relationships of extreme interdependence, exemplified by the honeybees and their coevolved flowers.

Defense Mechanisms

Coevolution is manifested in defense mechanisms as well as attractants: Botanical structures and chemicals (*secondary metabolites*) have evolved to discourage or to prevent the attention of plant eaters. These include the development of spines, barbs, thorns, bristles, and hooks on plant leaves, stems, and trunk surfaces. Cacti, hollies, and rose bushes illustrate this form of plant strategy. Some plants produce chemical compounds that are bitter to the taste or poisonous. Plants that contain organic tannins, such as trees and shrubs, can partially inactivate animals' digestive juices and create cumulative toxic effects that have been correlated with cancer. Grasses with a high silica content act to wear down the teeth of plant eaters. Animals have counteradapted to these defensive innovations by evolving a higher degree of resistance to plant toxins or by developing more efficient and tougher teeth with features such as harder enamel surfaces or the capacity of grinding with batteries of teeth.

updated by Christina J. Moose

Ants and Acacias

One noted example of mutualism can be found in Mexico and Central America, home to the bull's-horn acacia (*Acacia cornigera*). In its native habitat, colonies of stinging ants (*Pseudomyrmex ferruginea*) live inside the acacia's hollow thorns, found at the base of each leaf. There, the ants enjoy plentiful food, such as the tree's carbohydrate-rich nectar and protein-lipid Beltian bodies, nutritive structures located at the tip of each leaflet. The only known function of the Beltian bodies is to provide food for the symbiotic ants, which make their nests only in this species of tree and are utterly dependent on its food sources.

The acacia benefits from this arrangement as well. When an animal of any size brushes against the tree, worker ants swarm out and sting the animal, thus protecting the plant from herbivory. When epiphytic vines or the branches of another plant touch an inhabited acacia tree, the ants cut away the other plant's bark. By doing so, they destroy the invasive plant branch and allow more sunlight to reach the acacia—a crucial factor for plants in densely growing areas of the tropics. Scientists have found that acacias inhabited by ants grow more rapidly than uninhabited acacias, making ants and acacias mutual beneficiaries.

Bakker, Robert T. *The Dinosaur Heresies*. Reprint. Secaucus, N.J.: Citadel, 2001. Although the emphasis of the book is on dinosaur evolution, chapter 9, "When Dinosaurs Invented Flowers," discusses coevolved morphologies and strategies among angiosperm plants and extinct reptiles. A wonderful, thought-provoking book for all reading audiences. Illustrated.

Barth, Friedrich G. *Insects and Flowers: The Biology of a Partnership*. Translated by M. A. Biederman-Thorson. Princeton, N.J.: Princeton University Press, 1991. A delightful study of the coevolution of insects and flowers, highlighting both the complex sensory world of insects and the sometimes bizarre ways in which angiosperms have evolved to take advantage of insect senses in order to assure their own pollination.

Gilbert, Lawrence E., and Peter H. Raven, eds. *Coevolution of Animals and Plants*. Austin: University of Texas Press, 1980. A collection of scientific papers on the subject of evolved plant and animal relationships. The majority of the papers involve analyses of plant and animal biochemical relationships and mechanisms or ecological processes and patterns. Written for professionals in the field, though understandable by the general reader.

Gould, Stephen Jay. *The Panda's Thumb*. Reprint. New York: W. W. Norton, 1992. Chapter 27, "Nature's Odd Couples," focuses on a conspicuous example of a possible coevolution—an inferred mutualistic relationship between the extinct dodo bird and a large tree (*Calvaria major*) that is found on the island of Mauritius. Gould presents the evidence objectively, both for and against the dodo's possible role in facilitating the tree's germination.

Grant, Susan. *Beauty and the Beast: The Coevolution of Plants and Animals*. New York: Charles Scribner's Sons, 1984. This is one of the best books devoted solely to the subject of coevolution written for a general audience. Each of the ten chapters is devoted to a major subtopic within the phenomenon of coevolution, such as specific animal and plant symbioses or antagonisms.

Hughes, Norman F. *Paleobiology of Angiosperm Origins*. Reprint. New York: Cambridge University Press, 1994. The chapter on Cretaceous land fauna sketches out much of what is known about the earliest coevolved relationships between animals and the flowering plants (angiosperms) during the late Mesozoic period. Appropriate for readers who have some familiarity with botany, entomology, and evolutionary theory.

Thompson, John N. *The Coevolutionary Process*. Chicago: University of Chicago Press, 1994. Thompson advances a new conceptual approach to the evolution of species interactions, the geographic mosaic theory of coevolution. Thompson demonstrates how an integrated study of life histories, genetics, and the geographic structure of populations yields a broader understanding of coevolution.

COMMUNITY-ECOSYSTEM INTERACTIONS

Categories: Animal-plant interactions; ecology; ecosystems

Ecosystems are complex organizations of living and nonliving components. They are frequently named for their dominant biotic or physical features (such as marine kelp beds or coniferous forests). Communities are groups of species usually classified according to their most prominent members (such as grassland communities or shrub communities). The interactions between species and their ecosystems have lasting impacts on both.

In an ecological sense, a community consists of all populations residing in a particular area. Examples of communities range in scale from all the trees in a given watershed, all soil microbes on an agricultural plot, or all phytoplankton in a particular harbor to all plants, animals, and microbes in vast areas, such as the Amazon basin or the Chesapeake Bay.

An ecosystem consists of the community of species as well as the environment of a given site. A forest ecosystem would include all living things along with climate, soils, disturbance, and other abiotic factors. An estuarine ecosystem, likewise, would include all the living things present, in addition to climate, currents, salinity, nutrients, and more.

Interactions between species in communities and ecosystems range from mutually beneficial to mutually harmful. One such category of interaction is *mutualism*, which usually involves two species. Both species derive benefit from a mutualism. *Commensalism* is used to describe a situation in which one species benefits without harming the other. If the two species are neither helped nor harmed, a *neutralism* is said to occur, and an *amensalism* happens when one species is harmed while the other remains. During *competition*, both species involved are negatively affected. A number of terms are used to describe a relationship in which one species benefits at another's expense, including herbivory, predation, parasitism, and pathogenicity. The choice of term more often than not depends on the relative sizes of the species involved.

Competition

Plants typically compete for resources, such as light, space, nutrients, or water. One way an individual may outcompete its neighbors is to outgrow them, thus capturing more sunlight for itself (and thus producing more sugars and other organic molecules for itself). Another way is to be more fecund than the neighbors, flooding the surroundings with one's progeny and thereby being more likely to occupy favorable sites for reproduction. For example, in closed forests treefall gaps are quickly filled with growth from the canopy, thus shading the ground and making it more difficult for competing seedlings and saplings to survive.

Plants compete in the root zone as well, as plants with a more extensive root network can acquire more of the water and other inorganic nutrients necessary for growth and reproduction than can their competitors. In semiarid areas, for example, trees often have trouble colonizing grasslands because the extensive root systems of grasses are much more effective in capturing available rainwater.

Sometimes plants resort to chemical "warfare," known as *allelopathy*, in order to inhibit the growth of competitors in the surrounding area. The existence of allelopathy remains a controversial topic, and simpler explanations have been offered for many previously alleged instances of the phenomenon. Allelopathy cannot be rejected outright; however, the controversy most likely proves only that many aspects of nature cannot be pigeonholed into narrow explanations.

Competition involves a cost in resources devoted to outgrowing or outreproducing the neighbors. Because of the cost, closely related, competing species will diverge in their ecological requirements. This principle is known as *competitive exclusion*.

Mutualism, Commensalism, and Parasitism

Many flowering plants could not exist without one of the most important mutualisms of all: *pollination*. In concept, pollination is simple: In exchange for carrying out the physical work of exchanging genetic material (in pollen form) between individual plants (thus enabling sexual reproduction), the carrier is rewarded with nutrients in the form of nectar or other materials. Many types of animals are involved in pollination: insects such as bees, flies, and beetles; birds, particularly the hummingbirds; and mammals such as bats.

Another highly important mutualism is that between plant roots and fungal hyphae, or *mycorrhizae*. Mycorrhizae protect plant roots from pathogenic fungi and bacteria; their most important role, however, is to enhance water and nutrient uptake by the plant. In fact, regeneration of some plants is impossible in the absence of appropriate mycorrhizae. Mycorrhizae benefit, in turn, by receiving nutrients and other materials synthesized by the host plant. There are two types of mycorrhizae: *ectomycorrhizae*, whose hyphae may fill the space between plant roots but do not penetrate the roots themselves; and *vesicular-arbuscular mycorrhizae*, whose hyphae penetrate and develop within root cells.

Few people can envision a swamp in the southeastern United States without thinking of bald cypress trees (*Taxodium distichum*) draped in ethereal nets of Spanish moss (*Tillandsia usneoides*), which is actually not a moss but a flowering plant in the monocot family *Bromeliaceae*. *Tillandsia* is an *epiphyte*, a plant that grows on the stems and branches of a tree. Epiphytism is one of the most common examples of a *commensalism*, in which one organism, for instance the epiphyte, benefits without any demonstrable cost to the other, in this case the host tree. Epiphytes are common in tropical rain forests and include orchids, bromeliads, cacti, and ferns. In temperate regions more primitive plants, such as lichens, are more likely to become epiphytes.

Not all epiphytes are commensal, however. In the tropics, strangler figs, such as *Ficus* or *Clusia*, begin life as epiphytes but send down roots that in time completely encircle and kill the host. Mistletoes, such as *Phoradendron* or *Arceuthobium*, may draw off the photosynthetic production of the host, thus severely depleting its resources.

Herbivory and Pathogenicity

Plants, because of their ability to harvest light energy from the sun to produce the organic nutrients and building blocks necessary for life, are the primary *producers* of most of the earth's ecosystems. Thus, they face an onslaught of macroscopic and microscopic *consumers*. If macroscopic, the consumers are generally regarded as *herbivores* (plant-eating animals); if microscopic, they are *pathogens*. Either way, herbivores and pathogens generally devour the tissues of the host.

Plants have evolved a number of defense mechanisms in response to pressure from herbivores and pathogens. Some responses may be mechanical. For example, trees on an African savanna may evolve greater height to escape grazing pressures from large herbivores, but some large herbivores, specifically giraffes, may evolve to grow to greater heights as well. Plants may encase themselves in nearly indestructible outer coatings or arm themselves with spines in order to discourage grazers.

Other responses may be chemical. Cellulose, one of the important chemical components of plant tissues such as wood, is virtually indigestible—unless the herbivore itself hosts a bacterial symbiont in its stomach that can manage the job of breaking down cellulose. Other chemicals, such as phenols and tannins—the class of compounds that gives tea its brown color—are likewise indigestible, thus discouraging feeding by insects. Plants produce a wide range of toxins, such as alkaloids, which poison or kill herbivores. A number of hallucinogenic drugs are made from plant alkaloids.

Phytoalexins are another group of defensive compounds produced by plants in response to bacterial and fungal pathogens. Substances present in the cell walls of bacteria and fungi are released via the action of plant enzymes and spread throughout the plant. The bacterial and fungal substances function as hormones to stimulate, or elicit, phytoalexin production. Hence, these substances are referred to as *elicitors*. The phytoalexins act as antibiotics, killing the infective agents. Tannins, phenols, and other compounds also serve to defend against pathogen attack.

COMMUNITY STRUCTURE AND STABILITY

Categories: Ecology; ecosystems

An ecological community is the assemblage of species found in a given time and place. The species composition of different ecosystems and the ways in which they maintain equilibrium and react to disturbances are manifestations of the community's stability.

The populations that form a community interact through the processes of *competition*, *predation*, *parasitism*, and *mutualism*. The structures of communities are determined, in part, by the nature and strength of these *biotic* factors. *Abiotic* factors (physical factors such as temperature, rainfall, and soil fertility) are the other set of important influences determining community structure. An ecological community together with its physical environment is called an *ecosystem*. No ecosystem can be properly understood without a careful study of the biotic and abiotic factors that shape it.

Energy Flow

The most common way to characterize a community functionally is by describing the flow of energy through it. Based on the dynamics of *energy flow*, organisms can be classified into three groups: those that obtain energy through *photosynthesis* (called *producers*), those that obtain energy by consuming other organisms (*consumers*), and those that decompose dead organisms (*decomposers*). The pathway through which energy travels from producer through one or more consumers and finally to decomposer is called a *food chain*. Each link in a food chain is called a *trophic level*. Interconnected food chains in a community constitute a *food web*.

Very few communities are so simple that they can be readily described by a food web. Most communities are compartmentalized: A given set of producers tends to be consumed by a limited number of consumers, which in turn are preyed upon by a smaller number of *predators*, and so on. Alternatively, consumers may obtain energy by specializing on one part of their prey (for example, some birds may eat only seeds of plants) but utilize a wide range of prey species. *Compartmentalization* is an important feature of community structure; it influences the formation, organization, and persistence of a community.

Dominant and Keystone Species

Some species, called *dominant species*, can exert powerful control over the abundance of other species because of the dominant species' large size, extended life span, or ability to monopolize energy or other resources. Communities are named according to their dominant species: for example, oak-hickory forest, redwood forest, sagebrush desert, and tall-grass prairie. Some species, called *keystone species*, have a disproportionately large effect on community structure. These interact with other members of the community in such a way that loss of the keystone species can lead to the loss of many other species. Keystone species may also be the dominate species, but they may also appear insignificant to the community until they are gone. For example, cordgrass (*Spartina*) is the dominant plant in many tidal estuaries, and it is also a keystone species because so many members of the community depend on it for food and shelter.

The species that make up a community are seldom distributed uniformly across the landscape; rather, some degree of patchiness is characteristic of virtually all species. There has been conflicting evidence as to the nature of this patchiness. Moving across an environmental gradient (for example, from wet to dry conditions or from low to high elevations), there is a corresponding change in species and community composition. Some studies have suggested that changes in species composition usually occur along relatively sharp boundaries and that these boundaries mark the borders between adjacent communities. Other studies have indicated that species tend to respond individually to environmental gradients and that community boundaries are not sharply defined; rather, most communities broadly intergrade into one another, forming what is often called an *ecotone*.

Degrees of Species Interaction

These conflicting results have fueled a continuing debate as to the underlying nature of communities. Some communities seem to behave in a coordinated manner. For example, if a prairie is consumed by fire, it regenerates in a predictable sequence, ultimately returning to the same structure and composition it had before the fire. This process, called *ecological succession*, is to be expected if the species in a community have evolved together with one another. In this case, the community is behaving like an organism, maintaining its structure and function in the face of environmental disturbances and fluctuations (as long as the disturbances and fluctuations are not too extreme). The existence of relatively sharp boundaries between adjacent communities supports this explanation of the nature of the community.

In other communities, it appears that the response to environmental fluctuation or disturbance is determined by the evolved adaptations of the species available. There is no coordinated community response but rather a coincidental assembly of community structure over time. Some sets of species interact together so strongly that they enter a community together, but there is no evidence of an evolved community tendency to resist or accommodate environmental change. In this case, the community is formed primarily of species that happen to share similar environmental requirements.

Competition and Predation

Disagreement as to the underlying nature of communities usually reflects disagreement about the relative importance of the underlying mechanisms that determine community structure. Interspecific competition has long been invoked as the primary agent structuring communities. Competition is certainly important in some communities, but there is insufficient evidence to indicate how widespread and important it is in determining community structure. Much of the difficulty occurs because ecologists must infer the existence of past competition from present patterns in communities. It appears that competition has been important in many vertebrate communities and in communities dominated by sessile organisms, such as plants. It does not appear to have been important in structuring communities of plant-eating insects. Furthermore, the effects of competition typically affect individuals that use identical resources, so that only a small percentage of species in a community may be experiencing significant competition at any time.

The effects of predation on community structure depend on the nature of the predation. *Keystone predators* usually exert their influence by preying on species that are competitively dominant, thus giving less competitive species a chance. Predators that do not specialize on one or a few species may also have a major effect on community structure, if they attack prey in proportion to their abundance. This frequency-dependent predation prevents any prey species from achieving dominance. If a predator is too efficient, it can drive its prey to extinction, which may cause a selective predator to become extinct as well. Predation appears to be most important in determining community structure in environments that are predictable or unchanging.

Disasters and Catastrophes

Chance events can also influence the structure of a community. No environment is completely uniform. Seasonal or longer-term environmental fluctuations affect community structure by limiting opportunities for colonization, by causing direct mortality, or by hindering or exacerbating the effects of competition and predation. Furthermore, all communities experience at least occasional disturbance: unpredictable, seemingly random environmental changes that may be quite severe.

It is useful in this regard to distinguish between regular disturbances and rarer, less frequent catastrophic events. For example, fire occurs so often in tall-grass prairies that most of the plant species have become fire-adapted—they have become efficient at acquiring nutrients left in the ash and at sprouting or germinating quickly after a fire. In contrast, the 1980 eruption of Mount St. Helens, a volcanic peak in Washington State, was so violent and so unexpected that no members of the nearby community were adequately adapted to such conditions.

Natural disturbances occur at a variety of scales. Small-scale disturbances may simply create small openings in a community. In forests, for example, wind, lightning, and fungi cause single mature trees to die and fall, creating gaps that are typically colonized by species requiring such openings. Large disturbances are qualitatively different from small disturbances in that large portions of a community may be destroyed, including some of the ability to recover from the disturbance. For example, following a large, intense forest fire, some tree species may not return for decades or centuries because their seeds were consumed by the fire, and colonizers must travel a long distance.

Early ecologists almost always saw disturbances as destructive and disruptive for communities. Under this assumption, most mathematical models portrayed communities as generally being in some stable state; if a disturbance occurred, the community inevitably returned to the same (or some alternative) equilibrium. It later became clear, however, that natural disturbance is a part of almost all natural communities. Ecologists now recognize that few communities exhibit an equilibrium; instead, communities are dynamic, always responding to the last disturbance.

Long-Term Community Dynamics

The evidence suggests that three conclusions can be drawn about the long-term dynamics of communities. First, it can no longer be assumed that all communities remain at equilibrium until changed by outside forces. Disturbances are so common, at so many different scales and frequencies, that the community must be viewed as an entity that is constantly changing as its constituent species readjust to disturbance and to one another.

Second, communities respond in different ways to disturbance. A community may exhibit *resistance*, not markedly changing when disturbance occurs, until it reaches a threshold and suddenly and rapidly shifts to a new state. Alternatively, a community may exhibit *resilience* by quickly returning to its former state after a disturbance. Resilience may occur over a wide range of conditions and scales of disturbance in a dynamically robust system. On the other hand, a community that exhibits resilience only within a narrow range of conditions is said to be dynamically fragile.

Finally, there is no simple way to predict the stability of a community. At the end of the 1970's, many ecologists predicted that complex communities would be more stable than simple communities. It appeared that stability was conferred by more intricate food webs, greater structural complexity, and greater species richness. On the basis of numerous field studies and theoretical models, many ecologists now conclude that no such relationship exists. Both very complex communities, such as tropical rain forests, and very simple communities, such as Arctic tundra, may be very fragile.

COMPETITION

Categories: Ecology; ecosystems; evolution

The struggle for food, space, and pollinators in order to survive can occur between individuals of different species (interspecific competition) or between individuals of the same species (intraspecific competition).

Competition is a major driving force in *evolution*, the process by which living organisms change over time, with better-adapted species surviving and less well-adapted species becoming extinct. Evolution begins with *mutation*, changes in the nucleotide sequence of a gene or genes, resulting in the production of slightly altered genes which encode slightly different proteins. These altered proteins are the expressed traits of an organism and may give the organism an advantage over its competitors. The organism outcompetes its rivals in the environment, and hence the environment favors

Some plant species, including peach trees, release chemicals into the soil that inhibit the growth of other plants that might otherwise compete with them.

the better-adapted, fitter organism, a process called *natural selection*. A mutation may help an organism in one environment but may hurt it in a different environment (for example, an albino squirrel may flourish in snowy regions but may not do as well in warm regions). Mutations are random events whose occurrence can be increased by chemicals called mutagens or by ionizing radiation such as ultraviolet light, X rays, and gamma radiation.

Species Interactions

Natural selection influences the distribution and abundance of organisms from place to place. The possible selection factors include physical factors (temperature and light, for example), chemical factors such as water and salt, and species interactions. According to ecologist Charles Krebs, species interactions include four principal types: *mutualism*, which is the living together of two species that benefit each other (for example, fungi and algae living together as lichens); *commensalism*, which is the living together of two species that results in a distinct benefit (or number of benefits) to one species while the other remains unhurt (for example, plants called *epiphytes* that grow on other plants); *predation*, which is the hunting, killing, and eating of one species by another (examples include insects eating plants or snails eating algae); and *competition*, which is defined as an active struggle for survival among all the species in a given environment.

Competition is related to the acquisition of various resources: food, space, and pollinators. Food is an obvious target of competition. All organisms must have energy in order to conduct the cellular chemical reactions (such as respiration) that keep them alive. Photoautotrophic organisms (plants, algae, cyanobacteria) obtain energy by converting sunlight, carbon dioxide, and water into organic molecules, a process called photosynthesis. Photoautotrophs, also called *primary producers*, compete for light and water. For example, oak and hickory trees in eastern North America grow taller than most pines, thereby shading smaller species and eventually dominating a forest. A few other autotrophs, such as chemoautotrophic bacteria, obtain their energy from inorganic chemical reactions rather than from sunlight.

All other organisms—animals, zooplankton, and fungi—are heterotrophs, also called *consumers*; they must consume other organisms to obtain energy. Heterotrophs include herbivores, carnivores, omnivores, and saprotrophs. Herbivores (plant eaters such as rabbits and cattle) derive their energy from eating plants. Carnivores (meat eaters such as cats and dogs) eat other heterotrophs in order to get their energy needs met. Omnivores (such as humans) eat plants and animals. Saprotrophs (such as fungi and bacteria) decompose dead organisms to meet their energy requirements. Life on earth functions by intricately complex food chains in which organisms consume other organisms in order to obtain energy. Ultimately, almost all energy in organisms comes from the sun.

Types of Competition

Intraspecific competition occurs among individual members of the same population, for example, when sprouts grow from seeds scattered closely together on the ground. Some seedlings will be able to grow faster than others and will inhibit the growth of less vigorous seedlings by overshadowing or overcrowding them.

Interspecific competition involves two or more different species trying to use the same resources. All green plants depend on photosynthesis to derive the energy and carbon they need. Different areas or communities favor different growth characteristics. For plants with high light requirements, a taller-growing plant (or one with more or broader leaves) will have a competitive advantage if its leaves receive more direct sunlight than competitors. If, on the other hand, the species cannot tolerate too much sun, a shorter-growing species that can benefit from sheltering shadows of larger plants nearby will have the competitive advantage over other shade-loving plants.

Competition in nature leads to certain species dominating an environment and evolving to adapt to it, while the outcompeted species move elsewhere or become extinct. Humans are able to utilize the results of competition among species for their own benefit. This principle is useful in agriculture. Certain plant species (such as sunflowers and peach trees) release chemicals into the soil that inhibit the growth of other plants that might otherwise compete with them. Plant competition can be used to fight the growth of weeds and is useful in understanding which plants are compatible.

Competition is also useful in medical microbiological research. Certain fungal species produce and secrete molecules called antibiotics, which kill bacteria. Antibiotics give these fungi an edge in their competition against bacteria. Laboratory production of these antibiotics can treat bacterial diseases in humans.

Barbour, Michael G., ed. *Terrestrial Plant Ecology*. 3d ed. Menlo Park, Calif.: Benjamin/Cummings, 1999. Covers the entire breadth of modern plant ecology, blending classic topics with the results of new research, using as little jargon as possible.

Hartl, Daniel L. *Principles of Population Genetics*. 3d ed. Sunderland, Mass.: Sinauer Associates, 1997. Hartl's work, aimed at graduate-level biologists, is a detailed mathematical approach to species interactions and evolution. Approaches the study of populations from a genetic and statistical viewpoint and provides numerous examples and references.

Keddy, Paul A. *Competition*. 2d ed. New York: Kluwer, 2000. A somewhat controversial yet wide-ranging study of competition in all the natural kingdoms, using many nontechnical examples easily understood by the layperson. Argues that the challenge in ecology is to determine when and where each kind of competition is important in natural systems, focusing on variants of competition such as intensity, asymmetry, and hierarchies.

Krebs, Charles J. *Ecology: The Experimental Analysis of Distribution and Abundance*. 5th ed. San Francisco: Benjamin Cummings, 2001. This advanced textbook is a wonderfully comprehensive survey of ecology. Numerous experiments are cited, with a thorough but understandable discussion of mathematical modeling in ecology. Includes many references.

Raven, Peter H., and George B. Johnson. *Biology*. 5th ed. Boston: WCB/McGraw-Hill, 1999. Beautifully illustrated, clearly written, well-diagramed introductory biology textbook for undergraduates. Chapter 23, "Population Dynamics," is a clear presentation of species interactions, such as competition, that contains numerous examples.

COMPLEMENTATION AND ALLELISM: THE CIS-TRANS TEST

Categories: Genetics; methods and techniques

The cis-trans test is a method of determining whether two mutations are in the same or different genes. Genes are normally found in sets of two copies. If one copy is mutated and the other gene makes a normal product that compensates, the mutation is said to be recessive. If both copies of the gene are mutated and no normal product is made, then the phenotype of the organism will be mutant.

The cis-trans test was developed by Seymour Benzer and his coworkers in the 1950's. They worked with a *bacteriophage* (a virus that attacks only bacteria) called T4, studying one T4 viral gene called *rII*. Mutants of *rII* could be easily identified by the size of the *plaques* they made. A plaque is a clear circle in a continuous lawn of bacteria growing on nutrient agar which results when viruses attack and destroy the bacteria in that area.

Complementation (cis-trans) tests between *mutations* in different bacteriophage, or phage, strains which produce mutant plaques can be performed using a procedure called a *spot test*. Phages of one mutant strain are added to bacterial cells, then spread out on a plate containing nutrients and a solidifying agent (usually agar). Later, a drop of fluid containing phages with a different mutant strain is spotted onto the solid surface. In the area of the drop, some bacterial cells will be attacked by phages of both types. If the mutations complement each other, a normal plaque will result in that area. After looking at hundreds of different mutations, all of which had the same *phenotype* (that is, the expression of the gene) of large plaques, scientists at Benzer's laboratory determined that the *rII* gene was actually made up of two functional groups (which they called cistrons) and that every mutant could be assigned to one or the other of these groups.

Genetic Basis

Genes are located on cellular structures called *chromosomes*. For many years, scientists thought that genes were lined up along the chromosomes like beads on a string, each bead representing a different gene, such as for seed shape in plants. If normal or *wild-type* alleles were represented by black beads, it was thought, a red or white or green bead would represent a changed, or *mutant*, allele. This analogy was popular for many years, and genes, like beads, were thought to be indivisible. The work of scientists in the 1940's and 1950's challenged this theory and led to its eventual demise. The cis-trans test was a key part of this work.

The basis of the cis-trans test is the functional role of the gene. It is now known that each gene is made up of a particular sequence of *nucleotides* in *deoxyribonucleic acid* (DNA), defining the nucleotide sequence of a strand of *ribonucleic acid* (RNA). This RNA may, in turn, be used to define the sequence of amino acids in a protein. A mutant allele is a stretch of DNA in which the nucleotide sequence has been altered, resulting in an altered RNA. The result may be an altered protein, or sometimes no protein at all.

In most higher organisms, chromosomes occur in pairs called homologs. Such pairing means every gene (except those on the sex chromosomes) is normally found in two copies. If one copy is mutated and the other gene makes a normal product that compensates, the mutation is said to be *recessive*. If both copies of the gene are mutated and no normal product is made, then the *phenotype* of the organism (that is, the expression of the gene) will be mutant.

Genetic Crosses

In the cis-trans test, genetic crosses are arranged to yield an organism in which two recessive mutant alleles to be tested are on opposite *homologs*. In other words, one chromosome of a pair will have one mutant allele, and the other chromosome will have the other mutant allele. The alleles are then said to be in a *trans configuration*. If the two alleles are mutations of the same gene, the phenotype of the organism will be a mutant one. If the alleles belong to separate genes, the organism will have a normal, or *wild-type*, phenotype. When alleles produce a normal phenotype, they are said to complement each other. If the mutant alleles are arranged in the *cis configuration*, so that both are on the same chromosome, the resulting phenotype will be normal, whether the alleles are in the same or different genes.

For example, harebells (*Campanula*) normally have blue flowers, the wild-type phenotype, but occasionally mutants have white flowers. If a cis-trans test is done with two white-flowered mutants, in some cases the resulting progeny have blue flowers. This shows that the mutations in these two mutants are in different genes and thus display complementation. It is known that the blue pigment is produced by a biochemical pathway with two steps involving two enzymes that modify a colorless molecule. In other cases when a cis-trans test is done, all the progeny are white-flowered. This occurs when both mutants have mutations in the same gene, knocking out the activity of one of the enzymes, and thus complementation does not occur.

Recombination

Before the structure of DNA was understood, the gene was also defined as the basic unit of *recombination*; recombination within a gene was not thought to occur. In the analogy of genes as beads on a string, recombination was thought to involve the breakage and reunion of the string at positions between beads, never within them. It is now known that, in the process of recombination, pieces of chromosomes break off and rejoin in new combinations, although the rules that this process follows are not fully understood.

Recombination is essential to the cis-trans test. Only through recombination can cis configurations be obtained. The frequency of the occurrence of recombination is related to the closeness of two points on a chromosome. If recombination is desired between two regions that are very close, the chance that crossing over will occur is very low. Recombination can even be used to map mutations within a gene (a process called *fine structure analysis*), but it is a very long process, requiring the analysis of an extremely large number of progeny because the distance separating mutations within a gene will be very small.

Using the cis-trans test and recombination together led to the discovery of a small group of mutations called *pseudoalleles*. When two pseudoalleles are examined using the cis-trans test, an organism in trans configuration will have a mutant phenotype, leading to the conclusion that the alleles belong to the same gene. When recombination is used to try to map these mutations, however, it turns out that they are in separate structural genes. Pseudoalleles, then, are found in separate structural genes that interact in some functions.

Several examples of interaction between pseudoalleles can be found in *Drosophila* (fruit flies). In one such example, the two genes postbithorax (*pbx*) and bithorax (*bx*) are both involved in determining the normal formation of the fly's balancing organs (halteres), a pair of winglike structures that help the fly in its flight. These genes are adjacent on the chromosome but are structurally distinct. The fact that the gene products must interact is revealed by the results of the cis-trans test; when mutants for these genes are placed in trans configuration, the phenotype of the fly is mutant.

This intermediate-level college text reviews the important concepts in genetics and presents the experimental work that led to the development of important theories. Chapter 12, "The Nature of the Gene," gives an in-depth analysis of Seymour Benzer's viral work. Chapter 15, "The Manipulation of DNA," also explains many of the important techniques of molecular genetics.

Weaver, R. F., and P. W. Hedrick. *Genetics*. 3d ed. New York: McGraw-Hill, 1996. Written for college audiences, the discussion is nevertheless readable by advanced high school students. Unlike many texts, it includes full-color photographs and diagrams. Chapter 13 discusses the cis-trans test using bacterial genes as an example. Seymour Benzer's work with *rII* is covered briefly in the same chapter. Recombination and potential mechanisms of how it works on the molecular level are clearly explained in chapter 7.

COMPOSITAE

Categories: Angiosperms; economic botany and plant uses; *Plantae*; taxonomic groups

In number of species, the family Compositae *or* Asteraceae*, commonly known as the sunflower family, is among the largest families of flowering plants.*

The *Compositae* family consists of more than eleven hundred genera worldwide and possibly as many as twenty-three thousand species. Representatives of the family are found on every continent except Antarctica. Species diversity is high in the southwestern United States and Mexico, in southern Brazil and along the South American Andes Mountain range, along the Mediterranean region, in Southwest and Central Asia, in South Africa, and in Australia.

The plants typically are found in open, sunny habitats, although some species are found in lightly forested areas and at the edges of woodlands. Examples of common genera found in North America are goldenrod (*Solidago*), sunflower (*Helianthus*), daisy (*Chrysanthemum*), *Aster*, and ironweed (*Vernonia*). The predominant life-forms within the family are perennial herbs and shrubs, but some species exist as annuals, vines, lianas (woody vines), and trees. Leaf arrangement is most commonly alternate, although some genera do exhibit opposite leaves. Despite this gross morphological diversity, the feature that unites all the members of the family is the unique form of the compound inflorescence, or flowering head.

Inflorescence

At first glance, the flowering head of many *Compositae*, such as that of the sunflower, resembles a single large flower with what appears to be a set of petals surrounding a cluster of anthers and stamens. Upon closer inspection, this compound inflorescence, or capitulum, is really a collection of highly reduced and modified flowers borne on a flowering stalk (peduncle). The expanded and flattened top of the peduncle is the receptacle and is surrounded by a series of leaflike structures termed bracts that collectively comprise the *involucre*.

Two types of reduced flowers can be present within a capitulum, either ray or disc flowers, or both. The ray flower superficially resembles a petal and occupies the outer circumference of the capitulum. It can be either pistillate or sterile. The corolla is fused at the base, gradually expanding in width and eventually tapering to a tip. At maturity the tip of the ray flower corolla is oriented away from the center of the capitulum. The inner disc flowers can be either perfect (all reproductive parts present) or functionally staminate and possessing a corolla tube consisting of fused petals. At maturity the anthers and the stigmas will protrude from the corolla tubes. At the base of the corolla tube is a set of modified sepals termed the *pappus*. The pappus can consist of fine hairs, scales, or bristles, or it may be absent in some species. The seed is an achene and upon maturity is wind-dispersed with the assistance of the pappus.

Digital Stock

Dahlia *is one of numerous genera of* Compositae *that are used as ornamental plants.*

Pollination Biology

A variety of mechanisms account for successful pollination in the *Compositae*, wind pollination being a very common mode. "Hay fever," which in humans is an allergic reaction to plant pollen and other allergens, is greatly exacerbated in the late summer and early fall by the wind-pollinated ragweed (*Ambrosia*). Although often falsely accused, the goldenrods (*Solidago*) are not a major cause of hay fever, as they are pollinated by insects, not wind. By far, the majority of the species in the family are pollinated by insects, which are often attracted to the inflorescences by brightly colored ray flowers. The insect-pollinated flowers are typically generalists, attracting a variety of insects rather than a specific insect species. In some tropical taxa, birds or other animals are largely responsible for pollen exchange.

Economic Uses

Genera that contain species used for human consumption include endive and chicory (*Cichorium*), artichoke (*Cynara*), sunflower seeds and oil (*Helianthus*), lettuce (*Lactuca*), and dandelion greens (*Taraxacum*). Pyrethrum is a naturally occurring pesticide obtained from tansy (*Tanacetum*). Numerous genera are used as ornamental plants, such as marigolds (*Calendula*), *Zinnia*, bandana daisy (*Gaillardia*), and *Dahlia*. A number of plants are used for medicinal purposes. Coneflower (*Echinacea*) and fireweed (*Liatris*) are often used as herbal teas. Extracts from species of the *Compositae* are available from many health food retailers and practitioners of folk medicine. A current focus of pharmacological research is in determining those plant compounds responsible for producing beneficial effects in humans. Some species, however, contain compounds that at sufficient levels are quite toxic to animals, such as humans and livestock.

Evolutionary Success

Current opinion is that the family probably originated in South America or in the Pacific region, perhaps as early as the Tertiary period.

Several reasons have been proposed for the biological success of the family. First, the pappus is a very efficient agent for wind-borne dispersal of mature seeds, serving as a lofting device (similar to a parachute) to carry the small seeds on air currents over great distances. Second, the agents of pollination are diverse, ranging from mechanical (wind) to biological (insect or bird). Third, many members of the family exhibit unique chemical compounds (such as sesquiterpene lactones and polyacetylenes) that may discourage large herbivores and insects from foraging on the leaves, thus allowing plants to mature and engage in reproduction. It is the successful production of viable offspring that constitutes the major measure of evolutionary success in the family.

COMPOSTING

Categories: Agriculture; gardening; soil

Compost is a mixture of organic ingredients used for fertilizing or enriching land. Composting is the practice of making and using compost.

Composting is a way for gardeners and farmers to enrich and otherwise improve the soil while reducing the flow of household waste to landfills. Essentially the slow, natural decay of dead plants and animals, composting is a natural form of recycling in which living organisms decompose organic matter.

The decay of dead plants and animals starts when microorganisms in soil feed on dead matter, breaking it down into smaller compounds usable by plants. Collectively, the breakdown product is called humus, a crumbly, dark brown, spongy substance. Adding humus to soil increases its fertility. Compost and composting derive from the Old French *composter*, “to manure” or “to dung.”

History

The origins of human composting activities are buried in prehistory. Early farmers discovered the benefits of compost, probably from animal manure deposited on or mixed with soil. In North America, American Indians and then Europeans used compost in their gardens. Public accounts of the use of stable manure in composting date back to the eighteenth century. Many New England farmers also found it economical to use fish in their compost heaps.

While living in India from 1905 to 1934, British agronomist Sir Albert Howard developed today's home composting methods. Howard found that the best compost pile consists of three parts plant matter to one part manure. He devised the Indore method of composting, alternating layers of plant debris, manure, and soil to create a pile. Later, during the composting process, he turned the pile or mixed in earthworms.

How Composting Works

Composting is a natural form of recycling that takes from six months to two years to complete. Bacteria are the most efficient *decomposers* of organic matter. Fungi and protozoans later join the process, followed by centipedes, millipedes, beetles, or earthworms. By manipulating the composition and environment of a compost pile, gardeners and farmers can reduce composting time to three to four months. Important factors to consider are the makeup of the pile, the surface area, the volume, the moisture, the aeration, and the temperature of the compost pile.

Yard waste, such as fallen leaves, grass clippings, some weeds, and the remains of garden plants, make excellent compost material. Other good additions to a home compost pile include sawdust, wood ash, and kitchen scraps, including vegetable peelings, egg shells, and coffee grounds. Microorganisms digest organic matter faster when they have more surface area on which to work, so gardeners can speed the composting process by chopping kitchen or garden waste with a shovel or running it through a shredding machine or lawn mower.

The volume of the compost pile is important because a large compost pile insulates itself, holding in the heat of microbial activity, which in turn accelerates decomposition. A properly made heap will reach temperatures of about 140 degrees Fahrenheit in four or five days. Then the pile will settle, a sign that the process is working properly. Piles 3 feet cubed (27 cubic feet) or smaller cannot hold enough heat, while piles 5 feet cubed (125 cubic feet) or larger do not allow enough air to reach the microbes in the center of the pile. These portions are important only if the goal is fast compost. Slower composting requires no exact proportions.

Moisture and air are essential for life. Microbes function best when the compost heap has many air passages and is about as moist as a wrung-out sponge. Microorganisms living in the compost pile use the carbon and nitrogen contained in dead matter for food and energy. While breaking down the carbon and nitrogen molecules in dead plants and animals, they also release nutrients that higher organisms, such as plants, can use.

The ratio of carbon to nitrogen found in kitchen and garden waste varies from 15 to 1 in food waste to 700 to 1 in wood. A carbon-to-nitrogen ratio of 30 to 1 is optimal for microbial decomposers. This balance can be achieved by mixing two parts grass clippings (carbon to nitrogen ratio 19:1) and one part fallen leaves (carbon to nitrogen ratio 60:1). This combination is the backbone of most home composting systems.

Uses and Practice

In the twenty-first century, composting remains an invaluable practice. In landfills, yard and kitchen wastes use up valuable space. These materials make up about 20 to 30 percent of all household waste in the United States. Composting household waste reduces the volume of municipal solid waste and provides a nutrient-rich soil additive. Compost or organic matter added to soil improves soil structure, texture, aeration, and water retention. It improves plant growth by loosening heavy clay soils, allowing better root penetration. It improves the water-holding and nutrient-holding capacity of sandy soils and increases the essential nutrients of all soils. Mixing compost with soil also contributes to erosion control and proper soil pH balance, the amount of acidity or alkalinity present.

Some municipalities collect and compost leaves and other garden waste and then make it available to city residents for little or no charge. Some cities also compost sewage sludge, or human waste, which is high in nitrogen and makes a rich fertilizer. Properly composted sewage sludge that reaches an internal temperature of 140 degrees Fahrenheit

Image Not Available

contains no dangerous disease-causing organisms. One possible hazard, however, is that it may contain high levels of toxic heavy metals, including zinc, copper, nickel, or cadmium.

The basic principles of composting used by home gardeners also are used by municipalities composting sewage sludge and garbage, by farmers composting animal and plant waste, and by some industries composting organic waste. Food and fiber industries, for example, compost waste products from canning, meat processing, and dairy and paper processing.

CONIFERS

Categories: Forests and forestry; gymnosperms; *Plantae*

The conifers, which are woody plants consisting mostly of evergreen trees, make up the phylum Coniferophyta, one of four phyla of gymnosperms that have living representatives. The word "conifer" means cone-bearing. Most conifers bear their reproductive structures in cones.

With 50 genera and 550 of the 700 known gymnosperm species, the phylum *Coniferophyta* includes the bulk of the *gymnosperms*. *Coniferophyta* is also the most widespread and, in terms of numbers of individual trees, the most abundant of the gymnosperm phyla. The abundance and economic and ecological importance of the *Coniferophyta* are out of all proportion to the number of species, which does not begin to compare to the 235,000 species of angiosperms (phylum *Anthophyta*).

Conifers grow over almost the entire world. They are especially abundant in northern temperate and boreal regions. They predominate in the taiga, or northern boreal forest, which covers immense stretches of northern North America and northern Eurasia. They dominate that forest by virtue of large numbers of individuals of only about a dozen species, mainly of spruce, fir, and larch. They show greater diversity in midlatitude, mountain forests of the Northern Hemisphere. Conifers also occur in cool mountain areas of the tropics. In temperate regions of the Southern Hemisphere, they are widespread but less dominant than in the north. Junipers and pines are the most wide-ranging conifers, occurring across the northern continents and into the tropics. In the Southern Hemisphere, the most widely distributed conifer genus is *Podocarpus*.

Due to their abundance and wide range, their typically arboreal habit, and their stem structure, conifers are the only gymnosperms that yield timber on a commercial scale. They are the source of all of the world's softwood timber and nearly half of its total annual lumber supply.

A Long Fossil Record

The oldest known conifer fossils date to the late Carboniferous period of the Paleozoic era, some 300 million years ago. The earliest known angiosperms are less than half this old. Conifers diver-

Conifer Leaves

Many conifers are characterized by drought-resistant, needlelike, scalelike, or comblike leaves covered in a waxy outer layer that assists in water retention during cold winters, when water uptake from the frozen soil is limited.

sified greatly during the Paleozoic's relatively dry, cold Permian period (290-245 million years ago), which followed the Carboniferous. The drought-resistant, needlelike leaves characteristic of many modern conifers may have evolved during that dry period.

The modern families of conifers began to differentiate in the Mesozoic era (245 million to 65 million years ago). Conifers were the dominant vegetation during much of that era. They gradually gave way to the angiosperms, which achieved worldwide dominance by about ninety million years ago, during the Cretaceous period of the Mesozoic, and remain dominant today. In the early Tertiary period of the Cenozoic era, which dawned about 66 million years ago, a diverse coniferous flora covered large areas of the Northern Hemisphere.

Classification of Conifers

Class *Pinopsida*
- Order *Pinales*
  - Family *Araucariaceae* (araucarias)
    - Genera: *Agathis*, *Araucaria*, *Wollemia*
  - Family *Cephalotaxaceae* (plum yews)
    - Genus: *Gephalotaxus*
  - Family *Cupressaceae* (cypresses)
    - Genera: *Actinostrobus*, *Austrocedrus*, *Callitris*, *Calocedrus*, *Chamaecyparis*, *Cupressus*, *Diselma*, *Fitzroya*, *Fokienia*, *Juniperus*, *Libocedrus*, *Microbiota*, *Neocallitropsis*, *Pilgerodendron*, *Tetrachnis*, *Thuja*, *Thujopsis*, *Widdringtonia*
  - Family *Pinaceae* (pines)
    - Genera: *Abies*, *Cathaya*, *Cedrus*, *Keteleeria*, *Larix*, *Nothotsuga*, *Picea*, *Pinus*, *Pseudolarix*, *Pseudotsuga*, *Tsuga*
  - Family *Phyllocladaceae*
    - Genus: *Phyllocladus*
  - Family *Podocarpaceae* (podocarps)
    - Genera: *Acmopyle*, *Afrocarpus*, *Dacrycarpus*, *Falcatifolium*, *Halocarpus*, *Lagarostrobos*, *Lepidothamnus*, *Microcachrys*, *Microstrobos*, *Nageia*, *Parasitaxus*, *Prumnopitys*, *Retrophyllum*, *Saxegothaea*, *Sundacarpus*
  - Family *Taxodiaceae* (redwoods)
    - Genera: *Athrotaxis*, *Cryptomeria*, *Cunninghamia*, *Glyptostrobus*, *Metasequoia*, *Sciadopitys*, *Sequoia*, *Sequoiadendron*, *Taiwania*, *Taxodium*
- Order *Taxales*
  - Family *Taxaceae* (yews)
    - Genera: *Amentotaxus*, *Austrotaxus*, *Pseudotaxus*, *Taxus*, *Torreya*

Source: Data are from U.S. Department of Agriculture, National Plant Data Center, *The PLANTS Database*, Version 3.1, http://plants.usda.gov. National Plant Data Center, Baton Rouge, LA 70874-4490 USA, and Southern Illinois University at Carbondale, College of Science, http://www.sciencie.siu.edu/landplants/Coniferophyta.

Vegetative Features

Conifers have certain notable vegetative characteristics. For example, many, though not all, of them have needlelike leaves, and such leaves occur only in conifers. Some conifers have scalelike leaves, and a few have bladelike ones.

The stems and roots of conifers are also noteworthy, resembling the woody eudicots and magnoliids of *Anthophyta* in producing a dense mass of *secondary xylem*—that is, wood.

Reproductive Characteristics

In conifers, the ovules, which contain the eggs and eventually ripen into seeds, are not enclosed in ovary tissues within flowers as they are in the angiosperms. Instead, like other gymnosperms, conifers have *naked ovules*. These ovules are borne on scales that are arranged spirally along the axes of cones. Due to a complex evolutionary history, the structure of these cones is compound rather than simple.

In addition to ovulate, or female, cones, conifers produce male cones, which are smaller, shorter-lived, and generally less woody. The axis of a male cone bears reduced leaves, each with two *pollen sacs* on the undersurface. The pollen grains formed within the sacs contain the immature sperm. In most conifers, cones of both genders are present on the same tree. Although gymnosperms other than conifers may produce cones, conifers are distinctive in combining simple pollen cones with compound ovulate cones. The yews (genus *Taxus*) bear their ovules singly, at the tips of branchlets, rather than in cones. The seeds that develop from these ovules are enclosed in a fleshy covering called an *aril*.

In the spring, the male cones of conifers release their pollen to the wind. Some of it reaches female cones, which have their cone scales widely separated to receive it. After pollination, the female cones close their scales. Fertilization usually occurs, within the ovule, about three days to three or four weeks after pollination. In the pines, however, it is delayed for about fifteen months.

In most conifers, the mature seeds, with their contained embryos, are dispersed in the autumn of the year in which fertilization occurs. The most common dispersal agent is the wind, aided in many species by wings on the seeds. Conifer seeds that lack wings generally depend on dispersal agents such as birds or mammals. In some pines, the cones need the heat of a forest fire to open the scales and release the seeds.

Pine Family

Of the families of living conifers, the *Pinaceae*, or pine family, is the largest, containing ten to twelve genera, with about two hundred species worldwide. Most of these are resin-bearing trees.

This family is the most widespread and abundant conifer family in the Northern Hemisphere and very important economically. It supplies a great deal of lumber, pulpwood, and paper products. It is also important ecologically, providing essential cover, nesting habitat, and food for many species of wildlife.

The pine family's range is mainly in Eurasia and North America. Genera that occur all across this expanse are *Pinus* (pines), *Picea* (spruces), *Abies* (firs), and *Larix* (larches). Douglas firs (*Pseudotsuga*) and hemlocks (*Tsuga*) are restricted to North America and Asia. The true cedars (*Cedrus*) occur only in warm-temperate regions of Eurasia and northern Africa. Three genera of the pine family are restricted to China.

Pinus, the oldest genus in the pine family, arose at least 130 million years ago, in the early Cretaceous period. It grows predominantly in the Northern Hemisphere. The pines number more than ninety species, nearly half the total species of the *Pinaceae*. One of the world's oldest known plants is the bristlecone pine (*Pinus longaeva*), which grows in Utah, Nevada, and a small area of western California. Some bristlecone pines are about forty-six hundred years old. In contrast to other conifers, pines produce their adult needles in *fascicles*, or bundles. The number of needles per fascicle depends on the species.

Other Conifer Families

According to a commonly used classification system, there are seven families of conifers in addition to the *Pinaceae*. A notable one is the *Taxodiaceae*, which is today represented by widely scattered species that are the remnants of populations that were much more widespread during the Tertiary period. Bald cypress belongs to the *Taxodiaceae*, as do two redwood species renowned for their size and longevity. The coast redwood (*Sequoia sempervirens*) grows along coastal California and Oregon, and the "big tree" (*Sequoiadendron giganteum*) occurs on the western slope of the Sierra Nevada mountains in California. The coast redwood is generally the taller of the two species, reaching up to 117 meters in height. The big tree, however, generally exceeds the coast redwood in total mass and can live to be several thousand years old.

Another notable member of the *Taxodiacae* is the dawn redwood (*Metasequoia glyptostroboides*). This species was first known to science only from fossils discovered in the early 1940's. Not long afterward, the tree was found growing in China. A more recent living-fossil find belongs to the *Araucariaceae*, a conifer family restricted to the Southern Hemisphere. This tree, the Wollemi pine (*Wollemia nobilis*), had been thought to have gone extinct fifty million years ago. Then, in 1994, a stand was found growing in Australia.

The *Cupressaceae*, or cypress family, includes *Chamaecyparis* (false cypress), *Juniperus* (junipers, often called "cedars" in North America), and *Thuja* (arbor-vitae). These plants are distributed throughout the world. Some are important as timber or ornamentals.

The *Taxaceae* family, which includes the yews, is widely distributed in the Northern Hemisphere. The *Podocarpaceae* is largely restricted to the Southern Hemisphere. The *Sciadopityaceae* and *Cephalotaxaceae* are confined to east Asia.

CORN

Categories: Agriculture; economic botany and plant uses; food

The most important cereal in the Western Hemisphere, corn is used as human food (ranking third in the world), as livestock feed, and for industrial purposes.

Corn (*Zea mays*) is a coarse, annual plant of the grass (*Gramineae*) family. It ranges in height from 3 to 15 feet and has a solid, jointed stalk, and long, narrow leaves. A stalk usually bears one to three cobs, which develop kernels of corn when fertilized. Corn no longer grows in the wild; it requires human help in removing and planting the kernels to ensure reproduction. In the United States and Canada, "corn" is the common name for this cereal, but in Europe, "corn" refers to any of the small-seeded cereals, such as barley, wheat, and rye. "Maize" (or its translation) is the term used for *Zea mays* in Europe and Latin America.

Explorer Christopher Columbus took corn back to Europe with him in 1493, and within one hundred years it had spread through Europe, Asia, and Africa. It is said that a corn crop is being harvested somewhere in the world each month. Corn grows as far north as Canada and Siberia (roughly 58 degrees north latitude) and as far south as Argentina and New Zealand (40 degrees south). Although adaptable to a wide range of conditions, corn does best with at least 20 inches of rainfall (corn is often irrigated in drier regions) and daytime temperatures between 70 and 80 degrees Fahrenheit (about 24 degrees Celsius). Much of the United States meets these criteria, hence its ranking as the top corn-producing country in the world.

Origins and Hybridization

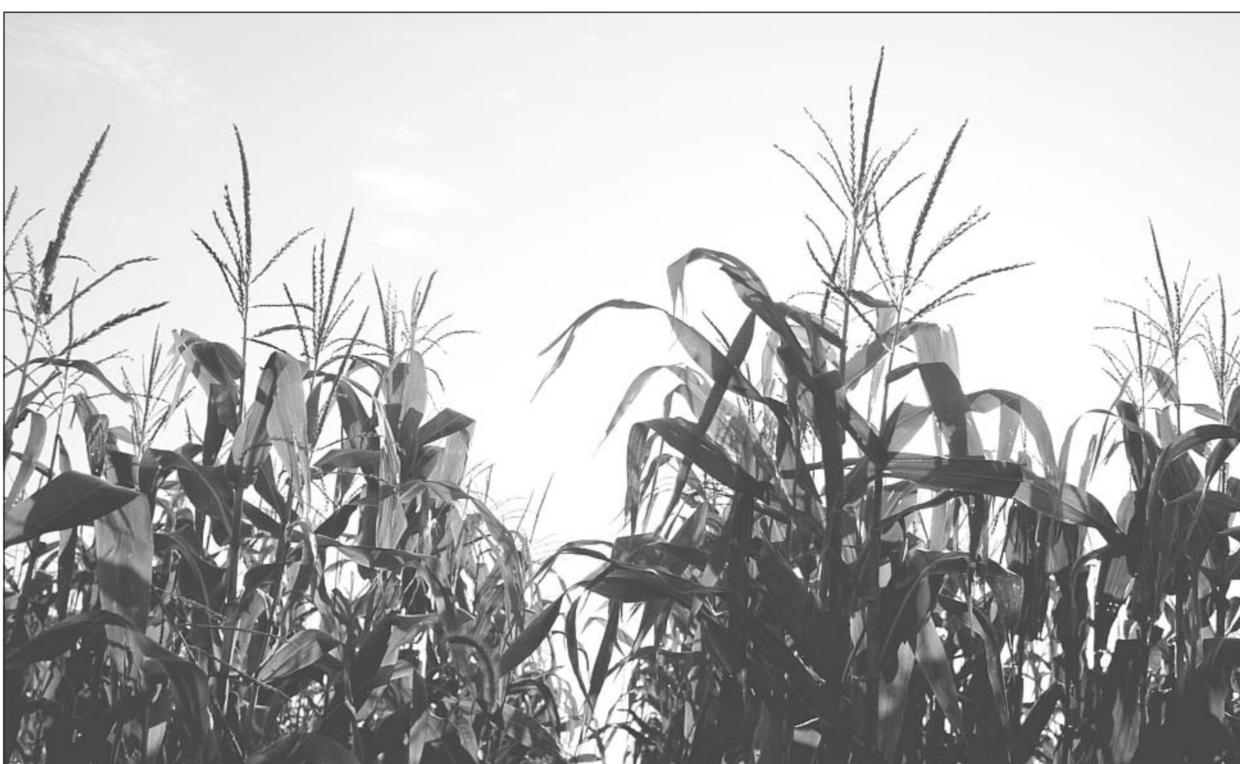
Corn's exact origins remain uncertain, but historical records show the gathering of wild corn, called *teosinte*, in ancient Mexico began around 7000 B.C.E. This corn evolved through unknown means to have tiny, eight-rowed "ears" of corn less than an inch long. Corncobs and plant fragments have been dated to 5200 B.C.E. (and up to a millennium earlier, according to some studies). By 3400 B.C.E., the fossil record shows a marked change in corn, notably increased cob and kernel size, indicating greater domestication. Fully domesticated corn (which could not survive without human help) had replaced the wild and other early types of corn by 700 C.E.

Extensive attempts at *hybridization* began in the late nineteenth century, but the increase in yield was usually a disappointing 10 percent or so. By 1920 researchers had turned to inbreeding hybridization programs. In these, corn is *self-fertilized*, rather than being allowed to *cross-pollinate* naturally. Following a complex sequence of crossing and testing different varieties, the lines with the most desirable traits were put into commercial use, and they often produced 25 to 30 percent gains in yield. Although these early hybrids focused on increasing the yield, researchers later began to look for insect-resistant and disease-resistant qualities as well. One of the hybridizers of the 1920's was Henry A. Wallace, founder of Pioneer Seed Company (the world's largest seed company) and later U.S. vice president under Franklin D. Roosevelt. By the 1950's hybrid corn varieties were in widespread use.

Types and Uses

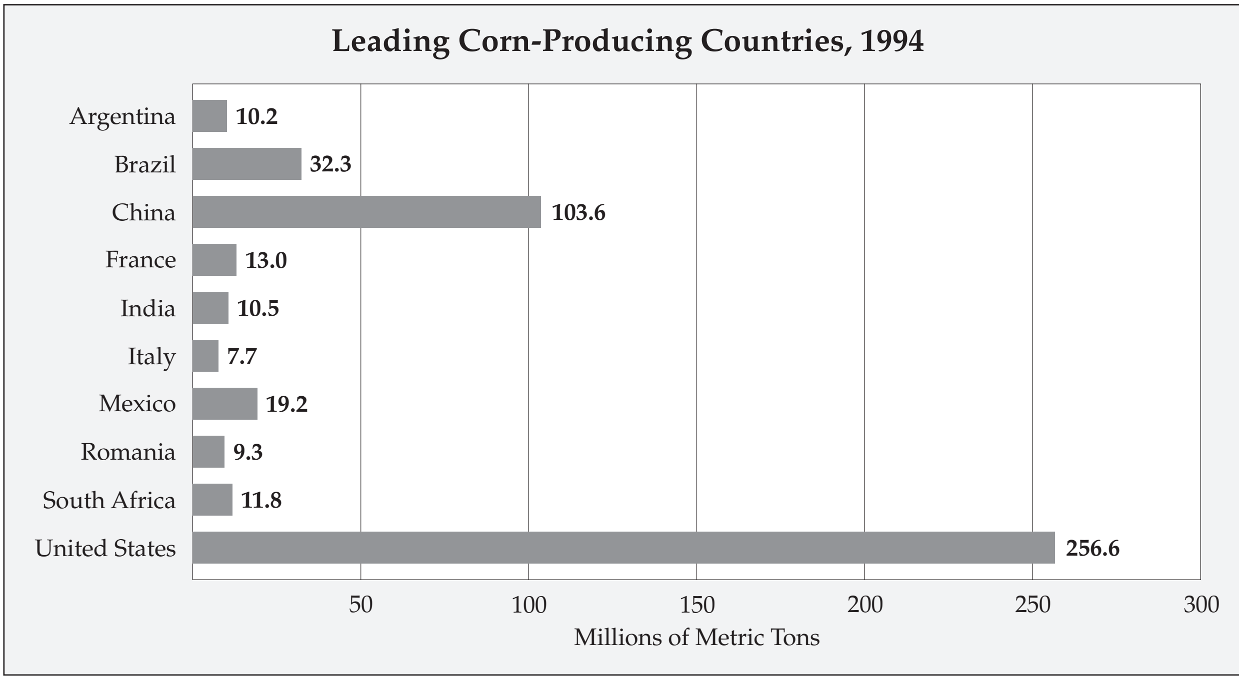
The types of corn still in use are dent, flint, flour, pop, and sweet. Dent corn, characterized by a "dent" in the top of each kernel, is the most important commercial variety. Flint corn tends to be resistant to the rots and blights known to attack other types; it is also more tolerant of low temperatures and therefore appears at the geographical edge of corn's range. Flour corn is known for its soft kernel, making it easier to grind into flour and thus popular for hand-grinding. A mainstay at American movie theaters and as a snack food, popcorn will, with an optimum moisture content of about 13 percent, explode to as much as thirty times its original volume when heated. Also popular in the United States and eaten fresh, sweet corn is so named because, unlike other types, most of the sugars in the kernel are not converted to starch.

Commercially, corn is used mostly for livestock feed and industrial processing. It is high in energy and low in crude fiber but requires supplements to make a truly good feed. Industrial processing creates a great variety of products found in everyday



PhotoDisc

Corn, one of the world's three major staple crops, no longer grows in the wild; it requires that humans remove and plant the kernels (seeds) to ensure reproduction.



Note: World total for 1994 was approximately 570 million metric tons.

life—underscoring the importance of corn to the world's economy.

Processing takes place in one of three ways: wet milling, dry milling, or fermentation. In wet milling, corn is soaked in a weak sulfurous acid solution, ground to break apart the kernel, and then separated. The resulting by-products are found nearly everywhere. The cornstarch supplies corn syrup (it is sweeter than sugar and less expensive, and billions of dollars' worth is produced for soft drink manufacturers each year), starches used in the textile industry, ingredients for cooking and candymaking, and substances used in adhesives, to name a few. Other by-products provide cooking oil; oil used in mayonnaise, margarine, and salad dressing; soap powders; and livestock feed. Dry milling is a simpler process, involving the separation of the *hull* from the *endosperm* (the food storage organ, which is primarily starch in most corn) and the *germ* (the plant embryo) by repeated grinding and sieving. Dry milling produces hominy, grits, meal, and flour, all of which are used for human consumption. Fermentation of corn changes the starch to sugar, which is then converted by yeast to alcohol. The process eventually results in ethyl alcohol, or ethanol (which is blended with gasoline to reduce carbon monoxide emissions), acetone, and other substances.

CRYPTOMONADS

Categories: Algae; microorganisms; *Protista*; taxonomic groups; water-related life

The phylum Cryptophyta *describes tiny, motile, unicellular organisms with two slightly unequal flagella bearing lateral hairs. Cryptomonads live mainly in marine and freshwater environments.*

Some cryptomonads are alga-like, with blue-green, red, and olive-brown photosynthetic pigments including chlorophylls *a*, *c2*, alpha-carotene, xanthophylls (alloxanthin, crocoxanthin, zeaxanthin, and monadoxanthin), and phycobiliproteins (phycoerythrin and phycocyanin). Cryptomonads are found in a variety of moist places, such as algal blooms in the ocean or in fresh water, and on beaches. Some members are intestinal parasites in animals.

Classification

Historically, botanists and zoologists alike have adopted cryptomonads. Botanically, cryptomonads would be included in kingdom *Plantae*, phylum *Cryptophyta*, class *Cryptophyceae*, order *Cryptomonadales*, and family *Cryptomonadaceae*. Zoologists would place the cryptomonads in kingdom *Animalia*, phylum *Sarcomastigophora*, class *Phytomastigophora*, order *Cryptomonadida*, and family *Cryptomonadidae*. Also, the cryptomonads are currently included in a separate kingdom, *Protoctista* (also known as *Protista*), with phylum, class, order, and family taxa being the same as that for the botanical taxa above.

Synonyms for *Cryptophyta* are *Cryptomonadales*, *Cryptophyceae*, and *Chromophyta*, and they were once placed with the algae. Genera for the cryptomonads include the following: *Chilomonas*, *Chroomonas*, *Cryptomonas*, *Cyathomonas*, *Falcomonas*, *Geminigera*, *Goniomonas*, *Guillardia*, *Hemiselmis*, *Komma*, *Plagiomonas*, *Pyrenomonas*, *Rhodomonas*, *Storeatula*, and *Teleaulax*. *Guillardia theta*, formerly known as *Cryptomonas phi*, has been studied most extensively, and the complete chloroplast genome is known (Genbank accession number AF041468).

Ecology

The cryptomonads are part of the nanoplankton (typically phytoplankton between 2 to 20 micrometers in diameter) and are a relatively small but ecologically and evolutionarily important taxon. Both freshwater and marine representatives are known. Many photosynthetic species likely retain their capacity to eat prey (mixotrophy). Fluctuations in their numbers are correlated with increases in levels of nitrogen in the water in which they live. Some species of cryptomonads form gelatinous colonies. A few cryptomonads have reached the palmelloid or sessile stage of organization, but most are free-living flagellates common in nutrient-rich water. A weakly filamentous member of the cryptomonads is *Bjornbergiella*. Well-known examples of cryptomonads are *Cryptomonas ovata*, *C. similis*, and *Chilomonas paramecium*.

The cryptomonads can form major blooms in Arctic and Antarctic waters as well as in North America's Chesapeake Bay. They can be very important food sources for smaller heterotrophic or mixotrophic plankton, including ciliates and dinoflagellates. Cryptomonads are found in freshwater lakes, ponds, and ditches—especially in colder waters. They are dominant species in many Antarctic lakes, and they are also found in interstitial water on sandy beaches. Reproduction in the cryptomonads is generally asexual in culture, but sexual reproduction has been documented in the *Cryptophyta*.

Characteristics

Cryptomonads are tiny flagellates, 5 to 30 microns (most around 10 to 20 microns). They are flattened dorsiventrally in shape and are asymmetrical, with a *periplast* (a proteinaceous structure that lies inside the plasmalemma and is attached to it). Cryptomonads are mostly algal forms, with an anterior (ventral) groove or pocket and a gullet, which has refractile *ejectosomes* or *trichocysts*. The unequal flagella are inserted nearly parallel to the pocket, not inside the gullet as in the euglenophytes. Mitochondria have flat cristae, while the plastids are secondary with a highly reduced eukaryotic nucleus, the *nucleomorph*.

Although there are a few colorless forms, such as *Chilomonas*, most cryptomonads have a chloroplast. The chloroplast is not contained directly, however, because there is a reduced eukaryote symbiotic within the cell containing a normal prokaryote chloroplast. Usually, there are two chloroplasts, which are secondary plastids. The chloroplast is bound by four membranes (two being chloroplast endoplasmic reticulum, or CER, continuous with the nuclear envelope and homologous to a food vacuole) with a tiny nucleus (nucleomorph) between the middle two membranes. Much like the dinoflagellates (with which the cryptomonads were formerly grouped), it has chlorophylls *a* and *c*; chlorophyll *b* is never present. Thylakoids are paired, and phycobilin pigments are present in the spaces between the thylakoids but not in phycobilisomes, such as in the cyanobacteria and *Rhodophyta*. Food reserves are starchlike, accumulating in the periplastidal space stored between the starch envelope and the chloroplast reticulum. If there is an eyespot, it is inside a plastid not associated with the flagella.

There is a large nucleus at the posterior end. Mitosis is open, and centrioles are not associated with mitosis. Cell division is by furrowing. No histones are associated with the chromosomes. The unique nucleomorph has deoxyribonucleic acid (DNA), is contained within a double membrane, and also has a nucleolus-like region. Molecular data suggest and strongly support the idea that the nucleomorph is a vestigial nucleus from the original endosymbiont, which became the cryptophyte chloroplast. Three chromosomes are associated with the nucleomorph: 240 kilobase pairs (kb), 225 kb, and 195 kb. The bulk of chromosome II (175 kb) is now sequenced with a preponderance of "housekeeping genes" apparently existing for the service of just a few genes encoding plastid proteins. There are parallels between the nucleomorphs of cryptomonads and chlorarachniophytes. The cryptomonad nucleomorph is depauperate in introns, with ribosomal ribonucleic acid (rRNA) genes at the chromosome ends just within the telomeres.

The longer flagellum has two rows of *mastigonemes* (lateral hairs), while the shorter flagellum has a single row. Mastigonemes are two-parted bristles or hairs made up of a rigid, tubular base and, usually, two terminal hairs. These bristles are formed within the endoplasmic reticulum (or nuclear envelope) and are thus transported to the exterior of the cell. The flagella are covered with scales, too.

Trichocysts or *ejectosomes* are in the oral groove, and they are scattered around the cell surface. There is a tightly spooled protein in the trichocysts, which can undergo a very rapid, irreversible conformational change in which it pops out of the cell, pushing the cell backward as a result. The trichocysts are considered a defense mechanism or are perhaps involved in predation.

Evolution

Evolution and phylogeny of cryptomonads have not been well documented using molecular techniques. An 18S ribosomal RNA phylogeny of cryptomonads has been made, however. The nucleus of the endosymbiont (the nucleomorph) does not seem to have a complete complement of genes for photosynthesis, these being relocated to the host nucleus now. Plastid targeting mechanisms of cryptomonads for light-harvesting complex proteins have been studied, though.

The primary plastid is of unknown origin and remains under scrutiny but is probably from a red algal lineage, as the presence of phycobilins is suggestive of the *Rhodophyta* (red algae). Chlorophyll *c* is unknown among the red algae, however. Molecular phylogenetic studies place the nucleomorph close to red algae, and the chloroplast genome map has characteristics suggesting a reduction series from red algae to cryptomonads to heterokonts. This does not imply any descendant relationship among extant groups but rather retention of ancestral character states from common ancestors.

Lateral gene transfer from an ancestral cryptomonad to a dinoflagellate is postulated from sequence analysis of two nuclear-encoded glyceraldehyde-3-phosphate dehydrogenase (GAPDH) genes isolated from the dinoflagellate *Gonyaulax polyhedra*. The plastid sequence forms a monophyletic group with the plastid isoforms of cryptomonads, distinct from all other plastid GAPDHs. This provides the first example of genetic exchange accompanying symbiotic associations between cryptomonads and dinoflagellates, which are common in present-day cells.

CULTURALLY SIGNIFICANT PLANTS

Categories: Economic botany and plant uses; food; medicine and health

Plants are often used as a tool for ceremonial purposes, as artistic media to express indigenous traditions, or as herbal remedies or hallucinogenics to fulfill cultural needs and expectations. Culturally significant plants grow on all continents and are used by all ethnicities.

Historically, humans have appropriated plants for numerous cultural applications. Since prehistoric times, plants have served as symbolic organisms to represent aspects of the life cycle and seasonal changes, to worship, and to make offerings to gods. Plants were incorporated into mythology and legends to show their meanings to various cultures.

Ethnobotany

American Indians are an example of a historic ethnic group which selected specific plant species for cultural uses, such as rituals and ceremonies. These plants have significant roles in the lives of modern American Indians involved in preserving botanical cultural activities by recording information about the horticultural habits of their ancestors, such as knowing where plants grow, when and how they are harvested, how they are prepared and for what functions, and their role in sustaining tribal ethnicity.

Ethnobotanists investigate how cultures identify with and use plants. This scientific field addresses how people throughout time have managed plants, including cultivation methods to improve the quantity and quality of yields and to meet specific needs and requirements. Researchers compare societies' interactions with plants to theorize and determine why people at varying times and places selected certain plants for ceremonies or social uses. The U.S. Department of Agriculture's National Plant Data Center (NPDC) issues culturally significant plant guides which update ethnobotany theories and knowledge.

Religious Uses

Plants, especially trees, have been assigned spiritual roles since prehistory. Humans' daily lives have been influenced by how they perceive and integrate plants into their activities. Christians use plants and flowers, such as the Easter Lily, to represent the history of Jesus Christ. At Palm Sunday ceremonies, palms are the primary Christian botanical symbol for immortality and are used to designate martyrs and divine people and places. Ancient legends describe the Tree of the Cross, which provided the wood for Christ's crucifixion.

Because trees can attain sizable heights and girths, humans have considered them remarkable and worthy of veneration. The strength and longevity of most trees reinforced people's ideas that groves have mythical qualities, and tree cults were formed to protect them. The rarity of trees in many regions, particularly in the Middle East and in African deserts, convinced people that trees were divine and that specific trees could be regarded as sacred.

In Siberia, ancient people were silent when in shaman forests to express respect for gods and spirits they believed dwelled there. Celtic tribal names were derived from tree nomenclature. Many cultures' rituals involved ceremonies with oak trees, because ancient people thought the dead resided inside oaks. Pagan peoples used trees to mark heroes' graves.

Image Not Available

Germanic tribes erected trunks as pillars, and in the ninth century the Frankish king Charlemagne had them cut down in his effort to Christianize Europe. Christians destroyed groves where tree cults worshiped and built churches on these sites. The interior decorations of cathedrals often included tree and acorn imagery that reminded worshipers of the groves. Other types of architecture incorporated plants in designs, such as palm fronds and bark on columns and branchlike arches.

Roman legends tell how the Trojan War hero Aeneas and his guide, the Sybil, were permitted entry to the Elysian Fields, a blessed place, by presenting the Golden Bough. Pre-Columbian people living on the American continents gave cacti as sacraments, hoping this would enable them to have communion with the gods. At Zeus's sanctuary in ancient Greece, an oak was believed to be an oracle because its leaves made noises which priestesses interpreted as Zeus's voice.

In Norse mythology, the ash tree Yggdrasil's roots and branches connected the underworld and heaven. One of the most famous culturally significant plants was the Tree of Knowledge of Good and Evil in the biblical Garden of Eden. Medieval miracle plays often featured the Garden of Eden. The Hanging Gardens of Babylon, an ancient wonder of the world, was an artificial, terraced mountain with lush greenery, which archaeologists have been unable to prove existed. Tales about the gardens enticed the imagination in the ancient world.

Trees are significant to many religions' origin. The Bodhdruma, or Bo Tree, is sacred to Buddhists because it is a pipal tree (*Ficus religiosa*, a form of fig tree) under which Siddhartha Gautama sat to receive enlightenment to become Buddha. In modern Thailand, Buddhists sprinkle water on religious statues of Buddha adorned with orchids, and many temples keep orchids in large pottery bowls filled with water to serve this purpose. Tree myths and traditions are also practiced in other parts of Asia. Indians believe that ghosts awaiting reincarnation live in fig trees. Because they are evergreen, pines represent immortality to many cultures.

Ceremony

Many plants are identified with ceremonial activities that commemorate holidays or anniversaries or celebrate a rite of passage in which an individual enters a new phase of life. When celebrating the new year, ancient peoples used plants in symbolic acts, such as drinking cactus juice to appeal to gods to bless them with sufficient rains and large crop yields. Before emancipation, African-American slaves jumped over a broom made from straw as a way to validate publicly their commitment to marriage when such unions were illegal.

In the modern world, vestiges of these ceremonial uses of plants retain some of their symbolic significance. Flowers are often used symbolically in romantic courtship. Plants convey meanings of love, fidelity, and longevity at weddings and are selected in accordance with personal preferences as well as regional and religious customs.

Plants memorialize people. In the United States on Mother's Day, women wear corsages that indicate whether their mother is alive or deceased. Red poppies pay tribute to soldiers' sacrifices on veterans' and memorial holidays. On Decoration (Memorial) Day, many people place flowers on graves as a form of respectful remembrance. Roses are often thrown into oceans near offshore plane crash sites. Flowers form makeshift memorials where people tragically died or at their homes.

At holidays, including Valentine's Day and Christmas, people give symbolic plants with meanings, such as renewal and protection, that have developed from religious and historical customs. Holly was sacred to Romans who feted Saturn, god of agriculture, at Saturnalia festivals during the winter solstice. Early Christians decorated with holly to avoid persecution; later, that plant was incorporated into Christian rituals. People went "wassailing" to pay tribute to apple orchards by anointing their roots with cider to wish for large spring yields.

Uses

Plants are used culturally for nutrition. Ancient peoples from diverse civilizations revered various crop spirits, including the Corn Mother and the Corn Maiden, which appeared in various forms in Europe, the Americas, Asia, and Africa. Often, people believed that spirits of crops resided within specific people in their communities. Human sacrifices and the ceremonial slaying of figures representing agricultural phases were sometimes held in the hope that such offerings would appease gods and assure ample harvests.

Many plants are harvested for medicinal uses. Often, plants are incorporated as drugs in religious rituals. Peyote has been used ceremonially by native peoples since pre-Columbian times for its hallucinogenic properties, which users thought assisted communication with gods and brought on supernatural powers. American Indians are guaranteed legal rights to use otherwise illegal plants for religious purposes.

Plants express cultural values. Plant fibers are used to weave baskets and clothing. Crushed plant parts create dyes which can be used to stain fabric, write, or draw. Plants inspire superstitions: For example, three-leaf clovers are considered lucky because Saint Patrick convinced Druid leaders to convert to Christianity by stating the shamrock was proof of the Trinity. Often, plants have different meanings: Peonies, for example, represent faithfulness to some cultures and shame in others. Literature and works of art—including Aesop's fables, William Shakespeare's plays, the children's story "Jack and the Beanstalk," and Wagnerian operas—have featured plant themes.

Cornfields are shorn into mazes for amusement. In the United States, nostalgia for old-fashioned plants resulted in heirloom seeds becoming popular. Authorities and ethnic groups are attempting to preserve, restore, and reestablish culturally significant plants in natural settings in order to retain traditional use of such plants for ceremonies, food, and craftsmanship and perhaps develop innovative future applications.

CYCADS AND PALMS

Categories: Angiosperms; economic botany and plant uses; gymnosperms; paleobotany; *Plantae*

Members of the phylum Cycadophyta, *cycads are descendants of giant, prehistoric seed-bearing, nonflowering plants that thrived when dinosaurs lived. Palms are flowering plants with primitive origins that share characteristics with cycads but are not related to them.*

Cycadophyta is one of the four phyla of *gymnosperms* in the kingdom *Plantae*. At one time, cycads grew on every continent. Fossil cycads have been located in areas where no modern cycads grow, such as Antarctica and Europe, suggesting that those places once had milder temperatures.

Origins and Habitat

The oldest cycad fossils are 245 to 208 million years old, from the Triassic period. The first cycads are believed to have appeared in the Permian period 270 million years ago. Some botanists hypothesize that cycads originated as *progymnosperms* in the Devonian period about 408 million to 360 million years ago. During the Jurassic and Cretaceous periods (65 million to 195 million years ago), cycads flourished on earth, dominating plant life. With the beginning of the Ice Age, cycads gradually diminished in population but did not disappear. Some Paleozoic- and Mesozoic-era cycad genera became extinct.

Modern cycads are classified in 150 to 200 species, 11 genera, and 3 families. The most commonly seen cycad species belong to the genus *Cycas* and exhibit some structural characteristics found in palms, conifers, and ferns. Botanists consider cycads valuable in the study of plant evolution. Modern cycads live primarily in the tropics and other regions with warm temperatures and high humidity and are indigenous to Asia, Africa, Australia, and Latin America. Growing in Florida, *Zamia integrifolia* is the only North American cycad species.

Cycad Structure

Cycads consist of a stem with large, long, narrow leaves similar to palm fronds, gathered at the top in a circular crown. Seeds are located in cones on branch ends. Trunks vary from tall stems as high as 20 meters (66 feet) to short trunks standing about 2 meters (6.5 feet). Some have tuberous stems below the soil surface. A trunk's base and crown are of almost equal thickness. New leaves are tender, hardening as they mature, and their bases form armor on stems. They vary in length from 20 centimeters to 3 meters (8 inches to 10 feet).

Cycads lack growth rings, but their age can be estimated by counting the number of whorls on leaf scars on stems to determine how many annual or biennial leaf productions have occurred. Using this method, botanists have speculated that it is possible, although rare, for some cycads to have life spans of one thousand years.

Seedling cycads have a taproot that is later replaced by secondary roots called *coralloid roots*, and subterranean stems anchor the aboveground stem to the soil. Some roots have bacteria which manufacture helpful amino acids and fix nitrogen. The *Zamia pseudoparasitica* is the only epiphytic cycad species.

Image Not Available

Cycad Reproduction

The reproductive cycle can last as long as fourteen months. Female and male cones grow on separate cycads. Pollen with spermatozoids, which are motile sperm, is produced in male cones and fertilizes female cones. Insects (not wind, as was believed until 1993) deliver pollen. Cone-generated heat creates a minty scent appealing to insects. Each cone can produce as much as 200 cubic centimeters (12.2 cubic inches) of pollen annually.

Seeds are scattered when cones fall apart. Only fertilized seeds germinate. Seedlings often require several years before their trunks emerge from the ground. Cycads aid scientists in developing theories about reproduction of extinct seed plants and provide insight on how insect polli-

Classification of Cycads

Class *Cycadopsida*
Order *Cycadales*
Family *Cycadaceae* (cycads)
Genus:
Cycas
Family *Stangeriaceae*
Genera:
Bowenia (natal grass)
Stangeria
Family *Zamiaceae* (sago palm family)
Genera:
Ceratozamia
Chigua
Dioon
Encephalartos
Lepidozamia
Macrozamia
Microcycas
Zamia

nation evolved. Such pollination occurred prior to the existence of angiosperms, or flowering plants (the phylum *Anthophyta*).

Palms

Although cycads and palms can outwardly resemble each other, palms are members of a different phylum and family, the family *Arecaceae* within the phylum *Anthophyta* (angiosperms). Modern palms are represented by approximately twenty-six hundred species. They are the fourth largest group of monocots. (Monocots are one of two large divisions of the angiosperms.) The earliest known palm fossils are eighty million years old and from the Late Cretaceous period. Fossilized palms with pollen indicate that these plants were some of the earliest flowering plant families.

Palms thrived during the Eocene epoch, and a variety of primitive genera grew in Asia, Europe, and North America. Most modern palms live in forests, deserts, swamps, and mountains of tropical regions in Asia, Africa, the South Pacific, the Mediterranean Basin, and the Americas. Some species are confined to specific islands, such as the *Maxburretia gracilis* on the Langkawi Islands. Some palm stands cover hundreds of square miles and consist of millions of plants.

Structurally, palms are similar; all have slender trunks. Most species lack branches and have a leafy cluster on top. Some palms are as tall as 30 meters (98 feet). Seedlings grow a large tip, and most of the bulk forms underground. Upon maturity, trunks maintain the same diameter. Coconut palms have an average diameter of 45 centimeters (18 inches). A network of roots both above and below the surface secures trunks to the ground. Palms are mostly vertical, although some grow horizontally or like vines. Some climbing rattan palms are 182 meters (597 feet) long.

Palm stems consist of masses of densely compacted fibrous strands. Leaves grow from nodes at the tips of stems, causing sharp scars when leaves are shed. Date palms have leaves 3 meters (10 feet) long, and coconut palm leaves average more than 4 meters (13 feet) long. Leaf production offers hints about the age of palms, which average 50 to 100 years, with some *Lodoicea maldivica* attaining 350 years and an Australian *Livistona eastonii* reaching 720 years. Palms first produce seeds approximately eight years after germination and mature at age thirty.

Palms have masses of small flowers, often numbering in the thousands, which are composed of sepals, petals, and male stamens. The female pistil in flowers either forms a soft, berrylike fruit, containing one or more seeds, or a more rigid fruit (a coconut or date), referred to as a drupe, which has a husk and shell encasing one seed. Insects, bats, and wind pollinate palms. Animals eat the fruit, distributing the seeds in their feces.

Uses of Cycads and Palms

Sago is a starch extracted from the stems of palms and cycads. It is used for cooking after the alkaloid is removed. Some leaves and seeds are also edible, but many seeds are poisonous. An amino acid produced by cycads, B-methylamino-L-alanine (BMAA), causes dementia in people who ingest the chemical. Researchers have attempted to discern why cycads manufacture this neurotoxin and do not react like other plants to its presence. The mapping of genes for susceptibility to BMAA may one day help to treat people with neurodegenerative conditions. Cycasin, the carcinogenic compound methylazoxymethanol, a glucoside found in cycad seeds, is also toxic.

Palms yield vegetable oil, waxes, sugars, fats, and saps which are distilled into liquor. Dates and coconuts are popular foods produced by palms. A date palm produces several hundred dates yearly. People consume stems, leaves, nuts, and roots. Rattan palm fibers are used for making furniture, baskets, bags, and other items. Some palm wood is appropriated for veneers, cups, and canes.

Coconut palms can each grow more than one hundred nuts annually. Palms provide essential nutrients for many world populations. Oily coconut liquid and coconut milk are considered delicacies. Leaves from coconut palms make useful thatching material. Coir, the husk's fiber, is twisted into rope. Coconuts have meat that is eaten or processed into *copra* for candles, oil, and other oil-based products. Palm products are crucial in regional and global trade.

Cycads and palms are used ornamentally for landscaping gardens. Some species are suitable for bonsai in interior displays. Because they are often poached to meet collectors' demands, cycads risk extinction. Smugglers locate and ship cycads (such as sago "palms") to clients throughout the world. A limited number of licenses to gather and trade cycads and other protected plants are issued by the Convention on International Trade in Endangered Species (CITES), a 1975 agreement observed by 156 ratifying countries as of 2001 to establish protective legal guidelines to monitor international trade of approximately twenty-five thousand rare plant species and five thousand rare animal species. CITES forbids collection activities that pose risks to wild plant populations.

In Hot Springs, South Dakota, Fossil Cycad National Monument was designated in 1922. In 1957 the site became the first national park service unit to be closed permanently, after collectors removed all of the 120-million-year-old fossils from a prehistoric cycad forest. Cycad conservation efforts in-

clude guarding habitats and artificially propagating species. Rare specimens such as the South African *Encephalartos woodii* cycad, of which only thirty-eight, all male, specimens existed in 2001, are implanted with microchips to track their shipment to botanical exhibitions.

Nong Nooch Tropical Gardens near Pattaya, Thailand, has one of the world's largest collections of Asian cycad and palm varieties. Botanists saved an undescribed cycad species that grows on limestone cliffs from being destroyed when limestone was gathered for construction material in Bangkok. The gardens hosted the 1998 International Palm Society Biennial and the 2002 Sixth International Symposium on Cycad Biology. In South Africa, the Modjadji Cycad Nature Reserve has both cycads and palms, including the largest stand of the enormous *Encephalartos transvenous* (Modjadji palm).

CYTOPLASM

Categories: Anatomy; cellular biology

The cytoplasm is defined as all of the living matter within the plasma membrane of a cell, except for the nucleus, which is isolated from the cytoplasm by the nuclear envelope.

The cytoplasm, bounded by the plasma membrane, is composed of fluid called the *cytosol* in which floats a large variety of molecules and molecular assemblages, *ribosomes* (responsible for polypeptide synthesis), and a variety of other structures called *organelles* (literally meaning "little organs"). Numerous biochemical processes occur in the cytosol, including protein synthesis (*translation*) and *glycolysis*.

Vacuoles

The *vacuole* is the largest, most noticeable, organelle in plant cells (up to 40 micrometers in length). Vacuoles are membrane-bound sacs that can occupy up to 90 percent of the plant's cell volume. The vacuole serves a wide range of purposes, depending on the cell type. It is filled with water and a variety of salts, sugars, organic acids, pigments, or proteins. The vacuoles of flower petal cells contain blue, red, or pink water-soluble pigments. In other cells, the vacuole is full of toxic compounds that deter insect attack. Vacuoles in seed cells contain storage proteins that are remobilized during seed germination and used for early seedling growth.

Plastids

Plastids are the next largest easily observable organelle (5 to 10 micrometers in diameter). *Plastids* are surrounded by a double membrane and are involved in a variety of biosynthetic reactions in the plant cell. All plastids start as immature *proplastids* in *meristematic* (young and undifferentiated) cells. Then, depending upon which tissue type grows from that meristem, proplastids may develop into one of several different mature plastid types.

The most prominent type of plastid is the *chloroplast*, contained primarily in leaf cells. Chloroplasts are colored by the green pigment *chlorophyll*. They are the site of *photosynthesis* and a number of other biosynthetic reactions. *Chromoplasts* are red, orange, or yellow, as a result of their high levels of *carotenoids*. They are found in the petals of flowers, old leaves, some fruits, and even in some roots, such as the carrot.

Parts of the Plant Cell

Part	*Location in Cell*	*Description/Purpose*
Cell wall	Outer layer	Outer boundary of cell, comprising middle lamella, primary wall, sometimes a secondary wall, and plasmodesmata.
Chloroplasts	Cytoplasm	Two-membrane-bounded organelles where photosynthesis occurs.
Chromatin	Nucleus	Site of the chromosomes (genetic material: DNA, histones).
Chromoplasts	Cytoplasm	Two-membrane-bounded organelles where attractants promoting pollination and seed dispersal are made.
Cytoplasm	Cytoplasm	One of three major parts of the cell, containing plastids and cytosol.
Cytoskeleton	Cytoplasm	Contains microtubules, actin filaments.
Cytosol	Cytoplasm	Viscous fluid in which other parts of the cell (membranes, plastids, and other organelles) are suspended.
Endomembrane system	Cytoplasm	Consists of the endoplasmic reticulum, Golgi complex, and vesicles.
Endoplasmic reticulum	Cytoplasm	Membranes in the cytoplasm that form transport pathways and other compartments. Rough endoplasmic reticulum has ribosomes attached to the cytoplasmic face.
Golgi complex	Cytoplasm	Stacks of membranes located near the nucleus where cell products are modified and prepared for secretion from the cell.
Leucoplasts	Cytoplasm	Two-membrane-bounded organelles that store starch and generate oils.
Microtubules	Cytoskeleton	Hollow cylinders of tubulin protein molecules that form networks in the cytoplasm and the mitotic spindle.

Leucoplasts are a nonspecific group of plastids named for their lack of pigments (the prefix *leuco* means “white”). They include *amyloplasts*, which synthesize and store starch, such as in potatoes, and a variety of other plastids specialized for synthesis of oils, proteins, and other products. Amyloplasts are also found in the cells of the *root cap*, where they are involved in gravity sensing, or *geotropism*, by the root tips. Plastids divide by fission, and there may be ten to one hundred per cell.

Mitochondria

Mitochondria are a medium-sized organelle (1 to 2 micrometers in length) with a double membrane. Mitochondria are the sites of *cellular respiration*, the major chemically derived source of adenosine triphosphate (ATP) in many cells. The outermost of the two membranes controls transport of molecules into and out of the mitochondrion. The inner membrane is the site of the *electron transport chain* and *oxidative phosphorylation*, two components of respiration. The aqueous space bounded by the inner membrane is the site of the *Krebs cycle*. Like chloroplasts, mitochondria divide by fission, and there may be ten to one hundred mitochondria per cell, depending upon cell type.

Microbodies

Small (0.5 to 1.5 micrometers in diameter) organelles called *peroxisomes* are bounded by a single membrane. Some peroxisomes contain the enzymes involved in the recycling and detoxification of the products of *photorespiration*. *Glyoxysomes*, an-

Part	*Location in Cell*	*Description/Purpose*
Middle lamella	Cell wall	Sticky layer between cells, binding them together.
Nuclear envelope	Nucleus	Binds nucleus.
Nucleoli	Nucleus	These substructures are composed of genes that encode RNA.
Nucleoplasm	Nucleus	Fluid-filled matrix contained within the nuclear membrane.
Nucleus	Nucleus	One of three major parts of cell, within cytoplasm.
Oil bodies	Cytoplasm	Organelles that store lipids, primarily triacylglycerols.
Peroxisomes	Cytoplasm	One-membrane-bounded organelle that contains enzymes that produce hydrogen peroxide.
Plasma membrane	Inside cell wall	Outer boundary of cytoplasm.
Plasmodesmata	Cell wall	Strands going through cell walls to move substances between protoplasts of contiguous cells.
Plastids	Cytoplasm	General name for chloroplasts, chromoplasts, leucoplasts: two-membrane-bounded organelles.
Primary wall	Cell wall	Outer wall, site of pit fields, division, metabolism.
Proplastids	Cytoplasm	Precursors to other plastids.
Ribosomes	Cytoplasm, nucleus	Structures composed of RNA, responsible for making proteins.
Secondary wall	Cell wall	Inner wall, rigid, with pits; found only in some cells.
Tonoplast	Cytoplasm	Membrane that surrounds the vacuole in a plant cell; also known as a vacuolar membrane.
Vacuoles	Cytoplasm	Organelle bounded by one membrane (the tonoplast) and filled with fluid; in many plant cells, there is a large central vacuole.

other type of peroxisome, are found in germinating seeds. They contain the enzymes involved in the conversion of fats to sugars during the mobilization of storage lipids.

Endomembrane System

The *endoplasmic reticulum* is a series of connected tubules that traverses the cytosol and is the largest member of the *endomembrane system*. The interior of the tubules is called the *lumen*. *Rough endoplasmic reticulum* (RER) is studded with *ribosomes*, while smooth endoplasmic reticulum (SER) is bare. Proteins synthesized on the ribosomes of the RER are inserted into the lumen during synthesis, where they are delivered to the *Golgi complex* for processing. The SER is typically where lipids are made but is rarely seen in plant cells because plastids perform most of the lipid synthesis in plants.

The Golgi complex is a series of stacked membranes that process and package proteins or polysaccharides for transport within or secretion out of the cell. Individual units are called *Golgi bodies* or *dictyosomes*, while collectively they are referred to as the Golgi complex. The endomembrane system gets its name from the fact that many of its components are connected in various ways.

Ribosomes

Ribosomes are small (25 nanometers in diameter), complex assemblies of proteins and *ribosomal RNA* (rRNA). They have two subunits, one large and one small, each made up of a unique mixture of proteins and rRNA. Ribosomes are the sites of protein synthesis. All proteins are large strings of *amino acids* bonded end-to-end. During protein synthesis, a strand of *messenger RNA* (mRNA) from the nucleus travels to the cytoplasm, and one end binds to a ribosome. The ribosome travels down the mRNA and "reads" the genetic information contained on it. The ribosome then "translates" that genetic information into a protein by stringing amino acids together, one at a time, in accordance with the information on the mRNA. Some ribosomes float freely in the cytosol, and others are bound to the endoplasmic reticulum, which is then called "rough ER" because of its appearance under the electron microscope. Proteins made on free ribosomes are released into the cytosol. Proteins made on ribosomes bound to rough endoplasmic reticulum cross the ER membrane and are released into the lumen of the ER for further processing and transport.

Cytoskeleton

All plant cells are surrounded by a *cell wall*. However, the cytoplasm itself is further structured and organized by components of the *cytoskeleton*. The three major components of the cytoskeleton are *microtubules*, *intermediate filaments*, and *microfilaments*.

Microtubules are hollow tubes 24 nanometers in diameter, made of individual, repeating subunits of the protein *tubulin*. They are involved in positioning and moving the chromosomes during *mitosis* and *meiosis*, in directing the laying down of cellulose strands during cell wall formation, and in determining where a new cell plate will form during cell division (that is, *cytokinesis*). Microtubules do not work alone, and numerous microtubule-associated proteins have been identified.

Intermediate filaments are a broad class of cytoskeletal components, and each type is composed of different proteins. They are all solid rods 8-12 nanometers in diameter. In animal cells (where they have been much more fully studied), intermediate filaments have been shown to provide flexible support to skin, nerve, and muscle cells. Although intermediate filaments have been found in plant cells, their exact roles are not yet fully understood. Much research remains to be done in this area.

Microfilaments are thin filaments (7-8 nanometers in diameter) made up of individual, repeating subunits of the protein *actin*. Microfilaments are involved in moving cellular organelles, such as plastids and mitochondria, around the plant cell and, like microtubules, interact with a variety of other proteins, especially *myosin*. In fact, the actin and myosin interaction is so well documented that many researchers refer to them together by simply calling them actinomyosin.

CYTOSKELETON

Categories: Anatomy; cellular biology

The cytoskeleton is a complex network of fibers that supports the interior of a cell. Cross-linked by molecular connectors into systems that support cellular membranes, it holds internal structures, such as the nucleus, in place and controls various kinds of cell movement.

Virtually all eukaryotic cells, including plant cells, have a cytoskeleton. Cytoskeletal systems extend internally from the membrane covering the cell surface to the surface of the membrane system surrounding the cell's nucleus. There are indications that a cytoskeletal support system reinforces the interior of the nucleus as well. The fibers of the cytoskeleton also anchor cells to external structures through linkages that extend through the surface membrane. The cytoskeletal material, rather than being fixed and unchanging, varies in makeup and structure as cells develop, move, grow, and divide.

Structural Elements

The cytoskeleton, depending on the cell type, is assembled from one or more of three major structural fibers: microtubules, microfilaments, and intermediate filaments. *Microtubules* are fine, unbranched hollow tubes with walls built from subunits consisting of the protein tubulin. Microtubules are about 25 nanometers in diameter, have walls about 4 to 5 nanometers thick, and range in length from a few to many micrometers. These structural elements, which may be arranged singly or in networks or parallel bundles, probably provide tensile strength and rigidity to cellular regions containing them. A tubular form combines lightness with strength and elasticity.

Microfilaments, also called actin filaments, are linear, unbranched fibers built up from the protein actin. Microfilaments are solid fibers that are much smaller than microtubules—about 5 to 7 nanometers in diameter, not much thicker than the wall of a microtubule. Microfilaments occur singly, in networks, and in parallel bundles in the cytoskeleton. The consistency of the *cytoplasm* (the living matter of a cell, exclusive of the nucleus), which can vary from highly liquid to solid and gel-like, is regulated by the degree to which microfilaments are cross-linked into networks. Microfilaments are also arranged in parallel bundles that give tensile strength and elasticity to cell regions and extensions. Many cell types contain numerous fingerlike extensions that are reinforced internally by internal parallel bundles of microfilaments.

Both microtubules and microfilaments form the basis for almost all cellular movements. In these motile systems, microtubules and microfilaments are acted upon by motile proteins that are able to convert chemical energy into the mechanical energy of movement. The motile proteins cause the microtubules or microfilaments to slide forcefully, or move cell structures and molecules over the surfaces of the two elements.

Microtubules and microfilaments occur as structural supports of the cytoskeleton of all plant, animal, fungal, and protozoan cells. The third structural element, the *intermediate filament*, is more abundant in animal cells than in plant cells. This type of fiber, called "intermediate" because its dimensions fall between those of microtubules and microfilaments, is about 10 nanometers in diameter. Unlike microtubules and microfilaments, which are each highly uniform in structure and made from a single type of protein, intermediate filaments occur in six different types, each made up of a different protein or group of proteins. Although the proteins making up the various intermediate filaments are different, they are related in both their three-dimensional structures and amino acid sequences.

Intermediate filaments occur in networks and bundles in the cytoplasm. They appear to be much more flexible than either microtubules or microfilaments, so it is considered likely that they form elastic ties holding cell structures in place, much like cellular rubber bands. However, the actual roles of these elements in the cytoskeleton remain uncertain in plant cells.

Assembly-Disassembly Reactions

Both microtubules and microfilaments can be readily converted between assembled and disassembled forms. In the conversion, the protein subunits of microtubules and microfilaments are exchanged rapidly between the fully assembled element and large pools of disassembled subunits in solution in the cytoplasm. Cells can control the balance between assembly and disassembly with high precision. As a result, the protein subunits can be recycled, and cytoskeletal structures containing microtubules and microfilaments can be set up or taken apart as the cell changes its function. As cell division occurs, for example, microtubules and microfilaments forming cytoskeletal structures typical of growing cells are rapidly disassembled and then reassembled into structures that take part in cell division. The assembly-disassembly reactions of microtubules and microfilaments proceed so readily that it is relatively easy to carry them out in a test tube. Microtubules and microfilaments, in fact, were among the first cell structures to be taken apart and put back together experimentally.

Cytoplasmic Streaming and Cell Division

Among the cell activities with which microfilaments are associated is *cytoplasmic streaming*, or cyclosis. The primary function of cytoplasmic streaming, which occurs within all live cells, is unknown. However, moving currents of cytoplasm are thought to facilitate the transport of nutrients, enzymes, and other substances between the cell and its surroundings, and within the cell itself.

A typical plant cell consists of a *cell wall* and its contents, called the *protoplast*. The protoplast consists of the cytoplasm and a nucleus. Within the cytoplasm are *organelles*, membranes, and other structures. Suspended in the cytoplasmic fluid is one or more liquid-filled *vacuoles*, and a vacuole is bounded by a membrane called the *tonoplast*.

In cytoplasmic streaming, the organelles and other substances travel within moving currents in between the microfilaments and the tonoplast. The organelles in the streaming cytoplasm are thought to be indirectly attached to the microfilaments, and this attachment creates a pulling or towing motion, responsible for the movement of cytoplasmic particles.

The microfilaments, in their constantly changing arrays, also facilitate specific activities within the cell, including cell cleavage during *mitosis*. Microfilaments mediate the movement of the cell nucleus before and following cell division. The microtubules, which are longer, move the split chromosomes to the newly forming cells in mitosis, and they play a role in cell plate formation in dividing cells.

In organizing other components of the cell, the cytoskeleton is thus intimately involved in the processes of cell division, growth, and differentiation. The cytoskeleton maintains the cell's overall shape and is responsible for the movement of various organelles within it. In single-celled organisms such as the amoeba, the cytoskeleton is responsible for the locomotion of the cell itself.

CYTOSOL

Categories: Anatomy; cellular biology

Within each eukaryotic cell are a number of distinct, membrane-bounded structures, generically called organelles, including the nucleus, mitochondria, the endoplasmic reticulum, and chloroplasts (only found in plants, algae and some protists). Each organelle is a specialized structure that performs a specific function for the cell as a whole. The rest of the cell, excluding the organelles, cell wall, and plasma membranes, is called the cytosol: the fluid mass that surrounds and provides a home for the organelles.

The cytosol is organized around a framework of fibrous molecules and protein filaments that constitute the *cytoskeleton*. Although the cytosol consists mostly of water, it contains many chemicals that control cell metabolism, including signal transmission and reception, cellular respiration, and protein transcription factors. The cytosol makes up more than 40 percent of the plant cell volume and contains thousands of different kinds of molecules that are involved in cellular biosynthesis. Because cytosol has so much material dissolved in it, it has a gelatinous consistency.

Function

The cytosol provides locations in the cell where chemical activities and energy transformations responsible for growth, repair, and reproduction can occur. Through *diffusion* and *active transport*, cytosol collects many essential nutrients from its surroundings, including carbon, hydrogen, oxygen, potassium, nitrogen, phosphorus, and a variety of *micronutrients*. The constant motion of the cytosol provides a mechanism for moving and supplying these vital nutrients by ionic transport to the organelles so that they can perform their specific jobs.

Cytosol also assists with the removal of unwanted waste products from the cell. *Glycolysis*, the initial step in cellular respiration, occurs in the cytosol. In cellular energy transactions, the cytosol helps distribute useful energy and dissipate the associated heat.

Cytosol plays a key role in the vital processes of protein production, sorting, and transportation. All plant proteins are synthesized by *ribosomes* in the cytosol. Cytosol provides the medium that assists in the transporting of *messenger ribonucleic acid* (mRNA) to ribosomes, where they synthesize proteins. The first portion of the amino acid sequence of a protein contains a *signal sequence* that is checked by proteins in the cytosol. Signal sequences are like street addresses that tell where the growing protein is to be transported. Some signal sequences direct a ribosome to the *endoplasmic reticulum* (ER), where the protein sequence is completed, is stored in the ER's *lumen* (the space inside the ER), and is eventually transported in a vesicle to another organelle or is exported through the cytosol out of the cell. Proteins lacking a signal sequence are completed by the ribosome and released into the cytosol.

DEFORESTATION

Categories: Forests and forestry; environmental issues

Deforestation is the loss of forestlands through encroachment by agriculture, industrial development, nonsustainable commercial forestry, or other human as well as natural activity.

Concerns about deforestation, particularly in tropical regions, have risen as the role that tropical forests play in moderating global climate has become better understood. Environmental activists decried the apparent accelerating pace of deforestation in the twentieth century because of the potential loss of wildlife and plant habitat and the negative effects on biodiversity. By the 1990's research by mainstream scientists had confirmed that deforestation was indeed occurring on a global scale and that it posed a serious threat to global ecology.

Deforestation as a result of expansion of agricultural lands or nonsustainable timber harvesting has occurred in many regions of the world at different periods in history. The Bible, for example, refers to the cedars of Lebanon. Lebanon, like many of the countries bordering the Mediterranean Sea, was thickly forested several thousand years ago. A growing human population, *overharvesting*, and the introduction of grazing animals such as sheep and goats decimated the forests, which never recovered.

Countries in Latin America, Asia, and Africa have also lost woodlands. While some of this deforestation is caused by a demand for tropical hardwoods for lumber or pulp, the leading cause of deforestation in the twentieth century, as it was several hundred years ago, was the expansion of agriculture. The growing demand by the industrialized world for agricultural products such as beef has led to millions of acres of forestland being bulldozed or burned to create pastures for cattle. Researchers in Central America have watched with dismay as large beef-raising operations have expanded into fragile *ecosystems* in countries such as Costa Rica, Guatemala, and Mexico.

A tragic irony in this expansion of agriculture into tropical rain forests is that the soil underlying the trees is often unsuited for pastureland or raising other crops. Exposed to sunlight, the soil is quickly depleted of nutrients and often hardens. The once-verdant land becomes an arid desert, prone to *erosion*, that may never return to forest. As the soil becomes less fertile, hardy weeds begin to choke out the desirable forage plants, and the cattle ranchers move on to clear a fresh tract.

Slash-and-Burn Agriculture

Beef industry representatives often argue that their ranching practices are simply a form of *slash-and-burn agriculture* and do no permanent harm. It is true that many indigenous peoples in tropical regions have practiced slash-and-burn agriculture for millennia, with only a minimal impact on the environment. These farmers burn shrubs and trees to clear small plots of land.

Anthropological studies have shown that the small plots these peasant farmers clear can usually be measured in square feet, not hectares as cattle ranches are, and are used for five to ten years. As fertility declines, the farmer clears a plot next to the depleted one. The farmer's family or village will gradually rotate through the forest, clearing small plots and using them for a few years, and then shifting to new ground, until they eventually come back to where their ancestors began one hundred or more years before.

As long as the size of the plots cleared by farmers remains small in proportion to the forest overall, slash-and-burn agriculture does not contribute significantly to deforestation. If the population of farmers grows, however, more land must be cleared with each succeeding generation. In many tropical countries, traditional slash-and-burn agriculture can then be as ecologically devastating as the more mechanized cattle ranching operations.

Percentage of Annual Deforestation by Country, 1990-1995

Logging

Although logging is not the leading cause of deforestation, it is a significant factor. Tropical forests are rarely clear-cut by loggers, as they typically contain hundreds of different species of trees, many of which have no commercial value. Loggers may select trees for harvesting from each stand. Selective harvesting is a standard practice in sustainable forestry. However, just as loggers engaged in the disreputable practice of *high-grading* across North America in the nineteenth century, so are loggers high-grading in the early twenty-first century in Malaysia, Indonesia, and other nations with tropical forests.

High-grading is a practice in which loggers cut over a tract to remove the most valuable timber while ignoring the damage being done to the residual stand. The assumption is that, having logged over the tract once, the timber company will not be coming back. This practice stopped in North America, not because the timber companies voluntarily recognized the ecological damage they were doing but because they ran out of easily accessible, old-growth timber to cut. Fear of a timber famine caused logging companies to begin forest plantations and to practice sustainable forestry.

While global satellite photos indicate significant deforestation has occurred in tropical areas, enough easily harvested old-growth forest remains in some areas that there is no economic incentive for timber companies to switch to sustainable forestry.

Logging may also contribute to deforestation by making it easier for agriculture to encroach on forestlands. The logging company builds roads for use while harvesting trees. Those roads are then used by farmers and ranchers to move into the logged tracts, where they clear whatever trees the loggers have left.

Environmental Impacts

Despite clear evidence that deforestation is accelerating, the extent of the problem remains debatable. The United Nations Food and Agriculture Organization (FAO), which monitors deforestation worldwide, bases its statistics on measurements taken from satellite images. These data indicate that between 1980 and 1990, at least 159 million hectares (392 acres) of land became deforested. The data also reveal that, in contrast to the intense focus on Latin America by both activists and scientists, the most dramatic loss of forestlands occurred in Asia. The deforestation rate in Latin America was 7.45 percent, while in Asia 11.42 percent of the forests vanished. Environmental activists are particularly concerned about forest losses in Indonesia and Malaysia, two countries where timber companies have been accused of abusing or exploiting native peoples in addition to engaging in environmentally damaging harvesting methods.

Researchers outside the United Nations have challenged the FAO's data. Some scientists claim the numbers are much too high, while others provide convincing evidence that the FAO numbers are too low. Few researchers, however, have tried to claim that deforestation on a global scale is not happening. In the 1990's the reforestation of the Northern Hemisphere, while providing an encouraging example that it is possible to reverse deforestation, was not enough to offset the depletion of forestland in tropical areas. The debate among forestry experts centers on whether deforestation has slowed, and, if so, by how much.

Deforestation affects the environment in a multitude of ways. The most obvious effect is a loss of *bio-*

Results of Deforestation

diversity. When an ecosystem is radically altered through deforestation, the trees are not the only thing to disappear. Wildlife species decrease in number and in variety. As forest habitat shrinks through deforestation, many plants and animals become vulnerable to extinction. Many biologists believe that numerous animals and plants native to tropical forests will become extinct from deforestation before humans have a chance to even catalog their existence.

Other effects of deforestation may be less obvious. Deforestation can lead to increased flooding during rainy seasons. Rainwater that once would have been slowed or absorbed by trees instead runs off denuded hillsides, pushing rivers over their banks and causing devastating floods downstream. The role of forests in regulating water has long been recognized by engineers and foresters. Flood control was, in fact, one of the motivations behind the creation of the federal forest reserves in the United States during the nineteenth century. More recently, disastrous floods in Bangladesh have been blamed on logging tropical hardwoods in the mountains of Nepal and India.

Conversely, trees can also help mitigate against drought. Like all plants, trees release water into the atmosphere through the process of *transpiration*. As the world's forests shrink in total acreage, fewer greenhouse gases such as carbon dioxide will be removed from the atmosphere, less oxygen and water will be released into it, and the world will become a hotter, dryer place. Scientists and policy analysts alike agree that deforestation is a major threat to the environment. The question is whether effective policies can be developed to reverse it or if short-term economic greed will win out over long-term global survival.

He also, however, identifies measures that may be taken to conserve species extinction, given the happy fact that many of them are concentrated in concentrated areas such as the rain forests.

DENDROCHRONOLOGY

Categories: Ecology; forests and forestry; gymnosperms; methods and techniques; paleobotany

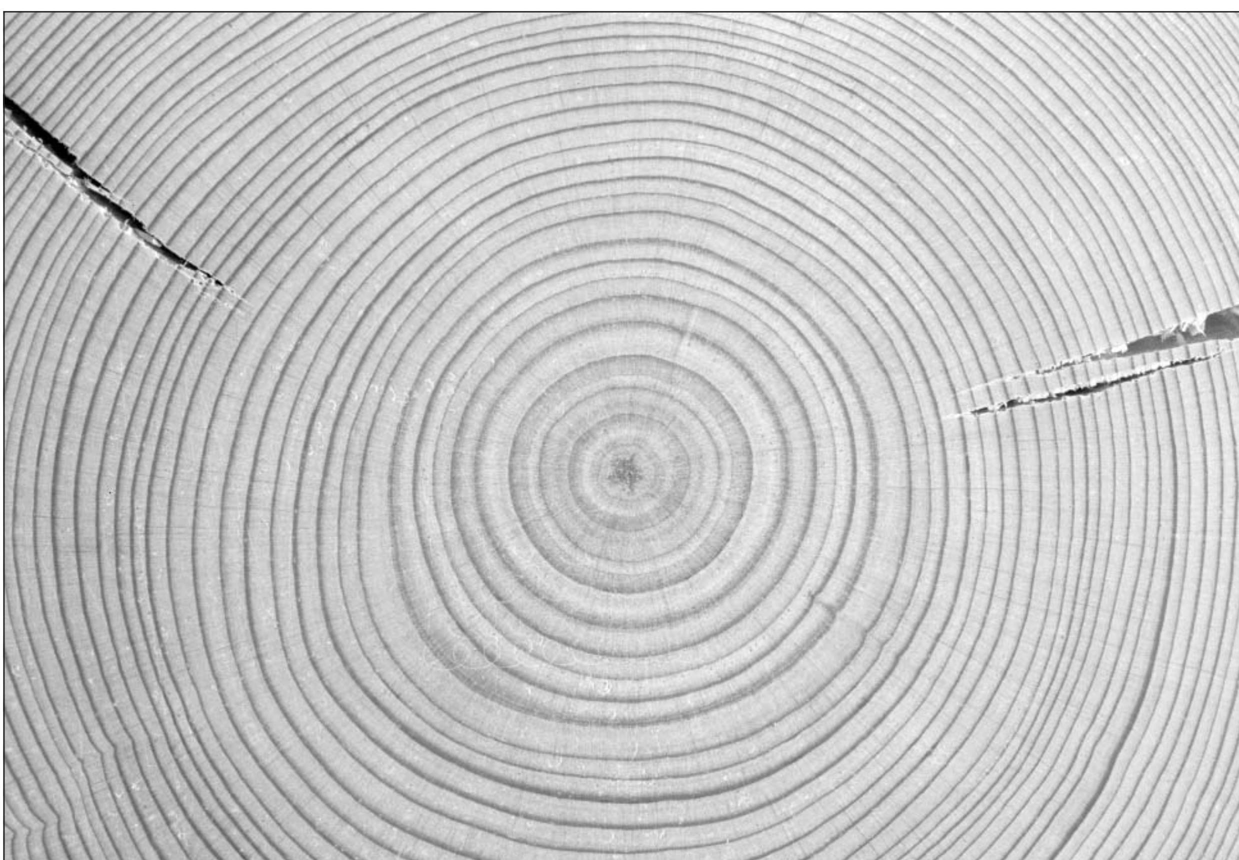
Dendrochronology is the science of examining and comparing growth rings in both living and aged woods to draw inferences about past events and environmental conditions.

In forested regions with seasonal climates, trees produce a growth ring to correspond with each growing season. At the beginning of the growing season, when conditions are optimum, the *vascular cambium* produces many files of large *xylem* cells that form wood. As the conditions become less optimal, the size and number of cells produced decreases until growth stops at the end of the growing season. These seasonal differences in size and number of cells produced are usually visible to the unaided eye. The layers produced during rapid early growth appear relatively light-colored because the volume of the large cells is primarily intracellular space. These layers are frequently called *springwood* because in northern temperate regions spring is the beginning of the growing season. Wood formed later, *summerwood*, is darker because the cells are smaller and more tightly compacted. The juxtaposition of dark summerwood of one year with the light springwood of the following year marks a distinct line between growth increments. The width of the ring between one line and the next measures the growth increment for a single growing season. If there is a single growing season per year, as in much of the temperate world, then a tree will produce a single *annual ring* each year.

Tree Rings and Climate

Leonardo da Vinci is credited with counting tree rings in the early 1500's to determine "the nature of past seasons," but it was not until the early 1900's that dendrochronology was established as a science. Andrew Douglass, an astronomer interested in relating sunspot activity to climate patterns on earth, began to record the sequences of wide and narrow rings in the wood of Douglas firs and ponderosa pines in the American Southwest. Originally, trees were cut down in order to examine the ring patterns, but in the 1920's Douglass began to use a Swedish increment borer to remove core samples from living trees. This instrument works like a hollow drill that is screwed into a tree by hand. When the borer reaches the center of the tree it is unscrewed, and the wood core sample inside is withdrawn with the borer. The small hole quickly fills with sap, and the tree is unharmed. Borers range in size from 20 centimeters to 100 centimeters or more in length, so with care, samples can be taken from very large, very old living trees.

Counting backward in the rings is counting backward in time. By correlating the size of a ring with the known regional climate of the year the ring



PhotoDisc

Dendrochronology, or tree ring counting, can be used to assess the age of a tree because the width of the ring between one line and the next measures the growth increment for a single growing season.

was produced, a researcher can calibrate a core sample to indicate the surrounding climate during any year of the tree's growth. By extending his work to sequoias in California, Douglass was able to map a chronology extending back three thousand years.

Tree Rings and History

In order to extend his chronologies so far back in time, Douglass devised the method of *cross-dating*. By matching distinctive synchronous ring patterns from living and dead trees of the same species in a region, researchers can extend the pattern further into the past than the lifetime of the younger tree. Archaeologists quickly realized that this was a tool that could help to assign the age of prehistoric sites by determining the age of wood artefacts and construction timbers. In this way archaeologists could calculate the age of pre-Columbian southwestern ruins, such as the cliff dwellings at Mesa Verde, Arizona, by cross-dating living trees with dead trees and the latter with timbers from the sites. In 1937 Douglass established the Laboratory of Tree-Ring Research at the University of Arizona, which continues to be a major center of dendrochronological research.

Fine-Tuning

In the mid-1950's Edmund Schulman confirmed the great age of living bristlecone pines in the Inyo National Forest of the White Mountains of California. In 1957 he discovered the Methuselah Tree, which was more than forty-six hundred years old. The section of forest in which he worked is now known as the Ancient Bristlecone Pine Forest. During the next thirty years, Charles Ferguson extended the bristlecone chronology of this area back 8,686 years. This sequence formed the basis for calibrating the technique of *radiocarbon dating*. In the 1960's, radiocarbon analysis began to be used to determine the age of organic (carbon-based) artefacts from ancient sites. It has the advantage of being applicable to any item made of organic material but the disadvantage of having a built-in uncertainty of 2 percent or more. Tree-ring chronologies provide an absolute date against which radiocarbon analyses of wood samples from a site can be compared.

At about the same time, Valmore LaMarche, a young geologist, began to study root growth of the ancient trees to determine how they could be used to predict the erosional history of a site. By cross-referencing growth ring asymmetry to degree of exposure and slope profiles, he was able to estimate rates of soil erosion and rock weathering, which in turn could be cross-referenced to the climatic conditions predicted by growth rings in the stem. LaMarche and his colleagues, particularly Harold Fritts, continued to "fine-tune" the reading of growth rings to be able to take into account factors such as soil characteristics, frost patterns, and daily, weekly, and monthly patterns.

The Oldest Tree

The Methuselah Tree, mentioned above, is the oldest known living tree. Schulman also cored a forty-seven-hundred-year-old living specimen in the White Mountains, but he did not name it or identify its location. While most of the living specimens older than four thousand years are found in the White Mountains, the oldest living tree was discovered in the Wheeler Peak area of what is now Great Basin National Park in eastern Nevada. This tree, variously known as WPN-114 and the Prometheus Tree, was estimated to be between forty-nine hundred and fifty-one hundred years old when it was cut down in 1964 as part of a research project. The controversy that followed has left many interesting but unanswered questions.

DESERTIFICATION

Category: Environmental issues

Desertification is the degradation of arid, semiarid, and dry, subhumid lands as a result of human activities or climatic variations, such as prolonged drought.

Desertification is recognized by scientists and policymakers as a major economic, social, and environmental problem in more than one hundred countries. It impacts about one billion people throughout the world. *Deserts* are climatic regions that receive fewer than 25 centimeters (10 inches) of precipitation per year. They constitute the most widespread of all climates of the world, occupying 25 percent of the earth's land area. Most deserts are surrounded by *semiarid* climates referred to as steppes, which occupy 8 percent of the world's lands. Deserts occur in the interior of continents, on the *leeward* side of mountains, and along the west sides of continents in subtropical regions. All of the world's deserts risk further desertification.

Deserts of the World

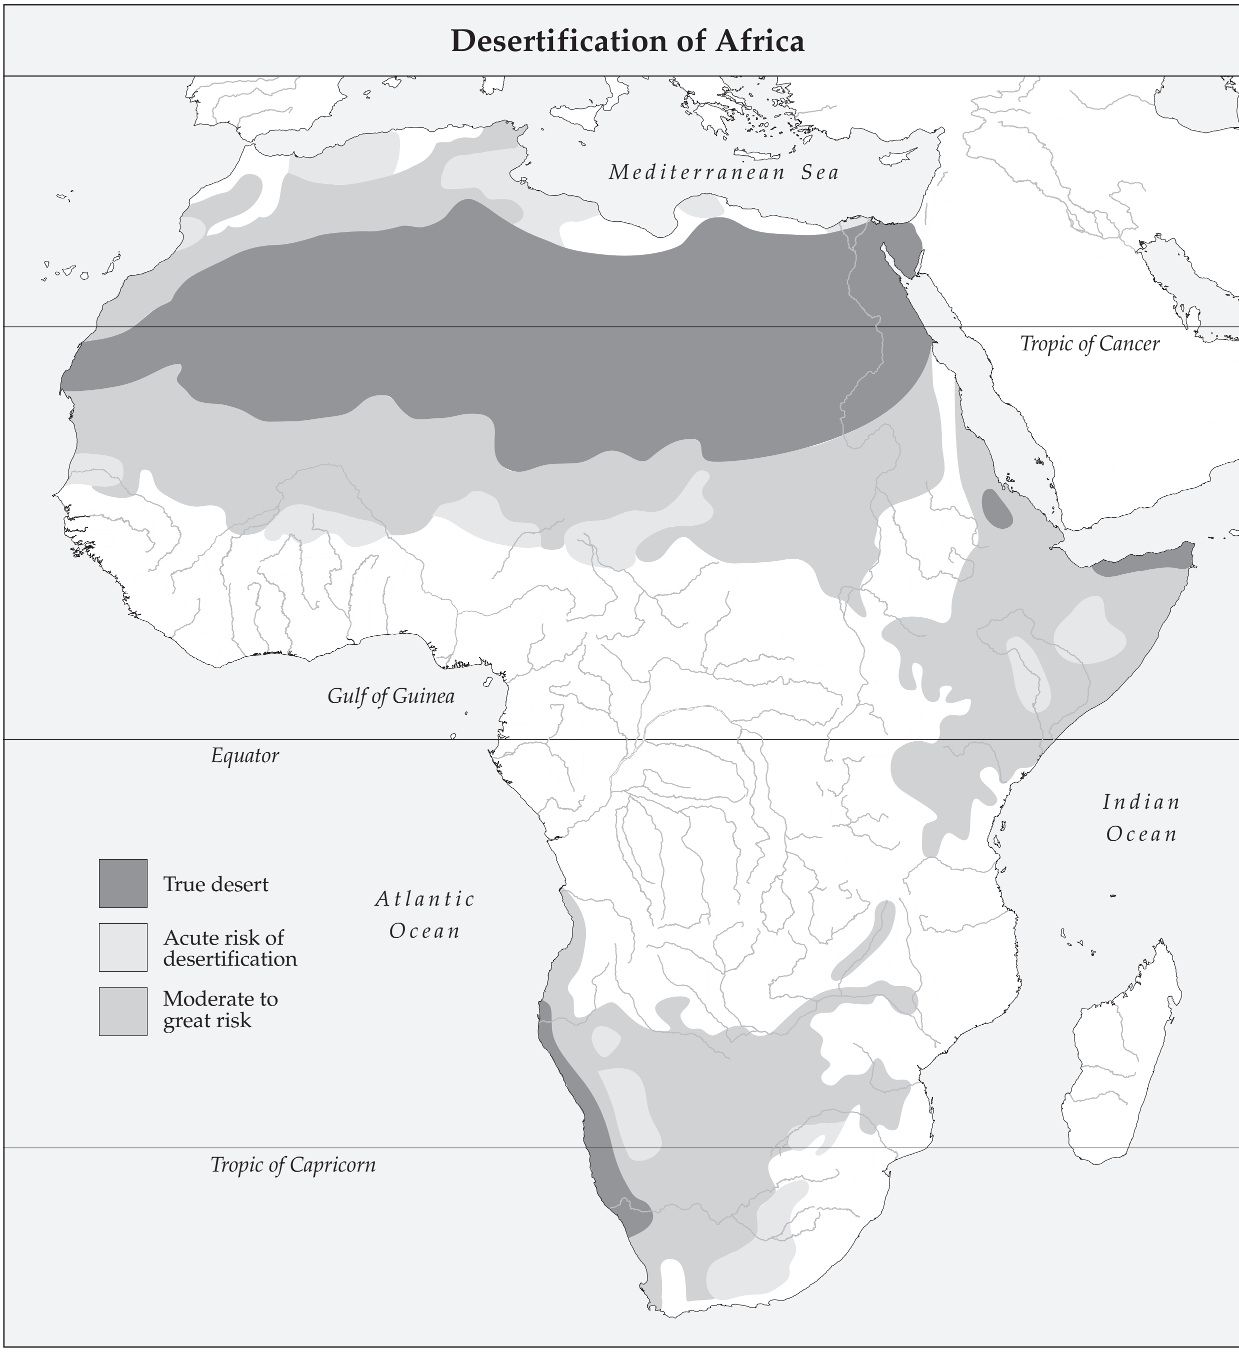
The largest deserts are in North Africa, Asia, Australia, and North America. Four thousand to six thousand years ago, these desert areas were less extensive and were occupied by prairie or savanna *grasslands*. Rock paintings found in the Sahara Desert show that humans during this era hunted buffalo and raised cattle on grasslands, where giraffes browsed. The region near the Tigris and Euphrates Rivers in the Middle East was also fertile. In the desert of northwest India, cattle and goats were grazed, and people lived in cities that have long since been abandoned. The deserts in the southwestern region of North America appear to have been wetter, according to the study of tree rings (*dendrochronology*) from that area. Ancient Palestine, which includes the Negev Desert of present-day Israel, was lush and was occupied by three million people.

Scientists use various methods to determine the historical climatic conditions of a region. These methods include studies of the historical distribution of trees and shrubs determined by the deposit patterns in lakes and bogs, patterns of ancient sand dunes, changes in lake levels through time, archaeological records, and tree rings.

The earth's creeping deserts supported approximately 720 million people, or one-sixth of the world's population, in the late 1970's. According to the United Nations, the world's *hyperarid* or *extreme deserts* are the Atacama and Peruvian Deserts (located along the west coast of South America), the Sonoran Desert of North America, the Takla Makan Desert of Central Asia, the Arabian Desert of Saudi Arabia, and the Sahara Desert of North Africa, which is the largest desert in the world. The *arid* zones surround the extreme desert zones, and the semiarid zones surround the arid zones. Areas that surround the semiarid zones have a high risk of becoming desert. By the late 1980's the expanding deserts were claiming about 15 million acres of land per year, or an area approximately the size of the state of West Virginia. The total area threatened by desertification equaled about 37.5 million square kilometers (14.5 million square miles).

Causes of Desertification

Desertification results from a two-prong process: climatic variations and human activities. First,



the major deserts of the world are located in areas of high atmospheric pressure, which experience subsiding dry air unfavorable to precipitation. Subtropical deserts have been experiencing prolonged periods of drought since the late 1960's, which causes these areas to be dryer than usual.

The problem of desertification was identified in the late 1960's and early 1970's as a result of severe drought in the Sahel Desert, which extends along the southern margin of the Sahara in West Africa. Rainfall has declined an average of 30 percent in the Sahel. One set of scientific studies of the drought focuses on changes in heat distribution in the ocean. A correlation has been found between sea surface temperatures and the reduction of rainfall in the Sahel. The Atlantic Ocean's higher surface temperatures south of the equator and lower temperatures north of the equator west of Africa are associated with lower precipitation in northern tropical Africa. However, the cause for the change in sea surface temperature patterns has not been determined.

Another set of studies is associated with land-cover changes. Lack of rain causes the ground and soils to get extremely dry. Without vegetative cover to hold it in place, thin soil blows away. As the water table drops from the lack of the natural recharge of the aquifers and the withdrawal of water by desert dwellers, inhabitants are forced to migrate to the grasslands and forests at fringes of the desert. *Overgrazing*, *overcultivation*, *deforestation*, and poor irrigation practices (which can cause salinization of soils) eventually lead to a repetition of the process, and the desert begins to encroach. These causes are influenced by changes in population, climate, and social and economic conditions.

The fundamental cause of desertification, therefore, is human activity. This is especially true when environmental stress occurs because of seasonal dryness, *drought*, or high winds. Many different forms of social, economic, and political pressure cause the overuse of these dry lands. People may be pushed onto unsuitable agricultural land because of land shortages, poverty, and other forces, while farmers overcultivate the fields in the few remaining fertile land areas.

Atmospheric Consequences

A reduction in vegetation cover and soil quality may impact the local climate by causing a rise in temperatures and a reduction in moisture. This can, in turn, impact the area beyond the desert by causing changes in the climate and atmospheric patterns of the region. It is predicted that by the year 2050 substantial changes in vegetation cover in humid and subhumid areas will occur and cause substantial regional climatic changes. Desertification is a global problem because it causes the loss of *biodiversity* as well as the pollution of rivers, lakes, and oceans. As a result of excessive rainfall and flooding in subhumid areas, fields lacking sufficient vegetation may be eroded by runoff.

Greenhouse Effect

Desertification and even the efforts to combat it may be impacting climatic change because of the emission and absorption of greenhouse gases. The decline in vegetation and soil quality can result in the release of carbon, while revegetation can influence the absorption of carbon from the atmosphere. The use of fertilizer to reclaim dry lands may cause an increase in nitrous oxide emissions. Although scientists involved in studies of rising greenhouse gases have not been able to gather evidence conclusive enough to support such theories, evidence of the impact of greenhouse gases on global warming continues to accumulate.

Policy Actions

As a result of the Sahelian drought, which lasted from 1968 to 1973, representatives from various countries met in Nairobi, Kenya, in 1977 for a United Nations conference on desertification. The conference resulted in the Plan of Action to Combat Desertification. The plan listed twenty-eight measures to combat land degradation by national, regional, and international organizations. A lack of adequate funding and commitment by governments caused the plan to fail. When the plan was assessed by the United Nations Environment Programme (UNEP), it found that little had been accomplished and that desertification had increased.

As a result of the 1977 United Nations conference, several countries developed national plans to combat desertification. One example is Kenya, where local organizations have worked with primary schools to plant five thousand to ten thousand seedlings per year. One U.S.-based organization promotes reforestation by providing materials to establish nurseries, training programs, and extension services. Community efforts to combat desertification have been more successful, and UNEP has recognized that such projects have a greater success rate than top-down projects. The Earth Summit, held in Rio de Janeiro, Brazil, in 1992, supported the concept of *sustainable development* at the community level to combat the problem of desertification.

DESERTS

Categories: Biomes; ecosystems

Regions characterized by 10 inches or less of precipitation per year as considered deserts. Plants in desert biomes are typically specialized to endure the harsh conditions found there.

Deserts are regions, or biomes, too dry to support grasslands or forest vegetation but with enough moisture to allow specially adapted plants to live. In deserts, hot days alternate with cold nights. Ninety percent of incoming solar radiation reaches the ground during the day, and 90 percent of that is radiated back out into space at night, the result of the absence of clouds, low humidity, and sparse vegetation. The surface of the ground in desert areas is devoid of a continuous layer of plant litter and is usually rocky or sandy. Nutrient cycling in deserts is tight, with phosphorus and nitrogen typically in short supply.

How Deserts Form

Most large landmasses have interior desert regions. Air masses blown inland from coastal areas lose their moisture before reaching the interior. Examples include the Gobi Desert in Mongolia and parts of the Sahara Desert in Africa.

Another factor in the formation of deserts is the *rain-shadow effect*. If moisture-laden air masses bump up against a mountain range, the air mass is deflected upward. As the air mass rises, it cools, and moisture precipitates as rain or snow on the windward side of the mountain range. As the air mass passes over the mountain range, it begins to descend. Because it lost most of its moisture on the windward side, the air mass is dry. As it descends, the air heats up, creating drier conditions on the lee side of the mountain range. Sometimes these differences in moisture are so pronounced that different plant communities grow on the windward and leeward sides.

Latitude can also influence desert formation. Most deserts lie between 15 and 35 degrees north or south latitude. At the equator, the sun's rays hit the earth straight on. Moist equatorial air, warmed by intense heat from the sun, rises. As this air rises, it cools and loses its moisture, which falls as rain; this is why it usually rains every day in the equatorial rain forests. The *Coriolis force* causes the air masses to veer off, to the north in the Northern Hemisphere and to the south in the Southern Hemisphere. The now-dry air begins to descend and warm, reaching the ground between 15 and 35 degrees north and south latitude, creating the belt of deserts circling the globe between these latitudes.

Deserts can also form along coastlines next to cold-water ocean currents, which chill the air above them, decreasing their moisture content. Offshore winds blow the air above cold ocean waters back out to sea. In deserts, rain is infrequent, creating great hardships for the native plants and animals. The main source of moisture for the plants and animals of coastal deserts is fog.

Desert Vegetation

Many typical desert perennial plants, such as members of the *Cactaceae* (the cactus family), have thick, fleshy stems or leaves with heavy cuticles, sunken stomata (pores), and spiny defenses against browsing animals. The spines also trap a layer of air around the plant, retarding moisture loss. Desert plants, many of which photosynthesize using C_4 or CAM (crassulean acid metabolism), live spaced out from other plants. Many desert plants are tall and thin, to minimize the surface area exposed to the strongest light. For example, the entire stem of the Saguaro cactus is exposed to sunlight in the early morning and late afternoon; at noon, only the tops of the stems receive full sun. These traits allow the plants to cope with heat stress and competition for

DIGITAL STOCK

The Gobi Desert, much of which is in Mongolia, is one of the world's largest.

water and avoid damage from herbivores (plant-eating animals).

Where the mixture of heat and water stress is less severe, perennial bushes of the *Chenopodiaceae* (goosefoot family) or *Asteraceae* (sunflower family) form clumps of vegetation surrounded by bare ground. Numerous annuals, called *ephemerals*, can grow prolifically, if only briefly, following rainfall.

Unrelated plant families from different desert areas of the world show similar adaptations to desert conditions. This has resulted from a process called convergent evolution.

Types of Deserts

Deserts are not all alike. Hot deserts are found in lower latitudes, and cold deserts are found at higher latitudes. North America contains four different deserts, which are usually defined by their characteristic vegetation, which ecologists call *indicator species*.

In Mexico's Chihuahuan Desert, lechuguilla (*Agave lechuguilla*) is the indicator species of the Chihuahuan Desert. Fibers from lechuguilla can be made into nets, baskets, mats, ropes, and sandals. Its stems yield a soap substitute, and its pulp has been used as a spot remover. Certain compounds in lechuguilla are poisonous and were once used as arrows and fish poisons. Two of the most common plants in the Chihuahuan Desert are creosote bush (*Larrea divaricata*) and soaptree yucca (*Yucca elata*). Cacti in the Chihuahuan are numerous and diverse, especially the prickly pears and chollas.

The Joshua tree (*Yucca brevifolia*), is the indicator species of the Mojave Desert in Southern California. Nearly one-fourth of all the Mojave Desert plants are *endemics*, including the Joshua tree, Parry saltbush, Mojave sage, and woolly bur sage.

The Great Basin Desert, situated between the Sierra Nevada and the Rocky Mountains, is a cold desert, with fewer plant species than other North American deserts. Great Basin Desert plants are small to medium-size shrubs, usually sagebrushes or saltbushes. The indicator species of the Great Basin is big sagebrush (*Artemisia tridentata*). Other common plants are littleleaf horsebrush and Mormon tea. The major cactus species is the Plains prickly pear.

In the Sonoran Desert in Mexico, California, and Arizona, plants come in more shapes and sizes than in the other North American deserts, especially in the *Cactaceae*. The indicator species of the Sonoran Desert is the saguaro cactus (*Carnegiea gigantecus*).

The Sahara Desert of northern Africa is the world's largest, at 3.5 million square miles. The Northern Hemisphere also contains the Arabian, Indian, and Iranian deserts and the Eurasian deserts: the Takla Makan, Turkestan, and Gobi. Deserts in the Southern Hemisphere include the Australian, Kalahari, Namib, Atacama-Peruvian (the world's driest), and the Patagonian.

Environmental Considerations

Desert ecosystems are subject to disruption by human activities. Urban and suburban sprawl paves over desert land and destroys habitat for plants and animals, some of which are endemic to specific deserts. Farmers and metropolitan-area builders can tap into critical desert water supplies, changing the hydrology of desert regions. Off-road vehicles can destroy plant and animal life and leave tracks that may last for decades.

DEUTEROMYCETES

Categories: Fungi; taxonomic groups

Deuteromycetes are an artificial group of fungi, of which there exist approximately fifteen thousand species, often referred to as "fungi imperfecti" because their only known reproductive mechanism is asexual.

Deuteromycetes—also known as *Deuteromycota*, *Deuteromycotina*, fungi imperfecti, and mitosporic fungi—are fungi that are unable to produce sexual spores and are therefore placed in their own separate phylum. The deuteromycetes are commonly called fungi imperfecti, that is, "imperfect fungi," a term accepted by many mycologists.

Reproduction

Reproduction in the deuteromycetes occurs in several different forms. Spores, or *conidia*, may be produced directly on the mycelium (the mass of hyphae, or tubular filaments, forming the body of a fungus) or on a structure of specialized mycelial cell called a *condiophore*. Some of these fungi do not produce spores. Nonsporulating fungi are able to propagate themselves by fragmenting the hyphae or by producing a mass of hyphae called a *sclerotium*. Sclerotia can be microscopic in size or as large as several millimeters in diameter.

Conidia can vary in size and shape from small (2-3 microns long) to large (250-300 microns long). Colors can range from clear (hyaline) to a variety of earth tones. Conidia may consist of one to several cells. Shapes of conidia range from simple and oval to elongated and filamentous.

Classification

Classification of the fungi as deuteromycetes is based on the presence of conidia; the kind of conidia according to their shape, color, and size; and whether the conidia are produced in fungal structures called *conidiomata*. Conidiomata may have the shape of a flask made of fungal tissue, called a *pycnidium*; a pin cushion, called a *sporodochium*; or a mass of conidiophores located under either the epidermis or the cuticle of a plant host, called an *aecervulus*.

There are three classes. The *hyphomycetes* contain the fungi that produce conidia and conidiophores on hyphae or groups of hyphae. The *agonomycetes* do not produce conidia. The *coelomycetes* contain the fungi that produce conidia in distinct conidiomata.

Economic and Research Uses

The fungi in the deuteromycetes are extremely important for humanity. Several members of the deuteromycetes are used in industry. Antibiotics, such as penicillin and griseofulvin, are produced by these fungi, especially those of the genus *Penicillium*. These fungi are often found in the soil, and it is believed that they produce antibiotic substances in order to reduce competition with soil bacteria and other fungi.

Enzymes are produced by many of these fungi to enable them to degrade plant residues, from which they obtain nutrients. The enzymes they produce have been used by humans in the manufacture of laundry detergent, paper, and condiments such as soy sauce; the enzymes have also been used in scientific experiments. These enzymes are easily produced under industrial conditions.

Some of the fungi in the genus *Penicillium* are also used in the production of cheeses, including blue cheese and brie. After the cheese is processed and formed into wheels, spores of the fungus are injected into blue cheese, and cheese wheels of brie are dipped into a solution of spores. The cheeses are then allowed to age before entering the market.

Deuteromycetes as Pathogens

Several thousand species of deuteromycetes are pathogenic to plants and plant parts. Many are responsible for the degradation of foods, including decay from rots and molds on grains, vegetables, and fruits. All of the deuteromycetes, like other fungi, are *heterotrophic* (eat or get their food from other organisms) and therefore need to attach to an organic substrate (a living foundation). Food products are excellent substrates for fungi and, within short periods of time, the fungi will consume and destroy these foods. Some fungi produce toxic chemicals that are harmful to those who eat the rotting food. One example is aflatoxin, which is produced by the fungus *Aspergillus flavus*, found on peanuts. A general screening for the fungus can be done using a black light, under which the fungus fluoresces a yellow-green color.

Because all plants and plant parts that serve as food sources for people are affected by deuteromycetes, diseases of plants and animals are one of the more important effects of this fungal group. The fungi use their ability to produce enzymes to enter into growing plant tissue and then destroy the tissue. Annual crop losses caused by fungi in the United States can be measured in billions of dollars. In addition, the small spores of deuteromycetes can affect animals and humans directly. The spores are released into air currents and are blown from place to place. As humans breathe this air, the spores enter the nasal passages and lungs and react with the immune system, creating the allergies.

DIATOMS

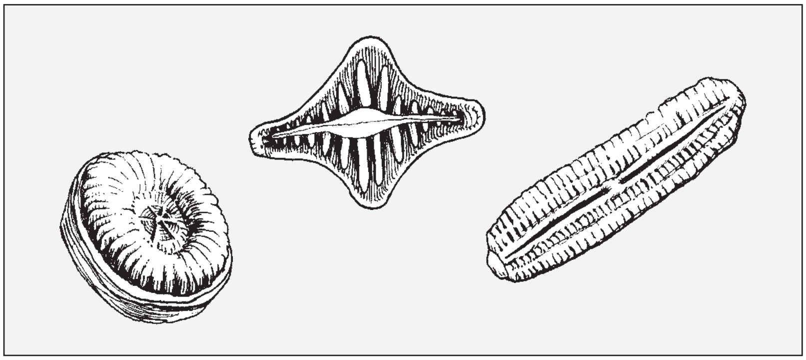
Categories: Algae; microorganisms; *Protista*; taxonomic groups; water-related life

Diatoms are unicellular microorganisms of the phylum Bacillariophyta *that are abundant in aquatic, semiaquatic, and moist habitats throughout the world, growing as solitary cells, chains of cells, or members of colonies.*

Diatoms, algal organisms of the phylum *Bacillariophyta*, have more than 250 genera and about 100,000 species. A distinctive siliceous cell wall called a *frustule* surrounds each vegetative cell. Diatoms have an extensive fossil record, going back some 100 million years to the Cretaceous period. Deposits of fossil diatoms, known as *diatomite* or *diatomaceous earth*, are mined commercially for use as abrasives and filtering aids. One subterranean marine deposit in Santa Maria, California, is about 900 meters in thickness. More than 270,000 metric tons of diatomaceous earth are quarried annually from a deposit in Lompoc, California. Analysis of fossil diatom assemblages provides important information on past environmental conditions. Although the ancestry of diatoms is obscure, they share similar pigments, food reserves, and plastid structure with the *chrysophytes* and complex, multicellular brown algae.

Classes

Diatoms are frequently separated into two classes based on differences in the symmetry of the cell wall. *Centric diatoms* (class *Centrobacillariophyceae*) may be circular, triangular, or rectangular but typically have surface markings that radiate from a cen-



Diatoms are unicellular or colonial algal marine organisms noted for their contribution to phytoplankton, contributing perhaps one-quarter of the world's primary photosynthetic production. They are noted for their frustules: cell walls made of silica and consisting of two halves that overlap each other, with a beautiful variety of ornamentation that makes these tiny organisms appear diverse and jewel-like.

tral area, an arrangement called radial symmetry. *Pennate diatoms* (class *Pennatibacillariophyceae*) are elongated with surface markings at right angles to the long axis, an arrangement called bilateral symmetry.

Cell Wall Components

The hallmark of the diatom is its distinctive and beautifully ornamented, boxlike cell wall, or frustule. The frustule is frequently highly differentiated and is almost always heavily impregnated with silica. An organic layer composed of carbohydrates and amino acids covers the siliceous frustule. The frustule is composed of two halves that fit together like the plates of a petri dish. The larger, overlapping half, the *epitheca*, sits atop the smaller *hypotheca*. The epitheca is composed of a relatively flat upper part (*valve face*) with downturned edges (*valve mantle*), called the *epivalve*, and one or more hooplike girdle bands called the *epicingulum*. Similarly, the hypotheca is composed of a *hypovalve* and a *hypocingulum*. The epicingulum and hypocingulum are collectively known as the *girdle*.

When viewed with the microscope, frustules may be seen in two very different perspectives, depending on the position in which they are lying. If the valve face and outline of the valve are visible, the frustule is said to be in valve view. If the valve mantle and girdle are visible, the frustule is said to be in girdle view.

The varied shapes and beautiful ornamentation of these walls give the diatom cell its intrinsic beauty and have long been used to classify diatoms. Many pennate diatoms possess a *raphe*, a slit along one or both valves, divided by a thickened bridge of silica (a central nodule) and terminated by polar nodules. Raphid pennate diatoms are capable of gliding movement that is caused by the secretion of mucopolysaccharides, derived from vesicles or crystalline bodies, through the raphe. Araphid pennate diatoms lack a raphe and posses a central, unornamented area known as the *sternum* or *pseudoraphe*. No centric diatom has a raphe.

Simple pores (*puncta*), more complex *areolae*, or chambers (*loculi*) are frequently arranged in regularly spaced lines (*striae*) which, in turn, may be strengthened by siliceous ribs (*costae*). Loculi and areolae open externally by a delicate pore plate and internally by a large, round hole. Because the protoplast is completely enclosed by the frustule, the flux of materials across the cell wall primarily occurs through these pores and slits. Additional processes and appendages may extend from the valves of different species.

Electron microscopical studies have revealed two additional openings in the valve: the *fultoportula* (strutted process) and the *rimoportula* (labiate process). The fultoportula consists of a tube that penetrates the wall and is supported internally by two or more buttresses. Fultoportulae are confined to a single order of centric diatoms. The rimoportula, found in centric and pennate diatoms, consists of a tube that opens to the outside by a simple aperture and internally by a longitudinal, liplike slit. Some researchers suggest that the raphe system may have evolved from one or more rimoportulae.

Reproductive Strategies

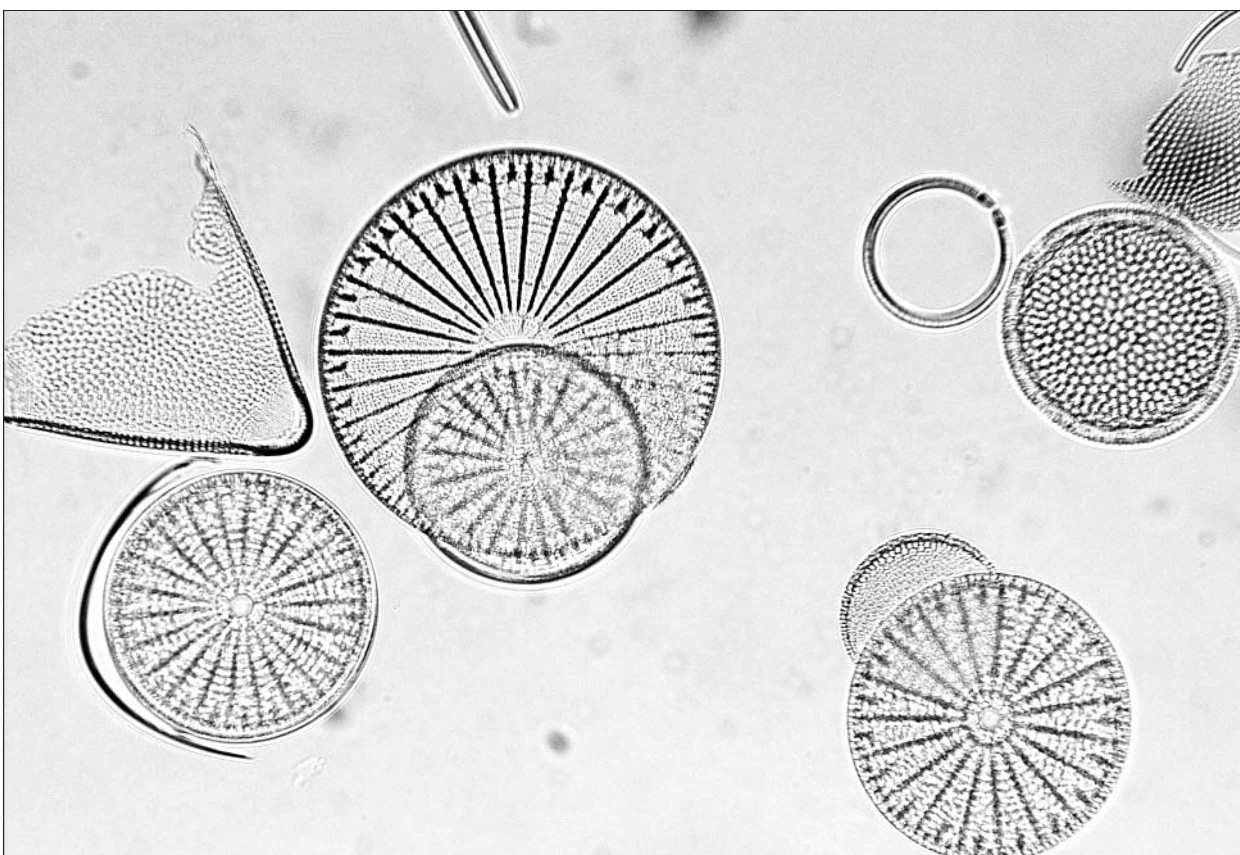
The most common mode of reproduction in diatoms is asexual by cell division of a diploid vegetative cell to produce two daughter cells. Following mitosis the protoplast expands, pushing apart the valves, and divides by furrowing. Each daughter cell receives the epitheca of the parent and forms a new hypotheca within a *silica deposition vesicle*. The daughter cell that receives the original epitheca remains the same size as the parent. However, the daughter cell that receives the original hypotheca forms a new hypotheca and is usually smaller than the parent cell. Thus, the average cell size of a population of diatoms may become progressively smaller during the growing season. The maximum size of the population is restored during sexual reproduction.

During sexual reproduction, diploid vegetative cells divide by meiosis to form haploid gametes (eggs and sperm in centric diatoms or amoeboid gametes in pennate diatoms). Fusion of the gametes results in a diploid zygote that enlarges to several times its original size by the uptake of water and forms valves. This enlarged zygote (*auxospore*) has a different valve morphology from that of the valves of vegetative cells. Auxospores, which do not serve as resting spores, divide by mitosis to form vegetative cells with the maximum size for the species.

Some centric diatoms form *resting spores* in response to the availability of various nutrients (especially nitrogen), temperature, light intensity, and pH. Resting spores are short cells with thick walls that differ from the walls of vegetative cells. Resting spores are usually formed within the frustule of a vegetative cell. A vegetative cell may give rise to one, two, or four resting spores. Resting spores germinate in light when environmental conditions improve.

Flagella

Flagellated cells are found only in the male gametes (*spermatazoids*) of some centric diatoms. Each spermatozoid bears a single flagellum covered with stiff tubular hairs (*mastigonemes*). Based on ultrastructural studies of two species, it appears that diatoms lack the normal 9 + 2 arrangement of microtubules in the shaft of the flagellum (*axoneme*). The two central microtubules are missing, leaving nine peripheral doublets (9 + 0). Further-



PhotoDisc

Micrograph showing diatoms in fresh water.

more, the basal body of these species consists of nine doublets of microtubules, instead of the normal nine triplets found in other eukaryotes.

Food Reserve

The most important carbohydrate food reserve is the *chrysolaminarin*, a beta-1,3-linked glucan, which is stored in special *vacuoles*. Chrysolaminarin (a water-soluble polysaccharide) is also the most important food reserve in the brown algae and chrysophytes. Diatoms may also accumulate various lipids. The fatty acid composition of these lipids differs somewhat from that found in the green algae and higher plants, notably in the absence of linolenic acid from most species. Lipids may be stored within or outside vacuoles.

Photosynthetic Pigments

All diatoms contain *chlorophylls a* and c_2. Chlorophylls c_1 and c_3 may also be present; however, chlorophyll *b* is never found in diatoms. Although the coloration of diatoms varies, living diatoms are frequently brown due to the presence of the accessory pigment *fucoxanthin*, which masks the green coloration of the chlorophylls. Diatoms also contain other *xanthophylls* (neofucoxanthin, diadinoxanthin, and diatoxanthin) and beta-carotene.

The photosynthetic pigments are stored within membrane-bound organelles called *plastids*. Many pennate diatoms have two large plastids, while centric diatoms generally have a large number of small discoid plastids. Four membranes surround the plastids of diatoms: a double-membrane envelope and a layer of endoplasmic reticulum that is continuous with the nuclear envelope. Each plastid contains more or less parallel lamellae composed of three stacked, flattened sacs (*thylakoids*) and at least one *pyrenoid*, which does not appear to be directly associated with any food reserve product.

Habitat

Diatoms are usually a major component of *benthic* and *planktonic* communities in all but the hottest and saltiest waters. While most diatoms live in water, a few species grow in damp soil and can tolerate extreme drought and heat for some time. Pennate diatoms are common members of the benthos and plankton in marine and freshwater habitats, while centric diatoms are more commonly found in the marine plankton. Some benthic diatoms grow attached to rocks, sand grains, other algae, aquatic plants, and even animals. Other benthic diatoms (usually raphid pennates) live freely on the surface of, or in, the substrate. Planktonic diatoms often produce spring and fall blooms in temperate lakes and oceans and summer blooms at higher altitudes. In coastal waters and lakes, they may produce resting spores to survive between growing seasons. One estimate suggests that 20-25 percent of the total primary production on earth is contributed by marine planktonic diatoms.

DINOFLAGELLATES

Categories: Algae; microorganisms; *Protista*; taxonomic groups; water-related life

Dinoflagellates, phylum Dinophyta*, are unicellular and colonial algal organisms from the kingdom* Protista *named for the spinning motions that result from the movement of their flagella.*

The two thousand to four thousand species that make up the *Dinophyta* phylum typically have two flagella. Dinokonts (*Dinophyceae*) have one flagellum running in a groove that cuts transversely across the cell and another flagellum, the sulcus, that runs backward in a longitudinal groove and is more or less perpendicular to the transverse one. In desmokonts (*Desmophyceae*), both flagella arise from a point at the front of the cell. The motions of the flagella, which make dinoflagellates spin like a top, help give rise to the name, for *dinos* in Greek means "whirling," and *flagella* means "whip." Single-celled species are the most common, but colonial species exist. The largest dinoflagellate, *Noctiluca*, may grow as large as 2 millimeters in diameter.

In the active phase of their life cycles, dinoflagellates come in two forms, unarmored (naked) or armored (thecate). All species have a complex outer covering, consisting of an outer membrane, flattened vesicles in the middle, and a continuous inner membrane. In thecate forms, however, the vesicles contain plates made of cellulose or some other polysaccharide. The plates may form a structure as simple as a bivalve-type shell; however, in some species they form wings and other appendages that give the beholder the appearance of some fantastic alien spaceship.

Cell Characteristics

Dinoflagellates are not members of the kingdom *Plantae* but rather are protists, and they have both plant and animal characteristics. Some species are autotrophic—in other words, they have their own chloroplasts and can produce their own sugars and organic materials through photosynthesis. Other species are heterotrophic—they have no chloroplasts and typically must prey on or parasitize other organisms or consume organic detritus in order to obtain nourishment. Some of the heterotrophic species, however, can acquire the chloroplasts of prey and become photosynthetic themselves.

The chloroplasts in normally photosynthetic dinoflagellates are unique in that the plastids are enclosed within a triple membrane, rather than the double membrane of chloroplasts of most other organisms, and also in the fact that the chloroplasts in some cases have their own nuclei. These two characteristics, when considered with the large number of nonphotosynthetic dinoflagellates, have led some to argue that dinoflagellate chloroplasts have been secondarily acquired from a eukaryotic endosymbiont. Photosynthetic pigments include chlorophylls *a* and *c*, carotenoids, and xanthophylls.

Photosynthetic dinoflagellates often form symbioses with other aquatic organisms such as sponges, cnidarians (jellyfish, sea anemones, and corals), molluscs (bivalves, gastropods, octopuses, and squids), turbellarians, and tunicates. These symbiotic dinoflagellates, or *zooanthellae*, lack armor. They carry out most of the photosynthesis that fuels the productivity of coral reefs.

Although classified as protists, dinoflagellates have cellular nuclei with characteristics intermediate between those of prokaryotes and those of eukaryotes. As in eukaryotes, the nucleus is surrounded by a nuclear membrane and contains a nucleolus. However, the chromosomes are attached to the nuclear membrane in such a way that chromosomes remain attached to the inner wall of the cell membrane in prokaryotes. Dinoflagellates are also highly unusual in that they have permanently condensed chromosomes—and dinoflagellate deoxyribonucleic acid (DNA) does not form a complex with proteins, as in typical eukaryotic cells. There remains disagreement over whether dinoflagellate characteristics represent some ancient evolutionary lineage or more recent derivation.

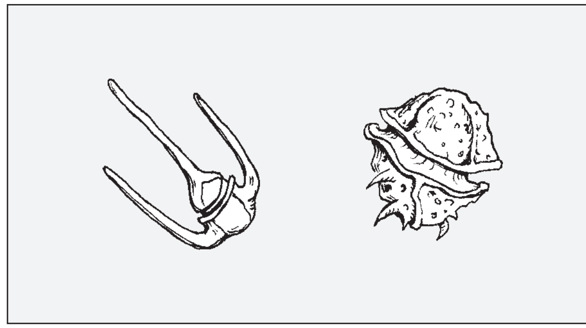
Life Cycle

Arguably the most accomplished shape shifters in the living world, dinoflagellates have incredibly complex life cycles. For example, *Pfiesteria* has at least twenty-four distinct stages in its life cycle, one of several reasons why scientists who work with the organism call it the "cell from hell." Dinoflagellate life cycles may include dormant cysts, cells without flagella (including amoeba-like stages), and more typical biflagellated cells.

Dinoflagellates may reproduce sexually or asexually. The cells are generally haploid, except for a zygote produced by the union of two gamete cells during sexual reproduction. The zygote undergoes meiosis shortly after fertilization. Dinoflagellate cells divide asexually in three ways: The parent cell of a naked dinoflagellate simply constricts and pinches off into two daughter cells; some armored types shed the theca prior to or during division; and other armored types split the parental theca, dividing the portions between the daughter cells. Unfavorable environmental conditions may trigger sexual reproduction as well as the formation of dormant cysts. Cysts may be transported large distances by currents, which in large part explains the dispersal of toxic dinoflagellate blooms up and down coastlines.

Pfiesteria exhibits all three forms, with the amoeboid and flagellated stages being toxic to fish. Encysted stages lie dormant in the bottom sediments of estuaries. The active amoeboid and flagellated stages are usually nontoxic. Amoeboid stages, which either inhabit the sediments or are free-swimming, consume bacteria, algae, small animals, or bits of fish tissues. Flagellated stages may ingest prey in a similar fashion but often siphon off the tissue of their prey through a cytoplasmic extension called the peduncle.

In the presence of an environmental trigger—such as substances given off by a school of live fish—amoeboid, flagellated, and encysted cells activate into toxic forms that swim toward the prey. The toxic forms then secrete toxins that immobilize and injure the prey with ulcerated, bleeding sores. *Pfiesteria* then feeds off materials that leak from the sores. Once the fish die, flagellated cells transform into amoeboid forms that feed on the carcass. If conditions suddenly become unfavorable, the active forms encyst and sink to the bottom. The entire cycle can take place in a matter of hours.



Kimberly L. Dawson Kurnizki

Dinoflagellates are unicellular or biflagellate algal organisms known for their whirling or spinning motion.

Red Tides and Toxins

Dinoflagellates are responsible for most of the *red tides* or *brown tides* that sicken and kill aquatic organisms and humans worldwide. Red tides are known from biblical times; one of the ten plagues reported to have been visited upon Egypt in the Book of Exodus (8:20-21) was most likely a red tide. Red tides were also known in ancient China and among Native Americans in Alaska and the Pacific Northwest.

Typically, the organisms that cause red and brown tides cause no harm until their populations explode or bloom. Adverse effects to other organisms result from oxygen depletion by irritation to skin and other organs, by the blocking of sunlight (in cases where the bloom is visible), or by the production of toxic substances, as in the case of *Pfiesteria*. In general, it is the toxic substances that sicken or kill humans and other vertebrates, such as manatees and birds. There is some controversy over whether human activities in estuarine and coastal waters have caused an increase in the frequency of these *algal blooms*.

In the mid-1990's a spate of horrific fish kills in the estuaries of North Carolina, Virginia, and Delaware began raising alarms up and down the East Coast of the United States. Ghastly lesions appeared on the affected fish, as if they were being eaten alive. People who spent a lot of time on or near the afflicted waters were affected, too, with symptoms ranging from memory loss to skin lesions. The single-celled culprit turned out to be *Pfiesteria piscicida*.

Several toxic syndromes that affect humans are caused by dinoflagellates: ciguatera fish poisoning, caused by toxins produced by *Gambierdiscus* and other species; paralytic shellfish poisoning, caused by toxins produced by *Alexandrium* and other species; neurotoxic shellfish poisoning, caused by toxins produced by *Gymnodinium breve*; diarrhetic shellfish poisoning, caused by toxins produced by *Dinophysis* species; and *Pfiesteria*-associated syndrome.

Bioluminescence

Dinoflagellates, besides being among the deadlier marine microorganisms, are also among the most beautiful. They are responsible for the *bioluminescence* of the sea that has enchanted mariners for millennia. The light is created through the reaction of oxygen with a substrate, luciferin (which has no relation to luciferins responsible for phosphorescence in other organisms such as lightning beetles), which is catalyzed by an enzyme, luciferase. Bioluminescence in dinoflagellates follows a circadian rhythm in which the maximum occurs at night.

DISEASES AND DISORDERS

Categories: Diseases and disorders; pests and pest control

The science and study of plant diseases is known as plant pathology, which can be briefly defined as the study of the nature, cause and control of plant disease.

Plant disease is as old as land plants themselves, as shown by the fossil record. Several biblical accounts of plagues have been attributed to plant diseases, and in Roman times cereal rust was so serious that an annual ritual, the Robigalia, was performed to appease the Rust God, Robigo. In the mid-nineteenth century the Irish Potato Famine, a result of *potato late blight* disease, caused the deaths of some 800,000 persons and the emigration of about 1.5 million more, mostly to North America. Similarly, but to a lesser extent, *brown spot* disease of rice caused the Bengal famine of 1943 in India. Plant diseases continue to cost billions of dollars annually worldwide. The combined costs of lost yield, reduced quality, and costs of pesticides and other control measures are inevitably passed on to consumers. No type of plant is free from disease.

Causes and Types

Plant disease results from the continuing action of an irritant that can be either physical or biological. Physical, or abiotic, causes of disease include water stress (either from excess or insufficient

Symptoms of Plant Diseases

Symptom	*Injurious Effects, Sample Diseases*
Conversion of host	Fungal hyphae ramify and totally consume tissue into masses of host tissues, eventually replacing them with pathogen tissue: hard or powdery masses of fungal tissue. Includes rye ergot, cereal smuts.
Leaf mosaics, mottling	Irregular patterns of chlorophyll loss, malformations, localized leaf-cell death, and/or enhanced growth by other leaf cells. Includes tobacco mosaic virus, peach leaf curl disease.
Leaf spots, leaf blights	Death of leaf cells from parasitism and /or toxin release from the pathogen; limited to discrete, necrotic spots, or may coalesce into larger lesions covering most or all the leaf. Includes rose black spot, bean bacterial blight, potato late blight.
Overgrowths, galls	Localized overgrowth of host tissue, typically on stems, trunks, or roots, resulting in fleshy to woody galls. Includes root knot nematode, crown gall disease, pine rust galls.
Root rots	Debilitation or death of roots by soil-borne pathogens, reducing the plant's ability to absorb water and minerals. Includes common root rots of most plants.
Storage rots/molds	Ramification of fleshy storage tissue by fungi or bacteria, accompanied by release of wall-softening enzymes and sometimes by substances toxic to humans and animals. Includes potato soft rot, *Aspergillus* mold of peanut (with aflatoxin formation).
Stunted growth	Reduced activity of various meristematic tissues, resulting in dwarfed, often malformed plants. Includes peanut stunt virus.
Trunk and/or stem blight	Death of outer tissues of host stems; cankers on trunks resulting from parasitic and toxic action of the pathogen. Includes fire blight of pear, chestnut blight.
Wilts	Physical plugging of xylem vessels by the pathogen, with toxins that injure plant vascular tissue and/or formation of ballonlike extensions (tyloses) from adjacent host cells. Includes Dutch elm disease.

quantities), poor nutrition, improper soil acidity, and other environmental factors. Brief, damaging effects such as hail, wind, and lightning are considered injuries, not diseases.

Biological, biotic, causes of disease include bacteria, viruses, fungi, nematodes, and other microorganisms acting as disease-causing agents, or *pathogens*. Such pathogens infect plants, colonize tissues, and extract nutrients by living as *parasites*. Those actions often result in disruptions of normal physiological processes in plants, including photosynthesis, water uptake and movement, nutrient transport, and reproduction. In some instances anatomical abnormalities such as stunting, growth distortions, and gall formation are induced. The resulting physiological and anatomical abnormalities constitute disease *symptoms*.

Typically, and most important to producers and consumers, yield is reduced, both in quantity and in quality. In addition to diseases of growing plants, there are *postharvest diseases*. Those include fruit and vegetable rots and decay of stored grains. They may begin either before or after harvest, but in either case such diseases can continue long after harvest, further reducing the quality and value of food, fiber, and feed products. Some pathogens also produce toxins in plants they infect. Those toxins can be injurious, sometimes even fatal, to humans or animals that eat the contaminated plant materials.

Three interacting components are required for any plant disease to occur: (1) a susceptible host plant, (2) either a biotic pathogen or an abiotic, nonliving, causal agent, and (3) environmental conditions favorable for development of disease. Each of those components may vary in their contribution to overall severity of the resulting disease. The most important influences are the existing level of genetic resistance or susceptibility of the host plant; the existing level of *virulence*, or ability to cause disease, of the pathogen; for abiotic causes, the plant's degree of nutrient deficiency or water deficiency; and the degrees of favorable or unfavorable temperature, humidity, light intensity or other environmental factors that influence the health and vitality of both host and pathogen. A fourth component, a *vector*, may be required for some diseases. A vector is a second organism, most commonly an insect, that transmits the pathogen from a diseased plant to a healthy plant and injects or otherwise introduces the pathogen into the plant while feeding or laying eggs. Most pathogens do not require vectors.

Kinds of Plant Pathogens and Typical Diseases

Most fungi, bacteria, and nematodes are free-living organisms in nature. They generally contribute to the ecosystem and cause no deleterious effects on plants. Only a small percentage of microorganisms are plant-parasitic or pathogenic. The most important plant pathogens include fungi, bacteria and related forms, viruses, viroids, and nematodes; each group contains species that cause serious, economically important diseases. Fungi constitute the largest number of plant pathogens. By their very nature, viruses and viroids function only as parasites within plant or animal cells and cannot exist as free-living organisms. Nematodes are microscopic, wormlike animals that most commonly reside in soil and feed externally or internally on plant roots.

Plant Disease Control and Management

Plant pathology, in contrast to human and veterinary medicine, focuses very little on diseases of individuals but rather on large populations. Exceptions include certain high-value individuals, such as trees of historic or particular aesthetic or economic value. Emphasis is largely on prevention of plant diseases rather than curative therapy. Control of plant disease, in absolute terms, is usually impossible or economically impractical to achieve. The realistic goal is more commonly management of plant disease, with the goal of achieving a level of disease prevention or reduction that is both economically and environmentally sound. Briefly, most plant disease management practices fall within one of five broad categories: exclusion, eradication, resistance, protection or therapy, and adaptation to or modification of cultural conditions or practices.

Exclusion is the practice of keeping pathogens separated from their host plants and can be accomplished in several ways. Quarantines between countries are commonly used, with varying degrees of success, to prevent importation of pathogens into countries where they currently do not exist. Success of quarantines often depends on the extent and physical nature of the separation between the countries and whether the pathogen is wind-, soil-, or seed-borne. A variant of exclusion is *evasion* or *avoidance* of the pathogen: for example, growing plants susceptible to certain bacterial pathogens only in irrigated, semiarid regions unfavorable to the pathogen. The use of pathogen-free, certified seed or pathogen-free nursery stock are other examples of exclusion aimed at preventing or limiting introduction of pathogens into new areas.

Eradication is the practice of killing pathogens either in the environment or in and on the diseased plant. This limits infection, helps prevent further spread to healthy plants in the area, and helps prevent introduction of pathogens by shipment of diseased plant parts into regions where they currently are not present. Eradication practices such as chemical treatment of soil prior to planting, sanitation procedures such as removing infected crop debris, and long-duration crop rotations can all be successful to various degrees. Eradication and destruction of infected, living plants are often practiced for diseases of orchard crops and landscape trees, such as citrus canker and Dutch elm disease.

Resistance, resulting from innate genetic properties of plants or by directed plant breeding, is usually the most cost-effective means of managing plant diseases. Unfortunately, resistant cultivars may succumb to new, more virulent, or more aggressive strains of the pathogen that can arise by natural selection from populations of the pathogen in nature. Several examples also exist of successful application of *genetic modification* or genetic engineering to the development of resistant varieties, by introducing genes from other species, including nonrelated plants, viruses, or bacteria. Successful breeding of plants resistant or more tolerant to plant diseases provides billions of dollars' worth of benefit annually to producers of all types of plants.

Protection is the practice of treating susceptible plants in some manner, often chemically, to prevent infection once a pathogen reaches the plant surface by growth of the pathogen through the soil to seeds or roots, by deposition of windborne fungal spores, or by splash-drop dispersal of bacteria onto aerial plant surfaces. Protective fungicides or bactericides must be on the seed or plant surface prior to arrival of a pathogen to be effective. Protective fungicides do not kill pathogens; rather, they prevent spore germination, host penetration, or other early stages of infection, if spore germination does occur. Protective fungicides and bactericides are widely used throughout plant agriculture. Some recently developed protective fungicides also have limited eradicative activity. Those fungicides not only function as surface protectants but also enter plant tissue and kill pathogens already inside the plant—an example of therapeutic chemical action.

Adaptation to and *modification* of cultural conditions or practices are used to take advantage of conditions that benefit the plant but are also detrimental to development and spread of the pathogen. Examples include planting when soil temperatures are favorable for germination and subsequent growth of seedlings, altering soil pH by addition of lime or sulfur, not overfertilizing, increasing or lowering temperature, lowering humidity, and increasing airflow in greenhouses. The goal of such practices is to foster plant health and survival as well as prevent or reduce plant disease.

Often it is advantageous to use several of these approaches simultaneously. By combining natural host resistance, even if incomplete, with manipulation of environmental conditions unfavorable to the pathogen, by utilizing pathogen-free seed or nursery stock, or other practices, growers can often reduce significantly the amount of chemical pesticides required to manage a disease. Such a combined approach to disease and insect management is known as *integrated pest management* (IPM). Major goals of IPM are to reduce significantly the amount of pesticides going into the ecosystem while limiting plant disease at an economically acceptable level.

DNA: HISTORICAL OVERVIEW

Categories: Cellular biology; genetics; history of plant science

The determination of the structure of DNA was preceded by years of research. Its discovery led to an avalanche of significant discoveries in molecular biology. The most important feature of the double-helix model was that it suggested how DNA might produce an exact copy of itself.

Deoxyribonucleic acid, or DNA, a molecule at the core of life itself, has existed for at least a few billion years. However, it was not until 1869 that Friedrich Miescher, a Swiss biochemist, was able to isolate it, though in a highly impure form. He discovered DNA in Tübingen, Germany, when he was a young postdoctoral student doing research on the chemistry of white blood cells. Through a series of chemical operations performed on pus cells, which have particularly large nuclei, he isolated a previously unobserved gelatinous substance. Analysis revealed that the new material contained phosphorus and nitrogen; Miescher named it *nuclein* because of its origin in cell nuclei. He recognized that the new substance's acidity was attributable to phosphoric acid.

Early Research

In the late nineteenth century, Albrecht Kossel, a German physiological chemist, discovered that nuclein contained *purines*, nitrogenous compounds with two rings, and *pyrimidines*, nitrogenous compounds with single rings. Furthermore, he showed that these nucleic acids were made of two different purines, adenine and guanine (A and G), and two different pyrimidines, thymine and cytosine (T and C). He also found a sugar among nucleic acid's decomposition products, but he was unable to identify it. Because nucleic acids were difficult to analyze, it was not until the first decade of the twentieth century that scientists realized that there are two types of *nucleic acid:* the thymus type, which is now known to be rich in DNA, and the yeast type, which is rich in *ribonucleic acid* (RNA).

Phoebus Levene, a Russian-American chemist who studied for a time with Kossel, was able to identify the sugar in yeast nucleic acid as ribose in 1908, but he did not definitively identify deoxyribose in thymus nucleic acid until 1929. He established that thymus nucleic acid contains the bases adenine, guanine, cytosine, and thymine and that yeast nucleic acid contains the bases adenine, guanine, cytosine, and uracil. He also isolated, from various nucleic acids, sugar-base fragments (called *nucleosides*) and base-sugar-phosphate groups (called *nucleotides*). In the 1920's he developed a theory that nucleic acids are linear chains of purines and pyrimidines joined to one another by means of the sugar-phosphate group. He took the simplest route and proposed that nucleic acids are composed of repeated sets of four nucleotides (the *tetranucleotide hypothesis*). Since this monotonous sequence could convey little information, most scientists believed that proteins, with their more than twenty amino acid building blocks, were more likely than nucleic acids to be the purveyors of the cell's genetic messages.

By World War II, scientists knew that DNA was an extremely long molecule, but most continued to believe that proteins were the sole carriers of genetic information and that nucleic acids played, at the most, a facilitating role. That DNA was the true source of genetic information was shown by Oswald T. Avery and his coworkers at the Rockefeller Institute for Medical Research. In a laboratory near Levene's, they discovered that protein-free DNA carried genetic information from a virulent form of *Pneumococcus* bacterial cells to a nonvirulent form. Avery stated that DNA is not merely structurally important but is also a functionally active substance in determining a cell's specific characteristics and biochemical activity. His discovery, which was published in a 1944 paper, greatly surprised those geneticists and biochemists who had long believed that genes, in order to perform their complex tasks, had to be made of proteins. Many of them continued to believe that protein contaminants in Avery's experiments must be the transforming agents, not the DNA itself.

The experiments of Alfred D. Hershey and Martha Chase in 1952 finally convinced most scientists that DNA, not protein, is the genetic material. They experimented with a *bacteriophage* (a virus that infects bacteria). The outer surface of a bacteriophage, or phage, consists of protein, but DNA exists within its head. Phages were known to multiply, in part, by injecting their genetic material into bacterial cells.

Hershey and Chase prepared two populations of phages. They labeled the phage protein in one group with a radioactive isotope. In the other group, it was the phage DNA that they radioactively labeled. The scientists then allowed the phages to attack cells of *Escherichia coli*, a colon bacteria. Afterward, their analysis showed that the phage protein had remained outside the bacteria, but the phage DNA had been injected into the bacteria. This research showed that the phages' genetic material was in the DNA rather than in the protein.

Research into DNA Structure

Only by understanding how covalent bonds link together the atoms of DNA and then by establishing their three-dimensional arrangement in space could scientists learn how this molecule carries genetic information. The British organic chemist Alexander Todd decided to clarify the chemical bonding of the nucleic acids by starting with the simplest units, the nucleosides. By the early 1950's he was able to show that the nucleic acids are linear, rather than branched, polymers and to specify exactly how the sugar ring (ribose or deoxyribose) is bonded to the various bases and to the phosphate group.

During the 1940's, while Todd was working out the detailed bonding of the nucleic acids, Erwin Chargaff, a biochemist at the College of Physicians and Surgeons in New York, was exploring the chemical differences in the base compositions of DNA from different sources. By 1950 his careful analyses of the base compositions of DNA samples from many plants and animals had revealed that the compositions varied widely, but his data also yielded the significant result that the ratios of adenine to thymine, and guanine to cytosine, were always close to one. Chargaff's work disproved the theory that DNA was made of repeating tetranucleotide units, but he did not attach any meaning to the one-to-one base ratios (now known as *Chargaff's rules*) because, along with other scientists, he continued to think of DNA as a single polynucleotide chain.

Linus Pauling, along with many other American chemists, was slow to accept DNA as the genetic material. Beginning in the 1930's, Pauling had done important work on hemoglobin and the structure of proteins. In 1948 he discovered the structure of the protein alpha keratin by using only a pen, a ruler, and a piece of paper: the alpha helix held together in its twisting turns by hydrogen bonds.

Moving Toward a Helical Model

In the early 1950's James Watson and Francis Crick, both of whom had become interested in DNA, were deeply impressed by Pauling's work, not so much because of the helical structure he had discovered ("helices were in the air," according to Crick) but because Pauling had the correct approach to biological problems. He believed that the chemists' knowledge of atomic sizes, bond distances, and bond angles would allow biologists to build accurate models of the three-dimensional structures of the complex molecules in living things. Crick, then in his mid-thirties, was a physicist working on the theory of the X-ray diffraction of proteins. Watson, in his early twenties, was a biologist whose interest in genes had led him to the Cavendish Laboratory of Cambridge University. At first glance, Watson and Crick made an odd team: Crick had expertise in crystallography and Watson in genetics, but neither had much knowledge of chemistry. Nevertheless, they were determined to discover the structure of DNA.

The work that ultimately led to the formulation of DNA's three-dimensional structure was performed by three different groups: Pauling and Robert Corey at the California Institute of Technology; Maurice Wilkins and Rosalind Franklin in John Randall's laboratory at King's College, London; and Watson and Crick at the Cavendish Laboratory. Particularly important were Franklin's X-ray studies of DNA. She showed that DNA existed in two forms, each with a distinctive X-ray picture: The wetter form (called the *B form*) gave an X-shaped pattern, and the slightly drier form (the *A form*) gave a more detailed array of spots. From these X-ray pictures, the workers in Randall's laboratory found that DNA had two periodicities in its B form: a major one of 3.4 angstroms and a secondary one of 34 angstroms. Gradually, their studies also began to suggest that DNA had a helical structure.

Watson and Crick decided to approach DNA's structure using Pauling's model-building approach. It was known that DNA's chemical formula, with its many single bonds that allowed free rotation of various groups, meant that the molecule could assume many different configurations. In their early research, Watson and Crick had to make some assumptions. For example, they assumed that the polynucleotide chain was coiled in a helix, somewhat like a vine winding around a cylinder. They reasoned that the different sizes and shapes of the bases probably led to their irregular sequence along the chain, whereas the orderly sugar-phosphate backbone must be responsible for the regular molecular features predicted from the X-ray photographs. Because of the high density of DNA, Watson and Crick proposed, as their first model, a triple helix. The three polynucleotide strands were arranged with the sugar-phosphate groups on the inside of the molecule and the bases on the outside. Wilkins, Franklin, and others came to Cambridge to see this model, but they thought it was ridiculous. Watson and Crick had understood neither the X-ray data nor the water content of the various forms of DNA.

In late 1952 Pauling, relying on poor X-ray photographs of DNA and faulty information about the density of its two forms, also proposed a triple helix. He had decided that packing the extremely bulky bases in the center of the molecule would be too difficult, and so, like Watson and Crick, he situated them on the periphery of his three-strand model. Before this work, Pauling had speculated, in some of his papers and talks, that the genetic material in living things had to be composed of two complementary strands. In studying the actual density determinations and X-ray photographs, however, he was led to the conclusion that this DNA, the product of laboratory manipulations, must be a triple helix.

Watson and Crick quickly abandoned their triple helix. Their search for another model of DNA was aided by a visit to Cambridge in the summer of 1952 by Erwin Chargaff. After talking with them, he was shocked that neither had precise knowledge of the chemical differences among the four bases. He explained to them his findings about the base ratios, which eventually suggested to them that these bases might be paired in the DNA structure. Watson, in fact, started manipulating paper models of the bases, in an attempt to mate them, but he did not understand which base forms actually existed in DNA. (Chemists had found that these nitrogenous bases could exist, depending on conditions, in two forms, the keto and the enol.)

Fortunately, an American crystallographer and Pauling protégé, Jerry Donohue, had an excellent knowledge of these base forms, which he communicated to Watson, who was still mired in like-with-like schemes. At Donohue's insistence, Watson began matching adenine with thymine and guanine with cytosine. This proved to be the key to the structure, for when these base pairs were joined with hydrogen bonds, their combinations were almost identical in size and shape. Thus, these base pairs could be fit into the interior of the helix, whereas the regular sugar-phosphate backbone at the molecule's exterior could account for its acidity and its interactions with water.

Watson-Crick Model

In the Watson-Crick model, DNA's structure consists of two strands, which may contain several million nucleotide units, that run in opposite directions (because of the asymmetry of the sugar-phosphate linkage). Although the hydrogen bonds that hold the chains together are much weaker than normal chemical bonds, they are so numerous that the union is tight. The two strands are not straight; rather, they wind around an imaginary axis in a helical fashion, as if wrapped around a cylinder. The sugar-phosphate groups form the coil, with their attached bases extending inward toward the axis of the helix.

In this double helix (which represents the B form of DNA), a single turn repeats itself every ten base

Image Not Available

pairs. More specifically, the space between one base pair and the next is 3.4 angstroms, and the helix makes one complete turn every 34 angstroms. Scientists later determined that the A form has eleven base pairs per turn.

The double helix is a right-hand helix, which means that an observer looking down the axis of the helix sees each strand, as it goes away from him, moving in a clockwise direction. This helix, which is about 20 angstroms in diameter, has a deep groove on its surface, winding parallel to a much shallower groove. The structure is stabilized by the hydrogen bonding of the complementary base pairs. The purine adenine (A) is always hydrogen-bonded to the pyrimidine thymine (T), while the purine guanine (G) is always hydrogen-bonded to the pyrimidine cytosine (C).

Because of this base-pairing scheme, each chain's sequence determines its partner's sequence. For example, if one strand has the first following sequence, then the other strand would have the second sequence.

TACGCAT

ATGCGTA

The complementary nature of these opposing sequences accounts for Chargaff's rules and, as Watson and Crick noted in their famous 1953 paper in *Nature*, provides a natural explanation for the replication of the molecule. Because of the specific phosphodiester bonding between the sugars, each strand has a top and bottom end, making the two strands antiparallel—that is, positioned relative to each other like two swimmers heading in opposite directions.

In the decades after the discovery of the double helix, scientists found that DNA could exist in structures other than the B-form double helix. For example, the chromosomes of some small viruses have single-stranded DNA molecules. Furthermore, some DNA molecules from living organisms turned out to be circular, which means that the polynucleotide chain formed a closed loop. In fact, the DNA molecules of some viruses interconvert between linear and circular forms, the linear being present inside the virus particle, the circular form existing in the host cell. While studying the conversion of the linear to the circular form of DNA, Jerome Vinograd, a physical chemist, discovered that the axis of the double helix can be twisted to form a superhelix, which can be right- or left-handed.

In the late 1970's and early 1980's, Alexander Rich at the Massachusetts Institute of Technology discovered a left-handed double helix containing about twelve nucleotides per turn. Because the backbones follow a zigzag path, this left-handed structure was called Z-DNA. Instead of the major and minor grooves of B-DNA, only a single groove winds around Z-DNA. Scientists have found the Z form of DNA in nature, specifically in regions of the DNA molecule where G and C bases form an extended, alternating sequence.

Implications of DNA Structure

DNA has been called the master key of life, and the discovery of its structure has been called the most influential event in modern biology. Watson and Crick's discovery of the double helix led to an avalanche of significant discoveries in molecular biology. The most important feature of their model was that it suggested how DNA might produce an exact copy of itself.

Because the model consists of two chains, each the complement of the other, either chain may act as a mold or template on which a complementary chain can be synthesized. As the two chains of DNA unwind and separate, each strand begins to construct a new complement onto itself. When the process is finished, two pairs of double helices exist where there was one before. Thus, the Watson-Crick model helped lead to an explanation, at the molecular level, of how genes duplicate themselves with great fidelity.

The Watson-Crick model also contributed to the solution of the pivotal problem of genetics: how genes control the making of proteins in cells. Though this problem was not solved directly by the double helix, the study of the interactions between DNA and the proteins it indirectly produces revealed that its structure contains, in the sequences of its bases, an intricate code that supervises the construction of the thousands of proteins used by cells. In working out this genetic code, scientists discovered little similarity between DNA's three-nucleotide sequences that code for particular amino acids and the structures of the amino acids themselves. Indeed, the transfer of information from DNA to the cellular mechanisms overseeing protein construction turned out to be quite complex, involving various types of RNA.

Watson and Crick, the originators of the revolution in molecular biology, also played important parts in its evolution. Their work was the catalyst for the development of its "central dogma," which explains how genetic information passes from DNA to the cell's proteins. In the first part of the process, DNA serves as the template for its *self-replication* (duplication). Then, RNA molecules are made on a DNA template (*transcription*). Finally, RNA templates determine all proteins (*translation*). Although DNA can therefore act on itself, the processes of transcription and translation were seen as moving in one direction only: DNA sequences are never made on protein templates, and DNA sequences are never made on RNA templates. In the course of time, some exceptions to these rules have been discovered, but the central dogma remains essentially valid, as does the double helix. Watson and Crick, along with many other scientists, solved, by means of ideas drawn from physics and chemistry, the basic mysteries of the gene.

DNA IN PLANTS

Categories: Cellular biology; genetics

DNA is the hereditary or genetic material, present in all cells, that carries information for the structure and function of living things.

In the plant kingdom, DNA, or deoxyribonucleic acid, is contained within the membrane-bound cell structures of the nucleus, mitochondria, and chloroplasts. DNA has several properties that are unique among chemical molecules. It is universal to all living organisms, having the same structure and function in each. It is capable of reproducing itself in a process known as self-replication. This property allows cell division, and thus continuity, growth, and repair. It carries in its structure the genetic code, or set of instructions, for cellular development and maintenance. Finally, it undergoes changes in chemical structure, from both environmental and internal causes, called mutations, which contribute to evolution, diversity, and disease.

Chemical Structure

DNA is a simple molecule, consisting of four nucleotides. Each nucleotide has a five-carbon sugar (deoxyribose), a phosphate, and one of four possible nitrogenous bases: the double-ringed purines of *adenine* (A) and *guanine* (G) and the single-ringed pyrimidines of *thymine* (T) and *cytosine* (C). Most of the properties of DNA relate to the unique bonds that form among the nucleotides: The sugar-phosphate components align themselves linearly, while the nitrogen rings bond perpendicularly. The nitrogen rings further bond in a very specific fashion: A always pairs with T, and G always pairs with C. The DNA molecule thus appears as a ladder, the sides being sugar-phosphate; the rungs, the A-T and G-C pairs.

Further bonding and folding produces a structure shaped like a spiral ladder, known as a *double helix*. This double helix is compactly packaged in ropelike structures known as *chromosomes*, which are visible under a light microscope before and during cell division. During the daily life of the cell, the DNA appears as an indistinguishable dark mass call chromatin (an inclusive term referring to DNA and the proteins that bind to it, located in the nuclei of eukaryotic cells).

The Watson and Crick Model

In the mid-1800's Gregor Mendel, an Austrian monk, postulated that genetic material existed. He discovered the laws of heredity using the pea and other plants in his garden to study the inheritance of such traits as flower color. Nearly seventy years passed before scientists James Watson and Francis Crick, in 1953, proposed the double helix as the most plausible model for each of the unique properties of the molecule. Their model was verified by X-ray diffraction techniques soon afterward.

Several researchers, working at Columbia University and elsewhere in the United States, had led the way prior to Watson and Crick by discovering the chemical composition of this genetic material and the nitrogenous base pairing: The amount of adenine always equaled that of thymine and likewise with guanine and cytosine. The Watson and Crick model also suggested that the two sides, or strands, of DNA run in opposite directions: That is, the phosphate sugar of one side points upward, while the other strand points downward. This property is known as *antiparallel bonding*. The Watson and Crick model could easily explain how DNA replicates during cell division and how genetic information is encoded in its structure.

Self-Replication

Self-replication, which allows the continuity of generations and the growth and repair of individual organisms, occurs during cell division. DNA must be able to produce exact copies of itself. The molecule is uniquely designed for this: A series of enzyme-mediated steps allows the double helix to unwind or unzip, like a zipper, separating the two strands. Next, nucleotides from digested food enter first the cell and then the nucleus. They bind to a corresponding nucleotide: A with T and G with C. The process continues until two new double-stranded molecules of DNA have formed, each a copy of the other and each going into the new cells that resulted from cell division.

The Structure of DNA

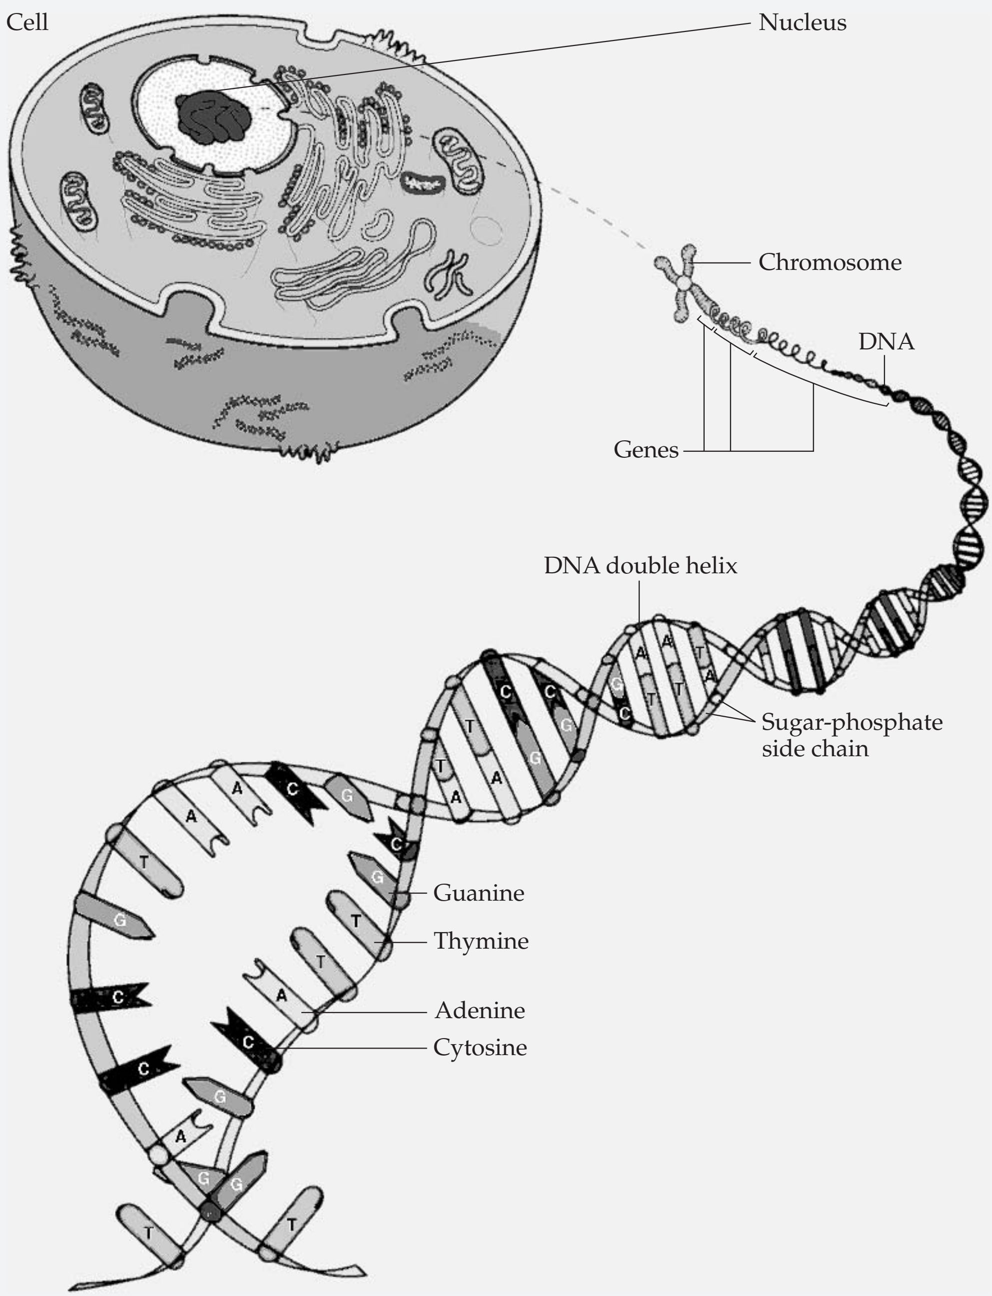

Image Not Available

Protein Synthesis

The information encoded in DNA allows for all the development and maintenance of the cell and the organism. The language of this code lies in a linear reading of adjacent nucleotides on each strand. Every three nucleotides specify or fit a particular amino acid, the individual units of proteins. A second molecule, *ribonucleic acid* (RNA), copies the molecular structure of DNA and brings the information outside the nucleus into the surrounding cytoplasm of the cell, where the amino acids are assembled, in specified order, to produce a protein. Postproduction modifications of these proteins, such as the addition of sugars, fats, or metals, allow a vast array of functional and structural diversity. Plant DNA codes for a variety of substances that are unique to plants. These products sustain not only the plants themselves but also entire ecological niches, as well as humankind.

Mitochondrial and Chloroplastic DNA

A second, independently functioning set of DNA exists in two organelles outside the cell's nucleus, the mitochondria and the chloroplast. It is in the *mitochondria*, the power sources of cells, where carbohydrates, fats, and proteins are broken down to their raw elements with the release of stored chemical bond energy in the form of heat (calories).

The second region in which DNA is housed outside the nucleus is in the *chloroplast*, a structure unique to plant cells. In chloroplasts, photosynthesis occurs, the process by which plants are able to transform carbon dioxide, water, and solar energy to produce sugars and, later, fats and proteins, with the release of oxygen. This critical process undertaken by plants sustains most life on earth.

Both mitochondrial and chloroplastic DNA replicate separately from nuclear DNA during cell division. It is postulated that these organelles once, billions of years ago, may have been independently living organisms that were incorporated into other cells to form the eukaryotic cells that make up nonbacterial life-forms such as fungi, protists, plants, and animals.

Plant Proteins

A large array of proteins that are unique to plants are encoded on plant DNA. A group that has received much attention are the so-called *phytochemicals*, substances with powerful health benefits. Well-studied classes are few, including the flavonoids, phytosterols, carotenoids, indoles, coumarins, organosulfurs, terpenes, saponins, lignans, and isothiocyanates. Each group contains specific proteins that are both antioxidants and anticarcinogens—protecting animal cells from cancer-causing agents. The carotenoids, such as beta-carotene, found in orange and yellow fruits and vegetables, and lycopenes, found in tomatoes, appear to protect animals against heart disease and stroke as well as cancer. The phytosterols, like those found in soybeans, are estrogenlike compounds that mimic female hormones. These appear to protect female organs from cancers and also appear to lower cholesterol.

Plant Hormones

Large segments of plant DNA are devoted to coding for specialized plant hormones. Hormones are substances that are produced by one group of cells, circulate to another site, and affect the DNA of the target cells. In plants, these hormones control cell division, growth, and differentiation.

There are five well-described classes of plant hormones: the auxins, gibberellins, cytokinins, ethylene, and abscisic acid. Among the auxins' functions is allowing phototropism, the property that makes plants bend toward the light. Produced in the roots, auxins travel to stems, making cells elongate on the dark side of plant tissue. Ethylene is a gaseous substance that ripens fruits and causes them to drop from the plant. Abscisic acid contributes to the aging and falling of leaves.

Genetically Modified Plants

Because plants are easy to manipulate, plant DNA is second only to bacterial DNA as a primary experimental subject for bioengineers. The direct modification of DNA by adding or removing a particular segment of genes that code for specific traits is the focus of bioengineering and biotechnology. Because plants provide the major food source for human and livestock populations, *genetically modified foods* have been developed that resist insects, bacteria, viruses, and other pests and decrease the need for external pesticides.

Genetically modified plant crops are designed to enhance a variety of characteristics, from looking and tasting good to growing faster or ripening more slowly to having no seeds. The introduction of genes from other kingdoms, such as the animal kingdom, into plant DNA is allowing scientists to develop future crops that may contain human vaccines, human hormones, and other pharmaceutical products. A tomato was the first federally approved bioengineered food to be sold in the United States. Today, dozens of produce items and livestock feed are in some way genetically modified.

DNA: RECOMBINANT TECHNOLOGY

Categories: Biotechnology; cellular biology; economic botany and plant uses; genetics

Recombinant DNA technology makes use of science's understanding of the molecular structure of DNA, the nucleic acid that encodes genetic information, to alter DNA in order to manipulate genetic traits. Such technology has immense implications for agriculture, horticulture, and the generation of medicinal compounds from plants.

Recombinant DNA technology has been essential for understanding DNA sequences. Because of their large, complex genomes, it was difficult to study one gene in eukaryotes, but recombinant DNA technology has allowed the isolation and amplification of specific DNA fragments facilitating the molecular analysis of genes. In addition, the tools of recombinant DNA technology have been used to create genetically modified plants. Such modifications include the introduction of resistance to insects, herbicides, viruses, and bacterial and fungal diseases into plants. Plants have also been made to produce antibodies so that plants can serve as edible vaccines.

DNA Structure

Organisms contain two kinds of nucleic acids: ribonucleic acid, or RNA, and deoxyribonucleic acid, or DNA. DNA is made of a double chain, or helix. The structure of one chain, or strand, is a backbone made up of repetitions of the same basic unit. That unit is a five-carbon sugar molecule called 2′-deoxyribose attached to a phosphate residue. RNA contains a ribose sugar instead. Also attached to the sugar part of the backbone are other molecules called bases. The four bases are adenine (A), guanine (G), cytosine (C), and thymine (T). DNA molecules are double strands that are held together because each base in one strand is paired to (hydrogen-bonds with) a base in the other strand. Adenine always pairs with the base thymine, and guanine always pairs with cytosine. A and T are called complementary bases. Likewise, G and C are complementary bases.

DNA is shaped much like a helical ladder, with the sugar and phosphate backbones being the sides of a ladder and the base pairs that hold the two strands together being the rungs of a ladder. DNA is often represented as a string of letters, with each letter representing a base. The order of A's, T's, G's, and C's (the rungs of the ladder) along a DNA double helix is the sequence of that DNA which contains the genetic information.

Restriction Enzymes

In recombinant DNA technology, scientists are able to use molecules called *restriction enzymes* to make cuts at specific sequences. Some restriction enzymes make cuts straight across the two strands of DNA in the double helix, creating blunt ends. Other restriction enzymes cut the two strands in a staggered pattern, leaving short, specific single strands at the cut sites. These single-stranded regions, called *sticky ends* or cohesive ends, can base-pair (hydrogen-bond) with complementary base sequences from other, similarly cut DNAs. These sticky ends allow joining of DNA from any source cut with restriction enzymes that create the same ends.

Cutting with restriction enzymes creates fragments of DNA with sequence-specific ends that can be spliced into small, self-replicating vehicle, or vector, molecules and introduced into a host cell where the vector molecules with the added DNA

Image Not Available

fragments replicate to produce a large amount of specific DNA for analyses. This process is *recombinant DNA cloning*.

DNA Cloning

One way to clone a specific gene is to clone all the DNA fragments generated from cutting with a restriction enzyme and then screen for the clone containing the desired gene. This method of cloning random DNA segments into a vector is called *shotgunning*. The entire collection of such cloned fragments, which together represent the entire genome of the organism, is called a gene library. Genomic DNA libraries are made by cloning the total genomic DNA of an organism.

Another way to clone a specific gene is to begin with messenger RNA (mRNA) from the organism. (Messenger RNA is a molecule that functions to create complementary copies of DNA strands. At a ribosome the messenger RNA then determine the order of amino acids that are joined to make a protein.) Using *reverse transcriptase* (an enzyme encoded by some RNA viruses that uses RNA as a template for DNA synthesis), scientists can make a DNA copy of the mRNA. The complementary strand is also synthesized to create a double-stranded DNA called cDNA (complementary DNA) that is complementary to the mRNA. These cDNAs are then cloned to create a complementary DNA library. Individual cloned cDNAs can be used to trap the corresponding mRNA on a nitrocellulose filter. At this point, the mRNA can be used in a cell-free protein synthesis system to allow identification of the protein encoded by that cDNA clone. Alternatively, the cDNA can be used to find sequences complementary to it in a genomic library to obtain a clone of the specific gene.

Nucleic Acid Hybridization

The ability to hybridize nucleic acids to find sequences complementary to a particular DNA is another essential tool that offers another way to identify cloned genes. This method is called *nucleic acid hybridization* or Southern blotting (named after E. M. Southern, who developed the method). In this procedure, DNA is cut with restriction endonucleases, and the resulting DNA fragments are separated by size using agarose gel electrophoresis. The DNA in the gel is denatured (made single-stranded) by high pH and transferred to a nitrocellulose filter. The DNAs are immobilized on the nitrocellulose in the same pattern as on the gel (a Southern blot). Aprobe—a specific DNA or RNA—is hybridized to the nitrocellulose. The probe is "labeled" with a radioactive or fluorescent (nonradioactive) tag so it can be detected. The probe is denatured by heat so it is single-stranded and able to anneal (hybridize) with its complementary sequence among the single-stranded DNAs tethered to the nitrocellulose. The probe is then detected to reveal the position of the DNAs that hybridized with the probe.

Polymerase Chain Reactions

Another tool of molecular biology is to use a *polymerase chain reaction* (PCR) to amplify specific segments of DNA in vitro (in the test tube). PCR requires a pair of sequences, called primers, about twenty base pairs long that are complementary to the ends of the region of DNA to be amplified. High temperature is used to denature the double-stranded DNA. At a lower temperature, the primers anneal (base-pair) to their complementary sequences, and a thermal-stable DNA polymerase copies the single-stranded templates. After the replication of the segment between the two primers (one cycle), the newly synthesized double-stranded DNA molecules are denatured by high temperature, the temperature is lowered, primers anneal, and a second cycle of replication occurs. The number of DNA molecules produced doubles with each cycle of replication. As a result, a million copies of a single DNA molecule can be produced in only a few hours, if the appropriate sequences for the two primers are known. PCR is a very sensitive method: Even a single DNA molecule can be amplified. PCR is much faster than recombinant DNA cloning and can produce a large amount of a specific piece of DNA.

Developing ways to determine DNA sequences (the sequences of adenine, thymine, guanine, and cytosine base pairs on the DNA "rungs") has led to the identification of the complete DNA sequences of the genomes of a number of organisms, including the model plant *Arabidopsis* as well as the much more complex human genome.

TABLE OF CONTENTS

PUBLISHER'S NOTE

Magill's Encyclopedia of Science: Plant Life is designed to meet the needs of college and high school students as well as nonspecialists seeking general information about botany and related sciences. The definition of "plant life" is quite broad, covering the range from molecular to macro topics: the basics of cell structure and function, genetic and photosynthetic processes, evolution, systematics and classification, ecology and environmental issues, and those forms of life—archaea, bacteria, algae, and fungi—that, in addition to plants, are traditionally studied in introductory botany courses. A number of practical and issue-oriented topics are covered as well, from agricultural, economic, medicinal, and cultural uses of plants to biomes, plant-related environmental issues, and the flora of major regions of the world. (Readers should note that, although cultural and medicinal uses of plants are occasionally addressed, this encyclopedia is intended for broad information and educational purposes. Those interested in the use of plants to achieve nutritive or medicinal benefits should consult a physician.)

Altogether, the four volumes of *Plant Life* survey 379 topics, alphabetically arranged from *Acid precipitation* to *Zygomycetes*. For this publication, 196 essays have been newly acquired, and 183 essays are previously published essays whose contents were reviewed and deemed important to include as core topics. The latter group originally appeared in the following Salem publications: *Magill's Survey of Science: Life Science* (1991), *Magill's Survey of Science: Life Science, Supplement* (1998), *Natural Resources* (1998), *Encyclopedia of Genetics* (1999), *Encyclopedia of Environmental Issues* (2000), *World Geography* (2001), and *Earth Science* (2001). All of these previously published essays have been thoroughly scrutinized and updated by the set's editors. In addition to updating the text, the editors have added new bibliographies at the ends of all articles.

New appendices, providing essential research tools for students, have been acquired as well:

- a "Biographical List of Botanists" with brief descriptions of the contributions of 134 famous naturalists, botanists, and other plant scientists
- a Plant Classification table
- a Plant Names appendix, alphabetized by common name with scientific equivalents
- another Plant Names appendix, alphabetized by scientific name with common equivalents
- a "Time Line" of advancements in plant science (a discursive textual history is also provided in the encyclopedia-proper)
- a Glossary of 1,160 terms
- a Bibliography, organized by category of research
- a list of authoritative Web sites with their sponsors, URLs, and descriptions

Every essay is signed by the botanist, biologist, or other expert who wrote it; where essays have been revised or updated, the name of the updater appears as well. In the tradition of Magill reference, each essay is offered in a standard format that allows readers to predict the location of core information and to skim for topics of interest: The title of each article lists the topic as it is most likely to be looked up by students; the "Category" line indicates pertinent scientific subdiscipline(s) or area(s) of research; and a capsule "Definition" of the topic follows. Numerous subheads guide the reader

through the text; moreover, key concepts are italicized throughout. These features are designed to help students navigate the text and identify passages of interest in context. At the end of each essay is an annotated list of "Sources for Further Study": print resources, accessible through most libraries, for additional information. (Web sites are reserved for their own appendix at the end of volume 4.) A "See also" section closes every essay and refers readers to related essays in the set, thereby linking topics that, together, form a larger picture. For example, since all components of the plant cell are covered in detail in separate entries (from the *Cell wall* through *Vacuoles*), the "See also" sections for these dozen or so essays list all other essays covering parts of the cell as well as any other topics of interest.

Approximately 150 charts, sidebars, maps, tables, diagrams, graphs, and labeled line drawings offer the essential visual content so important to students of the sciences, illustrating such core concepts as the parts of a plant cell, the replication of DNA, the phases of mitosis and meiosis, the world's most important crops by region, the parts of a flower, major types of inflorescence, or different classifications of fruits and their characteristics. In addition, nearly 200 black-and-white photographs appear throughout the text and are captioned to offer examples of the important phyla of plants, parts of plants, biomes of plants, and processes of plants: from bromeliads to horsetails to wheat; from Arctic tundra to rain forests; from anthers to stems to roots; from carnivorous plants to tropisms.

Reference aids are carefully designed to allow easy access to the information in a variety of modes: The front matter to each of the four volumes includes the volume's contents, followed by a full "Alphabetical List of Contents" (of all the volumes). All four volumes include a "List of Illustrations, Charts, and Tables," alphabetized by key term, to allow readers to locate pages with (for example) a picture of the apparatus used in the *Miller-Urey Experiment*, a chart demonstrating the genetic offspring of *Mendel's Pea Plants*, a map showing the world's major zones of *Desertification*, a cross-section of *Flower Parts*, or a sampling of the many types of *Leaf Margins*. At the end of volume 4 is a "Categorized Index" of the essays, organized by scientific subdiscipline; a "Biographical Index," which provides both a list of famous personages and access to discussions in which they figure prominently; and a comprehensive "Subject Index" including not only the personages but also the core concepts, topics, and terms discussed throughout these volumes.

Reference works such as *Magill's Encyclopedia of Science: Plant Life* would not be possible without the help of experts in botany, ecology, environmental, cellular, biological, and other life sciences; the names of these individuals, along with their academic affiliations, appear in the front matter to volume 1. We are particularly grateful to the project's editor, Bryan Ness, Ph.D., Professor of Biology at Pacific Union College in Angwin, California. Dr. Ness was tireless in helping to ensure thorough, accurate, and up-to-date coverage of the content, which reflects the most current scientific knowledge. He guided the use of commonly accepted terminology when describing plant life processes, helping to make *Magill's Encyclopedia of Science: Plant Life* easy for readers to use for reference to complement the standard biology texts.

CONTRIBUTOR LIST

About the Editor: Bryan Ness is a full professor in the Department of Biology at Pacific Union College, a four-year liberal arts college located atop Howell Mountain in the Napa Valley, about ninety miles north of San Francisco. He received his Ph.D. in Botany from Washington State University. His doctoral work focused on molecular plant systematics and evolution. In addition to authoring or coauthoring a number of scientific papers, he has contributed to *The Jepson Manual: Higher Plants of California*, *The Flora of North America*, a multivolume guide to the higher plants of North America, and more than a dozen articles for various Salem Press publications, including *Aging*, *Encyclopedia of Genetics*, *Magill's Encyclopedia of Science: Animal Life*, *Magill's Medical Guide*, and *World Geography*. For four years he managed The Botany Site, a popular Internet site on botany. He is currently working on a book about plant myths and misunderstandings.

DNA REPLICATION

Categories: Cellular biology; genetics; reproduction and life cycles

DNA, deoxyribonucleic acid, is the hereditary material of most living creatures. It carries genetic information that determines all types of plant lives. DNA replication is a process by which a single DNA molecule is copied, resulting in two identical molecules prior to the cell division. The accuracy and precision in DNA replication has ensured the continuity of life from generation to generation.

Following James Watson and Francis Crick's landmark proposal for the structure of the deoxyribonucleic acid (DNA) molecule in 1953, many scientists turned their attention to how this molecule is replicated. The process of replication is the key to continuity of plant as well as other forms of life. The DNA molecule consists of two polymer chains (strands) forming a *double helix*. Each strand is made up of a five-carbon sugar (2'-deoxyribose), phosphoric acid, and four nitrogen-containing bases. Two bases are *purines*, which have a double-ring structure; the other two are *pyrimidines*, which contain a single ring. The purine bases are adenine (A) and guanine (G), while the pyrimidine bases are thymine (T) and cytosine (C). The two strands of a DNA molecule running in opposite directions are held together by hydrogen bonding between the A-T and G-C base pairs, which form the "rungs" of the ladder that makes the double helix. Such complementary *base pairing* is the foundation for the DNA double helix as well as its replication.

Semiconservative Replication

The replication mechanism first proposed by Watson and Crick was that the strands of the original (*parental*) duplex separate, and each individual strand serves as a pattern or template for the synthesis of a new strand (*daughter*). The daughter strands are synthesized by the addition of successive nucleotides in such a way that each base in the daughter strand is complementary to the base across the way in the template strand. This is called *semiconservative replication*.

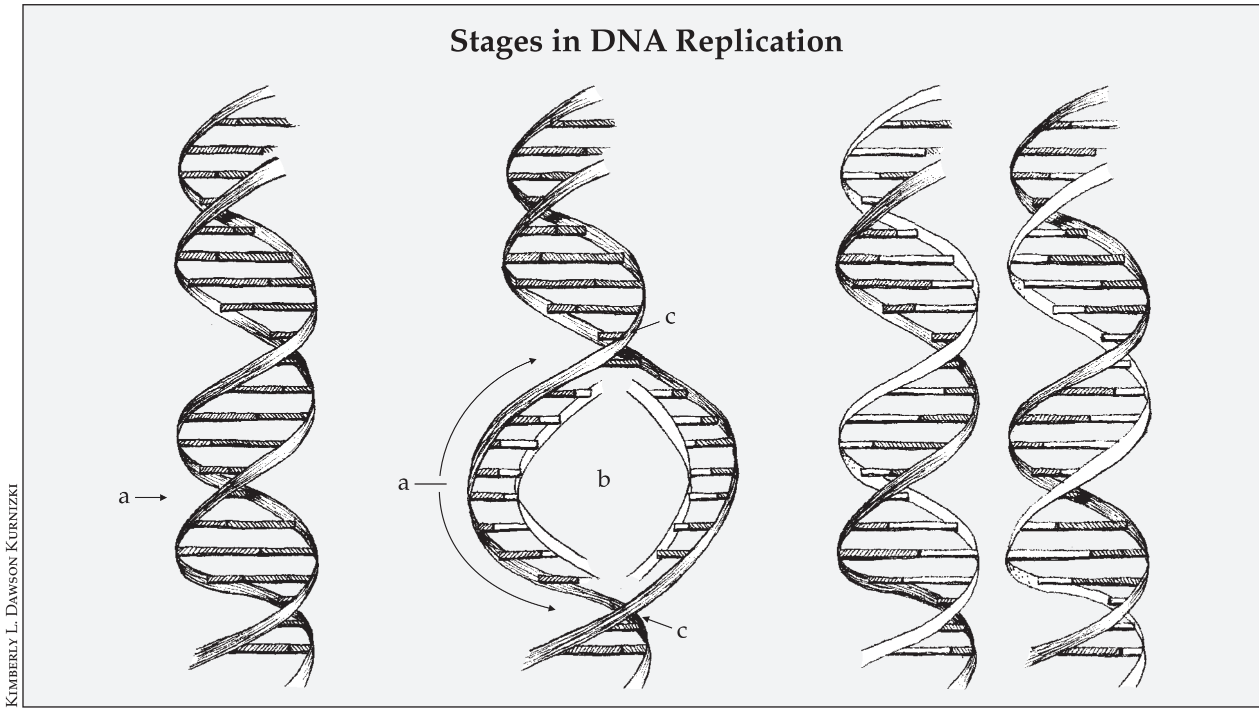
Although the mechanism is simple in principle, replication is a complex process, with geometric problems requiring energy, a variety of enzymes, and other proteins. The end result, nevertheless, is that a single double-stranded DNA is replicated into two copies having identical sequences. Each of the two daughter double-stranded DNA copies is made up of one parental strand and one newly synthesized strand, hence the name semi-conservative (literally, "half conserving") replication.

DNA Synthesis

DNA replication in plant cells occurs in three basic steps, each catalyzed by at least one enzyme. First, the two original, or parental, DNA strands of the double helix unwind and separate. Then each parental strand is used as a template for the formation of a new daughter strand. Finally, one parental strand and its newly synthesized daughter strand wind together into one double helix, while the other parental strand and its daughter strand wind together into a second double helix.

The process begins with the separation and unwinding of segments of the parental double helix. To accomplish this, an enzyme named *DNA helicase*, powered by adenosine triphosphate (ATP), works its way between the two strands. As this enzyme "plows" its way through the double helix, it breaks the hydrogen bonds that hold together the "rungs" of the ladder, formed by the base pairs. DNA helicase then "walks" along one strand, nudging the other strand out of its way as it goes. The result is that the two DNA strands separate, thus exposing their bases, as though the ladder had been split vetically, down through the rungs.

The second step of DNA synthesis requires the enzyme *DNA polymerase*, which performs a dual function during the replication. First, it recognizes bases exposed in a parental strand and matches them up with free nucleotides that have complementary bases. Second, DNA polymerase bonds to-



At left, a double-stranded DNA molecule, with the sides made of sugar-phosphate molecules and the "rungs" of base pairs. Replication begins at a point (a), with the separation of a base pair, as a result of the action of special initiator proteins (b). The molecule splits, or "unzips," in opposite directions (c) as each parental strand is used as a template for the formation of a new daughter strand (new bases pair with their appropriate "mate" bases to form new ladder "rungs"). Finally (right), one parental strand and its newly synthesized daughter strand form a new double helix, while the other parental strand and its daughter strand form a second double helix.

gether the sugars and phosphates of the complementary nucleotides to form the backbone of the daughter strand. Because the DNA polymerase can travel in only one direction on a DNA strand, from the 3′ end to 5′ end, the two DNA polymerase molecules, one on each parental strand, move in opposite directions. Only one daughter strand is synthesized continuously, while the duplication of another is done piece by piece. As the DNA helicase molecule continues to separate the parental strands, one polymerase simply follows behind it, synthesizing a long, continuous complementary daughter strand as it goes. The polymerase on the second parental strand travels away from the DNA helicase. As the helicase continues to separate the parental strands, this polymerase cannot reach the newly separated segment of the second strand. Hence a new DNA polymerase attaches to the second strand close behind the helicase to synthesize another small piece of DNA. These pieces are "sewn" together by another enzyme called *DNA ligase*. This process is repeated many times until the copying of a second parental strand is completed.

Proofreading and End-Sealing

Hydrogen bonding between complementary base pairs makes DNA replication highly accurate. However, the process is not perfect. This is a result partly of the fast pace (fifty to five hundred nucleotides added per second) and partly to the chemical flip-flops in the bases occurring spontaneously. DNA polymerase occasionally matches bases incorrectly, making on average one mistake in every ten thousand base pairs. Even this low rate of errors, if left uncorrected, would be devastating to the continuity of life. In reality, replicated DNA strands contain only one mistake in every billion base pairs. This incredible accuracy is achieved by several DNA repair enzymes, including DNA polymerase. Mismatches and errors are corrected through "proofreading" by DNA polymerase or other repair enzymes.

A separate problem in DNA replication lies at the end of a linear DNA molecule, which is not suitable for replication by polymerase. Yet another enzyme, *DNA telomerase*, is involved in solving this problem. It attaches a long stretch of repeating sequence of nucleotide 5′-TTGGGG-3′ to the strand already synthesized by polymerase. This ending sequence (called the *telomere*) offers protection and provides stability for plant DNA molecules.

Plant Propagation

Overall, the faithful replication and the amazing stability of each DNA molecule ensure the continuity and survival of species from generation to generation. DNA replication precedes every cycle of mitosis, so that two daughter cells derived from cell division can inherit a full complement of genetic material. The replication is also an essential prerequisite for plant sexual reproduction, a process by which the two sexual cells (pollen and egg) produced via meiosis are united to start a new generation.

The faithful DNA replication and subsequent cell divisions (mitosis) form the basis for plant growth as well as for vegetative propagation in many plant species. Growth in size and volume of the plant results from a combination of mitosis, cell enlargement, and cell differentiation. Mitosis is also essential in wound healing through the production of a mass of cells called callus. Vegetative propagation, an asexual process through mitosis, plays an important role in agriculture. Through vegetative propagation, individual plants of the progeny population are genetic copies both of the original source plant and of one another. Such plants are known as *clones*, and the process is called cloning. Examples of cloning include grafting hardwood cuttings of grapevines and apple trees and rapid propagation of liriope by crown division. The best-known example of vegetative propagation is probably the production of Macintosh apples via grafting. More recently, micropropagation via direct cell cultures and related biotechnology has played a critical role in agriculture.

DORMANCY

Categories: Gardening; physiology

Dormancy is the state in which a plant or plant part exhibits little or no growth and in which most, if not all, metabolic activity ceases for a period of time.

The vast majority of plant life functions best when there is ample water and temperatures are well above freezing throughout the year. Except for those in moist, tropical regions, however, plants are exposed to dry periods and temperatures below freezing for varying lengths of time during the year. Plants, unlike animals, do not have the luxury of body insulation or locomotion. Hence, plants cannot seek shelter or use other active ways to survive water shortages and cold weather. Consequently, many plants become dormant to avoid unfavorable environmental conditions. In dormancy, their *metabolic activity* either ceases or is drastically reduced.

Dormancy evolved as a means of surviving unfavorable environmental conditions. In the temperate zones, buds normally form from spring to midsummer. While there may be a little growth in the late summer, growth virtually ceases in the fall in preparation for winter. Entering a dormant state protects the buds from freezing temperatures.

Mature seeds contain a complete embryo along with a reserve food supply—and mature seeds are formed within ripened fruit. If it were not for germination inhibitors present in the fruit or seed, the seeds would begin to germinate while still in the fruit. In addition, the seeds of plants in temperate regions most often reach the soil in late summer or early fall, when the plants are most often faced with low moisture and imminent cold weather. Were the seeds to germinate at this time, survival would be unlikely.

Patterns of Growth and Death

The type of dormant response depends on the plant's pattern of growth and death. *Perennials* are plants that live year after year, undergoing a period of dormancy during the cold season. In *herbaceous* species, the aboveground portions die, but the plants survive as specialized underground stems. Woody shrubs and trees remain alive aboveground. *Deciduous* species shed their leaves in winter, while many nondeciduous species, often called *evergreens*, keep their leaves year-round but dramatically reduce their metabolic rates.

Biennial species live for two years. The first year is devoted to vegetative growth and the formation of underground storage tissues. After the plant lies dormant through the winter months, its second year of growth results in the stored food supply being used to produce flowers and seeds. *Annuals* are plants that complete an entire life cycle in one growing season. The plants die, producing seeds, which normally remain dormant until the following growing season.

Most perennial trees and shrubs in temperate regions produce buds in the summer. These buds, which can eventually develop into leaves, stems, or flowers, exhibit reduced metabolic activity even before leaves begin to *senesce* (age). As temperatures decrease in the fall, complete dormancy sets in. Specialized leaves called bud scales cover the dormant tissue. These scales block the diffusion of oxygen into the bud; they also prevent the loss of water from the tissue.

Almost all flowering plants produce seeds. The seeds develop as ovules within a structural component of the flower called the *ovary*. As the ovary ripens to form the fruit, the ovules mature into seeds. Each seed is composed of a reserved food supply and a new plant with embryonic root, leaf, and stem tissue. The embryonic plant and reserve food supply are surrounded by a tough seed coat. The seeds of many species, especially trees in the temperate zones, do not germinate immediately after maturing even under ideal moisture, temperature, and nutritional conditions because there is a built-in period of dormancy.

Although seasonal dormancy is most often correlated with temperature changes, variation in precipitation is the primary factor in regions where pronounced wet and dry seasons alternate. Some deciduous trees and shrubs drop their leaves and remain dormant during the dry season and grow new leaves when the rains return. Herbaceous perennials die back and go dormant at the beginning of the dry season, then regrow their aboveground biomass. Many desert annuals have seeds that will only break dormancy when sufficient rains come, which in some regions may be only every few years. Some particularly specialized seeds germinate only after they have been tumbled in the waters of a flash flood, which scrapes their seed coats.

Bud and Seed Dormancy

A number of environmental factors appear to induce bud dormancy. In many species, bud dormancy occurs in response to low temperatures; among other species, the proper short-day *photoperiod* is responsible for initiating dormancy. In still other species, both low temperature and short days are required to trigger the onset of dormancy. Hence, dormancy is generally initiated with the onset of the short or cold days of winter. In addition, dormancy in buds has been shown to occur under situations of limited supply of nutrients or drought conditions. Dormancy can therefore be seen as a survival mechanism. When temperature, water, or nutritional conditions are no longer favorable, the buds become dormant.

Seed dormancy can also be caused by a number of different factors. For several reasons, the presence of a hard *seed coat* will very often result in dormancy of the seed. In many cases, the seed coat is impermeable to water. Because water is required for the *germination* process, the impermeable nature of the seed coat will serve as an effective inducer of dormancy. In some instances, the seed coat may be impermeable to certain gases. Both carbon dioxide and oxygen are required for germination; some seed coats prevent the diffusion of oxygen into the seed, while others are impermeable to carbon dioxide. In a few species, the seed coat physically restricts the growth of the embryo. A growing embryo must develop sufficient thrust to break through a seed coat, and in some instances the seed coat prevents this from happening.

Seed germination is also dependent on temperature. The seeds of almost all species have a minimal temperature below which they will not germinate. The exact mechanism by which low temperature causes dormancy is poorly understood, but it appears that the temperature alters membrane structure, which somehow prevents the seed from germinating.

Light is also a factor in the dormancy of many seeds. In many species, light is required for germination; in some cases, however, the exposure to light will induce dormancy. Also, some species exhibit a sensitivity to the photoperiod. Certain species are dormant during short-day cycles and germinate during long-day cycles, while others remain dormant when exposed to long-day cycles and germinate under short-day cycles. The light apparently activates a plant regulator that blocks the metabolic reactions necessary for germination.

Genetic and Chemical Control

Numerous studies show that bud dormancy is induced in some varieties of certain species but not in other varieties of the same species. This difference suggests there may be genetic variation in the control mechanism. The exact mechanisms of genetic control are not clearly understood, but there are some clues about chemical control.

The plant hormone *abscisic acid* may be associated with bud dormancy, but the evidence is inconclusive. With seed dormancy, however, the involvement of abscisic acid is fairly certain. A number of studies have shown that abscisic acid, when applied to the seed, will block the activity of enzymes necessary for germination.

A number of germination-inhibiting substances are present in dormant seeds. *Respiratory inhibitors*, such as cyanide, are produced in some seeds. High concentrations of various inorganic salts prevent germination in some species, while an assortment of phenolic compounds are known to prevent the process in others. A compound known as *coumarin* is particularly widespread in seeds and is known to be an effective inhibitor of germination. A number of these germination-inhibiting substances are present in both fruit and seed and prevent the seeds from germinating within the fruit. In addition, the substances will cause the seeds to lie dormant in nature until sufficient rain has fallen to leach the substances from the seeds. This adaptation ensures that sufficient moisture will be available to support the young seedlings.

Breaking Dormancy

It is often desirable to break dormancy artificially in order to obtain faster growth or increase plant production. Treatments to release bud and seed dormancy can be categorized by their use of temperature, light, chemicals, or mechanical means. Artificial exposure to low temperatures, warmth, and altered photoperiods, either singly or in combination, mimics the natural environmental factors that break dormancy.

A number of chemicals break bud dormancy. Ethylene chlorohydrin has been used for years to release dormancy in many fruit trees, and natural hormones known as *gibberellins* will break dormancy in most cold-requiring plants when applied directly to the buds. Gibberellins, *cytokinins*, and *ethylene*, all natural plant hormones, have been shown to be involved in breaking seed dormancy, and the gibberellins and other substances, such as thiourea, are used to germinate seeds commercially. The *scarification* (mechanical breaking) of the seed coat has proven to be an effective means of overcoming dormancy in many seeds. The broken seed coats allow the seeds to take up the water and gases necessary for germination.

DROUGHT

Categories: Agriculture; environmental issues

Drought is a shortage of precipitation that results in a water deficit for some activity. Droughts occur in both arid and humid regions.

One problem in analyzing and assessing the impacts of drought, as well as in delimiting drought areas, is simply defining "drought" itself. Conditions considered a drought by a farmer whose crops have withered during the summer may not be seen as a drought by a city planner. There are many types of drought: *agricultural*, *hydrological*, *economic*, and *meteorological*. The Palmer Drought Severity Index is the best known of a number of indexes that attempt to standardize the measurement of drought magnitude. Nevertheless, there still is much confusion and uncertainty on what defines a drought.

Roger G. Barry and Richard J. Chorley, in *Atmosphere, Weather, and Climate* (1998), have noted that drought conditions tend to be associated with one or more of four factors: increases in extent and persistence of subtropical high-pressure cells; changes in the summer monsoonal circulation patterns that can cause a postponement or failure of the incursion of wet maritime tropical air onto the land; lower ocean surface temperatures resulting from changes in ocean currents or increased upwelling of cold waters; and displacement of midlatitude storm tracks by drier air.

Effects of Drought

Drought can have wide-ranging impacts on the environment, communities, and farmers. Most plants and animals in arid regions are adapted to dealing with drought, either behaviorally or through specialized physical adaptations. Humans, however, are often unprepared or overwhelmed by the consequences of drought. Farmers experience decreased incomes from crop failure. Low rainfall frequently increases a crop's susceptibility to disease and pests. Drought can particularly hurt small rural communities, especially local business people who are dependent on purchases from farmers and ranchers.

Drought is a natural element of climate, and no region is immune to the drought hazard. Farmers in humid areas grow crops that are less drought-resistant than those grown in arid regions. In developing countries the effects of drought can include malnutrition and famine. A prolonged drought struck the Sahel zone of Africa from 1968 through 1974. Nearly 5 million cattle died during the drought, and more than 100,000 people died from malnutrition-related diseases during just one year of the drought.

Subsistence and traditional societies can be very resilient in the face of drought. American Indians either stored food for poor years or migrated to wetter areas. The !Kung Bushmen of southern Africa learned to change their diet, find alternate water sources, and generally adapt to the fluctuation of seasons and climate in the Kalahari Desert.

More than any other event, the Dust Bowl years of the 1930's influenced Americans' perceptions and knowledge of drought. Stories of dust storms that turned day into night, fences covered by drifting soil, and the migration of destitute farmers from the Great Plains to California captured public and government attention. The enormous topsoil loss to wind erosion, continuous crop failures, and widespread bankruptcies suggested that the United States had in some way failed to adapt to the drought hazard.

Federal Drought Response in the United States

Beginning in the 1930's, the federal government took an increasing role in drought management and relief. In 1933 the federal government created the Soil Erosion Service, known today as the Natural Resources Conservation Service. No other single federal program or organization has had a greater impact on farmers' abilities to manage the drought hazard. President Franklin D. Roosevelt's Prairie States Forestry Project (1934-1942) planted more than 230,000 acres of shelterbelts in the Plains states for wind erosion control. The federal government purchased nearly 1 million acres of marginal farmland for replanting with grass. Federal agencies constructed water resource and irrigation projects.

Post-Dust Bowl droughts still caused hardships, but the brunt of the environmental, economic, and social consequences of drought were considerably lessened. Fewer dust storms ravaged the Plains. New crop varieties and better farming practices decreased crop losses during drought years. Government programs and better knowledge have enabled families and communities to cope better with drought.

Coping with Future Droughts

Numerous attempts have been made to predict droughts, especially in terms of cycles. However, attempts to predict droughts one or more years into the future have generally been unsuccessful. The

PhotoDisc

Low rainfall is one factor that can lead to drought, leaving the soil too parched for plants to grow. Drought is a natural element of climate, and no region is immune to drought hazard.

Impacts of Drought

While a farmer is aware of drought conditions in the course of his or her day-to-day activities, an urban dweller first knows about drought conditions only when he or she reads a newspaper article or views a television news item. However, droughts become important to urban inhabitants when they are affected directly.

Droughts affect urban and rural users whose water comes from wells when the water table lowers and the water supply either diminishes or becomes more expensive to pump. Redrilling wells to pump from lowered water levels can be expensive. Users hooked up to a water utility receive notices about drought from their water supplier.

In dry climates, California for example, drought is classified into five levels, depending on the severity of a drought and projected availability of water supplies. The classifications and penalties for excess use have been defined by the California State Water Resources Control Board. Drought levels increase as the projected severity increases. In the lowest level (Level 1), voluntary conservation measures are encouraged, and water conservation information is published by the supplier. As the anticipated severity increases, conservation measures become mandatory and more restrictive. The water utility imposes cutback goals. Fines for overuse may be imposed and, in egregious instances, water service can be terminated until corrective action is taken. To encourage conservation even when plentiful water supplies are projected, water rates have been implemented to include inverted rate blocks (the more one uses, the higher unit price one pays).

shorter the prediction interval has been, the more accurate the prediction has been. Nevertheless, progress has been made in estimating drought occurrence and timing. For example, the El Niño/Southern Oscillation may be a precursor of drought in some areas. Possibly with time, the physical mechanics of climate and drought will be understood adequately for long-term predictions to have value.

Perhaps of greater value is the current capacity to detect and monitor drought in its early stages (usually meaning within one to twelve months). Early recognition of potential drought conditions can give policymakers and resource managers the extra time needed to adjust their management strategies. Information on soil moisture conditions aids farmers with planting and crop selection, seeding, fertilization, irrigation rates, and harvest decisions. Communities that have a few months' warning of impending drought can increase water storage, implement water conservation measures, and obtain outside sources of water.

Unfortunately, the progress made in the world's developed countries has not always been available to the developing nations. Overpopulation and overuse of agricultural lands have resulted in regional problems of *desertification* and impeded the ability of developing nations to respond. Monitoring equipment can be costly. Furthermore, drought adjustments used in the United States may not be applicable to other countries' drought situations.

ECOLOGY: CONCEPT

Categories: Disciplines; ecology; ecosystems; forests and forestry

Ecology is the scientific study of ecosystems, which are generally defined as local units of nature, consisting of the aggregate of plants, animals, the physical environment, and their interactions.

Ecosystems consist of both *biotic* (living) and *abiotic* (nonliving) components. Biotic components include plants, animals, and microorganisms. The abiotic components are the physical factors of the ecosystem. The roots of ecology can be traced to the writings of early Greek philosophers such as Aristotle and Theophrastus, who were keen observers of plants and animals in their natural habitats. During the nineteenth century, German biogeographer Alexander von Humboldt and English naturalist Charles Darwin wrote detailed descriptions of their travels. They recognized that the distribution of living things is determined by such factors as rainfall, temperature, and soil.

The word "ecology" was first proposed in 1869 by the German biologist Ernst Haeckel. It soon came to be defined as "environmental biology," or the effect of environmental factors on living things. At the beginning of the twentieth century, American botanist Henry Cowles established *plant succession* as a major concept of ecology. During the next few decades, F. E. Clements helped establish plant ecology as a recognized branch of biology. Animal ecology developed separately and slightly later. Reflecting the independent development of plant and animal ecology, most ecological studies in the early twentieth century were concerned with either plant or animal communities but not both. Furthermore, most were descriptive rather than being involved with explanations of fundamental ecological processes.

However, other lines of research during this time increasingly emphasized interrelationships among all life-forms, especially those within lakes. From such beginnings emerged the concept of the ecosystem. The term, first used by British ecologist Arthur G. Tansley in the 1930's, is now considered the foundation stone of ecology.

Ecosystems at Work

Ecologists place all the organisms of an ecosystem into three categories: *producers*, *consumers*, and *decomposers*. Producers include algae and green plants that, because of their ability to generate biochemical energy by means of *photosynthesis*, produce all the food for the ecosystem. Consumers (herbivores, omnivores, and carnivores) are animals that feed directly on the producers. Decomposers are bacteria and fungi that break the large organic molecules of dead plants and organisms down into simpler substances. Ecosystems are dynamic. Each day, matter (nutrients) cycles through ecosystems as consumers eat producers, then moves to decomposers, which release nutrients into the soil, air, and water. Producers absorb nutrients as they photosynthesize, thus completing the cycle. Energy flows from the sun to producers, then consumers, and finally to decomposers.

Other changes in ecosystems occur over longer periods of time. Large-scale disturbances such as fire, logging, and storms initiate gradual, long-term changes known as *ecological succession*. Following a major disturbance, an ecosystem of pioneer species exists for a while but is soon replaced by a series of other temporary ecosystems. Eventually a permanent, or climax, ecosystem is formed, the nature of which is primarily determined by climate. Although generally considered to be stable, climax communities are subject to gradual changes caused by climatic fluctuations or subsequent disturbances.

Classifying Systems and Study

Ecologists attempt to name and classify ecosystems in a manner similar to the way that taxonomists name and classify species. Ecosystems may be named according to their dominant plants, such as deciduous forests, prairies, and evergreen forests. Others, such as coral reefs, are named according to their dominant animals. Physical factors are used to name deserts, ponds, tidal pools, and other ecosystems.

The science of ecology has developed a few major branches as well as several areas of specialization, with theoretical, or academic, ecology on one hand and applied, or practical, ecology on the other. Among the specialties that have developed from *theoretical ecology* are *autecology* (study at the level of individuals or species), *synecology* (study at the community level), and the *ecosystems approach*, which is largely concerned with the flow of energy and the cycling of nutrients within ecosystems. As one might expect, theoretical ecologists are generally associated with universities, where their basic research contributes to the understanding of a great diversity of ecosystems.

Applied ecologists are employed by a variety of governmental and environmental agencies as well as by universities. Their primary objective is to apply fundamental principles of ecology and related disciplines to the solution of specific problems. *Forestry*, although it developed independently from ecology, may be considered a specialty within the field of *applied ecology*. Foresters must be knowledgeable of a wide range of factors that influence the accumulation of tree biomass. Wildlife management, once concerned with only game species, has been extended to include a wide range of nongame animal species as well. Another branch of applied ecology is *conservation biology*. Concerned with biodiversity in all its aspects, conservation biologists attempt to prevent the extinction of threatened species around the globe. Disturbed ecosystems are rehabilitated by scientists working in a related field called *restoration ecology*.

The efforts of ecologists, whether theoretical or applied, represent attempts to understand and solve the many environmental challenges that humankind faces. Climate change, pollution, and other global and local problems contribute to a loss of biodiversity. All are made worse by increasing human activities.

ECOLOGY: HISTORY

Categories: Disciplines; ecology; ecosystems; history of plant science

Ecology is the science that studies the relationships among organisms and their biotic and abiotic environments. The term "ecology" is commonly, but mistakenly, used by people to refer to the environment or to the environmental movement.

The study of ecological topics arose in ancient Greece, but these studies were part of a catch-all science called natural history. The earliest attempt to organize an ecological science separate from natural history was made by Carolus Linnaeus in his essay *Oeconomia Naturae* (1749; *The Economy of Nature*), which focused on the balance of nature and the environments in which various natural communities existed. Although the essay was well known, the eighteenth century was dominated by biological exploration of the world, and the science of ecology did not develop.

Early Ecological Studies

The study of fossils led some naturalists to conclude that many species known only as fossils must have become extinct. However, Jean-Baptiste Lamarck argued in his *Philosophie zoologique* (1809; *Zoological Philosophy*, 1914) that fossils represented the early stages of species that evolved into different species that were still living. In order to refute this claim, geologist Charles Lyell mastered the science of biogeography and used it to argue that species do become extinct and that competition from other species seemed to be the main cause. English naturalist Charles Darwin's book *On the Origin of Species by Means of Natural Selection* (1859) blends his own researches with the influence of Linnaeus and Lyell in order to argue that some species do become extinct, but existing species have evolved from earlier ones. Lamarck had underrated and Lyell had overrated the importance of competition in nature.

Although Darwin's book was an important step toward ecological science, he and his colleagues mainly studied evolution rather than ecology. However, German evolutionist Ernst Haeckel realized the need for an ecological science and coined the name *oecologie* in 1866. It was not until the 1890's that steps were actually taken to organize this science. Virtually all of the early ecologists were specialists in the study of particular groups of organisms, and it was only in the late 1930's that some efforts were made to write textbooks covering all aspects of ecology. Since the 1890's, most ecologists have viewed themselves as *plant ecologists*, *animal ecologists*, *marine biologists*, or *limnologists*. Limnology is the study of freshwater aquatic environments.

Nevertheless, general ecological societies were established. The first was the British Ecological Society, which was founded in 1913 and began publishing the *Journal of Ecology* in the same year. Two years later ecologists in the United States and Canada founded the Ecological Society of America, which began publishing *Ecology* as a quarterly journal in 1920; in 1965 *Ecology* began appearing bimonthly. Other national societies have since been established. More specialized societies and journals also began appearing. For example, the Limnological Society of America was established in 1936 and expanded in 1948 into the American Society of Limnology and Oceanography. It publishes the journal *Limnology and Oceanography*.

Although Great Britain and Western Europe were active in establishing the study of ecological sciences, it was difficult for their trained ecologists to obtain full-time employment that utilized their expertise. European universities were mostly venerable institutions with fixed budgets; they already had as many faculty positions as they could afford, and these were all allocated to the older arts and sciences. Governments employed few, if any, ecologists. The situation was more favorable in the United States, Canada, and Australia, where universities were still growing. In the United States, the universities that became important for ecological research and the training of new ecologists were mostly in the Midwest. The reason was that eastern universities were similar to European ones in being well established, with scientists in traditional fields.

Ecology After 1950

Ecological research in the United States was not well funded until after World War II. With the advent of the Cold War, science was suddenly considered important for national welfare. In 1950 the U.S. Congress established the National Science Foundation, and ecologists were able to make the case for their research along with that of the other sciences. The Atomic Energy Commission had already begun to fund ecological researches by 1947, and under its patronage the Oak Ridge Laboratory and the University of Georgia gradually became important centers for radiation ecology research.

Another important source of research funds was the International Biological Program (IBP), which, though international in scope, depended upon national research funds. It got under way in the United States in 1968 and was still producing publications in the 1980's. Even though no new funding sources were created for the IBP, its existence meant that more research money flowed to ecologists than otherwise would have.

Ecologists learned to think big. Computers became available for ecological research shortly before the IBP got under way, and so computers and the IBP became linked in ecologists' imaginations. Earth Day, established in 1970, helped awaken Americans to the environmental crisis. The IBP encouraged a variety of studies, but in the United States, studies of biomes (large-scale environments) and ecosystems were most prominent. The biome studies were grouped under the headings of desert, eastern deciduous forest, western coniferous forest, grassland, and tundra (a proposed tropical forest program was never funded). Although the IBP has ended, a number of the biome studies continued at a reduced level.

Ecosystem studies are also large-scale, at least in comparison with many previous ecological studies, though smaller in size than a biome. The goal of ecosystem studies was to gain a total understanding of how an ecosystem—such as a lake, river valley, or forest—works. IBP funds enabled students to collect data, which computers processed. However, ecologists could not agree on what data to collect, how to compute outcomes, and how to interpret the results. Therefore, thinking big did not always produce impressive results.

Plant Ecology

Because ecology is enormous in scope, it was bound to have growing pains. It arose at the same time as the science of genetics, but because genetics is a cohesive science, it reached maturity much sooner than ecology. Ecology can be subdivided in a wide variety of ways, and any collection of ecology textbooks will show how diversely it is organized by different ecologists. Nevertheless, self-identified professional subgroups tend to produce their own coherent findings.

Plant ecology progressed more rapidly than other subgroups and has retained its prominence. In the early nineteenth century, German naturalist Alexander von Humboldt's many publications on plant geography in relation to climate and topography were a powerful stimulus to other botanists. By the early twentieth century, however, the idea of plant communities was the main focus for plant ecologists. Henry Chandler Cowles began his studies at the University of Chicago in geology but switched to botany and studied plant communities on the Indiana dunes of Lake Michigan. He received his doctorate in 1898 and stayed at that university as a plant ecologist. He trained others in the study of community succession.

Frederic Edward Clements received his doctorate in botany in 1898 from the University of Nebraska. He carried the concept of plant community succession to an extreme by taking literally the analogy between the growth and maturation of an organism and that of a plant community. His numerous studies were funded by the Carnegie Institute in Washington, D.C., and even ecologists who disagreed with his theoretical extremes found his data useful. Henry Allan Gleason was skeptical; his studies indicated that plant species that have similar environmental needs compete with one another and do not form cohesive communities. Although Gleason first expressed his views in 1917, Clements and his disciples held the day until 1947, when Gleason's individualistic concept received the support of three leading ecologists. Debates over plant succession and the reality of communities helped increase the sophistication of plant ecologists and prepared them for later studies on biomes, ecosystems, and the degradation of vegetation by pollution, logging, and agriculture.

Marine Ecology

Marine ecology is viewed as a branch of either ecology or oceanography. Early studies were made either from the ocean shore or close to shore because of the great expense of committing oceangoing vessels to research. The first important research institute was the Statione Zoologica at Naples, Italy, founded in 1874. Its successes soon inspired the founding of others in Europe, the United States, and other countries. Karl Möbius, a German zoologist who studied oyster beds, was an important pioneer of the community concept in ecology. Great Britain dominated the seas during the nineteenth century and made the first substantial commitment to deep-sea research by equipping the HMS *Challenger* as an oceangoing laboratory that sailed the world's seas from 1872 to 1876. Its scientists collected so many specimens and so much data that they called upon marine scientists in other countries to help them write the fifty large volumes of reports (1885-1895). The development of new technologies and the funding of new institutions and ships in the nineteenth century enabled marine ecologists to monitor the world's marine fisheries and other resources and provide advice on harvesting marine species.

Limnology is the scientific study of bodies of fresh water. The Swiss zoologist François A. Forel coined the term and also published the first textbook on the subject in 1901. He taught zoology at the Académie de Lausanne and devoted his life's researches to understanding Lake Geneva's characteristics and its plants and animals. In the United States in the early twentieth century, the University of Wisconsin became the leading center for limnological research and the training of limnologists, and it has retained that preeminence. Limnology is important for managing freshwater fisheries and water quality.

ECOSYSTEMS: OVERVIEW

Categories: Ecology; ecosystems

An ecosystem is made up of the complex interactions of a community of organisms of different species with one another and with their abiotic (nonliving) environment.

A *biological community* consists of a mixture of populations of individual species; a *population* consists of potentially interbreeding members of a species. Individual organisms interact with members of their own species as well as with other species. An ecosystem is formed by this web of interactions among species, along with the physical, chemical, and climatic conditions of the area.

Abiotic and Biotic Interactions

Abiotic environmental conditions include temperature, water availability, soil nutrient content, and many other factors that depend on the climate, soil, and geology of an area. Living organisms can alter their environment to some degree. A canopy formed by large forest trees, for example, will change the light, temperature, and moisture available to herbaceous plants growing near the forest floor. The environmental conditions in a particular area can also be affected by the conditions of neighboring areas. The disturbance of a stream bank can lead to erosion, which will affect aquatic habitat for a considerable distance downstream. It can be difficult to anticipate the wide-ranging affects of ecosystem disturbance.

Species and individuals within an ecosystem may interact directly with one another through the exchange of energy and material. *Predators*, for example, obtain their energy and meet their nutritional needs through consumption of prey species. Organisms also interact indirectly through modification of their surrounding environment. Earthworms physically modify soil structure, affecting aeration and the transport of water through the soil. These alterations of the physical environment, in turn, affect plant root growth and development as well as the ability of plants to secure nutrients.

Ecosystems are not closed systems: Energy and material are transferred to and from neighboring systems. The flow of energy or material among the components of an ecosystem, and exchanges with neighboring ecosystems, are governed by functions of the abiotic and biotic ecosystem components. These ecological processes operate simultaneously on many different temporal and spatial scales. At the same time that a microorganism is consuming a fallen leaf, the process of soil formation is occurring through chemical and physical weathering of parent material; plants are competing with one another for light, water, and nutrients.

Boundaries and Temporal Scales

Because of the exchange of energy and material, it is not possible to draw clear boundaries around an ecosystem. A *watershed*, for example, is formed by topographic conditions that create physical barriers guiding the gravitational flow of water, yet

NOAA/National Estuarine Research Reserve Collection

Wetlands ecosystem on Bear Island, South Carolina.

wind carries seeds and pollen over these barriers, and animals can move from watershed to watershed. The strength of the interactions among neighboring systems is the basis on which humans delineate ecosystem boundaries. In truth, all ecosystems around the world interact with one another to some degree.

Ecological processes operate on many different time scales as well. Some operate over such long time scales that they are almost imperceptible to human observation. The process of soil formation occurs over many human life spans. Other processes operate over extremely short time intervals. The reproduction of soil bacteria, the response of leaves to changing temperature over the length of a day, and the time required for chemical reactions in the soil are all very short when compared to a human life span.

Ecosystem Disturbances

Ecosystems are subject to disturbance, or perturbation, when one or more ecosystem processes are interrupted. Disturbance is a natural ecological process, and the character of many ecosystems is shaped by natural disturbance patterns. There are species that require disturbance in order to regenerate themselves. These species may be present in great abundance following a disturbance. Their abundance then decreases over time, and if there is no disturbance to renew the population, they will eventually die out and no longer be present in the ecosystem.

The successful reproduction of many prairie species may be dependent on periodic fires. Suppression of fire as a means of protecting an ecosystem may lead to the local extinction of small plants, which depend on periodic fires to increase light availability by removing larger grasses and providing nutrients to the soil. The formation of sandbars in streams may be controlled by periodic flood events that remove great amounts of sediment from stream banks. Protection of existing ecosystems can depend on the protection or simulation of *natural disturbances*. This is even true of old-growth forests; the natural disturbance interval due to fire or windstorm may be centuries, and yet interruption of the natural disturbance pattern may lead to shifts in species composition or productivity.

Increasing the frequency of disturbance can also affect ecosystem structure and function. Repeated vegetation removal will favor species that take advantage of early-successional conditions at the expense of species that are more adapted to late-successional conditions. In order to ensure continued functioning of ecosystem processes and the survival of all species, it is necessary to have a mix of systems in early-successional and late-successional stages in a landscape. Human resource utilization must be managed within this context in order to ensure the long-term sustainability of all ecosystem components and to reduce the chances of extinction of some species due to human alteration of natural disturbance intervals.

Ecosystem Stability

A system is stable, or in *equilibrium*, if it can return to its previous condition at some time after disturbance. The length of time required to return to the original condition is the *recovery time*. The reestablishment of a forest following harvesting and the renewed production of forage following grazing both depend on the inherent stability of the affected ecosystem. The stability of an ecosystem is dependent on its components and their interrelationships. Disturbance may primarily affect one component of an ecosystem, as with salmon fishing in the Pacific Ocean. The ability of the entire ecosystem to adjust to this disturbance depends on the complexities of the interrelationships between the salmon, their predators and prey, and their competitors.

The length of the recovery time varies with the type of system, the natural disturbance interval, and the severity of the disturbance. A system is usually stable only within some bounds. If disturbed beyond these recovery limits the system may not return to its previous state but may settle into a new equilibrium. There are examples in the Mediterranean region of systems that were overgrazed in ancient times that have never returned to their previous species composition and productivity. Forest managers, farmers, fishermen, and others must understand the natural resiliency of the systems within which they work and stay within the bounds of stability in order to ensure sustainable resource utilization into the future.

Matter and Energy Cycles

Ecological processes work through the cycling of matter and energy within the system. *Nutrient cycling* consists of the uptake of nutrients from the soil and the transfer of these nutrients through plants, herbivores, and predators until their eventual return to the soil to begin the cycle anew. Interruption of these cycles can have far-reaching consequences in the survival of different ecosystem components.

These cycles also govern the transport of toxic substances within a system. It took many years before it was realized that persistent pesticides such as DDT would eventually be concentrated in top predators, such as raptors. The decline in populations of birds of prey because of reproductive failure caused by DDT was a consequence of the transport of the chemical through ecosystem food webs. Likewise, radionucleides from the 1986 explosion at the Chernobyl nuclear reactor have become concentrated in certain components of the ecosystems where they were deposited. This is particularly true of fungi, which take radionucleides and heavy metals from their food sources but do not shed the substances. Humans eating mushrooms from these forests can receive larger than expected doses of radiation, because the concentration in the fungi is much greater than in the surrounding system.

A basic understanding of ecosystem properties and processes is critical in designing management methods to allow continued human utilization of systems while sustaining ecosystem structure and function. With increasing human population and advancing living standards, more and more natural ecosystems are being pushed near their limits of stability. It is therefore critical for humans to understand how ecosystems are structured and function in order to ensure their sustainability in the face of continued, and often increasing, utilization.

ECOSYSTEMS: STUDIES

Categories: Ecology; ecosystems; history of plant science

The study of ecosystems defines a specific area of the earth and the attendant interactions among organisms and the physical-chemical environment present at the site.

Ecosystems are viewed by ecologists as basic units of the *biosphere*, much as cells are considered by biologists to be the basic units of an organism. Ecosystems are self-organized and self-regulating entities within which energy flows and resources are cycled in a coordinated, interdependent manner to sustain life. Disruptions and perturbations to, or within, the unit's organization or processes may reduce the quality of life there or cause its demise. Ecosystem boundaries are usually defined by the research or management questions being asked. An entire ocean can be viewed as an ecosystem, as can a single tree, a rotting log, or a drop of pond water. Systems with tangible boundaries—such as forests, grasslands, ponds, lakes, watersheds, seas, or oceans—are especially useful to ecosystem research.

Image Not Available

Research Principles

The ecosystem concept was first put to use by American limnologist Raymond L. Lindeman in the classic study he conducted on Cedar Bog Lake, Minnesota, which resulted in his article "The Trophic Dynamic Aspect of Ecology" (1942). Lindeman's study, along with the publication of Eugene P. Odum's *Fundamentals of Ecology* (1953), converted the ecosystem notion into a guiding paradigm for ecological studies, thus making it a concept of theoretical and applied significance.

Ecologists study ecosystems as integrated components through which energy flows and resources cycle. Although ecosystems can be divided into many components, the four fundamental ones are *abiotic* (nonliving) *resources*, *producers*, *consumers*, and *decomposers*. The ultimate sources of energy come from outside the boundaries of the ecosystem (solar energy or chemothermo energy from deep-ocean hydrothermal vent systems). Because this energy is captured and transformed into chemical energy by producers and translocated through all biological systems via consumers and decomposers, all organisms are considered as potential sources of energy.

Abiotic resources—water, carbon dioxide, nitrogen, oxygen, and other inorganic nutrients and minerals—primarily come from within the boundaries of the ecosystem. From these, producers utilizing energy synthesize biomolecules, which are transformed, upgraded, and degraded as they cycle through the living systems that comprise the various components. The destiny of these *bioresources* is to be degraded to their original abiotic forms and recycled.

The ecosystem approach to environmental research is a major endeavor. It requires amassing large amounts of data relevant to the structure and function of each component. These data are then integrated among the components, in an attempt to determine linkages and relationships. This holistic ecosystem approach to research involves the use of systems information theory, predictive models, and computer application and simulations. As ecosystem ecologist Frank B. Golley stated in his book *A History of the Ecosystem Concept in Ecology* (1993), the ecosystem approach to the study of ecosystems is "machine theory applied to nature."

Research Projects

Initially, ecosystem ecologists used the principles of Arthur G. Tansley, Lindeman, and Odum to determine and describe the flow of energy and resources through organisms and their environment. Fundamental academic questions that plagued ecologists included those concerning controls on ecosystem productivity: What are the connections between animal and plant productivity? How are energy and nutrients transformed and cycled in ecosystems?

Once fundamental insights were obtained, computer-model-driven theories were constructed to provide an understanding of the biochemophysical dynamics that govern ecosystems. Responses of ecosystem components could then be examined by manipulating parameters within the simulation model. Early development of the ecosystem concept culminated, during the 1960's, in defining the approach of ecosystem studies.

Ecosystem projects were primarily funded under the umbrella of the International Biological Program (IBP). Other funding came from the Atomic Energy Commission and the National Science Foundation. The intention of the IBP was to integrate data collected by teams of scientists at research sites that were considered typical of wide regions. Although the IBP was international in scope, studies in the United States received the greatest portion of the funds—approximately $45 million during the life of IBP (1964-1974).

Five major IBP ecosystem studies, involving *grasslands*, *tundra*, *deserts*, *coniferous forests*, and *deciduous forests*, were undertaken. The Grasslands Project, directed by George Van Dyne, set the research stage for the other four endeavors. However, because the research effort was so extensive in scope, the objectives of the IBP were not totally realized. Because of the large number of scientists involved, little coherence in results was obtained even within the same project. A more pervasive concern, voiced by environmentalists and scientists alike, was that little of the information obtained from the ecosystem simulation models could be applied to the solution of existing environmental problems.

An unconventional project partially funded by the IBP was called the Hubbard Brook Watershed Ecosystem. Located in New Hampshire and studied by F. Herbert Bormann and Gene E. Likens, the project redirected the research approach for studying ecosystems from the IBP computer-model-driven theory to more conventional scientific methods of study. Under the Hubbard Brook approach, an ecosystem phenomenon is observed and noted. A pattern for the phenomenon's behavior is then established for observation, and questions are posed about the behavior. Hypotheses are developed to allow experimentation in an attempt to explain the observed behavior. This approach requires detailed scrutiny of the ecosystem's subsystems and their linkages. Since each ecosystem functions as a unique entity, this approach has more utility. The end results provide insights specific to the activities observed within particular ecosystems. Explanations for these observed behaviors can then be made in terms of biological, chemical, or physical principles.

Utility of the Concept

Publicity from the massive ecosystem projects and the publication of Rachel Carson's classic *Silent Spring* (1962) helped stimulate the environmental movement of the 1960's. The public began to realize that human activity was destroying the bioecological matrices that sustained life. By the end of the 1960's, the applicability of the IBP approach to ecosystem research was proving to be purely academic and provided few solutions to the problems that plagued the environment. Scientists realized that, because of the lack of fundamental knowledge about many of the systems and their links and because of the technological shortcomings that existed, ecosystems could not be divided into three to five components and analyzed by computer simulation.

The more applied approach taken in the Hubbard Brook project, however, showed that the ecosystem approach to environmental studies could be successful if the principles of the scientific method were used. The Hubbard Brook study area and the protocols used to study it were clearly defined. This ecosystem allowed hypotheses to be generated and experimentally tested. Applying the scientific method to the study of ecosystems had practical utility for the management of natural resources and for testing possible solutions to environmental problems. When perturbations such as diseases, parasites, fires, deforestation, and urban and rural development disrupt ecosystems from within, this approach helps define potential mitigation and management plans. Similarly, external causative agents within airsheds, drainage flows, or watersheds can be considered.

The principles and research approach of the ecosystem concept are being used to define and attack the impact of environmental changes caused by humans. Such problems as human population growth, apportioning of resources, toxification of biosphere, loss of *biodiversity*, global warming, acid rain, atmospheric ozone depletion, land-use changes, and eutrophication are being holistically examined. Management programs related to woodlands (the New Forestry program) and urban and rural centers (the Urban to Rural Gradient Ecology, or URGE, program), as well as other governmental agencies that are investigating water and land use, fisheries, endangered species, and exotic species introductions, have found the ecosystem perspective useful.

Ecosystems are also viewed as systems that provide the services necessary to sustain life on earth. Most people either take these services for granted or do not realize that such natural processes exist. Ecosystem research has identified seventeen naturally occurring services, including water purification, regulation, and supply, as well as atmospheric gas regulation and pollination. A 1997 article by Robert Costanza and others, "The Value of the World's Ecosystem Services and Natural Capital," placed a monetary cost to humanity should the service, for some disastrous reason, need to be maintained by human technology. The amount is staggering, averaging $33 trillion per year. Humanity could not afford this; the global gross national product is only about $20 trillion.

Academically, ecosystem science has been shown to be a tool to dissect environmental problems, but this has not been effectively demonstrated to the public and private sectors, especially decision makers and policymakers at governmental levels. The idea that healthy ecosystems provide socioeconomic benefits and services remains controversial. In order to bridge this gap between academia and the public, Scott Collins of the National Science Foundation suggested to the Association of Ecosystem Research Centers that ecosystem scientists be "bilingual"; that is, they should be able speak their scientific language and translate it so that the nonscientist can understand.

ELECTROPHORESIS

Category: Methods and techniques

Electrophoresis is a biochemical technique used to separate charged molecules in an electric field. Gel electrophoresis is one of the most common forms of this method, used to separate DNA, proteins, enzymes, and other molecules from the cell for laboratory investigation and manipulation.

Electrophoresis is widely used to separate, visualize, or purify charged biological molecules such as deoxyribonucleic and ribonucleic acids (DNA and RNA) and proteins, including enzymes. It is also used to estimate the size of DNA fragments and the molecular weight of proteins. Most biological molecules are electrically charged in solution; hence, when subjected to an electric field, they migrate as zones toward an electrode (a terminal source of electricity) of opposite electrical polarity. Positively charged molecules migrate to the negative electrical terminal, known as the cathode, and negatively charged molecules migrate toward the positive electrical terminal, known as the anode. The rate of migration depends on the size, shape, and charge of the molecules to be sorted as well as the strength of the electric field (voltage).

Types of Supporting Matrix

Electrophoresis is conducted in a sievelike *supporting matrix*, such as filter paper, cellulose acetate membrane, or, more commonly, a gel. Gels are made primarily of starch, agarose, or polyacrylamide. Starch and agarose are carbohydrates. *Gel electrophoresis* typically uses agarose, a purified form of agar-agar, extracted from seaweeds (marine red algae). Agarose gels have large pores, which allow large molecules to pass through.

Polyacrylamide is a synthetic polymer made of acrylamide and bisacrylamide. Acrylamide is a suspected human carcinogen (cancer-causing agent) and a potent neurotoxin (a compound that causes damage to the brain). Extreme caution is therefore required when handling polyacrylamide or its components. Polyacrylamide gels have smaller pores than agarose, therefore allowing only small molecules to pass through.

Separation of Nucleic Acids

The method of choice for separating nucleic acids, typically pieces of DNA, is agarose gel electrophoresis. The DNA fragments migrate through the agarose gel at a rate that is inversely proportional to their size. In other words, smaller fragments migrate faster through the gel than larger fragments.

In the laboratory, an agarose gel is prepared by dissolving agarose powder in a buffer solution (a salt solution) and heating to boiling. The viscous solution formed is then cooled and poured into a casting tray. A plastic-toothed comb is inserted in the melted agarose at the top. The agarose is allowed to solidify in the tray into a gelatinous slab and is then submerged into a buffer solution in a horizontal chamber. The buffer functions as a conductor of electricity through the agarose gel. After the gel is submerged, the comb is carefully removed, thereby creating a row of wells in the gel slab. The wells are then loaded with a sample consisting of a mixture of DNA fragments, sucrose or glycerol, and a blue dye. Sucrose sinks the DNA sample into the wells, while the dye marks the migration of the invisible DNA fragments through the gel. In order to establish an electric field in the chamber, a constant electric current from a power supply is generated between the electrodes at both ends of the gel. DNA is negatively charged because of its phosphate groups; therefore, the electric current drags the DNA fragments out of the wells toward the anode through a path known as a lane. Greater voltages result in faster migration of DNA fragments through the gel. The current is switched off when the blue dye moves about three-fourths of the way.

Upon completion of electrophoresis, the separated DNA fragments are made visible by staining the gel with ethidium bromide or methylene blue. Ethidium bromide is a fluorescent dye, a potent mutagen, and possible carcinogen. The stained gel is viewed with the aid of an ultraviolet box called the transilluminator. The separated DNA fragments appear as fluorescent orange bands. Each band corresponds to DNA fragments of equal length that have migrated to the same position in the gel. Methylene blue dye stains DNA bands blue under visible light.

Separation of Proteins

The principle behind the separation of proteins is similar to that of nucleic acids. Proteins can be separated by paper or cellulose acetate electrophoresis by simply placing a protein sample on a strip of filter paper or cellulose acetate saturated with a buffer, dipping the ends of the strip into chambers of buffer, and subject the strip to an electric field. The separation of most proteins, however, is performed in a polyacrylamide gel. The gel is cast and submerged in a vertical chamber of buffer.

Proteins can be separated on the basis of size (molecular weight) alone, net charge alone, or size and charge together. A common technique for separating proteins by size only is *sodium dodecyl sulfate-polyacrylamide gel electrophoresis* (SDS-PAGE). In this type of separation, a protein mixture is treated with the detergent sodium dodecyl sulfate. The detergent binds and causes the proteins to dissociate into polypeptides and become negatively charged. The proteins thereafter separate into bands according to their sizes alone. Bands are then visualized by staining with silver stain or a protein dye called coomassie blue.

Proteins can be separated on the basis of charge alone, using a method called *isoelectric focusing*. The separation is performed in a glass tube of polyacrylamide gel in which a pH gradient has been established. When a current is applied, each protein migrates until it reaches its characteristic pH (acidity or alkalinity level). At this point, the net charge on the protein becomes zero, and migration stops. The pH at which the net charge is zero is called the isoelectric focusing.

Complex mixtures of proteins of similar sizes are separated based on size and charge using the *two-dimensional gel electrophoresis*. In this technique, proteins are separated in two sequential steps. First, they are separated in a tube gel by isoelectric focusing based on their charges alone. Then the proteins migrate into a gel slab and separate by SDS-PAGE, based on their size alone. The proteins are visualized as spots in the gel slab.

Applications

Every species of organism examined by researchers has revealed immense genetic variation or polymorphism (many forms), an indication of the presence of different genotypes (genetic makeup) in the population. It is however, impossible to infer the genotypes of plants simply by observing their visible characteristics or phenotypes. In many plant science laboratories, researchers employ electrophoresis to determine the mode of reproduction of plant species, to detect genetic variation within and between plant populations, and to identify plant genotypes. Also, researchers establish genetic relatedness in plants, that is, establish the most probable paternal parent or pollen donor within and outside a study site that sired seeds collected from a known maternal plant. To accomplish these tasks, researchers rely upon protein and DNA markers generated by gel electrophoresis.

Protein markers known as *allozymes* have been used extensively in a number of genetic analyses. Allozymes are electrophoretically distinct forms of an enzyme produced by different alleles (alternate forms of a gene). (An enzyme is a protein that speeds up the rate of a chemical reaction in an organism, without being consumed in the process.) Allozymes catalyze the same chemical reactions but have slightly different sequences of amino acids, the building blocks of proteins.

To analyze allozymes, researchers extract enzymes from plants and separate them on starch or polyacrylamide gels. Gels made up of potato starch are most commonly used because of their low cost and ease of use. After electrophoresis, the gel is submerged in a solution containing a dye and a substrate appropriate for the enzyme studied. The enzyme reacts with the substrate to produce a colored band on the gel. If the gel yields one colored discrete band in a lane, then that particular plant contains just one form of the enzyme, therefore the genotype of the plant must be *homozygous* (having two identical alleles of a gene). If the gel yields two colored bands, then the plant contains two forms of the enzyme and is therefore *heterozygous* (having two different alleles of a gene). Allozyme electrophoresis enables researchers to learn about the mode of reproduction of plants. For example, plant populations with high numbers of heterozygotes indicate a high level of cross-pollination, that is, the transfer of pollen (plant male gamete) by wind, insects, birds, bats, or other animals from one flowering plant to another. High numbers of homozygotes within a plant population indicate a high level of self-pollination, the transfer of pollen within a flower or between flowers of the same plant.

In many plant laboratories today, protein markers have been superseded by DNA markers, which are fragments of DNA that are distinguished from one another because of the differences in their base sequences. To generate DNA markers, DNA is extracted from plants and cut into fragments with special enzymes known as *restriction enzymes*. The fragments are then separated by electrophoresis on an agarose gel and analyzed.

Some of the widely used DNA markers in many laboratories are different lengths of DNA fragments, known as *restriction fragment polymorphisms* (RFLPs) or short sequences of DNA bases that are repeated many times in tandem (head to tail), called variable number of tandem repeats (VNTR), a type of RFLP. RFLP analysis distinguishes between heterozygous and homozygous genotypes. Heterozygotes yield two fragments on a gel, while homozygous genotypes yield a single fragment. Another DNA marker, known as *random amplified polymorphic DNAs* (RAPDs), have become extremely popular DNA markers with plant scientists. They are DNA fragments amplified by a technique known as polymerase chain reaction (PCR) using a short primer consisting of ten nucleotides chosen randomly and then separated by size by agarose gel electrophoresis. Polymorphisms are revealed when a DNA fragment is amplified in one plant and fails to amplify in another. On a gel, the researcher checks for the presence or absence of the marker.

Many studies involving parentage of seeds and seed pods have been done using DNA markers. The DNA profiles of seeds or seed pods are compared to maternal and paternal plants. If seeds were produced by cross-pollination, then half of the DNA bands of the seeds would be found in the maternal plant and the other half from the paternal plant.

ENDANGERED SPECIES

Categories: Ecology; environmental issues

The International Union for the Conservation of Nature-World Conservation Union (IUCN) defines endangered species as those in immediate danger of extinction. Extinction means that the species is no longer known to exist. The IUCN defines threatened species as those at a high risk of extinction but not yet endangered. Vulnerable species are considered ones that are likely to become extinct at some point in the foreseeable future. Rare species are at risk but not yet at the vulnerable, threatened, or endangered levels.

Worldwide, the number of endangered plant species was estimated at more than 33,400 in 1999. This number is much higher than that of all of the endangered or threatened animal species combined. Although extinction is a natural process, and all species will eventually be extinct, human activities threaten the existence of plant and animal life worldwide.

Humans use plants for food; medicine; building materials; energy; to clean water, air, and soil of pollutants; to control erosion; and to convert carbon dioxide to oxygen. The process of extinction increased dramatically during the nineteenth and twentieth centuries because of habitat destruction or loss, deforestation, competition from introduced species, pollution, global warming, and plant hunting, collecting, and harvesting. Over time, pollutants and contaminates accumulate in the soil and remain in the environment, some for many decades. Pollution in the atmosphere also contributes to long-term changes in climate.

Habitat Loss

By far the most significant threat to plant species is habitat loss or destruction. Habitat loss can occur because of resource harvesting for food, medicine, and other products, deforestation, and the conversion of wilderness for agricultural, industrial, or urban uses. Wood consumption and tree clearing for agriculture and development threaten the world's forests, especially the tropical forests, which may disappear by the mid-twenty-first century if sufficient preventive action is not taken. Natural disasters, such as climatic changes, meteorites, floods, volcanic eruptions, earthquakes, drought, hurricanes, and tornados, also can be devastating to a habitat.

In Europe and Asia, the plant distribution is complex, with isolated populations of plants spread across a large area. The plants are greatly influenced by the cold climate and by humans. Plant species are disappearing, especially in Europe and the Mediterranean, because of habitat destruction and disturbances including urbanization, road construction, overgrazing, cultivation, forest plantation, fire, pollution, and overexploitation of resources, or for use in horticulture.

The mountain plants are threatened by development for industry and tourism, pollution, strip mining, walkers, and skiers. The wetlands are threatened by removal of peat for fuel, water extraction which lowers the water table, and increased drainage for building or agriculture or fear of malaria. Recreational use and susceptibility to pollution such as acid rain or fertilizer run-off present further threats.

In North America, the major causes of endangerment include loss of habitat, overexploitation of resources, introduction of invasive species, and pollution. A massive loss of wilderness has occurred through the clearing of forests, plowing of prairies, and draining of swamplands. For example, in the northeastern United States there are only 13 square miles of alpine habitat, an area in which grow thirty-three at-risk species. This area is heavily used by hikers and mountain bikers. The Florida Everglades are threatened because the water supply is diverted to supply cities, industries, and agriculture.

In California, the Channel Islands are home to seventy-six flowering plants which do not exist on the mainland. Eighteen species are located on just one island. These plants, including the San

Image Not Available

Clemente broom, bush mallow (*Malacothamnus Greene*), a species of larkspur, and the San Clemente Island Indian paintbrush (*Castilleja grisea*), have been devastated by introduced grazers, browsers, and by invasive other plants. In Hawaii, more than 90 percent of native plants and almost all land birds and invertebrates are found nowhere else in world. The Hawaiian red-flowered geranium (*Geranium arboreum*) is threatened by introduced feral pigs, agricultural livestock, and competition by nonnative plants.

In developing or highly populated nations in Asia, Africa, Central and South America, the Caribbean, the Pacific Ocean islands, Australia, and New Zealand, habitat loss occurs because of population needs. Land is cleared for agriculture, develop-

A Sampling of the World's Endangered Plant Species

Common Name	*Scientific Name*	*Habitat*
African teak	*Pericopsis elata*	Semideciduous forests of Central and West Africa
Almug or red sandalwood	*Pterocarpus santalinus*	Forests of India
Atlas or Moroccan cypress	*Cupressus atlantica*	Dry woodland on steep slopes of the Atlas Mountains, Morocco
Bastard quiver tree or Basterkokerboom	*Aloe pillansii*	Hot and arid areas of Namibia and South Africa
Camphor tree	*Dryobalanops aromatica*	Peninsular Malaysia and Sumatra
Carossier palm	*Attalea crassispatha*	Haiti's southwestern peninsula in scrub forest and agricultural land
Clay's hibiscus	*Hibiscus clayi*	Dry forests in a few locations on some of the Hawaiian Islands
Commoner lignum vitae or guaiac tree	*Guaiacum officinale*	Lowland dry forests and coastland areas of Caribbean, Colombia, Venezuela
Cook's holly	*Ilex cookii*	Puerto Rican cloud forests on ridgetops of Monte Javuya in Toro Negro State Park and Cerro de Punta
Dall's pittosporum	*Pittosporum dallii*	Rocky creeks in the mountains of New Zealand
Dragon's blood tree	*Dracaena cinnabari*	Woodland areas in the center and east of Socotra Island near Saudi Arabia and the Red Sea
Ebony	*Diospyros mun*	Limestone mountains in the Lao People's Democratic Republic and Vietnam
Egyptian papyrus	*Cyperus papyrus hadidii*	Shallow, freshwater marshes in Egypt
Fiddlewood or yax-nik	*Vitex gaumeri*	Damp forests with limestone or pine ridges in Belize, Guatemala, Honduras, Mexico
Four-petal pawpaw	*Asimina tetramera*	Scrub vegetation near the Atlantic coast in Florida
Gigasiphon	*Gigasiphon macrosiphon*	Tropical forests on the coastal plains of Kenya and Tanzania
Ginkgo	*Ginkgo biloba*	Temperate forests in southern China
Hainan sonneratia	*Sonneratia hainanensis*	Mangrove forests in Wenchang County, Hainan, China

ment, and population resettlement. In Central America and the Caribbean, the Swietenia mahogany is found only in a few protected or remote areas. The Caoba tree (*Persea theobromifolia*) was newly identified as a species as recently as 1977. The lumber is commercially important, and habitat loss has occurred as a result of the conversion of forests to banana and palm plantations. In Ecuador, only 6 percent of the original rain forest remains standing, because the rest has been converted to farmland. In Asia, including the Philippines, population pressures bring about deforestation and the clearing of land for agriculture.

In southern Africa, land is used for crops, livestock, and firewood production. Overgrazing and the introduction of agriculture have caused the Sahara Desert area to grow rapidly. The island of Madagascar has between ten thousand and twelve

Common Name	*Scientific Name*	*Habitat*
Hawaiian gardenia	*Gardenia brighamii*	Dry forest on the island of Kauai, Hawaii
Horseshoe fern	*Marattia salicina nov*	Lord Howe Island, Australia
Ley's whitebeam	*Sorbus leyana*	Carboniferous limestone cliffs in southern Breconshire, Wales
Madeira net-leaf orchid	*Goodyera macrophylla*	Cliffs and ravines in humid, maritime climate of Madeira, Portugal
Mellblom's spider orchid	*Caladenia hastata*	Coastal areas near Portland, Victoria, Australia
Millionaire's salad	*Deckenia nobilis*	Lowland forests of the Seychelles Islands off the east coast of Africa
Mongarlowe mallee	*Eucalyptus recurva*	Near Mongarlowe in New South Wales, Australia
Nubian dragon tree	*Dracaena ombet*	Tropical forests near the Red Sea Hills in Egypt, Saudi Arabia, East Africa
Saharan cypress	*Cupressus dupreziana*	Tassili N'Ajjer National Park, Algeria
Taiwan trident maple	*Acer buergerianum ssp. formosanum*	Lowland evergreen forest of Taiwan
Tennessee purple coneflower	*Echinacea tennesseensis*	Red cedar glades and dry environments in forest openings of Tennessee
Virginia round-leaf birch	*Betula uber*	Second-growth forest along Cressy Creek in Virginia
West Himalayan elm	*Ulmus walliciana*	Temperate areas near streams, rivers, and wetlands in Afghanistan, Nepal, Pakistan, India
None	*Anthoceros neesii*	Clay-loam soils in Austria, Czech Republic, Germany, Poland
None	*Diplocolea sikkimensis*	Tropical rain forests in India (Sikkim) and Nepal
None	*Distichophyllum carinatum*	Temperate mixed forests of Austria, Germany, Switzerland, China (Sichuan), Japan
None	*Andrewsianthus ferrugineus*	Coniferous forest of Bhutan, Nepal

Source: Compiled from the International Union for Conservation of Nature, World Conservation Union (IUCN) Red List of endangered species at the web site www.redlist.org (homepage www.iucn.org), and *Encyclopedia of Endangered Species*, edited by Bill Freedman, volume 2 (Detroit: Gale Research, 1999).

thousand plant species, of which 80 percent grow nowhere else in the world. Because of conversion to grassland through farming methods, only about one-fifth of the original species survive. In Australia there are 1,140 rare or threatened plants, and logging, clearing for grazing animals and crops, building developments, and mining have threatened many native species.

Plant Hunting, Collecting, and Harvesting

Habitat damage, the construction of facilities, and the opening of remote areas for human population have made many plants vulnerable to gathering and collecting. Some plants have been overharvested by gardeners, botanists, and horticulturists. One species of lady's slipper orchid (*Cypripedium calceolus*) is rare over much of its natural range except in parts of Scandinavia and the Alps because of collecting. Additionally, many mountain flowers or bulbs such as saxifrages, bellflowers, snowdrops, and cyclamen are endangered. In France and Italy, florulent saxifrage (*Saxifraga florulenta*), an alpine plant, has been overcollected by horticulturists and poachers.

Parts of the southeastern United States have poor soil that is home to the carnivorous or insectivorous plants—those that eat insects. These plants include sundews, bladderworts, Venus's flytrap, and pitcher plants. Collectors or suppliers have stripped many areas of all of these plants. In the Southwest, rare cacti are harvested for sale nationwide and worldwide. Endangered cacti include the Nellie Cory cactus (which has one remaining colony), *Epithelantha micromeres bokei*, *Ancistrocactus tubuschii*, saguaro cactus (*Carnegiea gigantea*), and *Coryphantha minima*. Near the Sierra Madre, two tree species—Guatemalan fir, or Pinabete, and the Ayuque—are endangered because of harvesting for use as Christmas trees or for the making of hand looms. Additionally, sheep eat the seedlings. In New Mexico, the gypsum wild buckwheat habitat is limited to one limestone hill, and the plants are threatened by cattle, off-road vehicles, and botanists.

In southern Mexico, there are 411 species of *epiphytes* (air plants or bromeliads in the genus *Tillandsia*), of which several are extremely rare. These plants are threatened by overcollection for the houseplant trade or conservatories. The African violet (*Saintpaulia ionantha*) of Tanzania may soon be extinct in the wild because of the horticultural trade and habitat loss due to encroaching agriculture.

Worldwide, orchids are overcollected for horticulture. Several species have been collected to extinction, are extremely rare, or have been lost because of habitat destruction. Examples include the extremely rare blue vanda (*Vanda caerulea*); *Paphiopedilum druryi*, believed extinct in its native habitat; *Dendrobium pauciflorum*, endangered and possibly extinct—only a single plant was known to exist in the wild in 1970; and the Javan phalaenopsis orchid, *Phalaenopsis javanica*. The latter was believed extinct. When it was rediscovered in 1960's, it was overcollected by commercial orchid dealers and thereby exterminated. There are no other known wild populations.

About 80 percent of the human populations in developing countries rely on traditional medicine, for which 85 percent of ingredients come from plant extracts. In Western medicine, one in four prescription medicines contain one or more plant products. Some at-risk species contain chemicals used in treating medical conditions, such as the African *Prunus africana* tree, whose bark has chemicals used to treat some prostate gland conditions, and the *Strophanthus thollonii*, a root parasite with chemicals used in heart drugs.

The Madagascan periwinkle (*Catharanthus roseus*) is commonly cultivated (its close relative *Catharanthus coriaceus* is rare and its medicinal importance unknown) and produces about seventy chemicals, some of which are useful in the treatment of cancer. The Indian podophyllum (*Podophyllum hexandrum*), a threatened species, is used to treat intestinal worms, constipation, and cancer. Rauwolfia (*Rauvolfia serpentina*), also a threatened species, is used to treat mental disorders, hypertension, and as a sedative. The lily *Amorphopahllus campanulatus* is used to treat stomachaches, and a fig, *Ficus sceptica*, is used to treat fever; both of these species are vulnerable because of habitat destruction.

The Micronesian dragon tree is believed to have magical and medicinal properties. It has been overharvested and is now extinct on several islands. In the United States' Appalachian Mountains, American ginseng is being overcollected because of an escalating demand for this plant's health benefits.

Conservation

The conservation of endangered plant species employs several compelling arguments: Plants enhance the world's beauty, have the right to exist, and are useful to people. The most persuasive argument may be that the survival of the human species depends on a healthy worldwide ecosystem. Three major goals of conservation are recovery, protection, and reintroduction.

Conservation methods depend on increasing public awareness by providing information about endangered or threatened species so that people can take action to reverse damage to the ecosystems. Other important strategies include achieving a widespread commitment to conservation and obtaining funding to protect rare or endangered species. Conservation efforts include setting aside protected areas, such as reserves, wilderness areas, and parks, and recognizing that humans must integrate and protect biodiversity where they live and work. Many countries are actively conserving species through protected areas, endangered-species acts, detailed studies of species and habitat, and information campaigns directed to the public.

Wilson, Edward O. *The Future of Life*. New York: Alfred A. Knopf, 2001. Harvard biologist Wilson, known for his work on species extinction, speaks out on the staggering impact of human activities on the many species—particularly plant species—worldwide, predicting major extinctions if the present rate continues. He also, however, identifies measures that may be taken to conserve species extinction, given the happy fact that many of them are concentrated in concentrated areas such as the rain forests.

ENDOCYTOSIS AND EXOCYTOSIS

Categories: Cellular biology; physiology; transport systems

Endocytosis is used by cells to move water, macromolecules, or larger objects, such as cell fragments or even whole cells, from outside a cell to the inside of the cell. Exocytosis is the reverse of endocytosis, that is, the movement of materials from the inside to the outside of the cell. Both types of transport move the materials using membrane-bound vesicles.

Endocytosis

In endocytosis, during which materials are moved into a cell, the cell's plasma membrane engulfs material and packs it into saclike structures called *vesicles*. The vesicles then detach from the plasma membrane and move into the cell. Once the vesicle is in the cytoplasm, it will typically fuse with some other membrane-bound organelle, such as a vacuole or the endoplasmic reticulum, and release its contents into the organelle. There are three types of endocytosis: *phagocytosis* (transport of actual particles), *pinocytosis* (transport of water, along with any solutes in the water), and *receptor-mediated endocytosis* (explained in detail below).

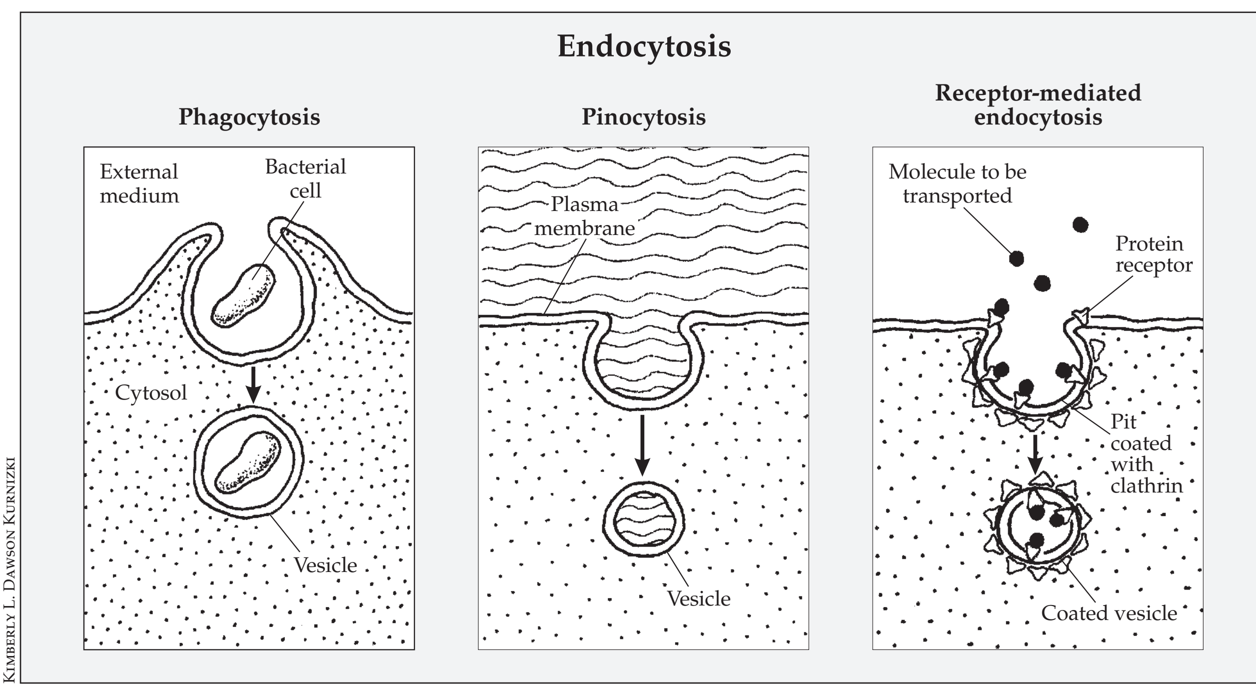
In receptor-mediated endocytosis, specific macromolecules outside the cell attach to the binding sites of receptor proteins. These receptors are embedded in the plasma membrane in specialized regions called *coated pits*. The macromolecules contact and bind with receptor proteins in the pit. The coated pit deepens inward to the cytosol and eventually is pinched off as a *coated vesicle* inside the cell. Coated vesicles contain the receptor proteins and whatever molecules they are importing and are coated on the outside by a protein called *clathrin*. After the contents of the vesicle are released inside the cell, the receptor proteins are reused to form new coated pits. Receptor-mediated endocytosis is especially useful for importing specific molecules, even when they are present at low concentrations.

Endocytosis is more difficult in plants than in animals because the plasma membrane of a plant cell is usually pressed against the rigid cell wall by turgor pressure, which hinders the plasma membrane from invaginating into the cytosol. Nevertheless, plant cells do have coated pits, and experiments with isolated *protoplasts* (plant cells without their cell walls) suggest that receptor-mediated endocytosis works in plant cells much as it does in animal cells.

In a special form of phagocytosis, symbiotic nitrogen-fixing bacteria (*rhizobia*) colonize root cells in legumes. First, root hairs surround rhizobia cells in a ball-like mass. Next, *infection threads*, composed of an extended portion of the cell membranes of the cell being invaded, are formed. The bacteria multiply inside the thread, which extends inwardly and penetrates through and between cortex cells. In the inner cortex cells, portions of the thread wrap around groups of bacteria in vesicles, which pinch off into the cytosol. A membrane which forms around a group of bacteria is called a *bacteroid*.

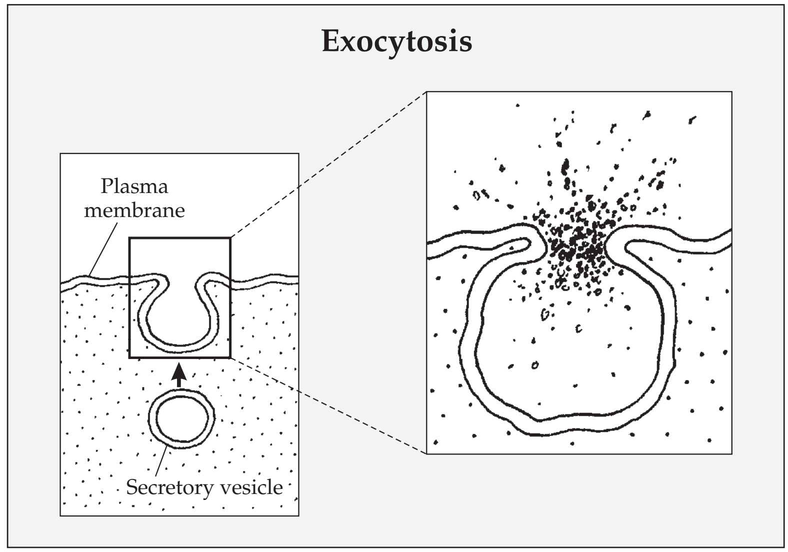
Exocytosis

Exocytosis, the transport of macromolecules and large particles outside the cell, is the reverse of endocytosis. In exocytosis, materials inside the cell are packed in a vesicle, which fuses to the plasma membrane. Some vesicles contain structural proteins and polysaccharides, whereas other



Three types of endocytosis: phagocytosis, in which the plasma membrane extends outward to engulf and draw in a particle to be taken into the cell; pinocytosis, in which the plasma membrane pouches inward, surrounding water and solutes, and then pinches off inside the cell; and receptor-mediated endocytosis, in which the molecules to be taken into the cell first bind to protein receptors in coated pits in the plasma membrane, which then form coated vesicles that pinch off and move into the cell.

vesicles, such as vacuoles, contain digestive enzymes. Each vesicle attaches to the plasma membrane. The site where it attaches opens, and the materials in the vesicle are dumped out of the cell. The vacated vesicle straightens and becomes a part of the plasma membrane. A problem arises if vesicles continually fuse with the plasma membrane, because large amounts of new membrane being added can double the amount of plasma membrane every thirty minutes, and the plasma membrane has little room to expand in cells with rigid cell walls. Nevertheless, plants cells regularly recycle excess plasma membrane via endocytosis.



The reverse of endocytosis, exocytosis is the process of moving materials outside the cell by packing them in a vesicle that fuses to the plasma membrane and then opens to dump out its contents.

Roles of Endocytosis and Exocytosis

Both exocytosis and endocytosis occur within seeds. Starch-digesting enzymes, such as alpha-amylase, move from cell to cell in cereal grains. In the cells of the *aleurone* layer, the endoplasmic reticulum manufactures these enzymes and packs them into vesicles. The enzymes are exuded from vesicles by exocytosis through the plasma membrane and must then be transported into the cells of the endosperm by endocytosis. Inside the endosperm cells, the enzyme-containing vesicle fuses with an *amyloplast*, a plastid specialized for storage of starch, where the enzymes hydrolyze starch into glucose.

Exocytosis of macromolecules plays other important roles in plants. For example, polysaccharides and proteins that are exported become structural components of cell walls. After cell division, exocytosis by secretory vesicles builds primary cell walls between newly divided nuclei. Epidermal cells of leaves extrude waxy substances onto leaf surfaces to minimize transpiration. Root-tip cells exude slimy polysaccharides to lubricate their movement as they grow and penetrate the soil.

Exocytosis of other substances by specialized cells also plays many roles in plants. For example, exocytosis is involved in the secretion of nectar by flower cells to attract pollinators. Exocytosis is also the process whereby oils are emitted by aromatic flowers, herbs, and spices. Such oils function both as attractants for pollinators and as defenses. For example, oils emitted by mustard plants irritate many animals, thus preventing many herbivores from eating them. Lignin, which is more rigid than cellulose and strengthens woody tissue, is expelled via exocytosis in woody plants and then accumulates in the middle lamella and cell walls. Enzymes that digest insects are released by the leaf cells of carnivorous plants, such as Venus's flytrap. Root exudates are released by some plants in response to environmental stress or to deter the growth of other plant species nearby.

Phytoremediation

Phytoremediation uses plant roots to clean polluted soil and water. They can remove, by endocytosis, and degrade both small organic molecular pollutants (ammunition wastes, chlorinated solvents, and herbicides) and large organic molecular pollutants (crude oil and polyaromatic hydrocarbons) in the environment. The degraded products can then be incorporated in the plant's tissues.

ENDOMEMBRANE SYSTEM AND GOLGI COMPLEX

Categories: Anatomy; cellular biology

The endomembrane system is a collective term applied to all of the membranes in a cell that are either connected with or are derived from the endoplasmic reticulum (ER), including the plasma membrane but not the membranes of chloroplasts or mitochondria. The membrane-bound organelles considered to be part of the endomembrane system are the vacuole, nuclear envelope, endoplasmic reticulum, Golgi complex, and various types of vacuoles.

Some components of the endomembrane system have direct, permanent connections with the endomembrane system (such as between the endoplasmic reticulum and the nuclear envelope), whereas other components share membrane and contents by trafficking *vesicles* (membrane-bound packages) from one component to another (for example, the ER sends numerous vesicles to the Golgi complex) across the *cytosol*. The endomembrane system is responsible for processing, sorting, and packaging membrane material, proteins embedded in membranes, and large water-soluble molecules (such as proteins or carbohydrates), either for export from the cell (called *exocytosis*) or for use within the cell. The endoplasmic reticulum is the ultimate source of all the membranes of the endomembrane system.

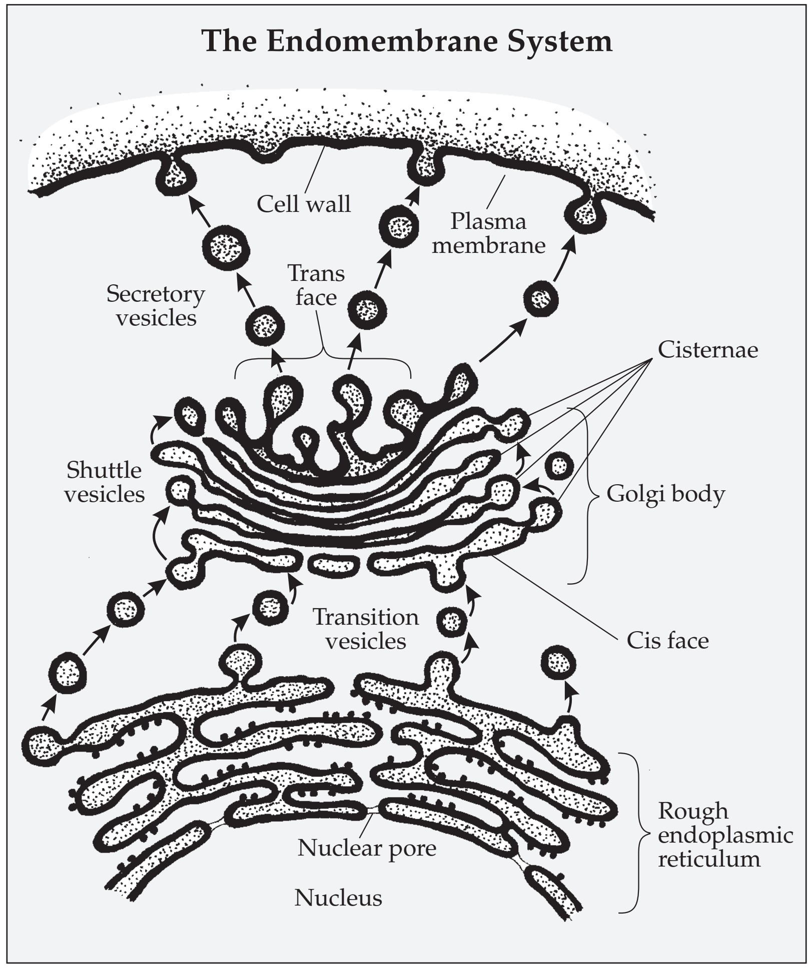
Golgi Complex

The Golgi complex is a major component of the endomembrane system and, in most cells, its primary role is secretion. The term "Golgi complex" refers collectively to all the *Golgi bodies* (once commonly called *dictyosomes* in plants) in a cell. It is named after Camillo Golgi (1843-1926), an Italian scientist who first described the structures in 1878. Golgi won the 1906 Nobel Prize in Physiology or Medicine for his contributions to the understanding of the structure of the nervous system.

When viewed through an electron microscope, a single Golgi body is composed of a series (of typically four to eight) round, flattened membranous sacs called *cisternae*. This "stack of sacs" has two sides; the cisterna on the *cis* side often faces the ER, while the cisterna on the *trans* side often faces away from the ER. The *medial cisternae* are in between. The *trans-Golgi network* is the collection of vesicles seen leaving the *trans* face of the Golgi body. *Intercisternal elements* are protein fibers that span the space between cisternae. They may help anchor the Golgi enzymes in the individual cisternae so they are not transported away and lost with the *shuttle vesicles*, described below. The intercisternal elements may also help stabilize the entire Golgi body.

An individual Golgi body is surrounded by a very faint, filamentous structure called the *Golgi matrix*. The matrix (along with the intercisternal elements) probably helps hold the Golgi body together as it is moved around the cell. The matrix also appears to exclude ribosomes and other cytosolic components from the immediate vicinity of the Golgi bodies and keeps the cytoplasm from interfering with the functioning of the complex. There are apparently no direct membrane connections among the individual cisternae in a Golgi body. Rather, membrane and contents move between cisternae via shuttle vesicles that pinch off of one cisterna, move in a trans direction, and fuse with an adjacent cisterna. The number of Golgi bodies in a plant cell can vary widely, from several dozen to more than ten thousand, depending on the size and function of the cell.

Entire Golgi bodies are transported around the cell via the *cytoskeleton*. They show a stop-and-go type of movement that may be associated with a need to approach a segment of the *rough ER*, or RER, to pick up proteins and then move closer to the plasma membrane or vacuole to deliver those proteins to the proper destination. Golgi bodies divide by fission, with new stacks pinching off of existing ones.



The endomembrane system, including the rough endoplasmic reticulum outside the cell's nucleus, transports materials to and from the cell's plasma membrane by means of vesicles transported through the Golgi complex (composed of flattened sacs called cisternae). The Golgi complex is responsible for the processing and packaging of proteins and other molecules for secretion from the cell or use within the cell.

KIMBERLY L. DAWSON KURNIZKI

Golgi Functioning

The Golgi complex is responsible for the processing and packaging of proteins and other molecules for secretion from the cell or use within the cell. A typical pathway for the secretion of a protein to the cell exterior (that is, exocytosis) would be as follows. A ribosome bound to the RER translates a piece of messenger RNA into a protein, and that protein is inserted into the lumen (the aqueous space enclosed by the RER membrane) of the RER. A vesicle forms by enclosing the protein and pinching off of the RER.

This *transition vesicle* travels across the cytosol (the traffic being directed by the *microtubules* and *microfilaments* of the cytoskeleton), fuses with the cisterna on the *cis* face of a Golgi body, and delivers the protein to the *lumen* of that cisterna. Enzymes in the lumen of the cisterna modify the protein by adding sugars (called "glycosylation") to produce a *glycoprotein*. A vesicle of Golgi membrane pinches off, forms a shuttle vesicle, and delivers the glycoprotein to the next cisterna in the stack, where the protein may be further glycosylated. The protein moves its way through the Golgi body and, eventually, leaves the *trans* face in a *secretory vesicle* that fuses with the plasma membrane. The contents of the secretory vesicle are moved out of the cell by exocytosis, while the membrane of the vesicle becomes incorporated into the plasma membrane.

In a similar fashion, the Golgi complex delivers matrix polysaccharides to the cell wall, large molecules and membrane lipids to the vacuole, or *integral* membrane proteins to the vacuolar membrane. In contrast to proteins (which are synthesized on the RER and merely modified during their transit through the Golgi body), cell wall matrix polysaccharides are synthesized from the ground up in the Golgi.

Surface-exposed proteins in the membrane of the vesicle contain the information needed to direct the vesicle to either the plasma membrane or some other place in the cell. Vesicles destined for the vacuole are visibly coated (as seen using an electron microscope) with protein, the major coat protein being *clathrin*. Vesicles destined for the plasma membrane appear smooth but undoubtedly have protein information on the exterior that directs them to the plasma membrane.

A single Golgi body can be involved in processing and packaging both glycoproteins and polysaccharides for delivery to the plasma membrane or intracellular locations at the same time. They also can be "retailored" to suit changing needs over the lifetime of a cell. That is to say, the enzymes in the cisternal lumen can be degraded and replaced with other enzymes that direct the synthesis of different molecules.

Other Endomembrane System Components

From the above, it can be seen how the ER and Golgi complex interact to deliver proteins and carbohydrates to the plasma membrane and vacuoles. In addition, the electron microscope often shows the ER to be physically connected to the nuclear envelope. Thus, the nuclear envelope is almost always included in a discussion of the endomembrane system. However, the exact functional nature of this nuclear connection remains unknown. The nuclear envelope is composed of two membranes, the outermost of which can be studded with ribosomes, much like the RER. The outer membrane of the nuclear envelope may, in some ways, be functionally similar to the RER, producing proteins which are passed across the outer membrane to the space between the two envelope membranes.

The fate of those membranes remains unclear. Whether they cross the inner membrane of the nuclear envelope as well and are delivered to the interior of the nucleus or diffuse to the lumen of a nearby section of ER and are processed through the Golgi complex is not known. The ER/nuclear envelope connection may be better understood by investigating the evolution of the eukaryotic cell.

Evolutionary Significance

According to the *endosymbiotic theory*, the ancestor of today's eukaryotic cells was a primitive prokaryote that engulfed a respiratory prokaryote (which eventually became established as mitochondria) and a photosynthetic prokaryote (which became chloroplasts). The other membrane-bound organelles of the cytoplasm were derived from infoldings of the plasma membrane. Thus the entire endomembrane system (plasma membrane, ER, Golgi complex, vacuoles, and nuclear envelope) probably has a common evolutionary background. Over time, the individual compartments became more specialized.

ENDOPHYTES

Categories: Animal-plant interactions; fungi; microorganisms

Fungi that spend at least a part of their lives within the aboveground parts of living plants—in leaves, stems, and in some cases reproductive organs—but cause no outward signs of infection are called endophytes. Some endophytes protect the host plant by deterring grazing animals or pathogenic fungi.

In the 1980's scientists began to realize that a great variety of microscopic fungal species live benignly within plants, as endophytes (from the Greek words *endos*, meaning "inside," and *phyton*, for "plant"), in contrast to fungi living on the surfaces of plants, as *epiphytes* (from the Greek *epi*, meaning "upon," plus *phyton*). Most endophytic fungi are *ascomycetes*. Many appear to be close relatives of plant pathogens.

Most endophytic fungi live and feed between the host plant's cells. Those endophytes that provide a benefit to the plant in return for their keep are considered to be partners with their host, in a symbiotic relationship called *mutualism*. Endophytic mutualism is well developed in some grasses, in which the fungal partner produces alkaloid substances that deter herbivores and pathogens.

Some fungi live within a plant benignly or mutualistically for a time, and then, if environmental stress or senescence afflicts the host or conditions otherwise change, the fungi turn pathogenic. For example, in a drought-weakened tree, previously benign fungi may initiate disease symptoms. Such fungi are said to have both an endophytic and a pathogenic phase. Other fungi may have a dormant, endophytic phase, then eventually become dependent on dead organic matter for sustenance.

Two Growth Patterns

The endophytes of grasses differ in growth habit from those of woody plants (both coniferous and angiospermous). Grass endophytes have been found to grow systemically, throughout the stems and leaves, of the mature plant, producing substantial fungal biomass. Hyphae, or filaments, of the fungal body even penetrate the grass ovule, which is the reproductive structure that develops into the seed. Via the infected seed, the fungus is transmitted to the next generation and thus is perpetuated down a plant's lineage.

In contrast, in most of the woody plants that have been investigated, individual endophytes are not systemic but instead are localized within leaves or stems, where they may be confined to specific plant tissues, such as bark or xylem (wood). Woody-plant endophytes typically propagate not by invading the host's ovule but rather via spores, which are carried to other plants by air, water, or animals. Presumably, the spores are able to disperse because they are not produced inside the plant host but rather on plant parts that have dropped off or are dying. This subject has been little investigated, however.

Abundance and Diversity

Endophytic fungi are common and widespread. Although research has focused mainly on grasses and woody plants, endophytes have also been found in mosses, ferns, and herbaceous angiosperms (flowering plants). Scientists have suggested that endophytic fungi may be as widespread among plants as are *mycorrhizae* (associations between certain fungi and plant roots), which characterize the vast majority of vascular plants. In mycorrhizae, part of the fungal body is external to the plant, whereas endophytes are wholly internal.

Endophytes are diverse, especially in trees and shrubs. Individual woody species and even individual plants typically harbor scores of fungal species, as has been shown for alder, oak, beech, maple, birch, ash, pine, spruce, fir, and other plants. Nevertheless, just one or a few species or genera of fungi usually dominate the fungal community of each woody plant species. These dominants commonly do not occur in plants other than the host species or closely related species.

Tropical trees are only beginning to be investigated for endophytes, but indications are that they are particularly rich in endophytic species. Given the high diversity of tropical trees, the endophytes still awaiting discovery may represent an enormous reservoir of biodiversity. In contrast to the wide variety of endophytes in woody plants, endophytes in grasses seem to be of low diversity. Grass endophytes are all closely related species, and each grass species seems to host only one or a few of them. Grasses, however, have been little examined for the nonsystemic kinds of endophytes that woody plants harbor in such variety.

Mutualisms and Ecology

Endophytic fungi that are mutualistic, or protective of the plant, are particularly well known in the pasture grasses tall fescue (*Festuca arundinacea*) and perennial ryegrass (*Lolium perenne*). The endophytes produce alkaloid toxins that defend these plants against insect attack and also cause serious illness in grazing livestock. Some endophytes, especially in grasses, increase host tolerance of other environmental stresses, such as drought. Many of the diverse endophytic species in woody plants have no known protective function, and some seem to be latent pathogens. Among those that are protective is one in the needles of Douglas fir (*Pseudotsuga menziesii*). It produces substances toxic to midges that form galls on the needles.

The ecological effects of endophytes in natural populations seem to be very complex. Endophytes sometimes are actually antagonistic to the host plant rather than mutualistic with it. The ecological role of endophytes and their host plants in natural environments has been little studied, however.

Economic Importance

The chemical substances produced by endophytic fungi are of considerable commercial interest to the pharmaceutical and food-processing industries and as potential biocontrol agents for plant diseases and pests. Endophytic fungi may eventually help farmers grow crops with minimal use of water, fertilizers, and pesticides.

ENDOPLASMIC RETICULUM

Categories: Anatomy; cellular biology

The endoplasmic reticulum is a network of sacs in the cytosol of eukaryotic cells that manufactures, processes, transports, and stores chemical compounds for use inside and outside of the cell.

The endoplasmic reticulum (ER) is an extensive, complex system of a more or less continuous distribution of convoluted membrane-bound cavities that take up a sizable portion of the cytosol. The internal space of the ER is called the *lumen*. The ER is attached to the double-layered nuclear envelope and provides a connection, or bridge, between the nucleus and the cytosol. In addition, it provides living bridges between cells by way of the *plasmodesmata*, small tubes that connect plant cells. The ER is a dynamic structure, constantly changing. It accounts for 10 percent or more of the volume of the cytosol.

In general, there are two kinds of endoplasmic reticulum, rough and smooth. *Smooth ER* is quite varied in appearance and most likely in function as well. Through a microscope, it appears as numerous nearly circular blotches, indicating that it consists of interlocking tubes of membranes. On the other hand, *rough ER* almost always appears as stacks of double membranes that are heavily dotted with *ribosomes*. Based on the consistent appearance of rough ER, it most likely consists of parallel sheets of membrane, rather than the tubular sheets that characterize smooth ER. These flattened, interconnected sacs are called *cisternae*, or cisternal cells. The cisternal cells of rough ER are also referred to as luminal cells. Rough ER and the *Golgi complex* are both composed of cisternal cells.

Smooth and Rough ER Functions

Because rough ER is covered with ribosomes, it has a bumpy appearance when viewed with an electron microscope. Rough ER is primarily involved in the production of proteins that will be exported from the cell to help with other functions of building the plant. Such proteins include antibodies, digestive enzymes, and certain hormones. Amino acid chains are assembled into proteins by the ribosomes. The protein units needed outside the manufacturing cell are transported into the rough ER for further processing. Once inside, they are shaped into the correct three-dimensional configuration that will be useful outside the cell. Necessary chemicals, such as carbohydrates or sugars, are then added to complete the proteins. The ER then transports these proteins to other areas of the ER, called *transitional ER*, where they are packed in vesicles to be sent to the Golgi complex for export, or secretion, to other parts of the plant. Occasionally, some of the completed proteins are transported to areas of the manufacturing cell where they are needed.

Because the smooth ER does not have attached ribosomes, it appears relatively smooth when viewed through an electron microscope. It also appears to bud off from vesicles that contain material from the lumen of the ER. Using the many different enzymes that are anchored to its walls, the smooth ER is involved with the synthesis, secretion, and storage of lipids as well as the manufacture of new membranes and the metabolism of carbohydrates.

Lipids are a group of fatty substances needed for building membranes and storing energy in plants. Among the more important lipids are phospholipids, which make up major components of the cell membrane. When a plant has excess energy available from photosynthesis, it sometimes stores that energy in the form of lipids known as triglycerides. When the plant is in need of more energy, the triglycerides can be broken down to produce it. Waxes are other important lipids stored in the smooth ER. They form protective coatings on the leaves of plants. Research indicates that smooth ER is also involved in the formation of cellulose for the cell wall.

Other Special ER Functions

Calcium is an essential nutrient for cellular function, growth, and development in plants. However, too much calcium can lead to cell death. To deal with high levels of calcium in the environment, many plants have developed a mechanism involving the ER to regulate bulk quantities of calcium through the formation of calcium oxalate crystals. Calcium oxalate crystals can account for more than 90 percent of the calcium found in a plant. Certain specialized ER cells, called crystal *idioblasts*, appear to participate in the formation of calcium oxalate and provide the storage locations for calcium in plants.

Plants have the capability to undergo rapid, large-scale movements when triggered by a wide variety of stimuli, such as changes in light intensity, temperature, and pressure. The ER is the plant sensor for pressure changes. For example, in Venus's flytrap and in the sensitive plant, the ER in cortex cells, referred to as *cortical ER*, provides the sense of touch. Inside the cytosol of these sensor cells, the ER aggregates at the top and the bottom of the cell. When the cells are compressed or squeezed, the cortical ER is strained and releases accumulated calcium, producing the sense of touch. The mechanism is very similar to muscle contraction in an animal. Because the cortical ER is interconnected through the plasmodesmata, which provide communication channels among cells and end at motor cells in specialized appendages such as *pulvini* (cushionlike swellings at the bases of leaves), flowers, or specialized leaves, a pressure stimulus at one cell can trigger a response throughout the whole plant.

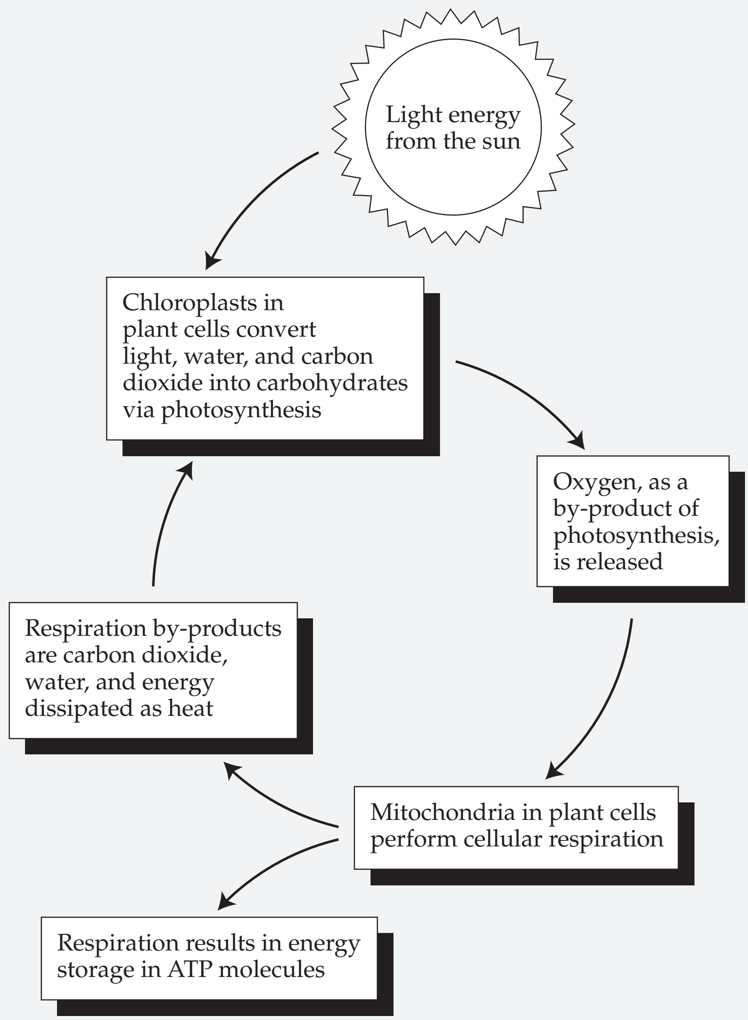
ENERGY FLOW IN PLANT CELLS

Categories: Cellular biology; photosynthesis and respiration; physiology

Life on earth is dependent on the flow of energy from the sun. A small portion of the solar energy, captured in the process of photosynthesis, drives many chemical reactions associated with living systems.

In living organisms, energy flows through chemical reactions. Each chemical reaction converts one set of substances, called the reactants, into another set, the products. All chemical reactions are essentially energy transformations, in which energy stored in chemical bonds is transferred to other, newly formed chemical bonds. *Exergonic* reactions release energy, whereas *endergonic* reactions

Transformation of Sunlight into Biochemical Energy



require an input of energy for a reaction to occur.

In plants, such reactions occur during the process whereby plant cells convert the energy of sunlight into chemical energy that fuels plant growth and other processes. During this process, called *photosynthesis*, carbon dioxide combines with simple sugars to form more complex carbohydrates in special structures called *chloroplasts*. These chloroplasts are membrane-bound organelles that occur in the cells of plants, algae, and some protists. The energy that drives the photosynthetic reaction is derived from the photons of sunlight; hence it is an endergonic reaction (it requires energy). Because plants, algae, and certain protists are the only living organisms that can produce their chemical energy using sunlight, they are called *producers*; all other life-forms are *consumers*. During seed germination, simple sugars, such as glucose, are broken down in a series of reactions called *respiration*. Energy is released to power the growth of embryo and young seedlings; hence, the reaction is exergonic. Within plant cells, both reactions occur.

In many reactions, electrons pass from one atom or molecule to another. These reactions, known as *oxidation-reduction* (or *redox*) reactions, are of great importance in living systems. The loss of an electron is known as *oxidation*, and the atom or molecule that loses the electron is said to be oxidized. Reduction involves the gain of an electron. Oxidation and reduction occur simultaneously; the electron lost by the oxidized atom or molecule is accepted by another atom or molecule, which is thus reduced.

Within plant cells, the energy-capturing reactions (photosynthesis) and the energy-releasing reactions (respiration) are redox reactions. Furthermore, all chemical reactions are orderly, linked and intertwined into sequences called *metabolic pathways*. All metabolic pathways in plant cells are finely tuned in three ways: the chemical reactions are regulated through the use of enzymes, exergonic reactions are always coupled with endergonic reactions, and energy-carrier molecules are synthesized and used for effective energy transfer.

Enzymes and Cofactors

Enzymes are biological catalysts, usually proteins, synthesized by plant cells. A number of characteristics make enzymes an essential component for energy flow in plant life. Enzymes dramatically speed up chemical reactions. Enzymes are normally very specific, catalyzing, in most cases, a single reaction that involves one or two specific molecules but leaves quite similar molecules untouched. In addition, enzyme activity is well regulated.

Many enzymes require a nonprotein component, or *cofactor*, for their optimal functions. Cofactors may be metal ions, part of or independent of the enzyme itself. Magnesium ions (Mg^{2+}), for example, are required in many important reactions in energy transfer, including photosynthesis and respiration. The two positive charges often hold the negatively charged phosphate group in position and help in moving it from one molecule to another. In other cases, ions may help enzymes maintain their proper three-dimensional conformation for optimal function. Some organic molecules can also be cofactors, including vitamins and their derivatives, and are usually called *coenzymes*. One example is the electron carrier nicotinamide adenine dinucleotide (NAD^+). NAD^+ is derived from nucleotide and vitamin-niacin. When NAD^+ accepts electrons, it is converted into NADH + H^+, which passes its electrons to another carrier; hence, NAD^+ is regenerated.

Plant cells regulate the amount and activity of their enzymes through various mechanisms. First, they control the synthesis of particular enzymes to meet their needs. They limit or stop the production of enzymes not needed by metabolic reactions and, hence, conserve energy. Second, plant cells may synthesize an enzyme in an inactive form and activate it only when needed. Third, plant cells can employ a feedback regulation mechanism by which an enzyme's activity is inhibited by an adequate amount of the enzyme's product. Furthermore, the activities of enzymes are affected by the environment, including temperature, pH (a measure of acidity versus alkalinity), and the presence of other chemicals. Different enzymes may require a slightly different physical environment for optimal function.

ATP: The Energy Carrier

During seed germination, stored glucose is broken down, making chemical energy available for movement, cellular repair, growth, and development. However, plant embryos cannot directly use the chemical energy derived from the breakdown of glucose. Within plant cells, most energy is transferred through a carrier—*adenosine triphosphate*, or ATP, known as the universal currency for energy transfer. Whether helping to convert light energy into chemical energy during photosynthesis or breaking down glucose in glycolysis and aerobic respiration, ATP acts as an agent to carry and transfer energy.

ATP is a nucleotide composed of the nitrogen-containing base adenine, the sugar ribose, and three phosphate groups. Energy released through glucose breakdown is used to drive the synthesis of ATP from adenosine diphosphate, or ADP, and inorganic phosphate (P_i):

$$\text{ADP} + P_i + \text{energy} \rightarrow \text{ATP}$$

The energy is largely stored in the bonds linking the phosphate groups. In reactions or processes where energy is needed, ATP releases energy through the hydrolysis and hence the removal of phosphate group:

$$\text{ATP} + H_20 \rightarrow \text{ADP} + P_i + \text{energy (7.3 kilocalories per mole)}$$

Sometimes the second phosphate group may also be removed via hydrolysis to generate the same amount of energy and adenosine monophosphate (AMP):

$$\text{ADP} + H_20 \rightarrow \text{AMP} + P_i + \text{energy (7.3 kilocalories per mole)}$$

The terminal phosphate group of ATP is not simply removed in most cases but is transferred to another molecule within a plant cell. This addition of a phosphate group to a molecule is defined as *phosphorylation*. The enzymes that catalyze such transfers are named *kinases*.

The following two examples of energy transfer involve ATP. The first is synthesis of sucrose by sugarcane:

$$\text{glucose} + \text{fructose} + 2\ \text{ATP} + 2\ H_20 \rightarrow \text{sucrose} + H_20 + 2\ \text{ADP} + 2\ P_i$$

The second example is the complete breakdown of glucose during cellular respiration:

$$\text{glucose} + 6\ O_2 + \text{36-38 ADP} + \text{36-38}\ P_i \rightarrow 6\ C0_2 + 6\ H_20 + \text{36-38 ATP}$$

Either ADP or ATP can be recycled through endergonic or exergonic reactions intertwined in the metabolic pathways. In the plant kingdom, energy flow begins with photosynthesis, through which ATP and then high-energy bonds are formed as sugar by the conversion of light energy from the sun. In respiration, these bonds are broken down to carbon dioxide and water, and energy is released. Some of this energy is used to power cellular processes, but some energy is lost in each energy-conversion step. The energy flow among all other organisms also starts from photosynthesis or plants, either directly or indirectly.

ENVIRONMENTAL BIOTECHNOLOGY

Categories: Biotechnology; disciplines; ecology; economic botany and plant uses; environmental issues

Environmental biotechnology includes any process using biological systems (plants, microorganisms, and enzymes) to clean up and detoxify environmental contamination from hazardous and nonhazardous waste.

Bioengineering, *bioremediation*, and *biotechnological pollution control* are similar terms for the same idea: using naturally occurring plants, microorganisms, enzymes, and genetically engineered variants to clean up toxic wastes. Environmental biotechnology is becoming increasingly popular in waste treatment and remediation because it has several desirable characteristics. It is a "green" technology: It uses natural systems and naturally occurring organisms to detoxify environmental pollutants. It is not a particularly new, therefore uncertain, technology, so there are few unintended consequences of its use.

Bioremediation is inexpensive compared with other treatment technologies. If one can provide the proper environment and nutrients for the remediating organisms, there is relatively little other infrastructure involved. It can be done on-site without having to move hundreds of cubic yards of contaminated material. It can even be done in contaminated aquifers and soils that cannot be moved.

Plants and Microorganisms

Natural bioremediation of pollution is constantly occurring in the environment; without it, past pollution would still be present. Environmental biotechnology typically involves three types of organisms or biological systems: plants, microorganisms, and enzymes that may come from either group. Using plants to bioremediate an environment is referred to as *phytoremediation*. Phytoremediation is typically used when the environment is contaminated by heavy metals such as lead, mercury, or selenium. Certain plants (*Astragalus*, for example) are able to accumulate high concentrations of metals such as selenium in their tissues. The plants can be harvested, the tissue burned, and the metal-contaminated ash (now small in volume) can be stored in a hazardous waste facility.

Bioremediation most commonly refers to the use of soil microorganisms (bacteria and fungi) to degrade or immobilize pollutants. It can be used to treat a wide variety of wastes, including some nuclear wastes such as uranium. In one bioremediation process, the contaminated site is made favorable for microbial growth. Nutrients, such as nitrogen and phosphorus, are added. The area is kept moist and periodically stirred (if it is soil) to make sure it has sufficient air, or air is pumped into the system (if it is an aquifer). Microbes already present at the site start growing and use the waste as a food source.

Cometabolism and Seeding

Frequently, wastes cannot be used as a food source by microorganisms. These can still be biodegraded by a process called *cometabolism*. In cometabolism, wastes are biodegraded during the growth of microbes on some other compound. For example, trichloroethylene (TCE), one of the most common groundwater contaminants, is cometabolized during the growth of bacteria that use methane for their food source. Many other wastes, such as DDT, atrazine, and PCBs, are cometabolized by microbes in the environment.

Waiting for organisms to grow can take a long time, especially in winter. Often, environmental engineers speed the process using microorganisms grown in the laboratory on various pollutants. Therefore, when they are added to the environment in high numbers, they start bioremediating the pollutants immediately. This process is called *seeding*.

Enzymes

Sometimes a waste is so toxic or is present in such high concentration that neither plants nor microorganisms can survive in its presence. In this case, *enzymes* can be used to try to degrade the waste. Enzymes are proteins with *catalytic* activity; that is, they make chemical reactions occur faster than they normally would. Enzymes are not alive in a strict sense, but they come only from living organisms. They have an advantage over living organisms in that they can retain their catalytic activity in toxic environments. For example, horseradish peroxidase is a plant enzyme that has been used to treat chlorinated compounds. The peroxidase causes the compounds to bind together, becoming less soluble and thereby much less likely to enter the food chain of an ecosystem.

Use and Technology

Bioremediation has been used on a large scale mostly to treat oil spills. The best example of this was during the *Exxon Valdez* oil spill in Alaska in 1989. Rather than try to remove oil from beaches physically (by steam spraying or absorbing it into other materials), engineers sprayed several beaches with a nutrient solution that helped naturally occurring oil-degrading microbes in the environment to multiply and begin decomposing the pollutant. The experiment was successful, and the U.S. Environmental Protection Agency recommended that Exxon expand its bioremediation efforts to more of the affected beaches.

Environmental biotechnology is a growing industry, and numerous venture capital firms have started to supply remediation technology for various types of wastes. One application of this technology is "designer microbes" for sewage treatment facilities receiving industrial pollutants. Another involves creating unique microorganisms, using genetic engineering techniques, that have the ability to degrade new types of pollutants completely. The first living thing to be patented in the United States, a bacterium that was genetically engineered at the General Electric Company, was created specifically to degrade petroleum from oil spills.

EROSION AND EROSION CONTROL

Categories: Agriculture; environmental issues; soil

Erosion is the loss of topsoil through several types of action of wind or water.

Erosion control is vital because soil loss from agricultural land is a major contributor to *nonpoint-source pollution* and *desertification* and represents one of the most serious threats to world food security. In the United States alone, some 2 billion tons of soil erode from cropland on an annual basis. About 60 percent, or 1.2 billion tons, is lost through water erosion, while the remainder is lost through wind erosion. This is equivalent to losing 0.3 meter (1 foot) of topsoil from 2 million acres of cropland each year. Although soil is a renewable resource, soil formation occurs at rates of just a few inches per hundred years, much too slowly to keep up with erosive forces. The loss of soil fertility is incalculable, as are the secondary effects of polluting surrounding waters and increasing *sedimentation* in rivers and streams.

Leading No-Tillage States, 1994-1997

State	*Percent of Cropland Planted Using No-Till Practices*		
	1994	*1996*	*1997*
Kentucky	44	51	48
Maryland	41	46	45
Tennessee	42	44	43
West Virginia	37	39	39
Delaware	37	38	38
Ohio	35	37	36

Source: Data adapted from G. R. Haszler, "No Tillage Use for Crop Production in Kentucky Counties in 1997," *Soil Science News and Views* 19 (1998).

Erosion removes the topsoil, the most productive soil zone for crop production, and the plant nutrients it contains. The thinning of the soil profile, which decreases a plant's rooting zone in shallow soils, can disturb the topography of cropland sufficiently to impede farm equipment operation. Erosion carries nitrates, phosphates, herbicides, pesticides, and other agricultural chemicals into surrounding waters, where they contribute to cultural eutrophication. Erosion causes sedimentation in lakes, reservoirs, and streams, which eventually require dredging.

Water Erosion

There are several types of wind and water erosion. The common steps in water erosion are *detachment*, *transport*, and *deposition*. Detachment releases soil particles from soil aggregates, transport carries the soil particles away and, in the process, scours new soil particles from aggregates. Finally, the soil particles are deposited when water flow slows. In *splash erosion*, raindrops impacting the soil can detach soil particles and hurl them considerable distances. In *sheet erosion*, a thin layer of soil is removed by tiny streams of water moving down gentle slopes. This is one of the most insidious forms of erosion because the effects of soil loss are imperceptible in the short term. *Rill erosion* is much more obvious because small channels form on a slope. These small channels can be filled in by tillage. In contrast, *ephemeral gullies* are larger rills that cannot be filled by tillage. *Gully erosion* is the most dramatic type of water erosion. It leaves channels so deep that equipment operation is prevented. Gully erosion typically begins at the bottom of slopes, where the water flow is fastest, and works its way with time to the top of a slope as more erosion occurs.

Wind Erosion

Wind erosion generally accounts for less soil loss than water erosion, but in states such as Arizona, Colorado, Nevada, New Mexico, and Wyoming, it is actually the dominant type of erosion. Wind speeds 0.3 meter (1 foot) above the soil that exceed 16 to 21 kilometers (10 to 13 miles) per hour can detach soil particles. These particles, typically fine- to medium-sized sand fewer than 0.5 millimeter (0.02 inch) in diameter, begin rolling and then bouncing along the soil, progressively detaching more and more soil particles by impact. The process, called *saltation*, is responsible for 50 to 70 percent of all wind erosion. Larger soil particles are too big to become suspended and continue to roll along the soil. Their movement is called surface *creep*.

The most obvious display of wind erosion is called *suspension*, when very fine silt and clay particles detached by saltation are knocked into the air and carried for enormous distances. The Dust Bowl of the 1930's was caused by suspended silt and clay in the Great Plains of the United States. It is possible to see the effects of wind erosion on the sides of fences and similar objects. Wind passing over these obstacles deposits the soil particles it carries. Other effects of wind erosion are tattering of leaves, filling of road and drainage ditches, wearing of paint, and increasing incidence of respiratory ailments.

Soil Conservation Methods

The four most important factors affecting erosion are soil texture and structure, roughness of the soil surface, slope steepness and length, and soil cover. There are several passive and active methods of erosion control that involve these four factors. Wind erosion, for example, is controlled by creating windbreaks, rows of trees or shrubs that shorten a field and can reduce the wind velocity by about 50 percent. Tillage perpendicular to the wind direction is also a beneficial practice, as is keeping the soil covered by plant residue as much as possible.

Highly erosive, steeply sloped land in the United States can be protected by placing it in the government-sponsored Conservation Reserve Program. The program provides incentives and assistance to farmers and ranchers for establishing conservation practices that have a beneficial effect on resources both on and off the farm. It encourages farmers to plant grass and trees to cover land that is subject to wind and water erosion.

Additional ways to prevent water erosion include planting permanent grass waterways in areas of cropland that are prone to water flow. Likewise, grass filter strips can be planted between cropland

Image Not Available

and adjacent waterways to impede the velocity of surface runoff and cause suspended soil particles to sediment and infiltrate before they can become contaminants. In this way, vegetation can improve water quality or provide food and habitat for wildlife. Tillage practices are also beneficial in combating water erosion. Tillage can be done along the contour of slopes. Long slopes can be shortened by terracing, which reduces the slope steepness.

Conservation tillage practices, such as minimal tillage and no-tillage, are being widely adapted by farmers as a simple means of erosion control. As the names imply, these are tillage practices in which as little disruption of the soil as possible occurs and in which any crop residue remaining after harvest is left on the soil surface to protect the soil from the impact of rain and wind. The surface residue also effectively impedes water flow, which causes less suspension of soil particles. Because the soil is not disturbed, practices such as no-tillage promote rapid water infiltration, which also reduces surface runoff. No-tillage is rapidly becoming the predominant tillage practice in southeastern states such as Kentucky and Tennessee, where high rainfall and erodible soils are found.

ESTROGENS FROM PLANTS

Categories: Economic botany and plant uses; medicine and health

While the female hormones called estrogens are common in mammals, only a few plants contain estrogens. Others synthesize compounds which are chemically unrelated to estrogens but resemble them in their molecular size and shape. These compounds are called phytoestrogens (plant estrogens) and may, when ingested by animals or humans, have properties similar to those of mammalian estrogens.

The precursor of estrogens in plants and animals is the linear (straight-chain) triterpene known as squalene. Cyclization of squalene, via the intermediate cycloartenol in plants and via the intermediate lanosterol in animals, forms a group of very important compounds known as the *steroids*. Steroids include cholesterol, mammalian sex hormones (including the estrogens and androgens), corticosteroids, insects' molting hormones, and plant brassinosteroid hormones. All steroids have a tetracyclic (four-ringed) structure; the rings are named A, B, C, and D. Differences in the functional groups attached to the tetracyclic skeleton, differences in the side-chain attached to ring D, and differences in the overall shape of the molecule determine a steroid's biological activity.

Estrogens have an aromatic A ring (a ring of six carbon atoms joined by alternating single and double bonds). This constrains the junction between the A and B rings, resulting in a "flat," or planar, molecule. This shape is essential for the potent biological activity of estrogens, and chemical modifications that alter the planar nature of an estrogen molecule reduce its biological activity.

Estrogens in Plants Versus Animals

In animals, one of the most potent estrogens is *estradiol*. It triggers the production of gonadotropins leading to ovulation. It is metabolized to the less active estrogens, *estrone* and *estriol*. Estrone and estriol are produced by the placentas of pregnant mammals, and both compounds accumulate in the urine during pregnancy.

In plants, estrogens are *secondary metabolites*. Although many thousands of secondary metabolites occur in plants, the distribution of particular secondary metabolites is often limited to just a few genera. This appears to be the case for estrogens. Estrone has been isolated from the seeds of pomegranate and from the date palm, in which it is a component of the kernel oil. Estriol has been isolated from the pussy willow. It is not known what function these estrogens have in plants. It is possible that, like other secondary metabolites, they may function in plant defense.

Image Not Available

Isoflavonoids as Phytoestrogens

Isoflavonoids are a type of secondary metabolite and are found almost exclusively in the legume (pea) family of plants. They are known to function in plant defense. They have been shown to deter herbivores and also to facilitate a plant's defense response to pathogen attack. Interestingly, some isoflavonoids have chemical structures that, in overall size, shape, and polarity, resemble estrogens. The resemblance includes the flatness, or planarity, of the molecules and the positions and orientation of oxygen atoms. Isoflavonoids that have these molecular characteristics can mimic the biological activity of estrogens and are called *phytoestrogens*.

In terms of biosynthetic origins and chemical structure, phytoestrogens and estrogens are quite different. Phytoestrogens, being isoflavonoids, are phenolic compounds, formed from phenylalanine (an amino acid) by the shikimate pathway. In contrast, estrogens are triterpenoids, formed from acetyl coenzyme A by the isoprenoid pathway.

Isoflavonoids that are considered to be phytoestrogens exhibit only weak estrogenic activity in animals and humans. Examples of phytoestrogens are *coumestrol*, *daidzein*, and *genistein*. Coumestrol and daidzein are found in alfalfa (known as lucerne in Europe) and clover. Both of these plants belong to the legume family and are important forage crops for animals. If the content of phytoestrogens in alfalfa or clover is high, the reproductive cycles of grazing animals may be adversely affected. This can pose a problem for farmers wanting to breed livestock in the normal way. For this reason, the amount of grazing in fields of alfalfa or clover has to be restricted. Alternatively, varieties of alfalfa or clover that have been bred to contain lower levels of isoflavonoids can be grown. Unfortunately, plant varieties with lower isoflavonoid content are often more susceptible to both pathogen attack and attack by herbivorous pests.

Phytoestrogens in the Human Diet

One of the major sources of phytoestrogens in the human diet is the soybean. Genistein is the major phytoestrogen in soybeans. It is present in some soybean products such as tofu, although it is not present in soy sauce. Genistein, extracted from soybean plants, can also be obtained as a dietary supplement. Dietary supplements, which are often pills, powders, or tinctures containing plant-derived products, can be purchased over the counter. In the United States, the manufacture and sale of such products, classified as "dietary supplements," is far less closely regulated and standardized than the manufacture and sale of food and drugs.

Genistein has been promoted as a possible preventive treatment or therapy for several diseases and conditions. There are claims that it reduces hot flashes associated with menopause, that it can prevent or delay the onset of osteoporosis in postmenopausal women, and that it can lower blood cholesterol levels. In each instance the potential effectiveness of genistein would be attributable to its acting as an estrogen replacement in older women, in whom the level of estradiol is naturally low. Genistein may also be effective in the treatment of certain breast cancers that require estrogen in order to grow. In this case it is theorized that the genistein, with weak estrogen activity, acts to reduce cancer growth by competing with the more potent estradiol for the estrogen receptor.

Some of the evidence for the role of phytoestrogens in women's health is circumstantial. It is based, in part, on observations that women who live in countries such as Japan and China, where soy products are widely consumed, have a lower incidence of diseases such as osteoporosis and breast cancer. Clearly, other factors, genetic and environmental, may be contributory. Health claims attributed to phytoestrogens, including genistein, need further evaluation in well-designed clinical trials before such claims can be accepted by the scientific and medical communities or relied upon by those using dietary supplements.

ETHANOL

Category: Economic botany and plant uses

Ethanol, sometimes called grain alcohol, is an alcohol produced by fermentation of carbohydrates from a broad range of plant matter for many uses in the chemical industry. It has potentially significant use as a gasoline replacement and is also the primary alcohol component of alcoholic beverages.

Ethanol is produced by carbohydrate fermentation processes, hydration of ethylene, and, to a lesser extent, reduction of acetaldehyde obtained from acetylene. Also called ethyl alcohol, alcohol, and grain alcohol, ethanol is a colorless liquid with a mild and distinct aroma and taste. It has a boiling point of 78.3 degrees Celsius and a melting point of ¯114.5 degrees Celsius. Ethanol is completely soluble in water and most organic solvents. It has a flash point of 8 degrees Celsius and is thus highly flammable. Ethanol undergoes numerous commercially important reactions and is thus a vital industrial chemical. It has been used as a partial replacement for gasoline (the hybrid fuel is called "gasohol"). As the major component of alcoholic beverages, ethanol has been known and recognized for thousands of years.

Primary Uses

Alcohol obtained from fermentation processes is generally included with other fermentation products and extracts from the carbohydrate-rich grains, fruits, and so on that are the raw materials for the many alcoholic beverages produced and consumed. Alcohol produced by yeast fermentation is obtained at a maximum concentration of 14 percent; therefore, alcoholic beverages other than beer and nonfortified wines require the addition of concentrated alcohol, which is obtained by distilling dilute alcohol from the fermentation of molasses and other sugar sources. In the United States and other highly industrialized countries, the alcohol added to beverages is increasingly being produced by other methods.

Ethanol is also used in large quantities for chemical synthesis in the organic chemical industry. It is used for the preparation of numerous esters vital to many polymer industries and for the production of diethyl ether (also called ether or ethyl ether), a major solvent. Other synthetic procedures lead to the manufacture of acetaldehyde, acetic acid, ethyl halides, and acetonitrile, which are in turn employed for the preparation of drugs, explosives, adhesives, pesticides, detergents, synthetic fibers, and other substances. Ethanol itself is used in vast quantities as a solvent.

Ethanol is added to gasoline to reduce air pollution, and it is frequently considered to be a likely replacement for gasoline when petroleum resources decline or drastically increase in price. Gasohol, ethanol combined with varying amounts of gasoline, is being vigorously promoted and is already in use in Brazil and elsewhere. *Biomass conversion* (conversion of plant matter) to ethanol by cost-efficient methods will speed the entry of gasohol into large-scale use in the industrial world.

Production Processes

Until biomass conversion becomes more widely used, carbohydrate fermentation processes are destined to be a decreasingly important source of industrial ethanol. Beverage alcohol is produced from a great variety of sources, including grains, potatoes, and fruit, but fermentation-based industrial alcohol is almost entirely obtained by yeast fermentation of molasses. Molasses (50 percent sucrose residue from sugar processing) is diluted with water to approximately 15 percent and under slightly acidic conditions is fermented by yeast to give 14 percent ethanol. Fractional distillation of the solution yields the commercial product: 95 percent ethanol. Approximately two and one-half gallons of blackstrap molasses is needed to make a gallon of 190-proof ethanol. (Alcohol content is usually described in terms of its proof value, which is twice its ethanol percentage.)

Although ethylene hydration was known in the early part of the nineteenth century, it was not until 1929 that it became an industrial process. Today it is the dominant method of producing ethanol. Ethylene, obtained from the thermal cracking of petroleum fractions or from natural gas separation processes, is treated with complex phosphoric acid-based catalysts at temperatures above 300 degrees Celsius and steam at pressures of thousands of pounds per square inch. The ethanol can be fractionally distilled, and the residual ethylene can be recycled. Ethylene can also be passed into concentrated sulfuric acid, and after hydrolysis the ethanol can be distilled from the diluted sulfuric acid.

The 95 percent alcohol produced by any of these methods can be converted to nearly pure (absolute) alcohol by removal of the water by azeotropic distillation using benzene or trichloroethylene. Trace amounts of the hazardous benzene or trichloroethylene remaining make the absolute alcohol undesirable for beverage purposes but useful for industrial purposes in which the 5 percent water interferes with use requirements.

EUDICOTS

Categories: Angiosperms; *Plantae*; taxonomic groups

The eudicots, class Eudicotyledones *(literally "true dicots"), are descended from a common ancestor and comprise three-quarters of all flowering plants. It is one of the two main classes of the angiosperms, the other being the monocots, or* Monocotyledones.

Eudicots, the common name used for class *Eudicotyledones*, are the most common group of flowering plants, comprising 75 percent of all angiosperms. The other 25 percent, monocots (*Monocotyledones*), are often characterized by pollen grains that have a single aperture (or line of weakness). Eudicots have pollen grains that typically possess three apertures, referred to as triaperturate pollen. Thus, there is no monocot-dicot division among the flowering plants. Whereas "monocot" remains a useful term, "dicot" does not represent a clade (a collection of organisms which have a single common ancestor) and should no longer be used. It is more useful to refer to eudicots, which represent a well-defined clade of angiosperms.

Previously, the angiosperms were divided into two major groups, traditionally recognized as classes: the dicots (short for dicotyledons, class *Magnoliopsida*) and the monocots (monocotyledons, class *Liliopsida*). Dicots have been distinguished from monocots by several morphological (external physical) and anatomical features, but all of these were subject to exception. For example, most dicots possess two seedling leaves, or *cotyledons*, and typically have net-veined leaves; monocots, in contrast, usually have one cotyledon and leaves with parallel venation.

The monocot-dicot division was recognized as early as the nineteenth century. However, later studies of *phylogeny* (the evolutionary history of a group of organisms) have demonstrated that this split does not reflect the evolutionary history of angiosperms. Phylogenetic trees (which are visual representations of the evolution of a group of organisms) showing historical relationships have been constructed based on deoxyribonucleic acid (DNA) sequences, as well as morphological, chemical, and other characteristics. These trees indicate that whereas the monocots form a *clade*, all dicots do not form a distinct group. The monocots appear among the groups of early-diverging (or early-evolving) lineages of angiosperms, all of which have traditionally been considered dicots. All early branches of the angiosperm phylogenetic tree, including the monocots, are best referred to informally as *basal angiosperms*.

Most angiosperms form a distinct clade, referred to by J. S. Doyle and C. L. Hotton as the eudicots, or true dicots. Whereas basal angiosperms are often characterized by pollen grains that have a single aperture (or line of weakness), eudicots have pollen grains that typically possess three apertures, referred to as triaperturate pollen. The eudicot clade receives strong support from analyses based on DNA sequence data. Importantly, the eudicots represent only a subset of the formerly recognized group dicots. Many basal angiosperms are traditional dicots but are not eudicots. Thus, there is no monocot-dicot split in the angiosperms. Whereas "monocot" remains a useful term, "dicot" does not represent a clade (a collection of organisms which have a single common ancestor) and should no longer be used. It is more useful to refer to eudicots, which represent a well-marked clade of flowering plants.

Eudicot (Dicot) Families Common in North America

Common Name	*Scientific Name*
Acanthus family	*Acanthaceae*
Borage family	*Boraginaceae*
Buckwheat family	*Polygonaceae*
Buttercup family	*Ranunculaceae*
Cactus family	*Cactaceae*
Daisy family	*Asteraceae*
Evening primrose family	*Onagraceae*
Gentian family	*Gentianaceae*
Ginseng family	*Araliaceae*
Madder family	*Rubiaceae*
Milkweed family	*Asclepiadaceae*
Mint family	*Lamiaceae*
Mustard family	*Brassicaceae*
Pea family	*Fabaceae*
Phlox family	*Polemoniaceae*
Pink family	*Caryophyllaceae*
Pokeweed family	*Phytolaccaceae*
Primrose family	*Primulaceae*
Purslane family	*Portulacaceae*
Rose family	*Rosaceae*
Saxifrage family	*Saxifragaceae*
Verbena family	*Verbenaceae*
Violet family	*Violaceae*
Waterleaf family	*Hydrophyllaceae*

Note: For a full list of angiosperm families, see the tables that accompany the essay "Angiosperms," in volume 1.

Classification

The eudicots contain 75 percent of all angiosperms, or about 165,000 species distributed among roughly 300 families. The eudicots include all the familiar angiosperm trees and shrubs and many herbaceous groups. Some of the larger, better-known families of eudicots include *Rosaceae* (rose family), *Fabaceae* (bean family), *Brassicaceae* (mustard family), *Ranunculaceae* (buttercup family), *Apiaceae* (parsley family), *Asteraceae* (sunflower family), and *Lamiaceae* (mint family). The eudicots include many familiar trees, such as those of the *Fagaceae* (oak or beech family), *Betulaceae* (birch family), *Juglandaceae* (walnut or hickory family), *Aceraceae* (maple family), and *Platanaceae* (plane tree or sycamore family).

A good understanding of the major groups of eudicots has emerged from the use of DNA sequence data. The early-diverging eudicots consist of a number of ancient lineages, including *Ranunculales*, a group containing the *Ranunculaceae* and *Papaveraceae* (poppy family). Other early-diverging eudicots include *Buxaceae* (boxwood family) and *Proteales*; the latter includes the *Platanaceae* and *Proteaceae* (sycamore and protea families).

Following the early-diverging eudicots is a large clade, referred to as the core eudicots, that contains most eucidots. The core eudicots consist of three major clades (rosids, asterids, and *Caryophyllales*) and several smaller ones (*Santalales*, *Saxifragales*, and *Gunnerales*). The rosids and asterids are very large groups, each containing roughly one-third of all angiosperms. Traditional classifications, such as presented by botanist Arthur Cronquist in 1981, do not reflect modern views of phylogenetic relationships. For comparison, the rosid clade now recognized is made up of members of the traditional subclasses *Rosidae*, *Dilleniidae*, and *Asteridae* (in the sense of Cronquist, 1981); the asterid clade contains members of subclasses *Asteridae*, *Dilleniidae*, and *Rosidae*; and *Caryophyllales* contains taxa previously placed in *Caropyllidae* and *Dilleniidae*.

Relationships among the core eudicots are still unclear, despite intensive study using DNA sequence data. The difficulty in clearly describing relationships among these groups appears to stem from the fact that following the origin and initial diversification of the eudicots, a rapid radiation (evolution of many organisms in a short period of time) occurred, yielding the groups of core eudicots seen today.

Evolution

The eudicots can be easily identified in the fossil record by their three-grooved pollen; they appeared in the fossil record as early as 110 million years ago. Prominent early fossil eudicots include *Platanaceae*. Following the origin of the eudicots, the fossil record also suggests a rapid diversification; by 90 to 80 million years ago, many of today's prominent families were established and are clearly recognizable in the fossil record. Thus, the fossil evidence suggesting a rapid radiation of eudicots agrees with the phylogeny obtained using gene sequence data.

Horticulturally important eudicots include numerous representatives of Ranunculaceae, *such as columbine.*

Economic Uses

Outside the grasses, such as wheat, corn, and rice (all in the monocot family *Poaceae*), most plants of economic importance are eudicots. Examples of economically important eudicot families include members of the bean or legume family (*Fabaceae*), such as soybean, lentils, and green beans; and the sunflower family (*Asteracae*), which includes sunflowers, lettuce, and artichokes. The mustard family (*Brassicaceae*) contains numerous members of economic importance, including cabbage, kale, cauliflower, mustard, and horseradish. The rose family (*Rosaceae*) provides fruits such as strawberries, raspberries, apples, cherries, peaches, and plums as well as numerous ornamentals. The family *Solanaceae* is the source of tomatoes and potatoes.

Most familiar horticultural plants are also eudicots. They include a diverse array of trees, shrubs, and annual and perennial herbs. Horticulturally important eudicots include begonias (*Begoniaceae*), dogwoods (*Cornaceae*), rhododendrons and heaths (*Ericaceae*), numerous members of the *Asteraceae* including sunflower, asters, chrysanthemums, and marigolds; and numerous representatives of *Ranunculaceae* such as columbine, buttercups, and monkshood. Some other families that contain ornamental plants include the cactus family (*Cactacae*), the geranium family (*Geraniaceae*), and members of the mint family (*Lamiaceae*).

Because 75 percent of all flowering plants are eudicots, they are extremely diverse in ecology and morphology. The eudicots are also diverse in *habit* (pattern of growth) and include annual and perennial herbs, shrubs, and trees. In size, they range from the smallest terrestrial angiosperms, plants 1 centimeter in height (*Lepuropetalon*, *Parnassiaceae*), to eucalyptus trees well over 100 meters. Flowers are also highly diverse in structure, form, and size across the eudicots. The smallest eudicot flowers are those of *Lepuropetalon*, which are less than 1 millimeter in diameter; the largest eudicot flowers are more than 0.3 meter (1 foot) in length.

EUGLENOIDS

Categories: Algae; microorganisms; *Protista*; taxonomic groups; water-related life

Organisms called euglenoids, the algal phylum Euglenophyta *in the kingdom* Protista*, make up a large group of common microorganisms numbering between 750 and 900 known species.*

Euglenoids can be found in both fresh and stagnant water. Some genera of euglenoids can also be found in marine habitats. *Euglena* and *Phacus* are representative common genera. Euglenoids are unicellular, except for those of the colonial genus *Colacium*. Because euglenoids have flexible cell coverings, move about freely, and ingest their food through a structure called a gullet, many scientists have classified the euglenoids as animals. Some species of euglenoids, however, have chloroplasts and are able to supply at least some of their food needs through photosynthesis.

Structure

The cells of most euglenoids are spindle-shaped and do not have cell walls or other rigid structures covering the plasma membrane. However, one genus, *Trachelomonas*, has a covering called a lorica, which is similar to a cell wall and contains iron and magnesium minerals. Spiral strips of protein that originate in the cytoplasm support the plasma membrane, creating a structure called a *pellicle*. The pellicle may be either flexible or rigid. Euglenoids with a flexible pellicle are able to change their shape, which helps them move about in muddy habitats.

A euglenoid has two *flagella*. One, a functional flagellum, has numerous tiny hairs along one side and pulls the cell through the water. This flagellum originates in a structure called a reservoir found on the anterior end of the cell. Another, smaller flagellum is contained within the reservoir but does not protrude.

Other features of euglenoids include the presence of a *gullet*, or groove, in many species, through which food is ingested. About one-third of the euglenoids have disk-shaped *chloroplasts* and can supply at least part of their own food through photosynthesis. Even these photosynthetic euglenoids are capable of ingesting dissolved or particulate food through their gullet if necessary.

A reddish-colored structure called an *eyespot*, or *stigma*, is located in the cytoplasm near the base of the flagella. This eyespot acts as a light-sensing device. The eyespot appears to be connected to the flagellum by special strands of cytoplasm, which may serve to transmit signals from one organelle to the other.

Euglenoid cells also contain a *contractile vacuole*. The contractile vacuole functions as a pump that removes excess water from the interior of the euglenoid cell. The water is pumped out of the cell through the reservoir. A new contractile vacuole is formed after each discharge of water.

Pigments and Food Reserves

Some scientists believe that similarities between euglenoids and green algae indicate that the chloroplasts of euglenoids originated in endosymbiotic green algae. The chloroplasts of both euglenoids and green algae contain chlorophyll *a* and chlorophyll *b*. Euglenoids and green algae also have some carotenoid pigments in common, although euglenoids contain two pigments derived from carotenoids that are not found in either green algae or the higher plants.

While there are some similarities in pigmentation between euglenoids and green algae, the two groups have different food reserves. Green algae have food reserves of starch, while euglenoids have a carbohydrate food reserve called *paramylon*, which normally is present in the form of small, whitish bodies of varying shapes scattered throughout the cell.

Reproduction

Reproduction in euglenoids takes place by mitotic cell division. Even as the euglenoids are swimming about, the cell begins to divide, starting at the end of the cell, where the flagellum is located. Eventually the cell splits lengthwise, forming two complete cells. Unlike the nuclear membrane in most organisms, the membrane surrounding the euglenoid nucleus does not break down during mitosis.

Many scientists believe that euglenoids do not reproduce sexually; meiosis and gametogenesis have never been observed in euglenoids. Some scientists suspect sexual reproduction must occur, even though it has not been seen. Other scientists believe that even individuals of the same euglenoid species have different amounts of DNA in their nuclei, which would preclude meiosis. Still others believe that euglenoids branched off the main evolutionary lines of protoctists before sexual reproduction had evolved.

Some species of euglenoids have developed the capacity to make thick-walled resting cells. Inside these cells, the euglenoids can wait out unfavorable environmental conditions. When conditions are favorable, the organisms break out of their resting cells and resume their normal shapes and activities.

EUKARYA

Categories: Cellular biology; evolution; taxonomic groups

The Eukarya *form one of the domains of life in the three-domain classification system.* Eukarya *consists of the advanced, complex organisms, formed by eukaryotic cells (cells with nuclei), including fungi, algae, plants, and animals. The other two domains of life,* Archaea *and* Bacteria*, consist of simpler organisms formed by prokaryotic (nucleus-free) cells.*

Two Types of Cell

The domain concept of biological organization is relatively new. As recently as the mid-twentieth century, two kingdoms—plant and animal—were widely accepted as describing the most significant split in the biological world. Every living thing was classified as either a plant or an animal. Subsequently, three additional kingdoms were recognized. Only in the late twentieth century did it become clear, based on molecular and other evidence, that distinctions at the level of the kingdom did not acknowledge the most fundamental differences among organisms. A higher category, the domain, was therefore posited. The general acceptance of the domain concept by the scientific community was an acknowledgment that, at least according to current knowledge, the differences between the prokaryotic organisms and the eukaryotic ones, and further, the split within the prokaryotic organisms, are the major dividing lines in the biological world.

Bacteria is the domain of prokaryotic organisms that are considered to be true bacteria, and *Archaea* is the domain of prokaryotic organisms able to live in extreme environments. *Eukarya* differs from the prokaryotic domains in basic characteristics of cellular organization, biochemistry, and molecular biology. Further, unlike the prokaryotic organisms, many of the *Eukarya* are truly multicellular. Eukaryotic cells, which are structurally more complex than prokaryotic ones, have many of their cellular functions segregated into semiautonomous, membrane-bound cell regions, called *organelles*. The principal organelle is the *nucleus*, which contains the genetic material, deoxyribonucleic acid (DNA). In prokaryotic organisms, in contrast, the DNA is not segregated from the rest of the cell.

Other distinguishing organelles in eukaryotic cells include the *mitochondria*. These are the sites of *respiration*, in which energy is generated by breaking down food, in the presence of oxygen, into water and carbon dioxide. The plants and the algae have additional organelles, the *plastids*. The most common plastid is the *chloroplast*, which contains chlorophyll, the key molecule that allows algae and plants to manufacture their own food from carbon dioxide and water, by photosynthesis. In contrast, in those bacteria that are photosynthetic, chlorophyll is not confined within an organelle.

Evolutionary Origin

Prokaryotic cells are much older than eukaryotic cells and had a long reign in the primordial seas before one of them, probably a member of the domain *Archaea*, gave rise to the first eukaryotic cell, between 2.5 billion and 1 billion years ago. This was at least a billion years after life had arisen. The first eukaryotic cell lacked mitochondria and chloroplasts. Subsequently, two kinds of prokaryotic organisms belonging to the domain *Bacteria* took up residence, as symbionts, inside early eukaryotic cells and eventually became so dependent on their hosts that they could no longer live on their own. These so-called *endosymbionts* developed into mitochondria and plastids.

Mitochondria, which were acquired before chloroplasts, arose from small bacteria that were heterotrophic: They obtained their food from other organisms rather than manufacturing it themselves. Chloroplasts arose from bacteria known as *cyanobacteria*, which were autotrophic, manufacturing their food themselves by photosynthesis. Thus, the evolution of the eukaryotic cell involved three prokaryotic cells—the original archaean host cell and two kinds of endosymbiotic bacteria. The early eukaryotic organisms were single-celled and are classified in a group called protists.

Early Diversification

From their beginning as single-celled protists, eukaryotic organisms evolved rapidly. The first multicellular eukaryotic organisms appeared about 800 million years ago, during the Precambrian era, and developed into three great lineages: the fungi, plants, and animals. Scientists have accorded each of these groups "kingdom" rank within the domain *Eukarya*, as the kingdoms *Plantae*, *Animalia*, and *Fungi*. In addition, the protists, which have living representatives today, are considered to constitute a fourth kingdom, the *Protista*, within the *Eukarya*. The *Protista* consist of the predominantly unicellular phyla and some of the multicellular lines associated with them. All four of the kingdoms within the *Eukarya* arose in the sea. Transition to the land occurred later.

The three multicellular kingdoms—plants, animals, and fungi—each probably descended from a separate ancestor from among the protists, and thus each of these lineages constitutes a relatively well-defined natural kingdom. The protists, however, are something of a "catch-all" kingdom. They consist of a variety of lineages, which include both photosynthetic organisms, the algae, and nonphotosynthetic ones. Because the algae are capable of photosynthesis, older classification schemes lumped them with the plants. Scientists think that many kingdoms will ultimately be recognized among the *Protista*.

The protist that gave rise to the plant lineage was probably a now-extinct member of the family *Charophyceae*, a group of specialized, aquatic, multicellular green algae (phylum *Chlorophyta*) that includes members living today. Like the algal protists, plants are autotrophic, but plants have more complex, structurally integrated bodies than do the algae.

In contrast to the algal protists and the plants, the nonphotosynthetic protists, as well as all the fungi and the animals, obtain their food heterotrophically, from other organisms. The fungi, although lacking chloroplasts and photosynthetic pigments, were once, like the algae, classified within the plant kingdom. This was partly because, like plants, fungi are sedentary. The fungi, however, have little in common, nutritionally or structurally, with plants and are now recognized as an independent evolutionary line within the *Eukarya*. Molecular evidence indicates that the fungi are actually more closely related to animals than to plants.

Colonization of the Land

Although all of the lineages that are now recognized as kingdoms within the *Eukarya* originated from aquatic organisms, the *Eukarya* eventually achieved great success on the land. Multicellularity helped these organisms make the transition to an environment of earth and air, which was more complex and demanding than the relatively uniform conditions of the sea. With their many cells, the *Eukarya* were able to develop specialized structures for coping with this new environment. The evolution of plants shows a trend toward structures specialized for anchorage, photosynthesis, and support. This trend eventually led to the development of complex plant bodies, with roots, leaves, and stems, allowing the plants as a kingdom to be fully terrestrial, not aquatic. Had it not been for plants' pioneering of the land, animals could not have become established there, because plants form the base of terrestrial animals' food chain.

Plants may have first invaded the land sometime in the Ordovician period of the Paleozoic era, 510 million to 439 million years ago. Forms resembling modern land plants arose in the Late Silurian period of the Paleozoic, more than 408 million years ago. By the close of the Paleozoic's Devonian period, about 360 million years ago, plants had diversified into a wide variety of shapes and sizes, from small creeping forms to tall forest trees.

In fossils of early plants, fungi are often found in close association with the roots. Some scientists think that plants were able to colonize the land only because they developed symbiotic relationships with such representatives of the fungal kingdom. Scientists also think that fungi, in turn, may have been able to make the transition to land only because of their close relationship with plants. According to this view, the fungi helped the plants gain a terrestrial foothold by absorbing water and mineral nutrients from the poorly developed soils of that time and passing them on to their plant partners. The plants provided the fungi with sugars that the plants had manufactured photosynthetically. This is much the way that relationships between plant roots and certain fungi work today. These symbiotic, so-called mycorrhizal relationships are characteristic of the vast majority of plants that dominate the modern world—the plants having vascular, or conducting, tissues. Of these plants, the most important by far are the angiosperms, or flowering plants (phylum *Anthophyta*).

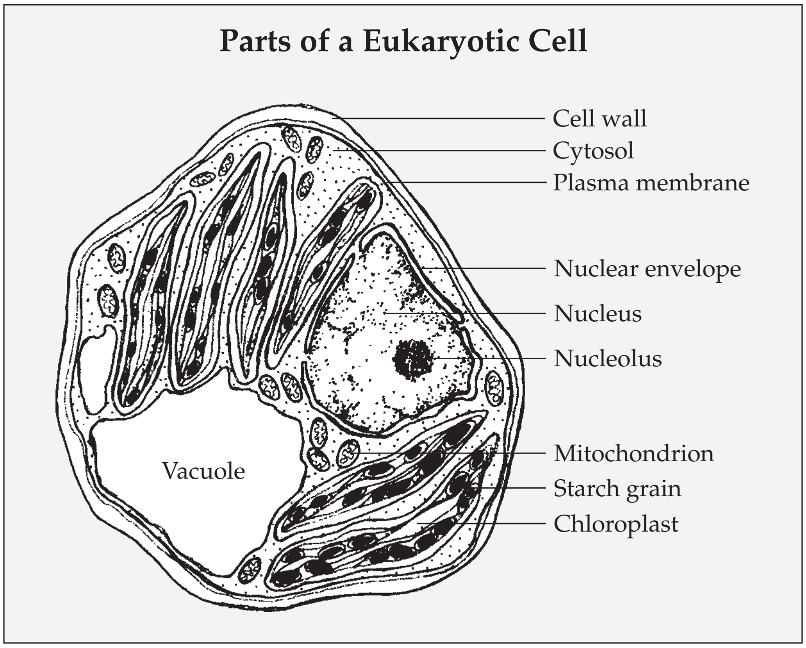
EUKARYOTIC CELLS

Category: Cellular biology

Eukaryotic cells (as opposed to prokaryotic cells) have internal, membrane-bound organelles and a distinct nucleus that physically separates the genetic material of the cell from the all of the other parts of the cell. All protists, fungi, plants, and animals are composed of eukaryotic cells.

The cells of all organisms can be divided into two broad categories: *prokaryotic* cells and *eukaryotic* cells. Prokaryotic cells are cells with a relatively simple structure, having no internal, membrane-



Kimberly L. Dawson Kurnizki

Eukaryotic cells constitute all but the simplest life-forms: protists, fungi, plants, and animals. Based on an electron microscope image of a leaf cell from a corn plant, this depiction shows the basic parts of the cell. Eukaryotic cells are distinguished from more primitive prokaryotic (mainly bacterial) cells by the presence of a nucleus that contains the genetic materials as well as membrane-bound organelles such as mitochondria and, in algae and plants, plastids such as chloroplasts.

bound organelles. The most striking feature of prokaryotic cells is that they lack a distinct *nucleus*, hence the name *prokaryotic*, literally translated from its Greek roots as "before nucleus." The prokaryotic organisms comprise two domains of the three domains of life: the ancient bacteria, *Archaea*; and the modern bacteria, *Bacteria* or *Eubacteria*. The *Archaea* are single-celled organisms that often inhabit extreme environments, such as hot springs. The remainder of bacteria are classified as *Eubacteria*.

All other organisms, including fungi, plants, and animals, are composed of eukaryotic cells and belong to the domain *Eukarya*. Eukaryotic cells are more structurally complex than prokaryotic cells, having internal, membrane-bound *organelles* and a distinct nucleus that physically separates the genetic material of the cell from the all of the other parts of the cell. Based on genetic analysis, the *Archaea* and *Eukarya* are more closely related to each other than they are to the *Bacteria*, suggesting that eukaryotic cells may have arisen from a single ancestral archaean cell.

Eukarya includes the traditional kingdoms *Plantae*, *Animalia*, *Fungi*, and *Protista*. Protists include a diverse assemblage of single-celled eukaryotic organisms including algae, amoebas, and paramecia. Because algae are photosynthetic, they have often been included in the study of plants, although they are not members of the plant kingdom.

Fungi include such organisms as smuts, rusts, molds, and mushrooms. Fungal cells have external cell walls and because of this have often been included in the study of plants. However, fungal cell walls have a completely different structure and composition from those of plant cell walls, and fungi lack plastids and photosynthetic pigments. Fungi represent a unique evolutionary line. They too, however, tend to be studied in botany courses, even though they are not plants.

Cell Parts

Eukaryotic cells are surrounded by a *cell membrane*, or *plasma membrane*, that is composed of a lipid structure in which other molecules, such as proteins and carbohydrates, are embedded. The cell membrane serves as a semipermeable, or selective, barrier between the cell and its environment. Some small, uncharged molecules can freely cross the cell membrane; others must be transported across the membrane before they can enter the cell. The cell membrane serves to protect the cell and to receive signals from the environment and other cells that help to direct cell activities.

In addition to the cell membrane, plant cells also have external *cell walls*. The presence of the external cell wall is one of the major characteristics that distinguishes plant cells from animal cells. The cell wall limits the size of the internal *protoplast* (the internal cytoplasm and nucleus) and prevents the plasma membrane from breaking when the protoplast enlarges following the uptake of water by the cell. Cell walls are not merely static support structures, however. They contain enzymes that are important in bringing essential molecules into the cell and in secreting molecules. They may also play important roles in the defense of the plant against bacterial and fungal pathogens.

Eukaryotic cells also have a prominent, membrane-bound organelle called the *nucleus*. The nucleus contains the genetic information of the cell that directs the cellular activity. A double membrane called the *nuclear envelope* surrounds the nucleus. Inside the nucleus, *deoxyribonucleic acid* (DNA) is transcribed to make molecules of *ribonucleic acid* (RNA), copies of the genetic information that can be delivered to the cytoplasm, where the RNA molecules serve to direct the manufacture of proteins. DNA in the eukaryotic nucleus exists as linear molecules that are associated with many proteins, and the DNA is packaged into a highly organized chromosomal structure by proteins called *histones*.

In addition to the nucleus, eukaryotic cells contain a number of internal membrane-bound organelles that help the cell carry out the functions necessary for life. The types of organelles found inside a eukaryotic cell reflect the function of that cell and the processes that it must carry out. Some of these organelles, such as *mitochondria* and *chloroplasts*, are important in capturing and releasing energy for cell function. Some, like the *Golgi complex* and the *endoplasmic reticulum* (ER), are involved in the manufacture, processing, and transport of proteins and other molecules within the cell. Others, such as *peroxisomes*, are involved in detoxifying chemicals and breaking down molecules.

The cell *cytoskeleton* is a highly dynamic structure that provides support and motility to cells as well as providing some of the apparatus that is used in the transduction of signals from the cell membrane to the nucleus. In plant cells, cytoskeletal elements form tracks for the movement of internal cellular organelles, such as the *cytoplasmic streaming* of chloroplasts, which can be observed by light microscopy. Work of the cytoskeleton is also necessary for the opening and closing of the stomata in plant leaves. The cytoskeleton consists of a variety of filamentlike proteins as well as proteins that serve as anchor points for filaments.

Origins of Mitochondria and Chloroplasts

The nucleus of the eukaryotic cell is not the only organelle that contains DNA and is enclosed by two membranes: The mitochondria of all cells and the chloroplasts of plant cells contain DNA and are surrounded by two membranes. The DNA of these organelles directs the synthesis of certain proteins that are necessary for the function of the organelles. This DNA is similar to DNA found in bacteria. Mitochondria and chloroplasts are thought to have evolved by a process known as *endosymbiosis*, in which bacteria were engulfed in the primitive eukaryotic cell, where they manufactured adenosine triphosphate (ATP), the nucleotide responsible for most of the chemical energy needed for metabolism, or captured energy from sunlight for the eukaryotic cell, establishing a mutually beneficial, or *symbiotic*, relationship with the eukaryotic cell.

Several lines of evidence support the endosymbiotic theory for the origin of mitochondria and chloroplasts. First, these organelles have areas of specialized cytoplasm called *nucleoids* that contain the DNA, much as bacteria do. The DNA molecules of the chloroplasts and mitochondria are circular and are associated with few proteins, like bacterial DNA, rather than linear and associated with histone proteins like most eukaryotic DNA. Chloroplasts and mitochondria also have ribosomes, structures that translate the genetic material into proteins, that are more similar to bacterial ribosomes than they are to eukaryotic ribosomes. These ribosomes are even sensitive to some of the same antibiotics, such as chloramphenicol and streptomycin, that inhibit the function of bacterial ribosomes.

Endomembrane System

The internal membranes of eukaryotic cells are dynamic, constantly changing structures. The concept of the *endomembrane system* describes all internal cytoplasmic membranes, with the exception of mitochondrial and plant plastid membranes, as a single continuum. In this model, the ER, generally the largest membrane system of eukaryotic cells, is the initial source of most other membranes. The ER is a network of interconnected, closed, membrane-bound *vesicles* that is contiguous with the nuclear envelope.

Vesicles from the ER carry proteins from the ER to the Golgi complex, fusing with its membranes. The Golgi complex can be described as a series of flattened membrane sacs, like a stack of hollow pancakes. The side closest to the nucleus receives vesicles from the ER, and the proteins inside these vesicles are processed and modified as they pass through the Golgi complex. Eventually, membrane vesicles containing the modified proteins will bud from the opposite surfaces of the Golgi complex and fuse with the cell membrane or the membranes of other organelles.

EUROPEAN AGRICULTURE

Categories: Agriculture; economic botany and plant uses; food; world regions

European agricultural practices are affected by the policies of the European Union, in addition to global conditions which influence farming everywhere.

Agriculture in Europe goes back to classical times. The development first of the Greek city-states, then of the Roman Empire, created urban centers that required substantial amounts of food to be imported from as far away as Egypt. In the year 2000 European agriculture was dominated by two major groups: the European Union (EU), with fifteen member states, and those European states outside the EU. The EU, which began with the Common Market created by the Treaty of Rome, signed in 1957, initially comprised France, West Germany, Italy, Belgium, the Netherlands, and Luxembourg. By the year 2000 it had expanded to include Great Britain, Ireland, Denmark, Greece, Spain, Portugal, Finland, Sweden, and Austria.

Land and Workers

Only 11 percent of the land in the world (slightly more than 5 million square miles) is suitable for agriculture. Among the continents, Europe has the highest percentage of land suitable for farming: 36 percent. (In North America, the comparable figure is 22 percent.) Overall, 80 percent of the land in Europe is usable in some way, either as agricultural land or as forestland.

Smaller farms are more extensive in the southern countries of the EU than in the northern countries. Some 60 percent of all farms in the EU are less than 5 hectares (12.5 acres) in size. Many of these small farms are either part-time or subsistence farms. Farms that are more than 50 hectares in size (125 acres, a small farm by U.S. standards) constitute only 6 percent of all farms but produce most of the crops.

The percentage of the labor force employed in agriculture is small where the farms are large—in Great Britain, it is a mere 2 percent. In the rest of the EU, except for some of the more recent members, such as Greece, Spain, and Portugal, the percentages are all in the single digits. Where the farms are

Selected Agricultural Products of Europe

small, or in non-EU countries, without the EU's agricultural policy to push production up with high prices, the percentage of the labor force employed in agriculture is much higher. In Poland, 27 percent of the labor force is employed in agriculture; in Romania, 21 percent; and in the Ukraine, 19 percent.

Crops

Europe produces about 19 percent of the world's grains eaten by humans or livestock and almost 24 percent of the world's coarse grains (barley, rye, oats). Most of all these grains are grown in Russia. Half the world's potatoes are grown in Europe; the Russian Federation grows the largest share. Europe also grows half of the world's peas, with 40 percent produced in the Russian Federation. Three-quarters of the world's sugar beets are grown in Europe, Ukraine being the largest European producer. Rapeseed production has been increasing; Germany is its largest producer in Europe, followed closely by France. European production is a bit more than 17 percent of world production.

Europe grows 20 percent of the world's tomatoes, although the tomato is not a native European plant. Spain and Italy are the leading producers of tomatoes in Europe. Overall, Europe grows 16 percent of the world's vegetables, with Italy being the largest European producer, closely followed by the Russian Federation and Spain.

More than half of the world's grapes are grown in Europe. These grapes feed Europe's great wineries, which produce 70 percent of the world's wine, a substantial proportion of which is drunk in Europe, although it remains an important export item. Europe also produces nearly three-quarters of the world's hops, which go into the much-prized European beers. Europe grows more than half the world's olives, almost all of them in Italy, Spain, and Greece. These countries also produce about 60 percent of the world's olive oil.

Agricultural Revolution

Beginning in the 1970's, Europe underwent what has been called a new agricultural "revolution." Ownerships were consolidated, especially in Britain but also in France and Germany. As a result, owners of the larger holdings were able to invest in modern agricultural machinery. Now, 44 percent of the world's tractors are owned in Europe, mostly in France, Italy, and Poland. This has helped make European agriculture so productive that, according to the U.S. Department of Agriculture, Europe's best farms are as efficient as the best in the United States.

European farmers vastly increased their yields in the second half of the twentieth century. Britain's wheat output is up 60 percent from what it was immediately after World War II; the growth in output

Leading Agricultural Crops of European Countries with More than 20 Percent Arable Land

Country	*Products*	*Percent Arable Land*
Albania	Temperate-zone crops	21
Belarus	Grain, potatoes, vegetables	29
Belgium	Sugar beets, fresh vegetables, fruits, grain, tobacco	24
Bulgaria	Grain, oilseed, vegetables, fruits, tobacco	37
Denmark	Grain, potatoes, rapeseed, sugar beets	60
France	Wheat, cereals, sugar beets, potatoes, wine grapes	33
Germany	Potatoes, wheat, rye, barley, sugar beets, fruit, cabbage	—

is nearly as great in France. In general, European agricultural productivity grew 5 percent a year between 1960 and 1999. Productivity grew much less in Eastern Europe than in Western Europe. This is partly because rainfall there varies so widely from year to year.

In 1979 the EU moved from being an importer of cereal grains to an exporter, as it did in 1975 for sugar and in 1976 for wine. Since 1960, the number of workers employed in agriculture has dropped by 50 percent, although the agricultural output remains the same or even higher. Authorities in Britain have estimated that farms there are at their most efficient when they employ no more than two or three people—a far cry from the hundreds of people who worked Europe's farms for subsistence wages in earlier centuries.

Irrigation and Drainage

Despite the generally favorable climate, Europe has 10 percent of the world's irrigated acreage. Most of that is in the Russian Federation, but Italy, Spain, and Romania also have significant amounts. A striking feature of European agriculture is the extent to which agricultural lands—some of them former wetlands—have been drained, to ensure uniform moisture for the crops being grown. In Finland, 91 percent of the agricultural land has been drained. Hungary has seen 70 percent of its land drained; the Netherlands, 65 percent; Britain, 60 percent; and Germany, 50 percent.

Environment

One factor that is assuming increasing influence over European agriculture is environmental concerns. The heavy use of fertilizers, pesticides, and herbicides has created damaging environmental conditions in some countries. The amount of cow manure generated in the Netherlands by its super-efficient dairy industry is more than the land of the entire country could absorb. The Dutch government subsidizes a company that composts some of this manure and sells it abroad as fertilizer for flowers. Sweden compensates farmers who reduce the runoff from their farms, a growing problem as the nitrogen content in water rises from fertilizer runoff. The EU has introduced a program to compensate those who set land aside for environmental protection, but more needs to be done to bring the EU's production levels closer to domestic demand, as well as to reduce the cost to consumers and taxpayers of the subsidies paid to farmers.

Organic Farming and Bioengineering

Several European countries, including the Czech Republic, France, and the United Kingdom, have introduced programs to encourage organic farming. At the beginning of the twenty-first century, however, a mere 2 percent of European crops were raised organically. Some scientists believe that environmental improvement could be generated if crops were developed that could ward off the insects that attack them, or that provide their own nitrogen, as the leguminous plants (peas and beans) do. Nevertheless, the European environmental movement has strongly opposed genetically modified foods, in part citing risks to health and the environment.

EUROPEAN FLORA

Category: World regions

Flowering plants in Europe vary from those growing in mediterranean to alpine to Arctic regions.

Many of Europe's flowering plants are similar to those in North America, belonging to many of the same genera but to different species. Some of the most common North American flowering plants have cousins in Europe, but their location varies according to their latitude and altitude.

Climate and Soil

The most important factor determining the location of plants is climate. The continent of Europe ranges from the coastal areas on the northern shores of the Mediterranean Sea and Black Sea to the Arctic Ocean north of the Scandinavian peninsula. Although most of Europe is in the temperate climate zone, the areas that border the Mediterranean Sea are nearly all frost-free. By contrast, those parts of Europe that form the Scandinavian peninsula and northern Russia have frost-free periods each year of as little as two months. As a result, there is a south-to-north gradation of the flowering plants.

Moreover, mountains separate land that is also separated by latitude. The division is perhaps more marked than on other continents because the Alps run west to east, the highest peaks being without vegetation, whereas the mountains in North America run north to south. Since climate is strongly a function of latitude, there is, in effect, a double line separating the vegetation of the part of Europe along the Mediterranean from the part that is north of the Alps, instead of the gradual gradation that is more characteristic of North America.

Another factor in determining where flowering plants will be found is soil. The soil in the south of Europe tends to be sandy; the low annual rainfall at the Mediterranean shoreline means that what little rain there is flows rapidly through the soil, leaving relatively little for plants. In the north, much of the soil is permanently frozen, so only plants that can grow in a short period of time in the summer and survive many months of frozen life will be found there. In between these areas, European soils vary between those that make ideal growing conditions for flowering plants, the black earth soils of central Europe, and those that are thin layers over underlying rock or that trap water in the soil layers just below the surface, creating marshy conditions.

An east-to-west factor also influences which flowering plants are found where in Europe. The Atlantic coastline is warmed year-round by the Gulf Stream, so that normal temperatures in the parts of the continent touched by this current (including much of the western Baltic Sea) have warmer temperatures in winter than their latitudes would indicate. Southern Norway, for instance, is on the same latitude as Greenland, most of which is covered with ice and snow throughout the year; but many plants, including agricultural crops, grow in southern Norway because of the Gulf Stream. Because rainfall is high, these parts of Europe tend to be wetter and cooler in summer than other parts of the world at the same latitudes. Europe has been occupied by humans for such a long period of time that there are almost no parts of Europe where the vegetation has been unaffected by humans. There are virtually no "virgin forests" in Europe.

Forests

Most of Europe's trees are similar to those in North America, but these are related by genus and are not members of the same species. This is true of oaks, maples, ashes, elms, birches, beeches, chestnuts, walnuts, apples, and hornbeams as well as conifers. Some of the native tree species of Europe have been brought to North America and have become a part of the American forest. The sycamore, for example, is the same species in North America as in Europe. The sycamore is a long-lived tree; some sycamores that were planted in North America during the colonial era are still alive. The mountain ash, with its bright orange berries, is another tree from Europe (where it is known as the rowan) that has emigrated to North America. The horse chestnut is yet another tree native to Europe that has long been settled in North America.

Among the evergreens, the Norway spruce has been widely planted and now seeds itself in North America. The Scots pine has been widely planted in North America; many Christmas trees sold every year in the United States are Scots pine. The European larch has become popular with the U.S. forest industry because it is suited to *reforestation* after *clear-cutting*.

Some North American species have made the opposite journey: Much of Scotland has been reforested with the Sitka spruce, a native of the Pacific

PhotoDisc

The raspberry bush found throughout eastern North America is a European native.

Northwest. Another native American evergreen that has made the trip to Europe is the white pine, known in Europe as the Weymouth pine. Plantations of white pine have been set up all over Europe, because Europe did not have a soft pine, and the wood of the white pine is easily worked.

Apple Trees

One important European tree that has had a large impact on the United States is the apple. The apple tree that produces the familiar fruit appears to have originated in southern Russia and made its way throughout Europe. Many apple varieties were cultivated by the Romans. The English and other European settlers of North America, finding only crab apples (North America's only native apple) when they arrived, imported familiar apple varieties from Europe. Orchards were among the first things the English settlers of New England planted in Massachusetts Bay.

Shrubs

Many European shrubs have become immigrants too. The box and holly are much prized for foundation planting, and the privet makes a neat hedge. The buckthorn bush has also made the journey, although it is less widely sold at nurseries. The juniper in Europe is the same as the juniper in North America, but the raspberry is not. Currants and gooseberries are European shrubs that have been widely transplanted, although one of the European currant varieties harbors a disease that affects the North American white pine. By contrast, the cranberry is a North American shrub that has lately been transplanted to Europe. North American blueberries are quite different from the related species in Europe.

The raspberry bush found throughout eastern North America is a European native. Because birds are frequent consumers of its fruit, it has spread well beyond the beds where it was originally planted. The heather that covers many of the hills of northern Europe, where it is a native, has become popular with American florists as a filler for bouquets. One of the most common landscape shrubs in the United States, the lilac, is of European origin, but it was among the earliest to make the trip to North America. Today the foundations of old colonial homesteads can often be located because, although the house is gone, the lilacs that once surrounded it survive.

Herbs

Herbs or wildflowers have spread across the continents much as shrubs have. Many of the most common North American wildflowers, such as the dandelion, are immigrants. So is the wild strawberry as well as the plantain that infests lawns. Many wildflowers are both European and American in origin, although in most cases the species differ. Among them are the violets, some of the cinquefoils, many buttercup varieties, and the marsh marigold. The clovers that are so familiar to Americans are all imports—the white clover, the red clover, and the alsike clover—are all natives of Europe.

Several genera of grasses are found on both continents: Kentucky bluegrass is really the European smooth meadow grass. Annual rye grass, often used to green up new lawns quickly, is a European import, as is red fescue, common in hayfields. Timothy hay, cultivated in the United States as feed hay, is also an import from Europe.

The marshes and swamps of Europe are populated mostly by indigenous plants. Large numbers of sedges that are native to Europe are grouped together in the *Carex* genus and can be found in Europe's wetlands. Wetlands may have more "virgin" plant communities than anywhere else in Europe, because they were unsuitable for cultivation. Europeans have drained many of the continent's wetlands to convert the land to farmland; the most notable case is the Netherlands, where land has been reclaimed from the sea so that crops can be grown on it. Among the shrubs, Europe's wetlands, like those in North America, harbor alders, but Europe's are different species from those found in North America. The same can be said for willows, which grow well where ample moisture is available.

Commercial Plants

Ever since the first agricultural revolution, ten thousand years ago, humans have adapted plants to their needs. This is especially true for the grains, most of which originated in the Middle East. Wheat, oats, barley, rye, and others that could become food for humans were altered from their original form by careful plant breeding. This is also true for the flowers that are the staple of the florists' trade—roses, chrysanthemums, begonias, and carnations are all adaptations of wild plants.

Tulips are widely known flowers that originated in Eurasia from Austria and Italy eastward to Japan, with two-thirds of them native to the eastern Mediterranean and the southeastern parts of Russia. The Dutch cultivated tulips beginning in the 1500's and made them into a staple export. The grape hyacinth is a European native, as is the full-size hyacinth. Crocuses are natives of the Mediterranean basin.

Olive Trees

One native flowering plant of Europe deserves special mention: the olive tree. Having originated along the shores of the Mediterranean Sea, it has been cultivated and modified to increase the size of its fruit since ancient times. It remains an important agricultural resource for Mediterranean nations, especially Greece, Italy, France, and Spain. The Spanish conquerors of Central America carried the olive to the new world, and it was successfully introduced into California.

The Maquis

Uncultivated olive trees form part of the vegetation of the maquis, an area in France and Spain where the native olive grows with the carob, a small native tree like the olive, and the holm oak. Most of these trees are so stunted by the impoverished soil, heavily eroded over the centuries, that they are little more than bushes. There are also a variety of shrubs characteristics of the maquis, such as a clematis vine, the Mediterranean buckthorn, and the common myrtle. A local variety of grass covers the ground between the trees and shurbs. Similar communities can also be found in Greece, where they provide grazing for goats.

Vines

The grapevine has been of commercial importance for centuries. The Greeks and Romans raised grapes and made wine from them. The wine grape appears to have originated in the Mediterranean basin, but many varieties of grape have developed. European varieties have been transplanted to North America, and the process has also worked in reverse. In the late nineteenth century, when a devastating disease known as *phylloxera* ravaged French vineyards, American grapevine rootstock was imported into France, and the French vines grafted onto it, because the American rootstock had shown itself less subject to the disease.

Another vine is the ivy. There are ivies native to almost every continent, but European ivy, sometimes called English ivy, has spread far beyond its native ground. It is popular as a wall covering and is frequently seen in gardens.

EUTROPHICATION

Categories: Algae; diseases and conditions; environmental issues; microorganisms; poisonous, toxic, and invasive plants; pollution; water-related life

The overenrichment of water by nutrients, eutrophication causes excessive plant growth and stagnation, which leads to the death of fish and other aquatic life.

The word "eutrophic" comes from the Greek *eu*, which means "good" or "well," and *trophikos*, which means " food" or "nutrition." Eutrophic waters are well-nourished and rich in nutrients; they support abundant life. Eutrophication refers to a condition in aquatic systems (ponds, lakes, and streams) in which nutrients are so abundant that plants and algae grow uncontrollably and become a problem. The plants die and decompose, and the water becomes stagnant. This ultimately causes the death of other aquatic animals, particularly fish, that cannot tolerate such conditions. Eutrophication is a major problem in watersheds and waterways such as the Great Lakes and Chesapeake Bay that are surrounded by urban populations.

The stagnation that occurs during eutrophication is attributable to the activity of microorganisms growing on the dead and dying plant material in water. As they decompose the plant material, microbes consume oxygen faster than it can be resupplied by the atmosphere. Fish, which need oxygen in the water to breathe, become starved for oxygen and suffocate. In addition, noxious gases such as hydrogen sulfide (H_2S) can be released during the decay of the plant material. The hallmark of a eutrophic environment is one that is plant-filled, littered with dead aquatic life, and smelly.

Eutrophication is actually a natural process that occurs as lakes age and fill with sediment, as deltas form, and as rivers seek new channels. The main concern with eutrophication in natural resource conservation is that human activity can accelerate the process and can cause it to occur in previously clean but nutrient-poor water. This is sometimes referred to as *cultural eutrophication*. For example, there is great concern with eutrophication in Lake Tahoe. Much of Lake Tahoe's appeal is its crystal-clear water. Unfortunately, development around Lake Tahoe is causing excess nutrients to flow into the lake and damaging the very thing that attracts people to the lake.

Roles of Nitrogen and Phosphorus

Nitrogen and phosphorus are the key nutrients involved in eutrophication, although silicon, calcium, iron, potassium, and manganese can be important. Nitrogen and phosphorus are essential in plant and animal growth. Nitrogen compounds are used in the synthesis of amino acids and proteins, whereas phosphate is found in nucleic acids and phospholipids. Nitrogen and phosphorus are usually in limited supply in lakes and rivers. Plants and animals get these nutrients through natural recycling in the water column and sediments and during seasonal variations, as algae and animals decompose, fall to the lower depths, and release their nutrients to be reused by other organisms in the ecosystem. A limited supply of nutrients—as well as variations in optimal temperature and light conditions—prevents any one species of plants or animals from dominating a water ecosystem.

Effects of Excess Nutrients

Although nutrient enrichment can have detrimental effects on a water system, an increased supply of nitrogen and phosphorus can have an initial positive effect on water productivity. Much like adding fertilizer to a lawn, increases in nutrients in a lake, river, or ocean cause it to be more productive by stimulating plant and animal growth in the entire food chain. *Phytoplankton*—microscopic algae that grow on the surface of sunlit waters—take up nutrients directly and are able to proliferate. Through photosynthesis, these primary producers synthesize organic molecules that are used by other members of the ecosystem. Increased algal growth thus stimulates the growth of zooplankton—microscopic animals that feed on algae and bacteria—as well as macroinvertebrates, fish, and other animals and plants in the food web. Indeed, many fisheries have benefited from lakes and oceans that are productive.

When enough nutrients are added to a lake or river to disrupt the natural balance of nutrient cycling, however, the excess nutrients effectively become *pollutants*. The major problem is that excess nutrients encourage profuse growth of algae and rooted aquatic weeds, species that can quickly take advantage of favorable growth conditions at the expense of slower-growing species. Algae convert carbon dioxide and water into organic molecules during photosynthesis, a process that produces oxygen. When large blooms of algae and other surface plants die, however, they sink to the bottom of the water to decompose, a process that consumes large amounts of oxygen. The net effect of increased algae production, therefore, is depletion of dissolved oxygen in the water, especially during midsummer.

Reduced oxygen levels (called *hypoxia*) can have dire consequences for lakes and rivers that support fish and bottom-dwelling animals. Oxygen depletion is greatest in the deep bottom layers of water, because gases from the oxygen-rich surface cannot readily mix with the lower layers. During summer and winter, oxygen depletion in eutrophic waters can cause massive fish kills. In extreme cases of eutrophication, the complete depletion of oxygen (*anoxia*) occurs, leading to ecosystem crashes and irreversible damage to plant and animal life. Oxygen depletion also favors the growth of anaerobic bacteria, which produce hydrogen sulfide and methane gases, leading to poor water quality and taste.

Excessive algal and plant growth has other negative effects on a water system. Algae and plants at the surface block out sunlight to plants and animals at the lower depths. Loss of aquatic plants can affect fish-spawning areas and encourage soil erosion from shores and banks.

Eutrophication often leads to loss of diversity in a water system, as high nutrient conditions favor plants and animals that are opportunistic and short-lived. Native sea grasses and delicate sea plants often are replaced by hardier weeds and rooted plants. Carp, catfish, and bluegill fish species replace more valuable coldwater species such as trout.

Thick algal growth also increases water turbidity and gives lakes and ponds an unpleasant pea-soup appearance. As algae die and decay, they wash up on shores in stinking, foamy mats.

Algal blooms of unfavorable species can produce toxins that are harmful to fish, animals, and humans. These toxins can accumulate in shellfish and have been known to cause death if eaten by humans. So-called red tides and brown tides are caused by the proliferation of unusual forms of algae, which give water a reddish or tealike appearance and in some cases produce harmful chemicals or neurotoxins.

Assessing Eutrophication

While eutrophication effects are generally caused by nutrient enrichment of a water system, not all cases of nutrient accumulation lead to increased productivity. Overall productivity is based on other factors in the water system, such as grazing pressure on phytoplankton, the presence of other chemicals or pollutants, and the physical features of a body of water. Eutrophication occurs mainly in enclosed areas such as estuaries, bays, lakes, and ponds, where water exchange and mixing are limited. Rivers and coastal areas with abundant flushing generally show less phytoplankton growth from nutrient enrichment because their waters run faster and mix more frequently. On the other hand, activities that stir up nutrient-rich sediments from the bottom, such as development along coastal waters, recreational activities, dredging, and storms, can worsen eutrophication processes.

The nutrient status of a lake or water system is often used as a measure of the extent of eutrophication. For example, lakes are often classified as *oligotrophic* (nutrient-poor), *eutrophic* (nutrient-rich), or *mesotrophic* (moderate in nutrients) based on the concentrations of nutrients and the physical appearance of the lake. Oligotrophic lakes are deep, clear, and unproductive, with little phytoplankton growth, few aquatic rooted plants, and high amounts of dissolved oxygen. In contrast, eutrophic lakes are usually shallow and highly productive, with extensive aquatic plants and sedimentation. These lakes have high nutrient levels, low amounts of dissolved oxygen, and high sediment accumulation on the lake bottom. They often show sudden blooms of green or blue-green algae (or blue-green bacteria, cyanobacteria) and support only warm-water fish species.

Mesotrophic lakes show characteristics in between those of unproductive oligotrophic waters and highly productive eutrophic waters. Mesotrophic lakes have moderate nutrient levels and phytoplankton growth and some sediment accumulation; they support primarily warm-water fish species. As a lake naturally ages over hundreds of years, it usually (but not always) gets progressively more eutrophic, as sediments fill in and eventually convert it to marsh or dryland. Nutrient enrichment from human sources can speed this process greatly.

Limiting Damage

The negative effects of eutrophication can be reduced by limiting the amount of nutrients—in most cases nitrogen and phosphorus—from entering a water system. Nutrients can enter water bodies through streams, rivers, groundwater flow, direct precipitation, and dumping and as particulate fallout from the atmosphere. While natural processes of eutrophication are virtually impossible to control, eutrophication from human activity can be reduced or reversed.

Phosphorus enrichment into water systems occurs primarily as the result of wastewater drainage into a lake, river, or ocean. Phosphate is common in industrial and domestic detergents and cleaning agents. Mining along water systems is also a major source of phosphorus. When phosphorus enters a water system, it generally accumulates in the sediments. Storms and upwelling can stir up sediments, releasing phosphorus. Treatment of wastewater to remove phosphates and the reduction of phosphates in detergents have helped to reduce phosphorus enrichment of water systems.

Nitrogen enrichment is harder to control; it is present in many forms, as ammonium, nitrates, nitrites, and nitrogen gas. The major sources of nitrogen eutrophication are synthetic fertilizers, animal wastes, and agricultural runoff. Some algae species can also fix atmospheric nitrogen directly, converting it to biologically usable forms of nitrogen. Since the atmosphere contains about 78 percent nitrogen, this can be a major source of nitrogen enrichment in waters that already have significant algal populations.

Efforts to control nitrogen and phosphorus levels have examined both point and nonpoint sources of nutrient loading. Point sources are concentrated, identifiable sites of nutrients that include municipal sewage-treatment plants, feed lots, food-processing plants, pulp mills, laundry detergents, and domestic cleaning agents. Nonpoint, or diffuse, sources of nutrients include surface runoff from rainwater, fertilizer from agricultural land and lawns, eroded soil, and roadways.

EVOLUTION: CONVERGENT AND DIVERGENT

Categories: Ecosystems; evolution; paleobotany

Some of the most dramatic examples of natural selection are the result of adaptation in response to stressful climatic conditions. Such selection may cause unrelated species to resemble one another in appearance and function, a phenomenon known as convergence. In other situations, subpopulations of a single species may split into separate species as the result of natural selection. Such divergence is best seen on isolated islands.

Convergent Evolution

Convergent evolution occurs when organisms from different evolutionary lineages evolve similar adaptations to similar environmental conditions. This can happen even when the organisms are widely separated geographically. A classic example of convergent evolution occurred with *Cactaceae*, the cactus family, of the Americas and with the euphorbs, or *Euphorbiaceae*, the spurge family of South Africa, both of which have evolved *succulent* (water-storing) stems in response to desert conditions.

The most primitive cacti are vinelike, tropical plants of the genus *Pereskia*. These cacti, which grow on the islands of the West Indies and in tropical Central and South America, have somewhat woody stems and broad, flat leaves. As deserts developed in North and South America, members of the cactus family began to undergo selection for features that were adaptive to hotter, dryer conditions.

The stems became greatly enlarged and succulent as extensive water-storage tissues formed in the pith or cortex. The leaves became much reduced. In some cactus species, such as the common prickly pear (*Opuntia*), the leaves are small, cylindrical pegs that shrivel and fall off after a month or so of growth. In most cacti, only the leaf base forms and remains as a small hump of tissue associated with an axillary bud. In some cacti this hump is enlarged and is known as a tubercle. Axillary buds in cacti are highly specialized and are known as areoles. The "leaves" of an areole are reduced to one or more spines. Particularly in columnar cacti, the areoles are arranged in longitudinal rows along a multiple-ridged stem.

With the possible exception of the genus *Rhipsalis*, which has one species reported to occur naturally in Africa, all cacti are native to the Americas. As deserts formed in Africa, Eurasia, and Australia, different plant families evolved adaptations similar to those in cacti. The most notable examples are the candelabra euphorbs of South Africa. Desert-dwelling members of the *Euphorbiaceae* frequently have succulent, ridged, cylindrical stems resembling those of cacti. The leaves are typically reduced in size and are present only during the rainy season. They are arranged in rows along each of several ridges of the stem. Associated with each leaf are one or two spines. As a result, when the leaves shrivel and fall off during the dry season, a spiny, cactuslike stem remains.

The succulent euphorbs of Africa take on all of the forms characteristic of American cacti, from pincushions and barrels to branched and unbranched columns. Other plant families that show convergence with the cacti, in having succulent stems or leaves, are the stem succulents of the milkweed family, *Asclepiadaceae*; sunflower family, *Asteridaceae*; stonecrop family, *Crassulaceae*; purslane family, *Portulacaceae*; grape family, *Vitaceae*; leaf succulents of the ice plant family, *Aizoaceae*; daffodil family, *Amaryllidaceae*; pineapple family, *Bromeliaceae*; geranium family, *Geraniaceae*; and lily family, *Liliaceae*.

Divergent Evolution

Some of the most famous examples of divergent evolution have occurred in the Galápagos Islands. The Galápagos comprise fourteen volcanic islands located about 600 miles west of South America. A total of 543 species of vascular plants are found on the islands, 231 of which are endemic, found nowhere else on earth. Seeds of various species arrived on the islands by floating in the air or on the water or being carried by birds or humans.

With few competitors and many different open habitats, variant forms of each species could adapt to specific conditions, a process known as *adaptive radiation*. Those forms of a species best suited to each particular habitat were continually selected for and produced progeny in that habitat. Over time, this natural selection resulted in multiple new species sharing the same ancestor. The best examples of divergent evolution in the Galápagos have occurred in the *Cactaceae* and *Euphorbiaceae*. Eighteen species and variety of cacti are found on the islands, and all are endemic. Of the twenty-seven species and varieties of euphorbs, twenty are endemic.

Image Not Available

An interesting example of the outcome of divergent evolution can be seen in the artificial selection of different cultivars (cultivated varieties) in the genus *Brassica*. The scrubby Eurasian weed colewort (*Brassica oleracea*) is the ancestor of broccoli, brussels sprouts, cabbage, cauliflower, kale, and kohlrabi (rutabaga). All of these vegetables are considered to belong to the same species, but since the origin of agriculture, each has been selected for a specific form that is now recognized as a distinct crop.

EVOLUTION: GRADUALISM VS. PUNCTUATED EQUILIBRIUM

Categories: Evolution; paleobotany

The gradualism model of evolution proposes that a progenitor species gradually gave rise to many new species, with no special mechanisms accounting for the origins of new genera or groups of higher classifications—only the accumulation of many small changes in the frequencies of alleles in gene pools. The punctuated equilibrium model of evolutionary change supposes long periods of little or no change interspersed with short intervals of rapid change.

Charles Darwin, author of *On the Origin of Species by Means of Natural Selection* (1859), believed that morphological change was inevitable and proceeded slowly, encompassing slight, successive, and gradual changes within lineages. Speciation, therefore, was the result of the gradual accumulation of changes within ancestral populations over time, ultimately leading to the formation of recognizably new and different species. According to Darwin, sudden, large-scale changes were improbable or impossible—an idea epitomized by the phrase *Natura non facit saltum*, or "Nature never makes leaps." Darwin's concept of the slow and gradual transformation of a species' entire ancestral population into distinct descendant species over time has been termed "phyletic gradualism," or *anagenesis*.

If true, the expectation of anagenic transformation leads to the supposition that the fossil record for any lineage should contain an "inconceivably great" number of intermediate forms. Darwin, however, realized that the fossil record is, in fact, not littered with an "interminable" and "enormous" number of intermediate forms. Darwin's solution to this problem with his theory was presented in a chapter of his book *On the Origin of Species by Means of Natural Selection* titled "On the Imperfection of the Geological Record." Here Darwin persuasively argued that the paleontological record of the past is extremely imperfect because of degradation of fossiliferous deposits and differential rates of deposition and fossilization among lineages. He also noted that, on geologic time scales, persistent, long-lived and widespread species are more likely to appear in the fossil record than short-lived species or species confined to narrow geographic ranges.

The "Modern Synthesis," Microevolution, and Species Formation

In the 1930's and 1940's Darwin's theory of natural selection was melded with then-current knowledge of genetics, heritability, and mathematics to produce the *modern synthesis theory of evolution*. Under this paradigm, evolution came to be defined as a change in gene frequency over time. The microevolutionary processes of mutation, migration, random genetic drift, and natural selection were recognized as the primary mechanisms that alter gene frequencies.

At this time other authorities began to carefully consider the mechanism(s) by which species arise. One particular mode of species formation, and one supported by considerable empirical evidence, is termed the *allopatric model of speciation*. Allopatric species are formed as subpopulations of a more widespread ancestral species become geographically isolated and, in time, reproductively isolated from one another.

Paleospecies and Punctuated Equilibria

These ideas, particularly those of gradual, inevitable change by microevolutionary processes and the imperfection of the fossil record, and were accepted by paleontologists for more than a century. However, in 1972 Niles Eldredge and Stephen J. Gould published a paper in which paleontologists were challenged to examine fossil sequences (and gaps) more objectively. Eldredge and Gould drew three important conclusions about the fossil record. First, some gaps in the fossil record are real and cannot be attributed to other factors; gradual series of transitional forms do occur, but they are extremely rare. Second, paleospecies often persist for millions of years without substantial morphological change. Third, they recognized that paleospecies found in older strata are sometimes rapidly replaced by morphologically different taxa in younger deposits.

Thus, a literal interpretation of the fossil record requires the acknowledgment of short, rapid bursts of evolution. That is, within the paleontological history of a lineage, morphological stasis is occasionally interrupted by near-instantaneous (in geological time) formation of morphologically different species. If these gaps are real, how are they to be explained? How is one species suddenly (in geologic time) replaced by a morphologically modified form in the fossil record?

To answer these questions, Eldredge and Gould developed the theory of *punctuated equilibria* that, in essence, fused a literal interpretation of the fossil record with the mode of speciation most often observed in extant populations (such as the allopatric model of speciation).

Eldredge and Gould's theory of punctuated equilibria is based on the following postulates or observations. First, speciation typically occurs via allopatric speciation. Second, the origin of descendant species is, in geological time, rapid and occurs in a limited geographic area. Third, most adaptive change occurs at the time of speciation. Fourth, speciation is typically followed by long periods of morphological stasis, particularly within large, widespread species. Fifth, the abrupt appearance of a new species within the range of the ancestral species is a result of ecological succession, immigration, or competition. Finally, apparent adaptive trends (such as macroevolutionary trends) observed in the fossil record are the result of species selection within lineages over time.

The authors reasoned that as long as a species is capable of successfully exploiting its habitat, adaptations that originated at the time of speciation are unlikely to be altered, and morphological stasis is the result. Thus, in terms of the geologic time scale, most species seem to persist unchanged over long periods of time. The origin of a new species, its growth in numbers, and the extension of its geographic range are, therefore, determined by reproductive and ecological characteristics. In short, under the punctuated equilibrium model new species can be successful if they are sufficiently distinct in their habitat requirements and if they are able to compete with or outcompete close relatives should they come into contact with one another. This theory of speciation and diffential reproduction and survival of species produces well-documented, large-scale evolutionary patterns or "macroevolutionary" trends.

Punctuated Equlibria and Plants

The theory of punctuated equilibria was constructed based on studies of animal fossils; unfortunately, no mention is made of plants. The theory has therefore received less attention from paleobotanists. It is true that in extant plants rapid changes in physiological or morphological characteristics associated with speciation are not uncommon. However, such phenomena are rarely documented in the fossil record.

For example, interspecific hybridization or polyploidization may (almost instantaneously) form new, reproductively isolated species whose niches may differ from those of their immediate progenitors. Thus, in plants, rapid species formation is empirically known. Stasis is also known from the fossil records of some plant lineages. For example, in terms of floral structure, extant members of the *Loraceae*, *Chloranthaceae*, *Nymphaceae*, and the magnoliids scarcely differ from their early- to mid-Cretaceous ancestors. Morphological stasis is also observed in gingkos, *Metasequoia*, cycads, lycopods, sphenopsids, and ferns as well as the genus *Pinus*, which arose in the Jurassic. Rapid radiations are also documented in the plant fossil record, as occurred after the rise of angiosperms during the early Cretaceous. Thus, the plant fossil record provides clear evidence for stasis in some lineages and rapid diversification in others. Despite these observations, paleobotanical examples of lineages whose evolution fits the predictions of the punctuated equilibrium model are few.

EVOLUTION: HISTORICAL PERSPECTIVE

Categories: Classification and systematics; evolution; history of plant science; paleobotany

Evolution is the theory that biological species undergo sufficient change with time to give rise to new species.

The concept of evolution has ancient roots. Anaximander suggested in the sixth century B.C.E. that life had originated in the seas and that humans had evolved from fish. Empedocles (c. 450 B.C.E.) and Lucretius (c. 96-55 B.C.E.), in a sense, grasped the concepts of adaptation and natural selection. They taught that bodies had originally formed from the random combination of parts, but that only harmoniously functioning combinations could survive and reproduce. Lucretius even said that the mythical centaur, half horse and half human, could never have existed because the human teeth and stomach would be incapable of chewing and digesting the kind of grassy food needed to nourish the horse's body.

Early Biological Theory

For two thousand years, however, evolution was considered an impossibility. The theory of forms (also called his *theory of ideas*) proposed by Plato (c. 428-348 B.C.E.) gave rise to the notion that each species had an unchanging "essence" incapable of evolutionary change. As a result, most scientists from Aristotle (384-322 B.C.E.) to Carolus Linnaeus (1707-1778) insisted upon the *immutability of species*.

Many of these scientists tried to arrange all species in a single linear sequence known as the *scale of being* (also called the great chain of being or *scala naturae*), a concept supported well into the nineteenth century by many philosophers and theologians as well. The sequence in this scale of being was usually interpreted as a static "ladder of perfection" in God's creation, arranged from higher to lower forms. The scale had to be continuous, for any gap would detract from the perfection of God's creation. Much exploration was devoted to searching for *missing links* in the chain, but it was generally agreed that the entire system was static and incapable of evolutionary change. Pierre-Louis Moreau de Maupertuis and Jean-Baptiste Lamarck (1744-1829) were among the scientists who tried to reinterpret the scale of being as an evolutionary sequence, but this single-sequence idea was later replaced by the concept of branching evolution proposed by Charles Darwin (1809-1882). Georges Cuvier (1769-1832) finally showed that the major groups of animals had such strikingly different anatomical structures that no possible scale of being could connect them all; the idea of a scale of being lost most of its scientific support as a result.

The theory that new biological species could arise from changes in existing species was not readily accepted at first. Linnaeus and other classical biologists emphasized the immutability of species under the Platonic-Aristotelian concept of *essentialism*. Those who believed in the concept of evolution realized that no such idea could gain acceptance until a suitable mechanism of evolution could be found. Many possible mechanisms were therefore proposed. Étienne Geoffroy Saint-Hilaire (1805-1861) proposed that the environment directly induced physiological changes, which he thought would be inherited, a theory now known as *Geoffroyism*. Lamarck proposed that there was an overall linear ascent of the scale of being but that organisms could also adapt to local environments by voluntary exercise, which would strengthen the organs used; unused organs would deteriorate. He thought that the characteristics acquired by use and disuse would be passed on to later generations, but the inheritance of acquired characteristics was later disproved. Central to both these explanations was the concept of adaptation, or the possession by organisms of characteristics that suit them to their environments or to their ways of life. In eighteenth century England, the Reverend William Paley (1743-1805) and his numerous scientific supporters believed that such adaptations could be explained only by the action of an omnipotent, benevolent God. In criticizing Lamarck, the supporters of Paley pointed out that birds migrated toward warmer climates before winter set in and that the heart of the human fetus had features that anticipated the changes of function that take place at birth. No amount of use and disuse could explain these cases of anticipation, they claimed; only an omniscient God who could foretell future events could have designed things with their future utility in mind.

Darwin's Theory

The nineteenth century witnessed a number of books asserting that living species had evolved from earlier ones. Before 1859, these works were often more geological than biological in content. Most successful among them was the anonymously published *Vestiges of the Natural History of Creation* (1844), written by Robert Chambers (1802-1871). Books of this genre sold well but contained many flaws. They proposed no mechanism to account for evolutionary change. They supported the outmoded concept of a scale of being, often as a single sequence of evolutionary "progress." In geology, they supported the outmoded theory of *catastrophism*, an idea that the history of the earth had been characterized by great cataclysmic upheavals. From 1830 on, however, that theory was being replaced by the modern theory of *uniformitarianism*, championed by Charles Lyell (1797-1875). Charles Darwin read these books and knew their faults, especially their lack of a mechanism that was compatible with Lyell's geology. In his own work, Darwin carefully tried to avoid the shortcomings of these books.

Darwin brought about the greatest revolution in biological thought by proposing both a theory of branching evolution and a mechanism of natural selection to explain how it occurred. Much of Darwin's evidence was gathered during his voyage around the world aboard HMS *Beagle* between 1831 and 1836. Darwin's stop in the Galápagos Islands and his study of tortoises and finchlike birds on these islands is usually credited with convincing him that evolution was a branching process and that *adaptation* to local environments was an essential part of the evolutionary process. Adaptation, he later concluded, came about through *natural selection*, a process that killed the maladapted variations and allowed only the well-adapted ones to survive and pass on their hereditary traits. After returning to England from his voyage, Darwin raised pigeons, consulted with various animal breeders about changes in domestic breeds, and investigated other phenomena that later enabled him to demonstrate natural selection and its power to produce evolutionary change.

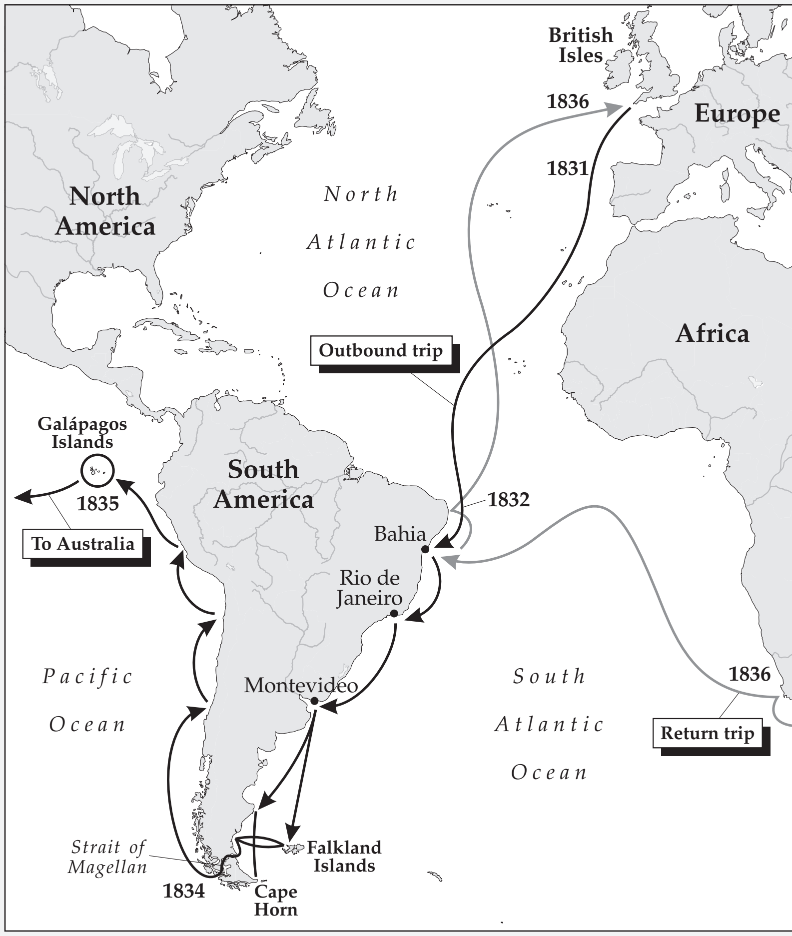
Darwin delayed the publication of his book for seventeen years after he wrote his first manuscript version. He might have waited even longer, except that his hand was forced. From the East Indies, another British scientist, Alfred Russel Wallace (1823-1913), had written a description of an identical the-

Charles Darwin and the *Beagle*

In 1831, a twenty-two-year-old Charles Darwin, who had been studying for the ministry at Cambridge, by luck was offered a position as naturalist on the ship HMS *Beagle*, which was about to embark on a round-the-world voyage of exploration. His domineering father was against the trip at first, but he finally relented. The expedition would turn the young man into a scientist. Over the next five years, Darwin recorded hundreds of details about plants and animals and began to notice some consistent patterns. His work led him to develop new ideas about what causes variations in different plant and animal species:

> [The] preservation of favourable individual differences and variations, and the destruction of those which are injurious, I have called Natural Selection, or the Survival of the Fittest. . . . slight modifications, which in any way favoured the individuals of any species, by better adapting them to their altered conditions, would tend to be preserved. . . .
> —*On the Origin of Species by Means of Natural Selection*, 1859

Until Darwin and such colleagues as Alfred Russel Wallace, the "fixity" or unchangingness of species had been accepted as fact, and the appearance over time of new species remained a mystery. Darwin's lucky trip laid the foundation for today's understanding of life and its diversity.



ory and submitted it to Darwin for his comments. Darwin showed Wallace's letter to Lyell, who urged that both Darwin's and Wallace's contributions be published, along with documented evidence showing that both had arrived at the same ideas independently. Darwin's great book, *On the Origin of Species by Means of Natural Selection*, was published in 1859, and it quickly won most of the scientific community to a support of the concept of branching evolution. In his later years, Darwin also published *The Descent of Man and Selection in Relation to Sex* (1871), in which he outlined his theory of *sexual selection*. According to this theory, the agent that determines the composition of the next generation may often be the opposite sex. An organism may be well adapted to live, but unless it can mate and leave offspring, it will not contribute to the next or to future generations.

After Darwin

In the early 1900's, the rise of Mendelian genetics (named for botanist Gregor Mendel, 1822-1884) initially resulted in challenges to Darwinism. Hugo de Vries (1848-1935) proposed that evolution occurred by *random mutations*, which were not necessarily adaptive. This idea was subsequently rejected, and

Mendelian genetics was reconciled with Darwinism during the period from 1930 to 1942. According to this modern synthetic theory of evolution, mutations initially occur at random, but natural selection eliminates most of them and alters the proportions among those that survive. Over many generations, the accumulation of heritable traits produces the kind of adaptive change that Darwin and others had described. The process of branching evolution through *speciation* is also an important part of the modern synthesis.

The branching of the evolutionary tree has resulted in the proliferation of species from the common ancestor of each group, a process called *adaptive radiation*. Ultimately, all species are believed to have descended from a single common ancestor. Because of the branching nature of the evolutionary process, no one evolutionary sequence can be singled out as representing any overall trend; rather, there have been different trends in different groups. Evolution is also an opportunistic process, in the sense that it follows the path of least resistance in each case. Instead of moving in straight lines toward a predetermined goal, evolving lineages often trace meandering or circuitous paths in which each change represents a momentary increase in adaptation. Species that cannot adapt to changing conditions die out and become extinct.

Evolutionary biology is itself the context into which all the other biological sciences fit. Other biologists, including physiologists and molecular biologists, study how certain processes work, but it is evolutionists who study the reasons why these processes came to work in one way and not another. Organisms and their cells are built one way and not another because their structures have evolved in a particular direction and can only be explained as the result of an evolutionary process. Not only does each biological system need to function properly, but it also must have been able to achieve its present method of functioning as the result of a long, historical, evolutionary process in which a previous method of functioning changed into the present one. If there were two or more ways of accomplishing the same result, a particular species used one of them because its ancestors were more easily capable of evolving this one method than another.

Robert Brandon is one of the most important and influential of contemporary philosophers of biology. This collection of his recent essays covers all the traditional topics in the philosophy of evolutionary biology and could serve as an introduction to the field.

Grant, Verne. *The Evolutionary Process: A Critical Study of Evolutionary Theory*. 2d ed. New York: Columbia University Press, 1991. A comprehensive study of the field of evolution, giving full time to critiques of the theory. Concentrates on general principals rather than specific examples.

Minkoff, Eli C. *Evolutionary Biology*. Reading, Mass.: Addison-Wesley, 1983. A comprehensive general textbook on evolutionary biology, including its historical aspects. The history of evolutionary theories and the mechanisms of the evolutionary process are described in detail. Many examples are given, and the book is profusely illustrated; it assumes no prior knowledge. Contains an excellent bibliography, arranged by topic.

Zimmer, Carl. *Evolution: The Triumph of an Idea*. New York: HarperCollins, 2001. A companion to the PBS series of the same title, this book presents both the history of the idea of evolution and the science that supports it. A thoroughly up-to-date presentation of the field at the dawn of the twenty-first century. Abundantly illustrated and written for a general audience.

EVOLUTION OF CELLS

Categories: Cellular biology; evolution; paleobotany

The earliest cells evolved sometime early in the Precambrian era, which includes the first four billion years of Earth's history. Attempts to understand life's origins are difficult, as there are very few clues left in the fossil record from those early times. The hypotheses and models of the origin of life that have been developed are based on contemporary understanding of how life works at the molecular and cellular levels and on assumptions about the conditions on Earth three billion to four billion years ago.

One assumption made about the origins of life involves the composition of the atmosphere shortly after the earth was formed. According to this assumption, the earth's atmosphere at this time contained very little free oxygen. It was an atmosphere perhaps made primarily of methane, ammonia, carbon dioxide, nitrogen, carbon monoxide, and water vapor. The first organisms are believed to have been anaerobic and did not require oxygen for *respiration*. This early atmosphere lacked a protective shield of ozone, which is derived from oxygen and which absorbs ultraviolet radiation from the sun. Intense ultraviolet radiation is lethal, and early forms of life may have evolved in water deep enough to avoid it. In some later stages of chemical evolution, however, ultraviolet radiation may actually have driven molecular interactions, producing more complex structures that were forerunners to living organisms.

Building Blocks of Life

The basic elements found in organic compounds are carbon, oxygen, hydrogen, nitrogen, phosphorus, and sulfur. These elements are also the main components of living cells and are the most plentiful elements in the solar system. The basic materials for the development of life were present on the early earth. Scientists have discovered that some of these building blocks, especially molecules of hydrogen sulfide, hydrogen cyanide, methanol, acetic acid, methyl formate, and a simple sugar called glycol aldehyde, exist in space and may have been brought to Earth by comets passing close by the plant. These compounds were, in fact, given off as Comet Hale-Bopp passed through the earth's solar system during 1995-1997. Perhaps comets "seeded" the earth with inorganic and organic compounds that triggered the chemical evolution that led to life itself.

Proteins and Amino Acids

One of the components of life is *proteins*. Proteins are made of even more basic organic molecules called *amino acids*. Proteins act as building materials for an organism's body and function in chemical reactions within an organism.

Amino acids may have been formed naturally in early earth history. In a process called photochemical dissociation, ultraviolet radiation is capable of separating the atoms in compounds such as water, ammonia, and hydrocarbons such as methane, allowing these atoms to recombine. Some of those atoms would have formed amino acids. A second form of energy that could trigger recombination of atoms is electrical discharge, occurring naturally as lightning. Lightning and ultraviolet radiation, acting separately or together, could have triggered the formation of amino acids in the atmosphere or in the oceans.

Other Building Blocks

Another of life's basic components is *nucleic acids*, such as deoxyribonucleic acid (DNA) and ribonucleic acid (RNA), which transmit genetic information from generation to generation. The building blocks of nucleic acids are nucleotides, which also participate, as nucleotide phosphates like adenosine triphosphate (ATP), in biochemical energy transactions.

Even with the first three components present on the early earth, living organisms could not develop unless those components were in close proximity to one another so they could interact. Some sort of structure was needed to contain all the components. Cell membranes would have provided just such a structure and so must be considered an essential fourth component of the first living organisms.

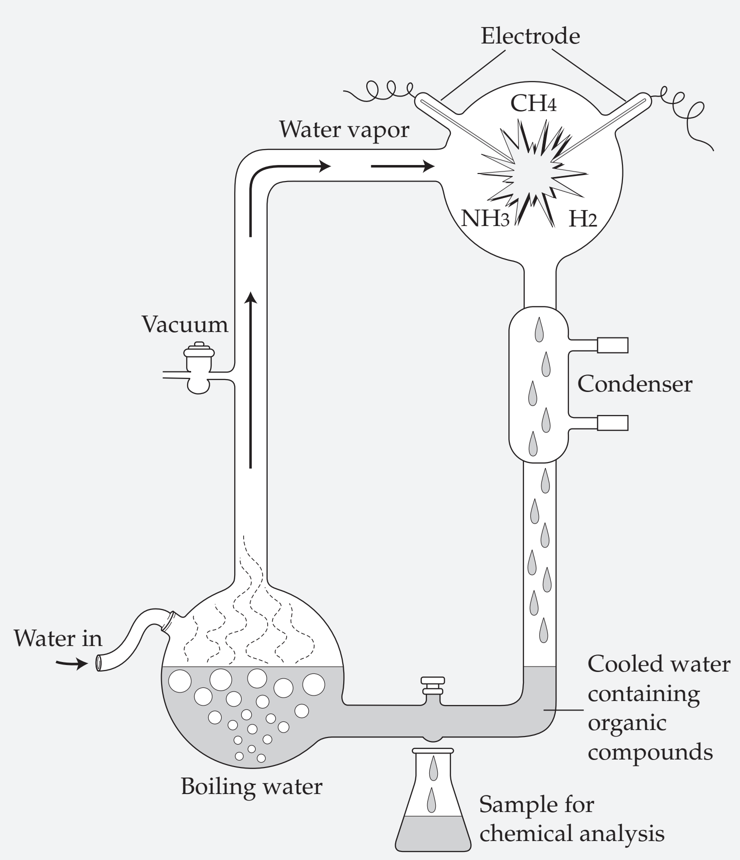
Wöhler's Experiment

Before 1828, many scientists believed that all organic molecules were products of living organisms. However, in 1828 the German chemist Friedrich Wöhler produced crystals of urea quite by accident after heating an inorganic compound called ammonium cyanate. Urea, a component of urine, is an organic compound. Over the next several decades, other chemists were able to duplicate Wöhler's experiment and, by using other simple inorganic compounds, succeeded in producing several other simple organic substances. This led many scientists to believe that life on Earth could have developed from inorganic materials. Between 1828 and the 1960's, however, scientists were able to produce only simple organic molecules from inorganic substances. It was only during the 1960's that scientists could create and detect complex protein molecules.

Miller-Urey Experiments

It was not until 1953 that scientists produced amino acids and similar molecules using simulated conditions like those assumed to have been present in the early earth's atmosphere. Stanley Miller, a graduate student working for Dr. Harold Urey, cre-

The Miller-Urey Experiment



It has been shown many times that organic compounds, the beginnings of life, including amino acids, are produced readily within water in sealed flasks containing reducing gases such as carbon dioxide energized by electrical discharges, ultraviolet light, or even shock waves. The most famous of these experiments, depicted here, was conducted by Stanley L. Miller and Harold C. Urey in 1953. Since then, however, scientists have come to believe that hydrothermal vents, openings along mid-ocean ridges where heated water is vigorously expelled into the sea, act as flow reactors capable of stripping oxygen from carbon dioxide to produce organic matter.

ated an atmosphere of methane, ammonia, hydrogen, and water vapor in a bottle, thinking that this mixture would have been similar to the atmosphere of the very early earth. As the mixture was circulated through the apparatus, sparks of electricity, to simulate lightning, were discharged into the mixture. At the end of eight days, the condensed water in the apparatus had become cloudy and deep red. Analysis of the material showed that it contained a number of amino acids along with a few other, more complicated organic compounds.

Other scientists carried out similar experiments, with much the same results, leading many scientists to believe that organic compounds could be produced from a mixture of gases, including a mix of carbon dioxide, nitrogen, and water vapor, also found in Earth's early atmosphere. What was necessary for the success of these experiments was the lack of free oxygen. The experimenters felt it almost inevitable that amino acids would have developed in the earth's pre-life environment. Amino acids are relatively stable and probably became abundant in the early oceans, over time, joining together into more complex molecules.

Amino Acids to Proteinoids

In order to form proteins, amino acid molecules must lose some water from their molecular structures, which happens when amino acids are heated to temperatures of 140 degrees Celsius. Volcanic activity would have been capable of providing such temperatures. A biochemist named S. W. Fox and his coworkers were able to produce proteinlike chains from a mixture of eighteen common amino acids. Fox termed these structures *proteinoids* and thought that billions of years ago proteinoids were the transitional structures leading to true proteins. Fox actually found proteinoids similar to those he created in the laboratory in lava and cinders spewed out by Hawaiian volcanoes. Amino acids formed in the vapors emitted by the volcanoes and were combined into proteinoids by the heat of escaping gases.

Proteinoids to Microspheres

When solutions of proteinoids in hot water are cooled, they form tiny spheres with many characteristics of living cells. These *microspheres* have a filmlike outer wall, somewhat like a cell membrane; are capable of osmotic swelling and shrinking; exhibit budding, as do yeast cells; and can be observed to divide into "daughter" microspheres. Sometimes these microspheres join together to form lines, or filaments, as some bacteria do, and it is possible to observe movement of internal particles within microspheres, similar to cytoplasmic streaming in living cells.

Nucleic Acids in the Laboratory

Complete long-chain nucleic acids have not yet been experimentally produced under pre-life conditions. However, short stretches of nucleic acid components were produced in 1976 by Har Gobind Khorana and his associates at the Massachusetts Institute of Technology. In yet another experiment, parts of a nucleic acid called peptide nucleic acid, or PNA, were produced by discharging electricity through a blend of methane, ammonia, nitrogen, and water. PNA is more stable than RNA and may have existed during the earth's very early days. However, the big questions remain: How did replication of these nucleic acids begin? How did the first organisms manage to pass along their genetic information to the next generation?

Life Begins in the Sea

The earliest organisms apparently originated in the sea, which contains many of the organic compounds, minerals, and other nutrients needed by living organisms. This reflects the viewpoint of many scientists, including Charles Darwin, who said in 1871 that life started in a "warm little pond," and Aleksandr I. Oparin, who proposed in the 1930's that many chemical substances would have washed out of the atmosphere and been carried into the oceans by rain, creating a "primordial soup" of nutrients for the first organisms. These organic molecules, kept in constant motion by the ocean currents, may have bumped together, recombining into larger molecules and increasing in complexity. Exactly how, or exactly when, the transition from not-quite-living to living took place is not known, but scientists assume that it could not happen under present-day conditions. Oxygen and microbial predators would destroy similar structures today.

Heterotrophs

The first living organisms were microscopic in size and unicellular. These earliest forms of life were not able to make their own food but instead assimilated small pieces of organic molecules present in the surrounding waters. They no doubt ate one another as well. Organisms with this type of nutritional mechanism are called *heterotrophs*. The food of these ancient organisms was digested externally by excreted enzymes before being ingested and metabolized by fermentation, a process that does not require free oxygen.

Autotrophs and Photoautotrophs

When nearby food resources became exhausted, the resulting food shortages might have caused selective pressures for evolutionary change. Some organisms evolved the ability to synthesize their food from simple inorganic substances. These became organisms called *autotrophs*. The autotrophs began to evolve in many different directions, using different substances, such as carbon dioxide, ammonia, and hydrogen sulfide, as food.

Another group evolved into the *photoautotrophs*, capable of carrying out *photosynthesis*, which uses solar energy to incorporate carbon dioxide into organic molecules and releases oxygen as a byproduct. Carbon combined with other elements to promote cellular growth, and the oxygen escaped into the atmosphere, which prepared the environment for the next important step in the evolution of primitive organisms.

As the photoautotrophs multiplied, photosynthesis began to gradually change Earth's original oxygen-poor atmosphere to a more oxygen-rich one. A rapid buildup of oxygen in the atmosphere was delayed, as iron in rocks exposed at the earth's surface was oxidized before oxygen could accumulate in the atmosphere. This allowed many microorganisms to evolve oxygen-mediating enzymes that permitted them to cope with the new atmosphere.

Once atmospheric oxygen concentrations reached about 10 percent, solar radiation converted part of the oxygen to ozone, forming a shield against ultraviolet radiation. Life, still primitive and vulnerable, was now protected and could expand into environments that formerly had not been able to harbor life, setting the stage for the appearance of aerobic organisms.

Aerobic Metabolism

Aerobic organisms use oxygen to convert their food into energy. Aerobic metabolism provides far more energy in relation to food consumed than does the fermentation carried out by anaerobic organisms. Aerobic metabolism provided a surplus of energy, which was an important factor in the evolution of more complex forms of life. With more energy available, organisms could move about more, colonize new niches, and engage in sexual reproduction, allowing new and innovative genetic recombinations to emerge, and may have increased the rate of evolution, which led to the evolution of complex multicellular organisms called metazoans.

Prokaryotes and Eukaryotes

The first organisms were unicellular organisms called *prokaryotes*, which today are classified in two of the three domains of life as either *Archaea* or *Bacteria*, the latter including the cyanobacteria, which are photosynthetic. Both of these domains comprise unicellular life-forms consisting of prokaryotes. Prokaryotic cells lack internal organelles and a membrane-bound nucleus. Their genetic material resides in the cytoplasm of the cell. Modern prokaryotes do have cell walls and most are able to move about. Prokaryotes are asexual, reproducing by binary fission, which limits the possibilities for variation.

Evolution proceeded from the prokaryotes to organisms with a definite nuclear wall, well-defined chromosomes, and the capacity to reproduce sexually. These more advanced life-forms are termed *eukaryotes*. Eukaryotic cells contain organelles such as mitochondria, which metabolize carbohydrates and fatty acids to carbon dioxide and water, releasing energy-rich phosphate compounds in the process. Some eukaryotes have organelles called chloroplasts, the structures in which sunlight is converted into energy in the process of photosynthesis.

The forms of life made of eukaryotic cells are now classified in the third great domain of life, *Eukarya*, which comprises most of the life-forms familiar as plants and animals—from fungi and plants to human beings—classified in several kingdoms, phyla, classes, genera, and millions of species. Biologists believe that the organelles in eukaryotic cells were once independent microorganisms that entered other cells and then established symbiotic relationships with the primary cell. This process is called the endosymbiont theory.

Ancestral Algae

The various divisions of algae make up an important group of photosynthetic eukaryotes. One group of algae, the *Chlorophyta*, or green algae, are the probable ancestors of terrestrial plants. Common characteristics of green algae and terrestrial plants include the chlorophyll pigments *a* and *b* in the chloroplasts of both green algae and land plants, a number of carotenoid pigment derivatives, starch as the carbohydrate food reserve, and cell walls made up of cellulose.

From Sea to Land

If, as scientists believe, life originated in the sea, how did it get onto the land? Did the ongoing push to find new sources of food drive organisms from the depths of the oceans to coastal areas, where environmental conditions were harsher? To cope with the intense wave action along shorelines, multicellular organisms with diversified parts, some designed to hold onto rocks, evolved. To prevent desiccation in coastal environments and to provide support against the pounding waves, these organisms also evolved rigid cell walls, which allowed them to increase in size. As plants increased in size, they had adapt to do two things: First, they needed to be able to move water and mineral nutrients from the substrate to other parts of the plant not tied directly to the ground. A second problem involved how to move the products of photosynthesis from the site of manufacture to those parts of the plant where photosynthesis could not take place.

The solution to these problems became more critical as plants began to colonize habitats farther from permanent supplies of water. Roots evolved to anchor plants in the ground and to supply the rest of the plant with water and mineral nutrients from the ground. Stems evolved to provide support for the leaves, the main organs of photosynthesis; in some cases, the stems themselves evolved the capability of photosynthesis. All of the aboveground portions of plants developed a waxy cuticle that slows down water loss and prevents desiccation. Internally, plants evolved specialized tissues, called the vascular tissues. One type of vascular tissue, the *xylem*, conducts water and mineral nutrients from the soil through the roots and stems to the leaves. The other type of vascular tissue, the *phloem*, transports the sugars manufactured in the leaves during photosynthesis to other parts of the plant body.

Many plants also evolved chemical attractants and defenses in the form of *secondary metabolites*: metabolic products, such as alkaloids, glycosides, or saponins, to deter plant-eating animals. With the appearance of flowering plants (angiosperms), plants began to evolve odors, colors, flowers, and fruits that attracted pollinators and herbivores, ensuring seed dispersal and the survival and propagation of flowering species. It was these specializations that allowed plants to move from the sea and colonize the land between 500 million and 450 million years ago.

EVOLUTION OF PLANTS

Categories: Evolution; paleobotany; *Plantae*

As a result of prehistoric events such as the Permian-Triassic extinction event and the Cretaceous-Tertiary mass extinction event, many plant families and some ancestors of extant plant were extinct before the beginning of recorded history.

The general trend of earth's plant diversification involves four major plant groups that rose to dominance from about the Middle Silurian period to present time. The first major group providing land vegetation comprised the seedless vascular plants, represented by the phyla *Rhyniophyta*, *Zosterophyllophyta*, and *Trimerophytophyta*. The second major group appearing in the late Devonian period was made up of the ferns (*Pterophyta*). The third group, the seed plants (sometimes called the Coal Age plants), appeared at least 380 million years ago (mya). This third group includes the gymnosperms (*Gymnospermophyta*), which dominated land flora for most of the Mesozoic era until 100 mya. The last group, the flowering angiosperms (*Anthophyta*), appeared in the fossil record 130 mya. The fossil record also shows that this group of plants was abundant in most parts of the world within 30 million to 40 million years. Thus, the angiosperms have dominated land vegetation for close to 100 million years.

The Paleozoic Era

The Proterozoic and Archean eons have restricted fossil records and predate the appearance of land plants. Seedless, vascular land plants appeared in the middle of the Silurian period (437-407 mya) and are represented by the rhyniophytes or rhyniophytoids and possibly the *Lycophyta* (lycophytes or club mosses). From the primitive rhyniophytes and lycophytes, land vegetation rapidly diversified during the Devonian period (407-360 mya). Pre-fern ancestors and maybe true ferns (*Pterophyta*) were developed by the mid-Devonian. By the Late Devonian the horsetails (*Sphenophyta*) and gymnosperms (*Gymnospermophyta*) were present. By the end of the period, all major divisions of vascular plants had appeared except the angiosperms.

Development of vascular plant structures during the Devonian allowed for greater geographical diversity of plants. One such structure was flattened, planated leaves, which increased photosynthetic efficiency. Another was the development of secondary wood, allowing plants to increase significantly in structure and size, thus resulting in trees and probably forests. A gradual process was the reproductive development of the seed; the earliest structures are found in Upper Devonian deposits.

Ancestors of the conifers and cycads appeared in the Carboniferous period (360-287 mya), but their documentation is poor in the fossil record. During the early Carboniferous in the high and middle latitudes, vegetation shows a dominance of club mosses and progymnosperms (*Progymnospermophyta*). In the lower latitudes of North America and Europe, a greater diversity of club mosses and progymnosperms are found, along with a greater diversity of vegetation. Seed ferns (lagenostomaleans, calamopityaleans) are present, along with true ferns and horsetails (*Archaeocalamites*).

Late Carboniferous vegetation in the high latitudes was greatly affected by the start of the Permo-Carboniferous Ice Age. In the northern middle latitudes, the fossil record reveals a dominance of horsetails and primitive seed ferns (pteridosperms) but few other plants.

In northern low latitudes, landmasses of North America, Europe, and China were covered by shallow seas or swamps and, because they were close to the equator, experienced tropical to subtropical climatic conditions. The first tropical rain forests appeared there, known as the Coal Measure Forests or the Age of Coal. Vast amounts of peat were laid down as a result of favorable conditions of year-round growth and the giant club mosses' adaptation to the wetland tropical environments. In drier areas surrounding the lowlands, forests of horsetails (calamites, sphenophylls), seed ferns (medullosans, callistophytes, lagenostomaleans), cordaites, and diverse ferns (including marattialean tree ferns) existed in great abundance.

The Permian period (287-250 mya) marks a major transition of the conifers, cycads, glossopterids, gigantopterids, and the peltasperms from a poor fossil record in the Carboniferous to significantly abundant land vegetation. The two most prevalent plant assemblages of the Permian were the horsetails, peltasperms, cycadophytes, and conifers. The second most prevalent were the gigantopterids, peltasperms, and conifers. These two plant assemblages are considered the typical paleo-equatorial lowland vegetation of the Permian. Other plants, such as the tree ferns and giant club mosses, were present in the Permian but not abundant. As a result of the Permian-Triassic extinction event, tropical swamp forests disappeared, with the extinction of the club mosses; the cordaites and glossopterids disappeared from higher latitudes; and 96 percent of all plant and animal species became extinct.

The Mesozoic Era

At the beginning of the Triassic period (248-208 mya), a meager fossil record reveals diminished land vegetation (that is, no coal formed). By the middle to late Triassic, the modern family of ferns, conifers, and a now-extinct group of plants, the bennettites (cycadeoids), inhabited most land surfaces. After the mass extinction, the bennettites moved into vacant lowland niches. They may be significant because of the similarity of their reproductive organs to the reproductive organs of the angiosperms.

Image Not Available

Late Triassic flora in the equatorial latitudes are represented by a wide range of ferns, horsetails, pteriosperms, cycads, bennettites, leptostrobaleans, ginkgos, and conifers. The plant assemblages in the middle latitudes are similar but not as species-rich. This lack of plant variation in low and middle latitudes reflects a global frost-free climate.

In the Jurassic period (208-144 mya), land vegetation similar to modern vegetation began to appear, and the ferns of this age can be assigned to modern families: *Dipteridaceae*, *Matoniaceae*, *Gleicheniaceae*, and *Cyatheaceae*. Conifers of this age can also be assigned to modern families: *Podocarpaceae*, *Araucariaceae* (Norfolk pines), *Pinaceae* (pines), and *Taxaceae* (yews). These conifers created substantial coal deposits in the Mesozoic.

During the Early to Middle Jurassic, diverse vegetation grew in the equatorial latitudes of western North America, Europe, Central Asia, and the Far East and comprised the horsetails, pteridosperms, cycads, bennettites, leptostrobaleans, ginkgos, ferns, and conifers. Warm, moist conditions also existed in the northern middle latitudes (Siberia and northwest Canada), supporting Ginkgoalean forests and leptostrobaleans. Desert conditions

Evolution of Plants

Origin	*Geologic Period*	*Plant Life*
420 mya	Silurian	Seedless vascular plants (earliest land plants)
400 mya	Devonian	Ferns
380 mya	Devonian	Progymnosperms
365 mya	Carboniferous	Seed plants: gymnosperms, conifers
245 mya	Permian	Cycads (earliest fossils, but may have preceded gymnosperms)
130 mya	Cretaceous	Angiosperms (flowering plants)

Notes: Dates are approximate and are often debated, but the paleobotanists generally agree on the sequence; mya = millions of years ago.

existed in central and eastern North America and North Africa, and the presence of bennettites, cycads, peltasperms and cheirolepidiacean conifers there are plant indicators of drier conditions. The southern latitudes had similar vegetation to the equatorial latitudes, but owing to drier conditions, cheirolepidiacean conifers were abundant, ginkgos scarce. This southern vegetation spread into very high latitudes, including Antarctica, because of the lack of polar ice.

In the Cretaceous period (144-66.4 mya), arid, subdesert conditions existed in South America, Central and North Africa, and central Asia. Thus, the land vegetation was dominated by cheirolepidiacean conifers and matoniacean ferns. The northern middle latitudes of Europe and North America had a more diverse vegetation comprising bennettites, cycads, ferns, peltasperms, and cheirolepidiacean conifers, with the southern middle latitudes dominated by bennettites and cheirolepidiaceans.

A major change in land vegetation took place in the late Cretaceous with the appearance and proliferation of flowering seed plants, the angiosperms. The presence of the angiosperms marked the end of the typical gymnosperm-dominated Mesozoic flora and a definite decline in the leptostrobaleans, bennettites, ginkgos, and cycads.

During the late Cretaceous in South America, central Africa, and India, arid conditions prevailed, resulting in tropical vegetation dominated by palms. The southern middle latitudes were also affected by desert conditions, and the plants that fringed these desert areas were horsetails, ferns, conifers (araucarias, podocarps), and angiosperms, specifically *Nothofagus* (southern beech). The high-latitude areas were devoid of polar ice; owing to the warmer conditions, angiosperms were able to thrive. The most diverse flora was found in North America, with the presence of evergreens, angiosperms, and conifers, especially the redwood, *Sequoia*.

The Cretaceous-Tertiary (K/T) mass extinction event occurred at about 66.4 mya. This event has been hypothesized to be a meteoritic impact; whatever the cause, at this time an event took place that suddenly induced global climatic change and initiated the extinction of many species, notably the dinosaurs. The K/T had a greater effect on plants with many families than it did on plants with very few families. Those that did become extinct, such as the bennettites and caytonias, had been in decline. The greatest shock to land vegetation occurred in the middle latitudes of North America. The pollen and spore record just above the K/T boundary in the fossil record shows a dominance of ferns and evergreens. Subsequent plant colonization in North America shows a dominance of deciduous plants.

The Cenozoic Era

Increased rainfall at the beginning of the Paleogene-Neogene period (66.4-1.8 mya) supported the widespread development of rain forests in southerly areas. Rain forests are documented by larger leaf size and drip tips at leaf edge, typical characteristics of modern rain-forest floras.

Notable in this period was the polar Arcto-Tertiary forest flora found in northwest Canada at paleolatitudes of 75-80 degrees, north. Mild, moist summers alternated with continuous winter darkness, with temperatures ranging from 0 to 25 degrees Celsius. These climatic conditions supported deciduous vegetation that included *Platanaceae* (sycamore), *Judlandaceae* (walnut), *Betulaceae* (birch), *Menispermaceae*, *Cercidophyllaceae*, *Ulmaceae* (elm), *Fagaceae* (beech), *Magnoliaceae*; and gymnosperms such as *Taxodiaceae* (redwood), *Cypressaceae* (cypress), *Pinaceae* (pine), and *Ginkgoaceae* (gingko). This flora spread across North America to Europe via a land bridge between the continents.

About eleven million years ago, during the Miocene epoch, a marked change in vegetation occurred, with the appearance of grasses and their subsequent spread to grassy plains and prairies. The appearance of this widespread flora supported the development and evolution of herbivorous mammals.

The Quaternary period (1.8 mya to present) began with continental glaciation in northwest Europe, Siberia, and North America. This glaciation affected land vegetation, with plants migrating north and south in response to glacial and interglacial fluctuations. Pollen grains and spores document the presence of *Aceraceae* (maple), hazel, and *Fraxinus* (ash) during interglacial periods.

Final migrations of plant species at the close of the last ice age (about eleven thousand years ago), formed the modern geographical distribution of land plants. Some areas, such as mountain slopes or islands, have unusual distribution of plant species as a result of their isolation from the global plant migrations.

EXERGONIC AND ENDERGONIC REACTIONS

Category: Cellular biology

Exergonic reactions are spontaneous chemical reactions in which the products are at a lower energy level than the reactants; these reactions release energy. Endergonic reactions are nonspontaneous chemical reactions in which the products are at a higher energy level than the reactants; these reactions consume energy.

The primary source of energy for life on the earth is the sun, which is the energy source for photosynthesis: the biological process that transforms radiant energy into chemical energy. Chemical energy is stored in biological molecules, which can then be used as the fuel to provide an organism's energy needs. Such biological molecules include sugars (or carbohydrates), proteins, and lipids (or fats). In the reactions of metabolism, many types of molecules are synthesized (*anabolism*), and many are broken down (*catabolism*). Changes in energy content occur in all these reactions. *Bioenergetics* is the science that studies the description of the basic mechanisms that govern the transformation and use of energy by organisms. A basic tenet of bioenergetics is that no chemical reaction can be 100 percent energy-efficient. In other words, in all reactions there is some transfer of energy, but some of it is always lost in the form of heat.

The energy (often measured in *calories*) contained in the molecular structure of a compound is called *Gibbs free energy* (after Josiah Willard Gibbs, 1839-1903, who founded the discipline of physical science) and is the energy available to perform work. The difference between the free energy of the products and the *free energy* of the reactants in a chemical reaction is called the *change in free energy* and is fundamental in determining if a reaction can occur spontaneously. If the change in free energy is negative, energy is released, and the free energy content is less in the products than in the reactants. Such reactions are considered exergonic. On the other hand, if the change in free energy is positive, the reaction is considered endergonic and is nonspontaneous (that is, endergonic reactions require a source of energy to enable them to occur).

Energy Coupling

Many cellular reactions are endergonic and cannot occur spontaneously. Nevertheless, cells can facilitate endergonic reactions using the energy released from other exergonic reactions, a process called *energy coupling*. As an example, consider a common endergonic reaction in plants in which glucose and fructose are joined together to make sucrose. To enable this reaction to take place, it is coupled with a series of other exergonic reactions as follows:

glucose + adenosine triphosphate (ATP) →
glucose-p + ADP

fructose + ATP →
fructose-p + adenosine diphosphate (ADP)

glucose-p + fructose-p →
sucrose + 2 P_i (inorganic phosphate)

Therefore, although producing sucrose from glucose and fructose is an endergonic reaction, all three of the foregoing reactions are exergonic. This is representative of the way cells facilitate endergonic reactions.

Role of ATP

The principal molecule involved in providing the energy for endergonic cellular reactions to take place is adenosine triphosphate, or ATP, the same molecule used in the example above. ATP is typically produced by joining an inorganic phosphate to adenosine diphosphate (ADP), which is an endergonic reaction. This, too, represents a characteristic of chemical reactions: If a reaction is exergonic in one direction, it will be endergonic in the opposite direction. Thus, the breakdown of ATP is exergonic, while the production of ATP is endergonic. The energy for production of most of the ATP in plant cells comes from the *light reactions* of photosynthesis and the *electron transport system* in the mitochondria.

The enigma is why ATP, and not any other molecule, is used. Although no complete justification is available, there are several points that support its significance. First, there is the high stability of the ATP molecule at the physiological pH (around 7.4) toward hydrolysis and decomposition in the absence of an enzyme catalyst. This stability allows ATP to be stored in the cell until needed. Second, ATP is one of the molecules (a nucleotide) that is used in synthesis of DNA. Finally, the magnitude of the change in free energy involved in the ATP-ADP transformation is of an amount useful for driving many of the endergonic reactions in the cell. As a result, it can play the role of an intermediate quite easily.

EXTRANUCLEAR INHERITANCE

Categories: Cellular biology; genetics; reproduction and life cycles

Extranuclear inheritance is a non-Mendelian form of heredity that involves genetic information located in cytoplasmic organelles, such as mitochondria and chloroplasts, rather than on the chromosomes found in the cell nucleus.

Extranuclear genes, also known as *cytoplasmic genes*, are located in mitochondria and chloroplasts of a cell rather than in the cell's nucleus on the chromosomes. Both egg and sperm contribute equally to the inheritance of nuclear genes, but extranuclear genes are more likely to be transmitted through the maternal line because the egg is rich in the cytoplasmic organelles where these genes are located, whereas the sperm contributes only its nucleus to the fertilized egg. Therefore, extranuclear genes do not follow genetic pioneer Gregor Mendel's statistical laws of *segregation* and *recombination*. Cytoplasmic genes are of interest in understanding evolution, genetic diseases, and the relationship between genetics and embryology.

History

Since the discovery of Mendel's principles, research in genetics has been guided by the belief that the fundamental units of inheritance are located on chromosomes in the cell nucleus. T. H. Morgan, one of the founders of modern genetics, declared that the cytoplasm could be ignored genetically. However, some biologists resisted the concept of a "nuclear monopoly" over inheritance. Embryologists, in particular, argued that nuclear genes, identical in every cell, could not explain how cells *differentiated* from one another in the course of development. They argued that differences among cells in the developing embryo must have a basis in the *cytoplasm*, the part of the cell outside the nucleus. Trying to formulate a compromise, some biologists suggested that Mendelian genes play a role in determining individual characteristics, while cytoplasmic determinants are responsible for more fundamental aspects of plants and animals. The discovery of a wide variety of cytoplasmic entities seemed to support the concept that cytoplasmic factors played a role in development and heredity.

In the 1940's, Boris Ephrussi's work on "petite" mutants in yeast suggested that inheritance of this trait depended on some factor in the cytoplasm rather than the nucleus. Yeast cells with the *petite mutation* produce abnormally small colonies when grown on a solid medium, with glucose as the energy source. Petite mutants grow slowly because they lack important membrane-bound enzymes of the respiratory system.

Similar studies have been made of slow-growing mutants of the bread mold *Neurospora*. Inheritance of the trait known as "poky" shows a non-Mendelian pattern. Microinjection of purified mitochondria from poky strains into normal strains has been used to demonstrate the cytoplasmic inheritance of this trait.

Chloroplasts

As early as 1909, geneticists were reporting examples of non-Mendelian inheritance in higher plants, usually green and white variegated patterns on leaves and stems. These patterns seemed to be related to the behavior of the *chloroplasts*, photosynthetic organelles in green plants. Because of the relatively large size of chloroplasts, scientists have been able to study their behavior in dividing cells with the light microscope since the 1880's. Like mitochondria, chloroplasts contain their own deoxyribonucleic acid (DNA) and ribonucleic acid (RNA). Although *chloroplast DNA* (cpDNA) contains many of the genes needed for chloroplast function, chloroplasts do not seem to be totally autonomous; nuclear genes are required for some chloroplast functions. Another interesting case of extranuclear inheritance in plants is that of *cytoplasmic pollen sterility*. Many species of plants seem to produce strains with cytoplasmically inherited pollen sterility.

Advances in experimental methods made in the 1960's allowed scientists to demonstrate that organelles located in the cytoplasm contain DNA. This finding came as a great surprise to most biologists. In 1966 the first vertebrate *mitochondrial DNA* (mtDNA) was isolated and characterized. Like bacterial DNA, mtDNA generally consists of a single double helix of "naked," circular DNA. The mitochondrial genome is usually smaller than that of even the simplest bacterium. Most of the proteins in the mitochondrion are encoded by nuclear genes, but mtDNA contains genes for mitochondrial ribosomal RNAs, transfer RNAs, and some of the proteins of the electron transport system of the inner membrane of the mitochondrion.

Extranuclear DNA

The DNA found in chloroplasts and mitochondria is chemically distinct from the DNA in the nucleus. Moreover, the extranuclear genetic systems behave differently from those within the nucleus. Even more surprising is the finding that mitochondria have their own, slightly different version of the genetic code, which was previously thought to be common to all organisms, from viruses to humans. In general, because of its greatly smaller size, the DNA found in cytoplasmic organelles has a limited coding capacity. Thus, by identifying the functions under the control of mitochondrial or chloroplast genes, all other functions carried on by the organelle can be assigned to the nuclear genome. Coordinating the contributions of the organelle and the nuclear genomes is undoubtedly a complex process.

In addition to the genes found in mitochondria and chloroplasts, extranuclear factors are found in various kinds of *endosymbionts* (symbiotic organisms that live within the cells of other organisms) and *bacterial plasmids*. Some biologists think that all organelles may have evolved from ancient symbiotic relationships. Endosymbionts may be bacteria, algae, fungi, protists, or viruses. Unlike the mitochondria and chloroplasts, some endosymbionts seem to have retained independent genetic systems. The "killer" particles in paramecia, discovered by T. M. Sonneborn in the 1930's, provide a historically significant example. After many years of controversy, the killer particles were identified as bacterial symbionts. These cytoplasmic entities are not vital to the host cell, as the paramecia are capable of living and reproducing without them. Certain peculiar non-Mendelian conditions found in fruit flies also appear to be caused by endosymbionts.

Although bacteria lack nuclei, their circular DNA is usually referred to as bacterial chromosomes. Some bacteria also contain separate DNA circles smaller than the bacterial chromosome. In the 1950's Joshua Lederberg proposed the name "plasmid" for such extrachromosomal hereditary determinants. Some of the most interesting examples of these entities are the F (fertility) factor, the R (resistance transfer) factors, and the Col (colicin) factors. *Resistance transfer factors* can transmit resistance to antibiotics between bacteria of different species and genera. *Col factors*, toxic proteins produced by bacteria that kill other bacteria, were studied as toxins for many years before their genetic basis was discovered. Because of their simplicity, the bacterial systems are better understood and can serve as models for the kinds of studies that should be performed for extranuclear genes in higher organisms as techniques improve.

Evolutionary Advantages and Uses

The recognition of extranuclear genetic systems raises important questions about their possible evolutionary advantage. In contrast to the remarkable universality of the nuclear genetic system, extranuclear genetic systems are quite diverse in function and mechanisms of transmission. Although extranuclear genes control only a small fraction of the total hereditary material of the cell, in eukaryotic organisms the genes found in mitochondria and chloroplasts are clearly essential for maintaining life.

Although organelle DNAs clearly play an important part in cell organization, it has been difficult to pinpoint the essential roles of organelle DNA and protein-synthesizing systems. Many technical difficulties, and the traditionally low priority of this field, meant that adequate techniques for studying organelle genomes emerged slowly. Studies of cytoplasmic genetics will doubtless have significant applications in medical science and agriculture as well as an impact on understanding of the evolution of genetic control mechanisms.

For example, M. M. Rhoades's work on corn in the 1940's forced American geneticists to take note of research on cytoplasmic genes, while plant breeders began to use cytoplasmically inherited pollen sterility in the production of hybrid seed. Cytoplasmic pollen sterility is a useful trait to incorporate into commercial inbred lines because it ensures cross-pollination and thus simplifies seed production. Unfortunately, a toxin-producing fungus to which the major corn cytoplasmic gene for pollen sterility was susceptible destroyed more than 50 percent of the corn crop in certain areas of the United States in 1970. This disaster prompted a return to hand-detasseling.

FARMLAND

Categories: Agriculture; economic botany and plant uses; soil

Land used as farmland typically has good agricultural soil and is able to produce food and fiber in an efficient way.

Land suitable for agriculture is not evenly distributed throughout the world; it tends to be concentrated in limited areas. In order to be considered good farmland, land must be located at the proper elevation and slope. Because the soil supplies the mineral nutrients required for plant growth, it must also have the appropriate fertility, texture, and pH. Approximately 64 percent of the world's land has the proper topography, and about 46 percent has satisfactory soil fertility to grow crops.

Plants require large amounts of water for photosynthesis and access to soil nutrients; therefore, farmland must receive an adequate supply of moisture, either from rainfall or from irrigation water. About 46 percent of the world's land has adequate and reliable rainfall. Because plant growth is dramatically affected by temperature, farmland must be located in areas with growing seasons long enough to sustain the crop from planting to harvest.

Approximately 83 percent of the world's land has favorable temperatures. Plants also require sufficient sunlight and atmospheric carbon dioxide levels to support the photosynthetic process necessary for growth and development. Virtually all the world's land has adequate sunlight and sufficient carbon dioxide to support plant growth. Crop production requires the right combination of all these factors, and only about 7 percent of the world's land currently has the proper combination of these factors to make the production of crops feasible without additional technological advances.

Farmland in the United States

With its temperate climate, the United States devotes considerably more of its land area to agriculture than do many other parts of the world. About 45 percent of the land in the United States is used for various forms of agriculture; however, only about 20 percent of the land is actual cropland. Of the rest, approximately 4 percent is devoted to *woodlands*, and the other 21 percent is used for other purposes, such as pastures and *grasslands*. Of the farmland devoted to crop production, only 14 percent is used at any given time to produce harvestable crops. Approximately 21 percent of this harvested cropland is used to produce food grains for human consumption. Feed grains for livestock are grown on 31 percent, and the remaining 48 percent of harvested cropland is devoted to the production of other crops.

There are seven major agricultural regions in the United States. The dairy region is located in the North Atlantic states and extends westward past the Great Lakes and along the Pacific Coast. The wheat belt is centered in the central and northern Great Plains and in the Columbia Basin of the Northwest. The general and self-sufficing regions primarily made up of small, family-owned farms are found mostly in the eastern highlands region, which includes the Appalachian Mountains, a few hundred miles inland from the Atlantic Coast, and the Ozark-Ouachita mountains west of the Mississippi River. The corn and livestock belt is found throughout the Midwestern states. The range-livestock region of the western United States stretches in a band from 500 to 1,000 miles wide and extends from the Canadian border to Mexico. The western specialty-crops area is primarily composed of irrigated land in seventeen western states and produces the vast majority of the nation's vegetable crops. The cotton belt, located in the southern states (most notably Georgia, Alabama, and Mississippi), contains more farmers than any other region. While this area has been known historically for its cotton production, many other crops, including tobacco, peanuts, truck crops, and livestock are also produced in the South.

In addition to these major regions, smaller farming areas are located throughout the country. To-

PhotoDisc

Two properties of productive farmland are receipt of an adequate supply of moisture, either from rainfall or from irrigation, and location in an area with a growing season long enough to sustain crops from planting to harvest.

bacco is produced throughout Kentucky, Virginia, Tennessee, and North and South Carolina. Apples and other fruits are grown in a variety of places, including the Middle Atlantic seaboard, around the Great Lakes, and the Pacific Northwest. Potatoes are produced in Maine, Minnesota, Idaho, North Dakota, and California. Citrus is grown in southern Texas, Florida, and California. Sugarcane is cultivated in southern Louisiana and Florida.

Loss of Farmland

In the United States, both the quantity of land devoted to farming and the number of farmers have been decreasing since 1965. Likewise, there has been a decrease in the amount of good farmland worldwide. Most of this decrease is attributed to a combination of *urbanization* and poor agricultural methods that have led to loss of *topsoil* through water and wind *erosion*. Historically, large tracts of farmland have been located near metropolitan areas. In recent times, these urban centers have grown outward into large suburban areas, and this sprawl has consumed many acres of farmland. Erosion destroys thousands of acres of farmland every year, and *desertification*—the conversion of productive rangeland, rain-fed cropland, or irrigated cropland into desertlike land with a resulting drop in agricultural productivity—has reduced productivity on 2 billion acres over the past fifty years. In many cases, the desertified land is no longer useful as farmland. Steps must be taken to preserve this valuable resource, or it is quite possible that the world will suffer mass food shortages in the future.

FERNS

Categories: Paleobotany; *Plantae*; seedless vascular plants; taxonomic groups

Ferns are among the most recognizable members of the phylum Pterophyta*, which are primitive, nonflowering, vascular plants that primarily reproduce by spores and occur in many variations, complicating classification.*

Approximately twelve thousand extant species of fern are classified in the phylum *Pterophyta*. These seedless plants display a diversity of physical and reproductive characteristics that separate them taxonomically. They have leaves containing branching veins known as megaphylls. Fossils from the Devonian period, about 395 million years ago, include some structures resembling *Pterophyta*. These plants are believed to have been the source for gymnosperms. Most early fernlike plants that evolved in a variety of forms during the next period, the Carboniferous (approximately 345 million to 280 million years ago), which is often referred to as the age of the ferns, became extinct afterward. Evaluating the many fossils from this period containing fernlike structures, paleobotanists have identified *Archaeopteris*, which they call the primitive fern, and *Protopteridium*, labeled the first fern, which they hypothesize are the ancestors of modern ferns. Botanists have linked two existing fern genera as possible descendants of Carboniferous ferns.

Some fossilized leaves thought to be ferns had characteristics indicating that they had seeds and were not ferns. Seed ferns, or *pteridosperms*, were trees and vines with fronds but were not directly related to true ferns. Before the seed ferns became extinct in the Cretaceous period, about 136 million years ago, they were the predecessors to angiosperms. Based on anatomical comparisons, modern ferns and seed ferns may have descended from the same ancestors. Eleven modern fern families are present in fossils from the Mesozoic era, approximately 245 million years ago.

Although many modern ferns are morphologically similar to one another, they deviate in expression of specific traits. Theories differ about the evolutionary origins and development of ferns, specifically their stems and leaves. Many botanists designate the family *Schizeaceae*, or the curly grass, in phylum *Pterophyta* as the evolutionary origin of ferns. Types of curly grass also belong to family *Thelypteridaceae*. Tropical ferns are classified in family *Dicksoniaceae*. Other familiar families in phylum *Pterophyta* include *Adiantaceae*, which represents the maidenhair ferns; *Hymenophyllaceae*, which are the filmy ferns; *Blechnaceae*, the deer ferns, with reddish leaves; and *Cyathaceae*, the arborescent tree ferns. Spleenworts are in family *Aspleniaceae*. Brackens in family *Dennstaeditaceae* are further classified into the tribes *Dennstaediteae*, *Lindsaeeae*, and *Mona-*

Classification of Ferns

Class *Filicopsida*
- Order *Hydropteridales*
  - Families:
    - *Azollaceae* (azollas)
    - *Marsileaceae* (water clovers)
    - *Salviniaceae* (floating ferns)
- Order *Marattiales*
  - Family:
    - *Marattiaceae* (vessel ferns)
- Order *Ophioglossales*
  - Family:
    - *Ophioglossaceae* (adder's-tongues)
- Order *Polypodiales*
  - Families:
    - *Anemiaceae* (flowering ferns)
    - *Aspleniaceae* (spleenworts)
    - *Blechnaceae* (chain ferns)
    - *Cyatheaceae* (tree ferns)
    - *Dennstaedtiaceae* (bracken ferns)
    - *Dicksoniaceae* (tree ferns)
    - *Dryopteridaceae* (wood ferns)
    - *Gleicheniaceae* (forking ferns)
    - *Grammitidaceae* (kihi ferns)
    - *Hymenophyllaceae* (filmy ferns)
    - *Lophosoriaceae* (diamond leaf ferns)
    - *Lygodiaceae* (climbing ferns)
    - *Osmundaceae* (royal ferns)
    - *Parkeriaceae* (water ferns)
    - *Polypodiaceae* (polypodys)
    - *Pteridaceae* (maidenhair ferns)
    - *Schizaeaceae* (curly grasss)
    - *Thelypteridaceae* (marsh ferns)
    - *Vittariaceae* (shoestring ferns)

chosorae. The family *Dryopteridaceae* is divided into six tribes.

Floating *Pterophyta* plants belong to the families *Salviniaceae* and *Azollaceae*, the latter of which is considered to display the plant world's most complex reproductive system. *Marsileaceae* is the water-clover family. Variants of *Pterophyta* that grow on forest floors belong to the family *Marattiaceae*. The royal ferns (family *Osmundaceae*) exhibit some primitive characteristics such as stipular leaf bases. Family *Ophioglossaceae*, which includes adder's-tongue, are not closely related to extant ferns and express primitive traits such as high-spore-yielding sporangia, indicating an origin among the progymnosperms. The epiphytic family *Polypodiaceae*, divided by tribes, also is isolated from most *Pterophyta* ferns and is considered most closely related to the family *Gleicheniaceae*.

Pteridium, the bracken, is the most familiar fern worldwide and is among the earth's six most common and oldest plants. Classification of ferns fluctuates according to different authorities. Many known groups of ferns have not been fully examined, while other species are being discovered in previously uncharted places. Some researchers consider such plants as whiskferns (*Psilotophyta*), horsetails (*Sphenophyta*), and club mosses (*Lycophyta*) to be closely related to ferns, but most botanists stress that ferns differ morphologically from those plants, although their life cycles are alike.

Reproduction

Pterophytes such as ferns exist as two alternating forms during their sexual reproductive cycle. Initially, in the gametophyte phase, ferns are a stem known as the rhizome, from which roots and leaves, called fronds, grow as the fern matures into an adult sporophyte. The sporophyte exists separately from the gametophyte, which usually dies as soon as the sporophyte's root sinks into soil. Growing on or near the soil surface, rhizomes, the most common stem form, can be as thin as threads or as thick as ropes and sometimes have hollows that house ants that scientists believe to be living in symbiosis with the fern, protecting it from insect predators. The roots also have differing characteristics of quantity, width, length, and texture that aid in classification.

Ferns do not flower or create seeds; instead, they produce brown sacs, or sporangia, on the bottom surfaces of their fronds which contain single-cell spores. These spores vary in size and have tetrahedral or oval shapes. Spore arrangement aids fern classification. Spores are distributed by wind to germinate and form a small, heart-shaped *prothallus* which has sexual organs. The prothallus is tiny, averaging 8 millimeters (0.3 inch), and often is not visible before it dies. Water is necessary for fertilization to occur, opening the sex organs by swelling. Sperm from the antheridium fertilizes eggs, located in the archegonium on either the same or a different prothallus, which protects the resulting embryos until they mature. Embryos renew the cycle by maturing as rhizomes, which form fronds and roots to spread ferns to different areas. While spores are haploid (with one set of chromosomes), fern cells have two sets of chromosomes, one set acquired from the egg and one from sperm. Ferns create genetically identical clones in colonies.

Most fern reproduction is vegetative (asexual, without gametophytes) and occurs during the sporophytic stage, in which rhizomes produce fern clones or fragments are distributed by wind, water, or insects. The walking ferns, members of the species *Camptosorus rhizophyllus* and *Camptosorus sibiricus*, grow from sprouts emerging where parent leaves touch soil. As a result, large groups of identical ferns can be formed.

Sexual reproduction's role is to introduce ferns to new habitats and geographical areas. Genetic changes that occur because of meiotic cell division before the production of spores result in subtle variations.

Structure and Distribution

Most *Pterophyta* tissues, specifically those in ferns, are created near the top of the fronds, with the most mature cells being located at the base. Some fern genera have deviations in leaf structure. Fern leaves, known as the pteridophyll, have a fiddlehead, called the crosier, from which they unroll, instead of unfolding, as do other plants' leaves. Ferns are vascular, and most have pinnate leaves with leaflets extending from a central rib. Other types of leaves include palmate ferns, in which the leaflets emerge from one place, and staghorn ferns, with dichotomous leaves.

Leaves can be simple or compound, depending on whether they are segmented. Such appearances help identify species, especially when they are closely related. Leaves and their bases protect the stems, which have a surface consisting of one layer of flat epidermal cells with wide outer walls. Sometimes stems are covered with leaf armor, which is

NOAA/National Estuarine Research Reserve Collection

Bracken ferns by a roadside in Georgia.

formed by the hardened remains of leaf bases. This armor thickens stems and can store food in addition to shielding ferns from harm. Scales and hairs are also often present on stems, guarding them and providing identifiable traits for classification. Internally, stems have vascular tissues called steles.

Fronds are of varying shapes and sizes, ranging from 1 millimeter to 30 meters (0.04 inch to 100 feet). Some leaves appear feathery, while others look solid. They exhibit different shades of green and textures, such as glossy or leathery. Fern height also ranges broadly, from a few millimeters (0.1 inch) to as tall as 10 to 25 meters (30 to 80 feet) for some tropical tree ferns.

Habitats

Pterophyta habitats are numerous. The greatest number of species live in tropical rain forests. Most ferns are terrestrial, while some ferns are vines; others are epiphytes, wrapping around trees; and some float on bodies of water. Ferns prefer damp, warm environments but can also grow in arid and cold settings. Because less moisture and lower temperature occur at higher latitudes than in tropical and subtropical zones, fewer native ferns are found at the higher latitudes, although some species can live in the polar regions of the Arctic and Antarctic. Epipteric ferns grow in rocky landscapes, with different species preferring acidic or alkaline stones and others thriving in marshes, bogs, forests, and fields. Several ferns grow at high elevations, living on volcanoes and mountains. Ferns adapt to arid, sunny, and salty conditions by developing harder tissues, waxy surfaces, hair or scale coverings, and altered life cycles.

Species are occasionally introduced into areas where they are not indigenous and then thrive to become common. Hybrids also occur between species within genera, adding to classification confusion. Rarely, hybridization between genera happens. Because they are primarily sterile, hybrids reproduce with vegetative propagation or apogamy, whereby spores with the same number of chromosomes as parent cells generate gametophytes that bud a sporophyte without undergoing fertilization.

Some ferns, including the bracken, are regarded as weeds because they cover fields and bodies of water, blocking light and oxygen necessary for other organisms to survive.

Uses

Economically, *Pterophyta* are not as significant as other plants. Nevertheless, some ferns species are edible, with crosiers being considered delicacies. Other ferns are used medicinally.

By contrast, *Osmunda* and *Pteridium* ferns are considered to be carcinogenic. The aquatic mosquito fern (*Azolla*) hosts *Anabaena azollae*, which converts nitrogen for use by plants such as rice, enhancing production in rice paddies and other fields. Animals often root for fern rhizomes, which store starches. The braken fern *Pteris vittata* absorbs arsenic, a carcinogenic heavy metal, from soil. By removing this toxin, ferns can restore contaminated areas into viable agricultural, industrial, and recreational sites.

The most important economic use of *Pterophyta* is as ornamental garden plants and houseplants. Fern fronds are used in cut-flower arrangments as ornamental greenery. Botanical collectors have identified rare ferns, for which they pay high prices; there is even an underground economy of smuggling ferns illegally from protected areas. Masses of fern roots are used to cultivate such epiphytic greenhouse plants as orchids. In the Middle Ages, some people believed that at midnight on June 24, St. John's Day, ferns would produce blossoms which contained magical seeds.

FERTILIZERS

Categories: Agriculture; economic botany and plant uses; nutrients and nutrition; soil

Fertilizers are materials used to modify the chemical composition of soil in order to enhance plant growth. They represent an important use of natural resources because agricultural systems depend upon an ability to retain soil fertility.

Soil is a dynamic, chemically reactive medium, and agricultural soils must provide structural support for plants, contain a sufficient supply of plant nutrients, and exhibit an adequate capacity to hold and exchange minerals.

Topsoil, the 6-inch layer of soil covering the earth's landmasses, is the *root zone* for the majority of the world's food and fiber crops. As plants grow and develop, they remove the essential mineral nutrients from the soil. Because crop production normally requires the removal of plants or plant parts, nutrients are continuously being removed from the soil. Therefore, the long-term agricultural use of any soil requires periodic fertilization to replace these lost nutrients. Fertilizers are associated with every aspect of this nutrient replacement process. The application of fertilizer is based on a knowledge of plant growth and development, soil chemistry, and plant-soil interactions.

Soil Nutrients

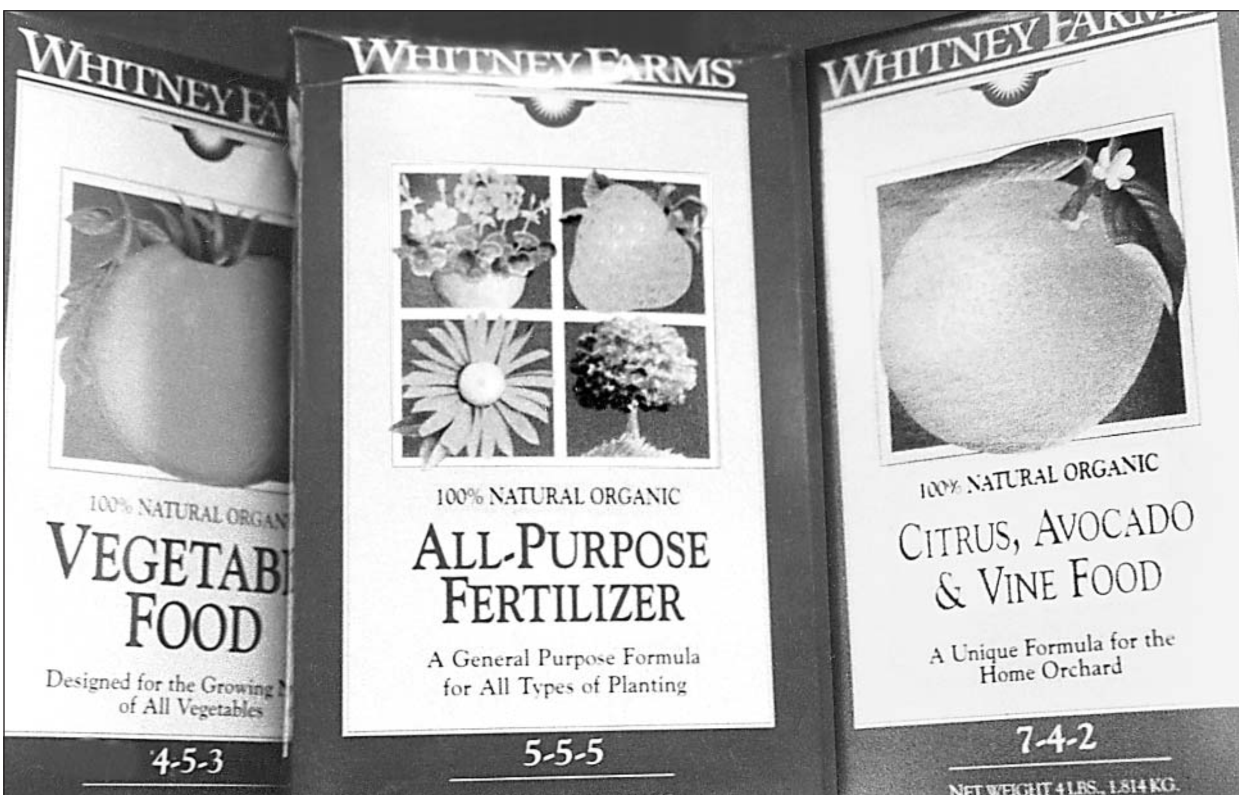
Plants require an adequate supply of both macronutrients (calcium, magnesium, sulfur, nitrogen, potassium, and phosphorus) and micronutrients (iron, copper, zinc, boron, manganese, chloride, and molybdenum) from the soil. If any one of these nutrients is not present in sufficient amounts, plant growth and, ultimately, yields will be reduced. Because micronutrients are required in small quantities, and deficiencies in these minerals occur infrequently, the majority of agricultural fertilizers contain only macronutrients. Although magnesium and calcium are utilized in large quantities, most agricultural soils contain an abundance of these two elements, either derived from parent material or added as lime. Most soils also contain sufficient amounts of sulfur from the weathering of sulfur-containing minerals, the presence of sulfur in other fertilizers, and atmospheric pollutants.

The remaining three macronutrients (nitrogen, potassium, and phosphorus) are readily depleted and are referred to as fertilizer elements. Hence, these elements must be added to most soils on a regular basis. Fertilizers containing two or more nutrients are called mixed fertilizers. A fertilizer labeled 10-10-10, for example, means that the product contains 10 percent nitrogen, 10 percent phosphorus, and 10 percent potassium. These elements can be supplied in a number of different forms, some of which may not be immediately useful to plants. In the United States, where fertilizer labeling is regulated for sales, most states require that the label reflect the percentage of nutrients available for plant use. Fertilizers are produced in a wide variety of single and mixed formulations, and the percentage of available nutrients generally ranges from a low of 5 percent to a high of 33 percent. Mixed fertilizers may also contain varying amounts of different micronutrients.

Sources and Production

Nitrogen fertilizers can be classified as either chemical or *natural organic*. Natural organic sources are derived from plant and animal residues and include such materials as animal manure, cottonseed meal, and soybean meal. Because natural organic fertilizers contain relatively small amounts of nitrogen, commercial operations rely on chemical fertilizers derived from sources other than plants and animals. Major chemical sources of nitrogen include ammonium compounds and nitrates. The chemical fixation of atmospheric nitrogen by the Claude-Haber ammonification process is the cornerstone of the modern nitrogen fertilizer manufacturing process. Once the ammonia is produced, it can be applied directly to the soil as anhydrous ammonia, or it can be mixed with water and supplied as a solution of aqueous ammonia and used in chemical reactions to produce other ammonium fertilizers, urea, or nitrates for nitrate fertilizers.

Some organic fertilizers contain small amounts of phosphorus, and organically derived phosphates from guano or acid-treated bone meal were used in the past. However, the supply of these materials is scarce. Almost all commercially produced agricultural phosphates are applied as either phosphoric acid or superphosphate derived from rock phosphate. The major phosphate component in commercially important deposits of rock phosphate is apatite. The apatite is mined, processed to separate the



Yasmine Cordoba

Commercial fertilizers containing two or more nutrients are called mixed fertilizers. The numbers on the packaging refer to nitrogen, phosphorus, and potassium content. For example, the fertilizer above labeled 5-5-5 contains 5 percent nitrogen, 5 percent phosphorus, and 5 percent potassium, respectively.

phosphorus-containing fraction from inert materials, and then treated with sulfuric acid to break the apatite bond. The superphosphate precipitates out of the solution and sets up as a hard block, which can be mechanically granulated to produce a fertilizer containing calcium, sulfur, and phosphorus.

Potassium fertilizers, commonly called "potash," are also obtained from mineral deposits below the earth's surface. The major commercially available potassium fertilizers are potassium chloride extracted from sylvanite ore, potassium sulfate produced by various methods (including extraction from langbeinite or burkeite ores or chemical reactions with potassium chloride), and potassium nitrate, which can be manufactured by several different chemical processes. Although limited, there are sources of organic potassium fertilizers, such as tobacco stalks and dried kelp.

While the individual nitrogen, phosphorus, and potassium fertilizers can be applied directly to the soil, they are also commonly used to manufacture mixed fertilizers. Between two and ten different materials with widely different properties are mixed together in the manufacturing process. The three most common processes used in mixed fertilizer production are the ammonification of phosphorus materials and the subsequent addition of other materials, bulk blending of solid ingredients, and liquid mixing. Fillers and make-weight materials are often added to make up the difference between the weight of fertilizer materials required to furnish the stated amount of nutrient and the desired bulk of mixed products. Mixed fertilizers have the obvious advantage of supplying all the required nutrients in one application.

Application and Environment

The application of fertilizer to agricultural soil is by no means new. Farmers have been applying *manures* to improve plant growth for more than four thousand years. For the most part, this practice had little environmental impact. Since the development of chemical fertilizers in the late nineteenth century, however, fertilizer use has increased tremendously. During the second half of the twentieth century, the amount of fertilizer applied to the soil increased more than 450 percent. While this increase has more than doubled the worldwide crop production, it has also generated some environmental problems.

The production of fertilizer requires the use of a variety of natural resources, and some people have argued that the increased production of fertilizers has required the use of energy and mineral reserves that could have been used elsewhere. For every crop, there is a point at which the yield may continue to increase with the application of additional nutrients, but the increase will not offset the additional cost of the fertilizer. The economically feasible practice, therefore, is to apply the appropriate amount of fertilizer that produces maximum profit rather than maximum yield. Unfortunately, many farmers still tend to *overfertilize*, which wastes money and contributes to environmental degradation. Excessive fertilization can result in adverse soil reactions that damage plant roots or produce undesired growth patterns. Overfertilization can actually decrease yields. If supplied in excessive amounts, some micronutrients are toxic to plants and will dramatically reduce plant growth.

The most serious environmental problem associated with fertilizers, however, is their contribution to *water pollution*. Excess fertilizer elements, particularly nitrogen and phosphorus, are carried from farm fields and cattle feedlots by water runoff and are eventually deposited in rivers and lakes, where they contribute to the pollution of aquatic ecosystems. High levels of plant nutrients in streams and lakes can result in increased growth of phytoplankton, a condition known as *eutrophication*. During the summer months, eutrophication can deplete oxygen levels in lower layers of ponds and lakes. Excess nutrients can also be leached through the soil and contaminate underground water supplies. In areas where intense farming occurs, nitrate concentrations are often above recommended safe levels. Water that contains excessive amounts of plant nutrients poses health problems if consumed by humans and livestock, and it can be fatal if ingested by newborns.

Importance to Food Production

Without a doubt, the modern use of fertilizer has dramatically increased crop yields. If food and fiber production is to keep pace with the world's growing population, increased reliance on fertilizers will be required in the future. With increasing attention to the environment, future research will be aimed at finding fertilizer materials that will remain in the field to which they are applied and at improving application and cultivation techniques to contain materials within the designated application area. The use of technology developed from discoveries in the field of molecular biology to develop more efficient plants holds considerable promise for the future.

FLAGELLA AND CILIA

Categories: Anatomy; bacteria; cellular biology; microorganisms

Flagella and cilia are hairlike structures, made primarily of protein, found on the surfaces of cells and used for movement by microorganisms and some specialized cells, such as the gametes of certain plants with motile sperm. Because flagella and cilia are so similar, many scientists use the term "undulipodia" for both in reference to eukaryotic organisms.

Although the term "flagellum" is used in reference to both prokaryotes (archaea and bacteria) and eukaryotes (fungi, protists, plants, and animals), the structure and mechanism of action of this structure in prokaryotes are quite different from the structure and mechanism of action in eukaryotes. Eukaryotic flagella and cilia, however, are structurally and functionally identical. The differences between them are in their number, length, and position. Flagella are less numerous, longer, and usually polar, while cilia are more numerous and shorter, covering much of the cell's surface. Because the dividing line between eukaryotic flagella and cilia is not precise, many scientists use the term *undulipodia* as a collective word for both eukaryotic flagella and cilia. In some algae, other protists, and the gametes of certain plants with motile sperm, flagella and cilia can occur.

Bacterial Flagella

Bacterial flagella are composed of a single protein called *flagellin*. Molecules of this globular protein are stacked to form a thin filament approximately 0.01-0.015 micrometer in diameter. The filament protrudes through the cell wall at the tip of the bacterium (polar flagella) or over the entire surface of the bacterium (peritrichous flagella). *Spirochetes* are unusual in this regard because the flagella do not pierce the cell wall but are located in the space between it and the plasma membrane. The base of each flagellum connects to a rotary motor anchored in the plasma membrane. The cell provides energy to the motor, which then rotates the flagellum to allow cell movement. Rotational movement may be counter-clockwise, which leads to generally straight-line motion, or clockwise, which leads to a more random tumbling motion.

Eukaryotic Flagella and Cilia

Eukaryotic flagella and cilia, or undulipodia, are more complex and larger (approximately 0.25 micrometer in diameter) than their prokaryotic counterparts. The main component of these eukaryotic structures is the *microtubule*; a long, cylindrical structure composed of *tubulin* proteins. In eukaryotic flagella and cilia, two central microtubules are surrounded by a circular arrangement of nine microtubule pairs. Eukaryotic flagella and cilia also contain more than five hundred other proteins, including dynein and kinesin, motor proteins that use cell energy to slide the microtubules past each other, causing an undulating motion (hence the name undulipodium). Unlike bacterial flagella, eukaryotic flagella and cilia are considered to be intracellular structures because they are covered by a continuation of the plasma membrane.

Although absent from fungi, undulipodia are found in many protists and in some plants. Unicellular algae (such as *Chlamydomonas* and *Euglena*) and colonial algae (*Volvox*) use undulipodia for locomotion. Multicellular algae (*Phaeophyta*, *Rhodophyta*) produce flagellated sperm. Among the true plants, bryophytes (*Hepatophyta*, *Anthocerotophyta*, and *Bryophyta*), ferns and their allies (*Psilotophyta*, *Lycophyta*, *Sphenophyta*, and *Pterophyta*), and some gymnosperms (*Cycadophyta* and *Ginkgophyta*) also produce flagellated sperm. Other gymnosperms (*Coniferophyta*) and angiosperms (*Anthophyta*) do not produce cells with flagella or cilia.

FLOWER STRUCTURE

Categories: Anatomy; angiosperms

Flowers are the modified shoots bearing modified leaves that serve as the sexual reproductive organs of angiosperms. This strategy for reproduction has been so successful that angiosperms now dominate the plant world, and accordingly there are many variations on the basic structure of a flower.

Flowers are organs of sexual reproduction produced by the angiosperms (phylum *Anthophyta*), the largest phylum of photosynthetic organisms, with roughly 250,000 species. This large number represents a great diversity of flower types, but all flowers have some common structural elements.

Flower Parts

Flowers are modified shoots bearing modified leaves. In the typical flower, the modified leaves can be grouped into four sets based on appearance and function: sepals, petals, stamens, and pistils. The *sepals* and *petals* are lowermost on the shoot toward the sides of the flower. The *stamens* and *pistils* are at the tip of the shoot at the inside. While sepals and petals are easy to see, stamens and pistils are often visible only when the flower is closely examined. Two other important parts are the *pedicel*, a stalk on which flowers are frequently borne, and the top of the pedicel, called the *receptacle*, to which the other flower parts are typically attached.

Of the four main parts, the sepals are generally the most leaflike and generally are attached to the bottom of the receptacle. Sepals protect the immature flower during the bud stage. Flowers typically have three to eight sepals, depending on the species. Collectively, the sepals in a flower are called the *calyx*. Above the sepals are the *petals*. Although flattened like the sepal, each petal is usually soft and colored—white, yellow, pink, blue, purple, orange, maroon, or even brown. Petals attract insects, hummingbirds, bats, or other animals, aiding the reproductive process. Usually, the number of petals in a flower will be the same as the number of sepals. Collectively, the petals in a flower are called the *corolla*.

The *stamens*, located inside the petals, are composed of a small *anther* (ball-shaped, egg-shaped, or tubular) and a threadlike *filament* connecting the anther to the rest of the flower. The anther, in turn, is composed of two or four tiny chambers, within which powdery *pollen* grains are produced and stored. Each grain of pollen contains the immature sperm of the plant. Thus, the stamens function as the male part of the flower in sexual plant reproduction, and they may number from one to dozens. The term *androecium* refers collectively to all the stamens within a flower.

The *pistils* form the final set of parts. Each pistil is often shaped like a vase, although the shape varies. The *ovary*, the base of the pistil, is swollen and hollow. The wall of the ovary, called the *pericarp*, is typically green, and the hollow space in the ovary is called the *locule*. Within the locule are one or more tiny globular *ovules*, each containing an egg nucleus and thus functioning as the female structure in sexual reproduction. In addition to the ovary, the pistil is typically composed of two or more parts: the *style*, a slender necklike structure above the ovary, and the *stigma*, a swollen area at the top of the style that traps pollen grains with minute hairs covered by a sticky, sugary film. While most flowers have only one pistil, many have several pistils, attached to the receptacle. The pistils within a flower are collectively called the *gynoecium*.

Functions of Flower Parts

Flowers and their parts function to achieve sexual reproduction, including pollination and seed formation. After pollination is finished, the flower begins the process of seed and finally fruit formation. During *pollination*, pollen grains are released from the anther and carried to the stigma, either by animals (such as insects, birds, and bats) or by wind. Animals, attracted by the flower's colors or aromas, visit flowers to obtain food—either the pollen itself or the *nectar*, a sugary liquid produced by small glands called nectaries at the base of the flower. The animal brushes up against the anthers, which deposit pollen on the animal's body. The animal transfers the pollen to the stigma of either the same flower (self-pollination) or a second flower (cross-pollination). During wind pollination, the anthers release their pollen, which is then borne by air currents. Some of the grains are deposited on a stigma of the same or another flower.

Each pollen grain germinates and produces a slender thread of protoplasm that grows downward through the style and into the ovary. This thread, the *pollen tube*, contains the sperm and grows toward an ovule, where it deposits its sperm. The sperm then fuses with the egg, achieving fertilization as the first cell of the new generation is produced. The ovule matures to form a seed. At the same time, the surrounding ovary enlarges greatly, becoming a fruit as other parts of the flower recede and die off.

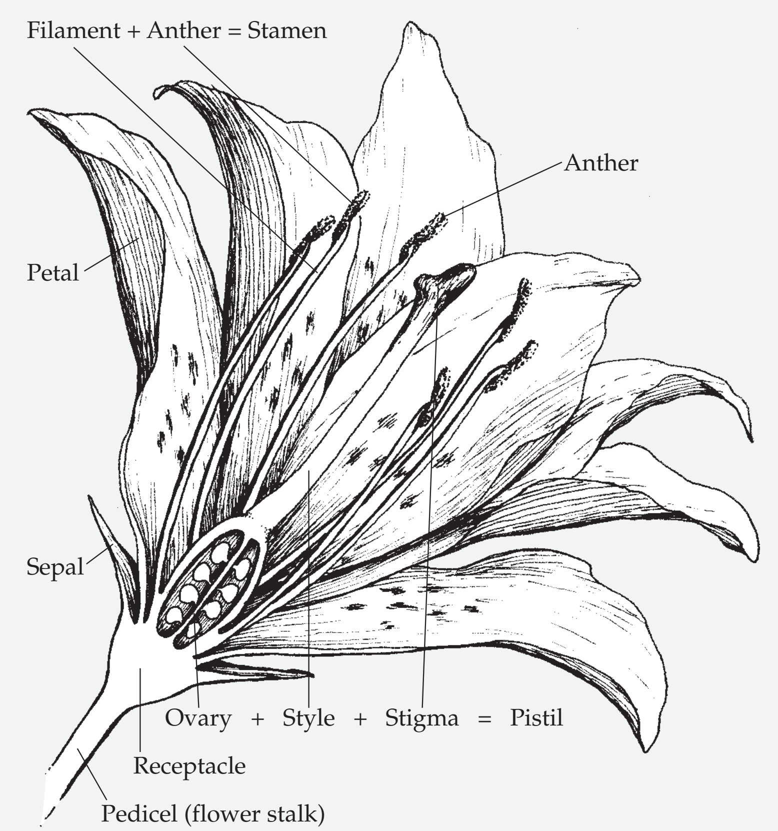
Because the stamens and pistils are intimately involved in reproduction, botanists refer to these as *essential parts*. The sepals and petals are termed *nonessential parts*, though in fact they remain important. The sepals and petals are sometimes called the *perianth* because they are found on the periphery of the anthers. A *complete flower* is one that has all four sets of parts. A *perfect flower* is one that has both androecium and gynoecium and is thus bisexual.

Structural Variations

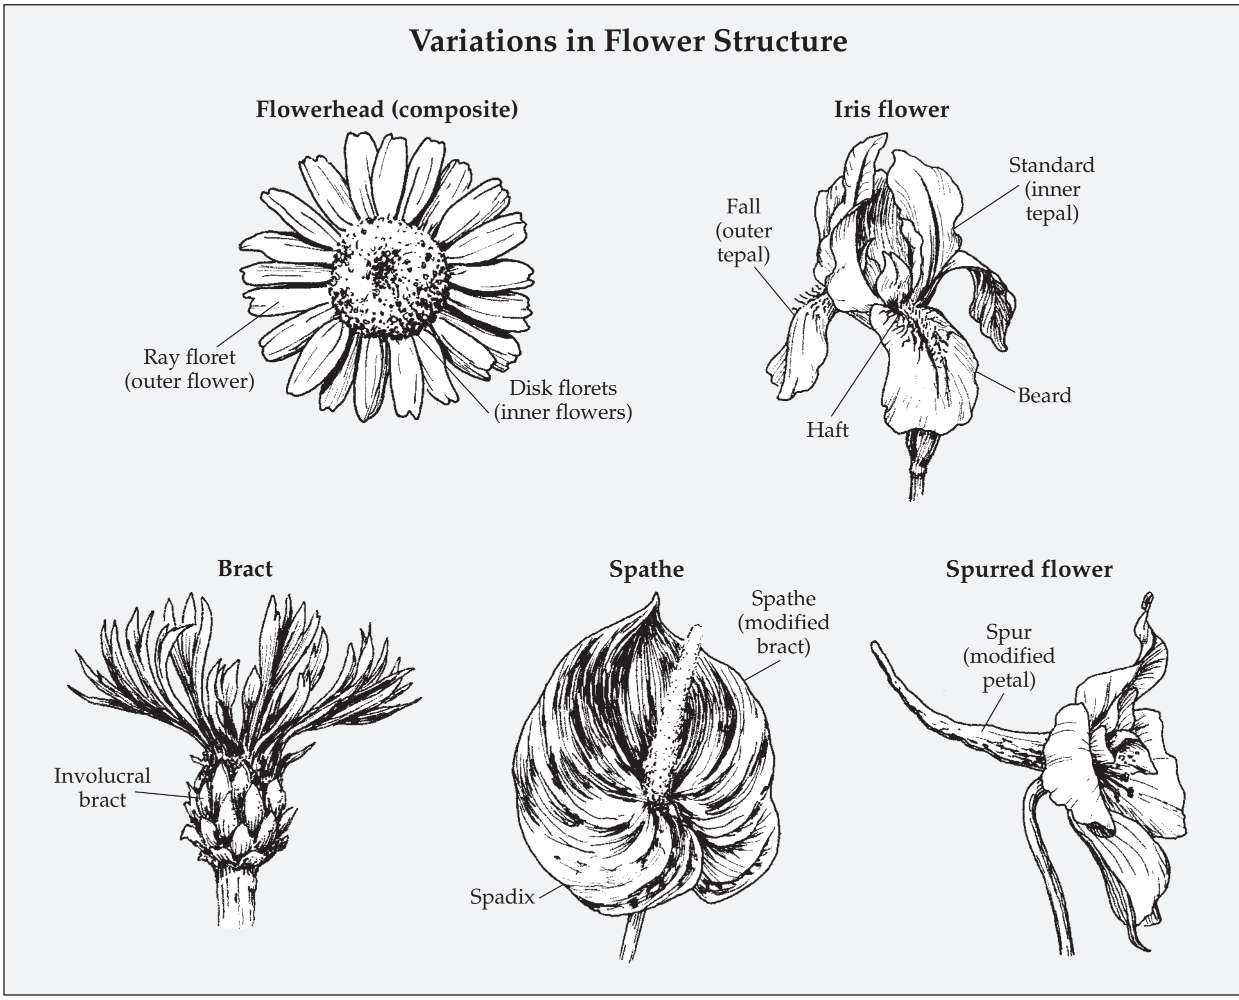
Many plant species produce flowers that deviate from the idealized format. Certain lilies, for example, do not have sepals and petals that are clearly distinguishable from each other. In magnolias and some water lilies, each flower produces perianth parts that intergrade from a sepal-like form toward the outside to a petal-like form toward the inside.

Many flowers have evolved to become simpler and are called *incomplete flowers*; they may lack one or more sets of parts. *Apetalous flowers* have only sepals, although some, such as those of the liverleaf and anemone, may be petal-like. Elms, mulberries, oaks, plantains, pigweeds, and goosefeet have sepals that remain green and are usually tiny. *Naked flowers*, including those of birches and willows, develop neither sepals nor petals. Grass flowers are associated with tiny green parts called *bracts*, which are neither sepals nor petals. The nature of the perianth is related to the way a plant undergoes

Parts of a Flower



In the idealized flower, the parts are free down to the receptacle. Many flowers, however, exhibit connation, in which similar parts are fused above the receptacle: for example, the petals of the morning glory, fused to form a corolla, or the sepals of carnations, which form a calyx tube. Many plants have pistils composed of individual fused segments, called carpels, while others, such as the mallow, have connate stamens, forming a stamen tube.



Kimberly L. Dawson Kurnizki

Flowers take on many different forms, which have evolved to facilitate pollination by animals, wind, or water. Smaller, less showy flowers tend to be pollinated by wind (which can easily lift and carry their pollen), whereas animal-pollinated flowers have evolved colors, odors, and even structures that mimic insects or store nectar—all designed to attract the pollinators.

pollination. Flowers with a well-developed corolla or a calyx made up of petal-like sepals are attractive to animals and insects, which function to pollinate them. Apetalous and naked flowers are wind-pollinated; they do not need to waste their energy making showy flower parts.

Some incomplete flowers lack either the androecium or the gynoecium. These *imperfect flowers* are unisexual and fall into two categories: *staminate flowers* are male flowers, having only stamens and no pistils; *pistillate flowers* are female, having only pistils and no stamens. Forced into cross-pollination, imperfect flowers benefit the plant by preventing some of the harm inherent in self-pollination.

In the idealized flower, the parts are free down to the receptacle. Many flowers, however, exhibit *connation*, in which similar parts are fused above the receptacle. The petals of the morning glory are fused to form a funnel-shaped corolla. Carnations have connate sepals, forming a calyx tube. Many plants have pistils composed of individual fused segments, called *carpels*, while others, such as the mallow, have connate stamens, forming a stamen tube.

Other flowers show *adnation*, which involves the fusion of different parts. The stamens of phlox flowers are fused to the petals. The sepals, petals, and stamens of roses are all fused, forming a cup-shaped structure called a *hypanthium*. The presence of a hypanthium can be best observed in plum and cherry blossoms, whose individual sepals, petals, and stamens are attached to the rim of the hypanthium. Finally, many flowers have a hypanthium that is fused to the wall of the ovary. The result is that the sepals, petals, and stamens emerge from the top of the ovary, a good example being the apple blossom. Flowers of the latter category are said to have an inferior ovary, whereas the others have superior ovaries.

Flowers' corollas also vary: In flowers with a regular corolla, such as buttercups, lilies, and roses, all the petals are equal in size and shape, giving the flower a star shape. In flowers with irregular corollas, such as the snapdragon, pea, and orchid, one or more of the petals are unequal. Some irregular flowers, such as the violet, touch-me-not, and columbine, have a rounded, cone-shaped, or pointed extension of the corolla called a spur, which serves to store nectar.

Although not technically floral structures, color, shape, and inflorescences (the loose or dense clusters in which flowers appear on a plant) are other ways in which flowers differ, important because they allow certain pollinators to enter but exclude others. Bowl-shaped flowers are visited by a variety of insects, such as beetles and bees. Irregular flowers are typically pollinated by honeybees and bumblebees, and in some cases the insects fit the flower like a key fits a lock. Flowers with long spurs are pollinated by long-tongued insects such as moths. Color, determined by special molecules called pigments that occur within the cells of the plant, attracts different pollinators as well: red flowers are pollinated by birds, specifically hummingbirds and butterflies. White flowers are often open at night and are visited by moths. One group of plants have brown or maroon flowers and an odor of rotting flesh. These "carrion flowers" are pollinated by an array of insects, particularly beetles and flies. Interestingly, the way that humans perceive color is often different from the way that other animals perceive color. For example, xanthophylls reflect not only yellow but also a deep violet that bees can perceive but that humans cannot.

FLOWER TYPES

Categories: Anatomy; angiosperms

The flower is the most distinctive feature of the phylum Anthophyta*, commonly referred to as angiosperms or flowering plants, and is responsible in making them the most dominant, diverse, and widespread of all groups of plants.*

There are already about 250,000 species of flowering plants that have been discovered and named. The basis for their diversity comes from their incredible reproductive success in a wide variety of habitats. The success of this group is also reflected by the diversity of their flowers that show astonishing displays of different forms, sizes, shapes, and colors—all of these to lure pollinators and effect sexual reproduction.

Flowers are considered as an organ system because they are made up of two or more sets, or whorls, of leaflike structures. A typical flower is composed of four whorls, which are the *sepals*, *petals*, *stamens*, and a *pistil* with one or more *carpels*. Much of the variation among flowers is based on variation of these basic parts.

Complete and Incomplete Flowers

A flower that has all four whorls of floral parts is said to be a *complete flower* (such as the hibiscus and the lily). An *incomplete flower* lacks any one or more of these parts (such as those of elms, willows, oaks, and plantains). With or without sepals and petals, a flower that has both stamen and pistil is called a *perfect flower*. Thus, all compete flowers are prefect, but not all perfect flowers are complete. In contrast, flowers that have only stamens or only pistils are called *imperfect flowers*.

Unisexual and Bisexual Flowers

Unisexual flowers are either *staminate* (bearing stamens only) or *pistillate* (bearing pistils only) and are said to be imperfect. *Bisexual flowers* are perfect because they have both stamens and pistil. When staminate and pistillate flowers occur on the same individual, the plant is called *monoecious* (examples include corn and the walnut tree). When staminate and pistillate flowers are borne on separate individual flowers, the plant is said to be *dioecious* (examples include asparagus and willow).

Superior or Inferior Ovaries

The position of the ovary also varies among different flower types. A flower has a *superior ovary* when the base of the ovary is located above where the sepals, petals, and stamens are attached. This point of attachment is referred to as the *receptacle* or *hypanthium*, the fused bases of the three floral parts (tulips and St. John's wort are examples). An *inferior flower* has an ovary below where the sepals, petals, and stamens are attached (as do daffodils and sabatia). Some flowers show an *intermediate type*, where the receptacle partly surrounds the ovary; the petals and stamens branch from the receptacle about halfway up the ovary (as in cherry, peach, and almond flowers).

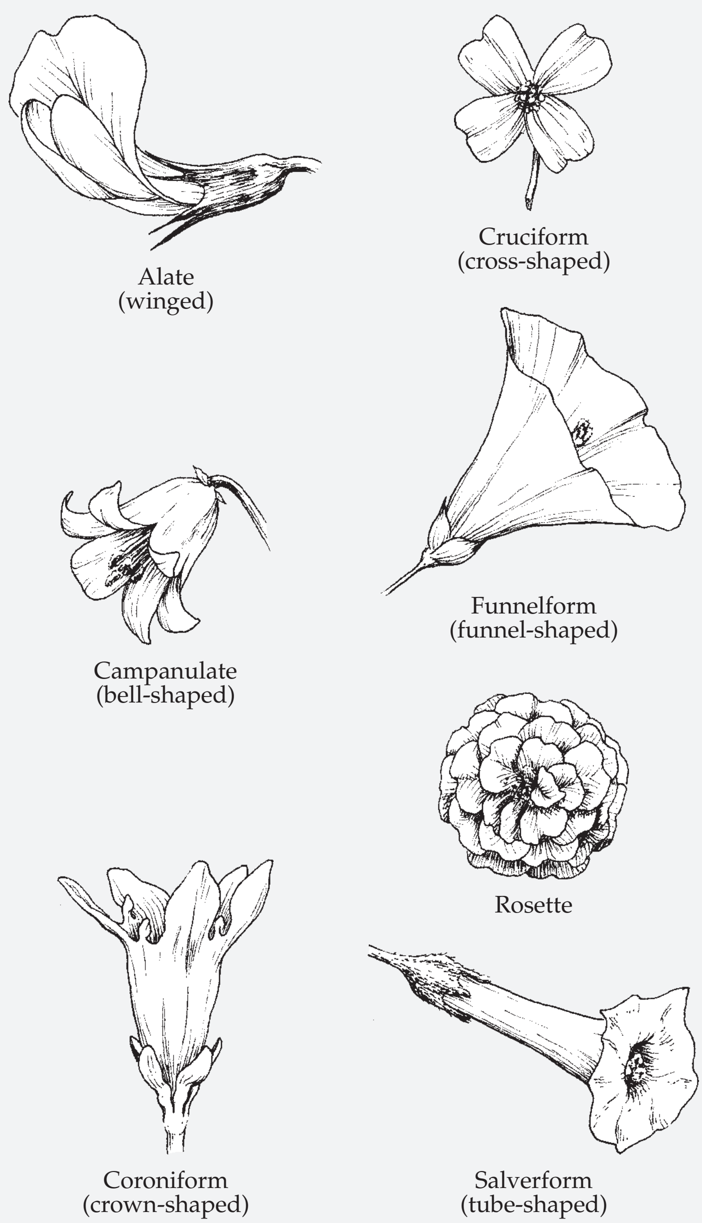
Hypogynous, Epigynous, and Perigynous Flowers

The position of the ovary in relation to the attachment of floral parts also varies from superior to inferior ovaries. Flowers in which the sepals, petals, and stamens are attached below the ovary are called *hypogynous*, and the ovaries of such flowers are said to be superior (as in pelargonium and silene). Flowers in which the sepals, petals, and stamens appear to be attached to the upper part of the ovary due to the fusion of the hypanthium are called *epigynous*, and the ovaries of such flowers are said to be inferior (as in cornus and narcissus). Flowers in which the hypanthium forms a cuplike or tubular structure that partly surrounds the ovary are called *perigynous*. In such flowers, the sepals, petals, and stamens are attached to the rim of the hypanthium, and the ovaries of such flowers are superior.

Fused and Distinct Floral Parts

The parts of a flower may be *free* or *united*. Fusion of like parts (such as petals united to petals) is called *connation*. When like parts are not fused, they are said to be *distinct* (one petal is distinct from another petal). Fusion of unlike parts (stamens united to petals) is called *adnation*, and the contrasting condition is called *free* (stamens are free from petals). Fused structures may be united from the moment of origin onward, or they may initially be separate and grow together as one later in development.

Flower Shapes: Perianth Forms



Kimberly L. Dawson Kurnizki

Regular and Irregular Flowers

In many flowers, the petals of similar shape radiate from the center of the flower and are equidistant from one another. Such flowers are said to have *regular* or *radial symmetry*. In these cases, even though there may be an uneven number of sepals and petals, any line drawn through the center of the flower will divide it into two similar halves. The halves are either exact duplicates or mirror images of each other. Flowers with radial symmetry are also called *actinomorphic flowers* (examples: stonecrop, morning glory). Flowers with *irregular* or *bilateral symmetry* have parts arranged in such a way that only one line can divide the flower into equal halves that are more or less mirror images of each other. Flowers with bilateral symmetry are also called *zygomorphic flowers* (examples: mint, pea, snapdragon). A few flowers have no plane of symmetry and are referred to as *asymmetrical*.

Corolla Shapes

Corolla is the collective term for all the petals of a single flower. This is usually the showy part of the flower. In fused corollas, any extension of the petal beyond its fused part is called the *limb*. The tubelike structure where the petals are united at the bottom of the fused corollas is called the *tube*. The opening at the top of the tube in fused corollas is called the *throat*. In the following different types of corolla shapes, numbers 1 to 6 are actinomorphic, while numbers 7 to 11 are zygomorphic.

1. *Rotate*: wheel-shaped with a short tube and large limb (example: bluets).

2. *Campanulate*: bell-shaped with an extended, flaring tube (example: bellflower).

3. *Funnelform*: funnel-shaped with a continuously expanding tube and little flaring (example: bindweeds).

4. *Tubular*: an elongated tube with minimal limb (example: trumpet vine).

5. *Salverform*: an elongated tube with a conspicuous limb, trumpet-shaped (examples: Russian olive, morning glory).

6. *Urceolate*: an inflated tube with a terminal constriction, urn-shaped (example: highbush blueberry).

7. *Bilabiate*: two-lipped, usually because of the presence of a landing platform formed by basal lobes (examples: snapdragon, salvia).

8. *Ligulate*: petals connate at the margins to form a strap-shaped corolla (example: asters).

9. *Galeate*: helmet-shaped (example: pedicularis).

10. *Spurred*: with an extension or spur that often produces nectaries (examples: impatiens, utricularia).

11. *Papilionaceous*: like a butterfly with a central standard petal and lateral wing petal (example: lupines).

Flowers of Monocots and Dicots

Floral variation provides part of the basis for dividing the flowering plants into two major groups: the *dicotyledons* and the *monocotyledons*. The informal name "dicot" is given to plants having two cotyledons (seed leaves) in each seed; "monocot" refers to plants that have one cotyledon in the seed. In monocots, the flower parts occur in threes or multiples of three; for example, three sepals, three petals, six stamens, and a pistil with three carpels. In dicots, flower parts usually occur in fours or fives or multiples of four or five. Although dicots and monocots may have other numbers of floral parts, many other features are unique to each group. Dicots include about 80 percent of all angiosperm species, including many herbaceous plants and all woody, flower-bearing trees and shrubs. Monocots are primarily herbaceous, but they also include some trees, such as palms and Joshua trees.

Types of Inflorescence

Flowers may be solitary, or they may be grouped together in an *inflorescence*, a cluster of flowers. An inflorescence has one main stalk, or *peduncle*. It may also bear numerous smaller stalks called pedicels, each with a flower at its tip. The arrangement of pedicels on a peduncle characterizes different kinds of inflorescences. Some of the common types of inflorescences are as follows:

Spike: The flowers, which are with a very short or with no pedicel, are attached along the elongate and unbranched peduncle of the inflorescence (examples: plantain, spearmint, tamarisk).

Raceme: The flowers are with pedicels of about the same length, which are attached along the elongate and unbranched peduncle of the inflorescence (examples: lily of the valley, snapdragon, mustard, currant). The oldest flowers are at the base of the inflorescence and the youngest at the apex.

Panicle: The flowers are with pedicels, which are attached along the branches arising from the peduncle of the inflorescence (examples: oats, rice, fescue).

Corymb: The flowers are with pedicels of unequal length, which are attached along an unbranched, elongate peduncle, forming a flat-topped inflorescence (examples: hawthorne, apple, dogwood).

Umbel: The flowers are with pedicles, which are all attached at about the same point at the end of the peduncle—this is specifically called a *simple umbel* (examples: onion, geranium, milkweed). A *compound umbel* is formed when the peduncle produces branches that end at approximately the same level, forming a flat top, and the ends of these branches arise from a common point (examples: carrot, dill, parsley).

Head: The flowers do not have pedicels, and they all cluster tightly on the expanded tip of the peduncle (examples: sunflower, daisy, marigold). This type of inflorescence is also referred to as *capitulum*.

Cyme: The flowers with pedicels are located at the ends of the peduncle and lateral branches as well as along the length of the lateral branches. The youngest flowers in any cluster occur farthest from the tip of the peduncle (example: chickweed).

Catkin: The flowers have no pedicels, are unisexual (either staminate or pistillate), and are attached along the length of the peduncle (examples: hazelnut, willow, birch, walnut). The flowers are usually very small and fall as a group. This type of inflorescence is also referred to as *ament*.

Spadix: The flowers have no pedicels and are attached along the length of the thickened or fleshy peduncle, which is enveloped by a conspicuously colored bract called a spathe (example: philodendron, anthurium).

Some types of inflorescences characterize different groups of plants. For example, nearly all members of the carrot family (*Apiaceae*) have compound umbels. All members of the sunflower family (*Asteraceae*) have heads, including chrysanthemums, zinnias, marigolds, and dandelions. All members of the arum family (*Araceae*) have a spadix inflorescence.

FLOWERING REGULATION

Categories: Angiosperms; physiology; reproduction and life cycles

All flowering is regulated by the integration of environmental cues into an internal sequence of processes. These processes regulate the ability of plant organs to produce and respond to an array of signals. The numerous regulatory switches permit precise control over the time of flowering.

Control over the time of flowering is essential for the survival of flowering plants (angiosperms). Insect pollinators may be present only at certain times; unless an insect-pollinated plant is flowering at that time, pollination and the production of the next generation cannot occur. Embryo and seed development may be successful only under certain climatic conditions. The ability to respond to environmental cues is an essential factor in the regulation of flowering.

While the basic biochemical sequence of events may be common to all angiosperms, the specific regulatory steps vary greatly among species. A floral *promoter* is produced by the leaves and is transported to the shoot apex, which results in the initiation and, ultimately, the production of flowers. To analyze control points in this sequence, it is helpful to focus separately on environmental signals such as temperature and photoperiod and the way organs perceive and respond to these signals.

Chemical Communication

The regulation of flowering requires interactions between the shoot apex and other organs and thus depends heavily on chemical signals. There is strong evidence for the existence of a floral promoter called *florigen*, which may be produced in the leaves. The existence of florigen was first proposed by M. Kh. Chailakhyan, a Soviet plant physiologist, in 1937. Florigen was believed to be produced in leaves, because if leaves were removed before the photoperiod was right for flowering (a process called photoinduction), no flowering occurred. Later work by Anton Lang showed that the

The role of day length in the regulation of flowering had been recognized by 1913. The impact of photoperiod on flowering in numerous species soon became apparent, but some plants, including sunflowers, are day-neutral; they flower independently of photoperiod.

plant hormone *gibberellin* could induce flowering in certain plants, even without appropriate photoinduction. This prompted Chailakhyan to consider the possibility that florigen was actually composed of two different substances, gibberellin and a new substance he called *anthesin*.

In the late 1970's Lang, Chailakhyan, and I. A. Frolova, working with tobacco plants, discovered that there was also a floral inhibitor they called *antiflorigen*. Later, several genes controlling the production of an inhibitor in pea cotyledons and leaves were identified in other laboratories. In addition to leaf-derived inhibitors, root-derived inhibitors have been shown to regulate flowering in black currant and tobacco plants. Aside from the clear role of gibberellin in flowering, none of the other promoters and inhibitors has been identified. Nutrient levels and allocation throughout the plant may also control the time of flowering.

Photoperiod

One major role of environmental signals is to control the timing of the production of florigen and antiflorigen. This link between environmental and internal signals has been most clearly established for photoperiod. The role of day length in the regulation of flowering had been recognized by 1913. The impact of photoperiod on flowering in numerous species soon became apparent.

In the 1930's W. W. Garner and H. A. Allard found an unusually large tobacco plant growing in a field. The plant stood out because it failed to flower; they named it the Maryland Mammoth. Maryland Mammoth cuttings flowered in a greenhouse that December, and subsequent experimentation demonstrated that flowering would occur only when days were short and nights long. The Maryland Mammoth is an example of a *short-day plant*. Short-day plants generally flower in the spring or fall, when day lengths are shorter. Other examples of short-day plants are poinsettias, cockleburs, Japanese morning glories, and chrysanthemums. Plants such as spinach, lettuce, and henbane will flower only if a critical day length is exceeded; they are categorized as *long-day plants* and generally flower during long summer days.

Photoperiodic control mechanisms may be more complex, as in the case of ivy, a *short-and-long-day plant*, which requires at least a twelve-hour photoperiod followed by a photoperiod of at least sixteen hours. Still other plants, including sunflowers and maize, are *day-neutral*: They flower independent of photoperiod. By the 1940's it was established that night length, not day length, is critical in the photoperiodic control of flowering. For example, flowering in the short-day Japanese morning glory can be prevented by a brief flash of light during the critical long night. In comparing short-day and long-day plants, the distinguishing factor is not the absolute length of night required; rather, the difference is whether that night length provides the minimum (short-day plants) or maximum (long-day plants) period of darkness required to permit flowering.

How a plant perceives night length and translates this into the appropriate response in terms of flowering is not fully understood. A pigment known as *phytochrome*, however, plays a critical role. Phytochrome exists in two forms (P_r and P_{fr}) that are interconvertible. P_r absorbs red light and is converted to P_{fr}, which absorbs far-red light and is subsequently converted back to the P_r form of the pigment. Sunlight contains both red and far-red light, and thus an equilibrium between the two forms is achieved. At noon, about 60 percent of the phytochrome is in the P_{fr} form. In the dark, some P_{fr} reverts to P_r, and some breaks down. Because of the absence of red light, no new P_{fr} is generated.

The relationship between phytochrome and photoperiodic control of flowering has been established using night-break experiments with red and far-red light. (In these experiments, darkness is interrupted by momentary exposure to light.) Flowering in the Japanese morning glory, a short-day plant, can be inhibited by a flash of red light (as well as light equivalent to sunlight) in the middle of a long night. Far-red light has no effect. A flash of far-red light following a flash of red negates the inhibitory effect of the red light. In long-day plants, flowering can be induced when the dark period exceeds the critical night length with a red-light night break. Far-red light flashes do not result in flowering. The effect of the red flash can be negated by a subsequent far-red flash. In these experiments, the light flashes alter the relative amounts of P_r and P_{fr}.

Circadian Rhythms

How the perception of light by phytochrome is linked to the production of gibberellin and anthesin in long-day and short-day plants is not clear. One idea is that plants measure the amount of P_{fr} present. Flowering in short-day plants would be inhibited by P_{fr}, and these plants would not flower until very little or no P_{fr} remained after a long night. To flower, long-day plants would require some minimum level of P_{fr}, which would not be available if the nights were too long—but this explanation is not viable because P_{fr} vanishes within a few hours after the dark period begins.

Alternately, levels of phytochrome may influence an internal biological clock that keeps track of time. The clock establishes a free-running *circadian rhythm* of about twenty-four hours; this clock needs to be constantly reset to parallel the natural changes in photoperiod as the seasons change. Phytochrome interacts with the clock to synchronize the rhythm with the environment, a prospect that is strengthened by night-break experiments, where the time of the light flash during the night is critical. In the case of the Japanese morning glory, there are times during the night that a red light flash completely inhibits flowering and other times when it has no effect. In these experiments, the phase of the rhythm of the clock defines the nature of the interaction with phytochrome.

Studies on the relationship between flowering and day length have focused on the production of gibberellin and anthesin. There is evidence that the production of inhibitors by leaves is also under photoperiodic control. This has been demonstrated for photoperiodic tobacco plants and for some peas. In the case of the pea, the inhibitory effect is most obvious for short days, but lower levels of inhibitors continue to be produced as the days grow longer.

Temperature

Plants also use temperature as an environmental clue to ensure flowering. Assessing two environmental factors provides added protection. Some plants have a *vernalization* requirement—a chill that promotes or is essential for flowering. The control point regulated by vernalization may be different for different species. Vernalization has been shown to affect the sensitivity of leaves to respond to photoperiod. In some plants, only leaves initiated after the shoot apex has been chilled will induce flowering after the appropriate photoperiod.

Clearly, the competence of the leaves and shoot apex to respond to environmental and internal signals is crucial to the regulation of flowering. Pea mutants have been identified that have shoot apexes with differential sensitivity to floral induction or inhibition. Another pea mutant has an apex that is not competent to initiate flowers and remains perpetually vegetative. The competence of a day-neutral tobacco apex changes with age. In another species, the apexes of shoots cannot respond to vernalization early in development; this period of time is considered to be the juvenile phase.

A juvenile phase of development is most common in woody perennials. During this time, flowering cannot occur even under optimal environmental conditions. Maturation occurs gradually and may be accompanied by changes in leaf morphology and the ability of cuttings to root. The most significant occurrence is that the plant becomes competent to flower.

Genetic Control of Flowering

The Maryland Mammoth, discussed above, is an example of a short-day plant resulting from a mutation. Mutations that affect flowering time can lead to delayed flowering or to rapid flowering, regardless of photoperiod. Harmful effects of such mutations may include inadequate photosynthetic capability to sustain the crop (when flowering occurs too soon) or susceptibility to pests or cold temperatures at the end of the season (because of flowering too late). A focus of work on genetic modification of plants is the achievement of optimal flowering times.

FLUORESCENT STAINING OF CYTOSKELETAL ELEMENTS

Categories: Cellular biology; methods and techniques

Fluorescent antibody staining is a precise technique for marking elements of the cytoskeleton so they become visible under a microscope. The technique has revealed much about the location and functions of the cytoskeleton within a cell. It also offers some of the most visually appealing of the microscopic images available to biologists.

Cells require an internal system of fibers in order to maintain and change their shape. Perhaps the most straightforward function of the cytoskeleton is to provide cell support, a scaffolding that gives each cell a distinctive three-dimensional shape. Without such support every cell would be shaped like a fried egg. The fibers found in the cytoskeleton serve other functions as well: for example, as rails along which substances shuttle from one part of the cell to another. Equally important is the role of the cytoskeleton in cell movement and change in cell shape. The various cytoskeletal fibers can be rearranged, dissolved, and reconstructed at new locations when need be. The cytoskeleton is also a key component of some highly specialized cell structures, such as *cilia* and *flagella*.

Fluorescent antibody staining techniques allow scientists to observe exactly how various cytoskeletal fiber types are oriented within the cell. This technique has greatly increased knowledge of how the cytoskeleton does its jobs. It is also among the most aesthetically beautiful of all the procedures used by cell biologists.

The Cytoskeleton

The cytoskeleton is composed of three different kinds of fibers, each with different, specialized functions. *Microfilaments* are the smallest (6 nanometers in diameter). They are made up of a protein similar to the actin protein in muscle. It is thus not surprising that microfilaments participate in cell movement and shape changes. They usually are found in bundles just inside the surface of the cell, where they are best situated to help the cell change shape.

Intermediate filaments are somewhat larger. Unlike microfilaments, they seem to serve as passive scaffolding elements within the cell. They typically form an interlaced meshwork in the cytoplasm. The proteins that make up these fibers are subtly different in different kinds of cells; the significance of such variation is not clear.

The largest fibers are called *microtubules* (25 nanometers in diameter). They are hollow spirals of protein building blocks. The microtubules have important, specialized roles in particular regions of cells and at certain times in a cell's life. For example, they help move the chromosomes around during division of one cell into two. They are important components of both cilia and flagella—whiplike structures on the surfaces of some cells that serve as oars to help them swim about or to move substances along their surfaces.

Technique

The properties of the cytoskeleton depend upon its precise three-dimensional architecture within the intact cell. Thus, it is important that the researcher use methods designed to analyze the intact cytoskeleton inside whole cells. The most popular method is to fasten a fluorescent dye onto an antibody. The most commonly used dyes are *rhodamine* (for red fluorescence) and *fluorescein* (for greenish-yellow fluorescence). When such a fluorescent antibody is then added to cells, it can be located using a special *fluorescence microscope*.

Although this procedure works reasonably well, it can be improved by amplifying the signal—that is, by devising a method to add more than one molecule of fluorescent dye to each anticytoskeleton antibody molecule, which will increase the amount of fluorescent light emitted. The brighter light is much easier to see. This can be done using the so-called *secondary-antibody procedure*. A "secondary antibody" must be prepared using the first antibody (against the cytoskeletal protein) as an antigen. This time, the secondary antibody is made fluorescent. The cytoskeletal proteins are then tagged in two steps: First, the primary antibody is added to cells, then the fluorescent secondary antibody is added. Because of the nature of the secondary antibody, numerous molecules of it can adhere to each molecule of primary antibody. In this way, many fluorescent molecules can be attached to each molecule of primary antibody. The result is that the researcher can now see strikingly beautiful images in the fluorescence microscope: brilliantly colored glowing strands of the cytoskeleton, arranged in various patterns depending on what is happening inside the cell.

What Biologists Have Learned

Fluorescent antibody techniques have helped scientists learn that microfilaments and microtubules are dynamic fibers, made up of many kinds of protein (perhaps as many as several hundred), which grow and shrink as necessary. (Intermediate fibers are more stable.) In addition to proteins, whose primary role is to construct the filament itself, there are proteins associated with each fiber type whose role is to make the decisions about when, where, and how fast to assemble or disassemble the filaments. They can be assembled or disassembled like a set of building blocks. The building blocks can be moved from one part of a cell to another quite rapidly if required. Within a few seconds, the distribution of fibers can change dramatically within a living cell. This phenomenon occurs, for example, if a moving cell encounters an obstacle and changes direction. Under certain conditions, microtubule proteins can be added to one end of a microtubule at the same time that they are removed from the opposite end. The result is that the microtubule appears to "move" toward the growing end. This process has been likened to the movement of the tread on a Caterpillar-type tractor.

The first cell function to be definitely attributed to the cell's cytoskeleton was cell division. This process is an elaborate, highly choreographed minuet in which the microtubules move two sets of *chromosomes* (the structures that carry the genetic information) apart from one another and the microfilaments squeeze the cell in two between the chromosome sets. The result is two cells where there was only one, and each has a complete set of genes. How are the activities of the two kinds of fibers coordinated in both time and space, so that this elegant process occurs properly? It is now understood that changing concentrations of calcium atoms inside cells help to coordinate the actions of the several fiber types. Fluorescent antibody staining has revealed that the chromosome-moving microtubules change in length during movement and that they generate a force sufficient to drag the chromosomes through the cell.

Explains the structure of cells and how they work. Chapter 30, on immunity, is a straightforward, basic introduction to how the immune system is constructed and how antibodies are produced in response to antigens. The section on the cytoskeleton in chapter 5 has several good immunofluorescence photographs, drawings of the structure of each fiber type, photographs of cilia, and other useful information.

FOOD CHAIN

Categories: Ecology; food; nutrients and nutrition

The food chain concept allows ecologists to interconnect the organisms living in an ecosystem and to trace mathematically the flow of energy from plants through animals to decomposers.

The food chain concept provides the basic framework for production biology and has major implications for agriculture, wildlife biology, and calculating the maximum amount of life that can be supported on the earth. As early as 1789, naturalists such as Gilbert White described the many sequences of animals eating plants and themselves being eaten by other animals. However, the use of the term "food chain" dates from 1927, when Charles Elton described the implications of the food chain and food web concept in a clear manner. His solid exposition advanced the study of two important biological concepts: the complex organization and interrelatedness of nature, and energy flow through ecosystems.

Food Chains in Ecosystem Description

Stephen Alfred Forbes, founder of the Illinois Natural History Survey, contended in 1887 that a lake comprises a system in which no organism or process can be understood unless its relationship to all the parts is understood. Forty years later, Elton's food chains provided an accurate way to diagram these relationships. Because most organisms feed on several food items, food chains were cross-linked into complex webs with predictive power. For instance, algae in a lake might support an insect that in turn was food for bluegill. If unfavorable conditions eliminated this algae, the insect might also disappear. However, the bluegill, which fed on a wider range of insects, would survive because the loss of this algae merely increases the pressure on the other food sources. This detailed linkage of food chains advanced agriculture and wildlife management and gave scientists a solid overview of living systems. When Arthur George Tansley penned the term *ecosystem* in the 1930's, it was food-chain relationships that described much of the equilibrium of the ecosystem.

Digital Stock

Unlike calories, which are reduced at each step in a food chain, some toxic substances become more concentrated as the molecules are passed along. The pesticide DDT provides the most notorious example of biological magnification: DDT was found to be deposited in animal body fat in ever-increasing concentrations as it moved up the food chain to species such as pelicans. High levels of DDT in these birds broke down steroid hormones and interfered with eggshell formation.

Today most people still think of food chains as the basis for the "balance of nature." This phrase dates from the controversial 1960 work of Nelson G. Hairston, Frederick E. Smith, and Lawrence B. Slobodkin. They proposed that if only grazers and plants are present, grazing limits the plants. With predators present, however, grazers are limited by predation, and the plants are free to grow to the limits of the nutrients available. Such explanations of the "balance of nature" were commonly taught in biology books throughout the 1960's and 1970's.

Food Chains in Production Biology

Elton's explanation of food chains came just one year after Nelson Transeau of Ohio State University presented his calculations on the efficiency with which corn plants converted sunlight into plant tissue. Ecologists traced this flow of stored chemical energy up the food chain to herbivores that ate plants and on to *carnivores* that ate *herbivores*. Food chains therefore undergirded the new "production biology" that placed all organisms at various *trophic levels* and calculated the extent to which energy was lost or preserved as it passed up the food chain.

With data accumulating from many ecologists, Elton extended food chains into a pyramid of numbers. The *food pyramid*, in which much plant tissue supports some herbivores that are in turn eaten by fewer carnivores, is still referred to as an *Eltonian pyramid*. In 1939 August Thienemann added *decomposers* to reduce unconsumed tissues and return the nutrients of all levels back to the plants. Early pyramids were based on the amount of living tissues, or *biomass*.

Calculations based on the amount of chemical energy at each level, as measured by the heat released when food is burned (calories), provided even more accurate budgets. Because so much energy is lost at each stage in a food chain, it became obvious that this inefficiency was the reason food chains are rarely more than five or six links long and why large, fierce animals are uncommon. It also became evident that because the earth intercepts a limited amount of sunlight energy per year, there is a limit on the amount of plant life—and ultimately upon the amount of animal life and decomposers—that can be fed. Food chains are also important in the accounting of carbon, nitrogen, and water cycling.

Value of Food Chains in Environmental Science

Unlike calories, which are dramatically reduced at each step in a food chain, some toxic substances become more concentrated as the molecules are passed along. The concentration of molecules along the food chain was first noticed by the Atomic Energy Commission, which found that radioactive iodine and strontium released in the Columbia River were concentrated in tissue of birds and fish. However, the pesticide DDT provided the most notorious example of biological magnification: DDT was found to be deposited in animal body fat in ever-increasing concentrations as it moved up the food chain to ospreys, pelicans, and peregrine falcons. High levels of DDT in these birds broke down steroid hormones and interfered with eggshell formation.

Because humans are *omnivores*, able to feed at several levels on the food chain (that is, both plants and other animals), it has been suggested that a higher world population could be supported by humans moving down the food chain and becoming vegetarians. A problem with this argument is that much grazing land worldwide is unfit for cultivation, and therefore the complete cessation of pig or cattle farming does not necessarily free up substantial land to grow crops.

While the food chain and food web concepts are convenient theoretical ways to summarize feeding interactions among organisms, real field situations have proved far more complex and difficult to measure. Animals often switch diet between larval and adult stages, and they are often able to shift food sources widely. It is often difficult to draw the boundaries of food chains and food webs.

FOREST AND RANGE POLICY

Categories: Economic botany and plant uses; ecosystems; forests and forestry

Forest and range policies are laws protecting forests and rangelands. Such policies usually seek to sustain and protect biodiversity while setting guidelines for the sustainable use of natural resources.

Many national governments have established forest and range policies. *Rangeland*, land that supplies forage for grazing and browsing animals, covers almost one-half of the ice-free land on earth. More than three billion cattle, sheep, goats, camels, buffalo, and other domestic animals graze on rangelands. These animals are important in converting forages into milk and meat, which provide nourishment for people around the world. Forests cover almost 30 percent of the earth and provide humans with lumber, fuel woods, food products, latex rubber, and valuable chemicals that constitute prescription and nonprescription drugs. Rangelands and forests also function as important ecosystems that help provide food and shelter for wildlife, control erosion, and purify the atmosphere. Forests and rangelands have been undergoing destruction and degradation at alarming rates at the hands of humans.

Protecting Forests and Rangelands

The nearly 15 billion acres of forest that originally existed on the earth have been reduced to approximately 11 billion acres by human conversion of land to cropland, pastureland, cities, and nonproductive land. Forests, if properly maintained or left alone, are the most productive and self-sustaining ecosystems that land can support. Tropical rain forests are the natural habitat for at least 50 percent, and possibly up to 90 percent, of the species on earth. In the late 1990's, Harvard biologist Edward O. Wilson stated that 25 percent of the earth's species could become extinct by the year 2050 if the current rate of tropical forest destruction were not stopped.

Many national governments have established policies for protecting forest habitats and the biological diversity found within them. National parks and reserves provide protection for both forests and rangelands. Some countries have laws that prohibit clearing, burning, or logging of particular forests.

China, which suffered from erosion and floods as a result of centuries of deforestation, began an impressive *reforestation* campaign during the 1990's, planting almost 11 million acres of new trees. Korea attained 70 percent reforestation after losing almost all its forested land in a civil war during the 1950's. Japan has enacted strict environmental laws, which have allowed it to reforest 68 percent of its land area. Japan has relied upon imported timbers in order to allow its new forest projects to flourish. Even with such worldwide success in reforestation, it is estimated that protection and sustainable management of forests and rangelands still need to be increased by a factor of three if forests are to be saved.

Multiple Use

Protecting forestland involves an interdisciplinary approach. In the United States, 191 million acres of forestland are managed by the U.S. Forest Service. The Forest and Rangeland Renewable Resource Planning Act (RPA) of 1974 and the National Forest Management Act (NFMA) of 1976 mandated management plans for forests and rangelands to ensure that resources would be available on a sustained basis. Management policies must sustain and protect biodiversity; old-growth forests; riparian areas; threatened, endangered, and sensitive species; rangeland; water and air quality; access to forests; and wildlife habitat.

The Forest Service provides inexpensive grazing lands for more than three million cattle and sheep every year, supports multimillion-dollar mining operations, maintains a network of roads eight times longer than the U.S. interstate highway system, and allows access to almost one-half of all national forest land for commercial logging. The Forest Service is responsible for producing plans for the multiple use of national lands.

Sustainability policies require that the net productive capacity of the forest or rangeland does not decrease with multiple use. This involves making sure that soil productivity is maintained by keeping erosion, compaction, or displacement by mining or logging equipment or other motorized vehicles within tolerable limits. It further requires that a large percentage of the forest remains undeveloped so that soils and habitats, as well as tree cover, will remain undisturbed and in their natural state.

The RPA and NFMA, along with the Endangered Species Act (ESA) of 1973, mandate policies that encourage the proliferation of species native to and currently living in the forest. Natural ecosystem processes are followed to ensure their survival. Even though forests and rangelands are required to be multiple-use areas, policy maintains that there can be no adverse impact to threatened, endangered, or sensitive species. Species habitats within the forest are to remain well distributed and free of barriers that can cause fragmentation of animal populations and ultimately species loss. If a forest contains fragmented areas created by human activity, corridors that connect the forest patches are constructed. In this way species are not isolated from one another, and viable populations can exist.

The Forest Service creates artificial habitats to encourage the survival of species in cases of natural disaster. When Hurricane Hugo devastated the Francis Marion National Forest in South Carolina in 1989, winds snapped 90 percent of the trees with active woodpecker cavities in some areas of the forest. The habitat destruction caused 70 percent of the red-cockaded woodpecker population to disappear. The Forest Service and university researchers created nesting and roosting cavities to save the woodpeckers. Within a four-year period, the population had dramatically recovered.

Timber, Oil, and Mineral Leasing

Logging activities in forests are covered by the Resource Planning Act of 1990. Forested land must be evaluated for its ability to produce commercially usable timber without negative environmental impact. There must be reasonable assurance that stands managed for timber production can be adequately restocked within five years of the final harvest. Further, no irreversible resource damage is allowed to occur. Policy further requires use of the *silviculture* practices that are best suited to the land management objectives of the area. Cutting practices are then monitored. The 1990's were characterized by a trend toward restricting logging methods in order to protect habitats and preserve older stands of trees. In the 1993 Renewable Resource Assessment update, the Forest Service found that timber mortality, at 24.3 percent, was still interfering with biological diversity. Some forested areas were withdrawn from timber production because of their fragility.

Multiple use under the NFMA allowed forests to be available for oil and gas leasing. Certain lands were exempted from mineral exploration by acts of Congress or executive authority. However, the search for and production of mineral and energy sources remained under the jurisdiction of the Forest Service, which was charged to provide access to national forests for mineral resources activities. The Federal On-Shore Oil and Gas Leasing Reform Act of 1987 gave the Forest Service more authority in making lease decisions.

Pest and Weed Control

Pesticides are sometimes used during attempts to ensure the health of forestland. Policy in the United States requires the use of safe pesticides and encourages the development of an *integrated pest management* (IPM) plan. Any decision to use a particular pesticide must be based on an analysis of its effectiveness, specificity, environmental impact, economic efficiency, and effects on humans. The application and use of pesticides must be coordinated with federal and state fish and wildlife management agencies. Pesticides can be applied only to areas that are designated as wilderness when their use is necessary to protect or restore resources in the area. Other methods of controlling disease include removing diseased trees and vegetation from the forest, cutting infected areas from plants and removing the debris, treating trees with antibiotics, and developing disease-resistant plant varieties.

Forest Service policy on integrated pest management was revised in 1995 to emphasize the importance of integrating noxious weed management into the forest plan for ecosystem analysis and assessment. Noxious weed management must be coordinated in cooperation with state and local government agencies as well as private landowners. Noxious weeds include invasive, aggressive, or harmful nonindigenous or exotic plant species. They are generally opportunistic, poisonous, toxic, parasitic, or carriers of insects or disease. The Forest Service is responsible for the prevention, control, and eradication of noxious weeds in national forests and grasslands.

In North Dakota, one strategy for promoting weed-free forests uses goats to help control leafy spurge. The goats graze on designated spurge patches during the day and return to portable corrals during the night. A five-year study found that the goats effectively reduced stem densities of spurge patches to the extent that native livestock forage plants were able to reestablish themselves.

A strategy that has been implemented in Wyoming, Colorado, Idaho, Utah, and Montana requires pack animals on national forest land to eat state-certified weed-free forage. Another strategy involves the use of certified weed-free straw and gravel in construction and rehabilitation efforts within national forests. *Biocontrols*, *herbicides*, and *controlled burning* are also commonly used during IPM operations in forests.

Other Protection Issues

Natural watercourses and their banks are referred to as *riparian areas*. The plant communities that grow in these areas often serve as habitats for a large variety of animals and birds and also provide shade, bank stability, and filtration of pollution sources. It is therefore important that these areas remain in good ecological condition. Riparian areas and streams are managed according to legal policies for *wetlands*, floodplains, water quality, endangered species, and wild and scenic rivers.

Dirt roads in national forests are often closed when road sediment pollutes riparian areas and harms fish populations. Forest and rangeland roads are also closed to prevent disruption of breeding or nesting colonies. Seemingly harmless human endeavors—such as seeking mushrooms, picking berries, or hiking in the forest—can cause problems for calving elk and nesting eagles. Therefore, the amount of open roads in the forest is being reduced in order to preserve habitat and return land to a more natural state.

Fire management is important to healthy forests. In many cases fires are prevented or suppressed, but prescribed fires are used to protect and maintain ecosystem characteristics. Some conifers, such as the giant sequoia and the jack pine, will release their seeds for germination only after being exposed to intense heat. Lodgepole pines will not release their seeds until they have been scorched by fire. Ecosystems that depend on the recurrence of fire for regeneration and balance are called *fire climax ecosystems*. Prescribed fires are used as a management tool in these areas, which include some *grasslands* and pine habitats.

In 1964 the U.S. Congress passed the Wilderness Act, which mandates that certain federal lands be designated as wilderness areas. These lands must remain in their natural condition, provide solitude or primitive types of recreation, and be at least 5,000 acres in area. They usually contain ecological or geological systems of scenic, scientific, or historical value. No roads, motorized vehicles, or structures are allowed in these areas. Furthermore, no commercial activities are allowed in wilderness areas except livestock grazing and limited mining endeavors that began before the area received wilderness designation.

Grazing Practices and Problems

Approximately 42 percent of the world's rangeland is used for grazing livestock; much of the rest is too dry, cold, or remote to serve such purposes. It is common for these rangelands to be converted into croplands or urban developments. The rate of loss for grazing lands worldwide is three times that of tropical forests, and the area lost is six times that of tropical forests. There are more threatened plant species in North American rangelands than any other major biome.

Rangeland grasses are known for their deep, complex root systems, which makes the grasses hard to uproot. When the tip of the leaf is eaten, the plant quickly regrows. Each leaf of grass on the rangeland grows from its base, and the lower half of the plant must remain for the plant to thrive and survive. As long as only the top half of the grass is eaten, grasses serve as renewable resources that can provide many years of grazing. Each type of grassland is evaluated based on grass species, soil type, growing season, range condition, past use, and climatic conditions. These conditions determine the herbivore *carrying capacity*, or the maximum number of grazing animals a rangeland can sustain and remain renewable.

Overgrazing occurs when herbivore numbers exceed the land's carrying capacity. Grazing animals tend to eat their favorite grasses first and leave the tougher, less palatable plants. If animals are allowed to do this, the vegetation begins to grow in patches, allowing cacti and woody bushes to move into vacant areas. As native plants disappear from the range, weeds begin to grow. As the nutritional level of the forage declines, hungry animals pull the grasses out by their roots, leaving the ground bare and susceptible to damage from hooves. This process initiates the desertification cycle. With no vegetation present, rain quickly drains off the land and does not replenish the groundwater. This makes the soil vulnerable to erosion. Almost one-third of rangeland in the world is degraded by overgrazing. Among the countries suffering severe range degradation are Pakistan, Sudan, Zambia, Somalia, Iraq, and Bolivia.

The United States has approximately 788 million acres of rangeland. This represents almost 34 percent of the land area in the nation. More than one-half of the rangeland is privately owned, while approximately 43 percent is publicly owned and managed by the Forest Service and the Bureau of Land Management (BLM). State and local governments manage the remaining 5 percent. Efforts to preserve rangelands include close monitoring of carrying capacity and removal of substandard ranges from the grazing cycle until they recover. New grazing practices, such as cattle and sheep rotation, help to preserve the renewable quality of rangelands. Grazing is managed with consideration to season, moisture, and plant growth conditions. Noxious weed encroachment is controlled, and native forages and grasses are allowed to grow.

Most rangelands in the United States are shortgrass prairies located in the western part of the nation. These lands are further characterized by thin soils and low annual precipitation. They undergo numerous environmental stresses. Woody shrubs, such as mesquite and prickly cactus, often invade and take over these rangelands as overgrazing or other degradation occurs. Such areas are especially susceptible to desertification. Recreational vehicles, such as motorcycles, dune buggies, and four-wheel-drive trucks, can damage the vegetation on ranges. According to the 1993 Renewable Resource Assessment update, many of the rangelands in the United States were in unsatisfactory condition.

Steps to restore healthy rangelands include restoring and maintaining riparian areas and priority watersheds. These areas are monitored on a regular basis, and adjustments are made if their health is jeopardized by sediment from road use or degradation of important habitats caused by human activity. The Natural Resources Conservation program is teaching private landowners how to burn unwanted woody plants on rangelands, reseed with perennial grasses that help hold water in the soil, and rotate grazing of cattle and sheep on rangelands so that the land is able to recover and thrive. Such methods have proven to be successful.

FOREST FIRES

Categories: Ecology; ecosystems; environmental issues; forests and forestry

Whether natural or caused by humans, fires destroy life and property in forestlands but are also vital to the health of forests.

Evidence of forest fires is routinely found in soil samples and tree borings. The first major North American fires in the historical record were the Miramichi and Piscataquis fires of 1825. Together, they burned 3 million acres in Maine and New Brunswick. Other U.S. fires of significance were the Peshtigo fire in 1871, which raged over 1.28 million acres and took fourteen hundred human lives in Wisconsin; the fire that devastated northern Idaho and northwestern Montana in 1910 and killed at least seventy-nine firefighters; and a series of fires that joined forces to sweep across one-third of Yellowstone National Park in 1988.

Fire Behavior

Fires need heat, fuel, and oxygen. They spread horizontally by igniting particles at their edge. At first, flames burn at one point, then move outward, accumulating enough heat to keep burning on their own. Topography and weather affect fire behavior. Fires go uphill faster than downhill because warm air rises and preheats the uphill fuels. Vegetation on south- and west-facing slopes receives maximal sunlight and so is drier and burns more easily. Heat is pulled up steep, narrow canyons, as it is up a chimney, increasing heat intensity. For several reasons, only one-third of the vegetation within a large fire usually burns. This mosaic effect may be caused by varied tree species that burn differently, old burns that stop fire, strong winds that blow the fire to the leeward side of trees, and varied fuel moisture.

Forest Management

One of the early criteria of forest management was fire protection. In the second quarter of the twentieth century, lookout towers, firebreaks, and trails were built to locate fires as quickly as possible. Low fires that otherwise would have burned through the forest at ground level and cleared out brush every five to twenty-five years were suppressed. As a result, the natural cycle of frequent fires moving through an area was broken. Fallen trees, needles, cones, and other debris collected as kindling on the forest floor, rather than being incinerated every few years.

It took foresters and ecologists fifty years to realize that too much fire suppression was as bad as too little. Infrequent fires cause accumulated kindling to burn hot and fast and explode into treetops. The result is a devastating *crown fire*, a large fire that advances as a single front. Burning embers of seed cones and sparks borne by hot, strong winds created within the fire are tossed into unburned areas to start more fires.

In the 1970's *prescribed burning* was added to forest management techniques used to keep forests healthy. Fires set by lightning are allowed to burn when the weather is cool, the area isolated, and the risk of the fire exploding into a major fire low. More than 70 percent of prescribed burning takes place in the southeastern states, where natural fires burn through an area more frequently than in the West.

Causes of Fires

Forest fires may be caused by natural events or human activity. Most natural fires are started by lightning strikes. Dozens of strikes can be recorded from one lightning storm. When a strike seems likely, fire spotters watch for columns of smoke, and small spotter planes will fly over the area, looking for smoke. Many of the small fires simply smoulder and go out, but if the forest is dry, multiple fires can erupt from a single lightning storm.

The majority of forest fires are human-caused, and most are the result of carelessness rather than arson. Careless campers may leave a campsite without squelching their campfire completely, and winds may then whip the glowing embers into flames. A smoker may toss a cigarette butt from a car window. Sparks from a flat tire riding on the rim may set fire to vegetation alongside the highway. The sun shining through a piece of broken glass left by litterers may ignite dry leaves.

In some areas, prescribed fires are set in an attempt to re-create the natural sequence of fire. In Florida, prescribed burns provide wildlife habitat by opening up groves to encourage healthy growth. Other fires start accidentally but are allowed to burn until they reach a predetermined size.

Benefits of Fire

Some plant species require very high temperatures for their seed casings to split for germination. After fire periodically sweeps through the forest, seeds will germinate. Other species, such as the fire-resistant ponderosa pine, require a shallow layer of decaying vegetable matter in which to root. Fires burn excess debris and small trees of competing species and leave an open environment suitable for germination. Dead material on the forest floor is processed into nutrients more quickly by fire than by decay, and in a layer of rich soil, plants will sprout within days to replace those destroyed in the fire.

Fire's Disadvantages

Erosion is one of the devastating effects of a fire. If the fuels burn hot, tree oils and resins can be baked into the soil, creating a hard shell that will not absorb water. When it rains, the water runoff gathers mud and debris, creating flash floods and extreme stream *sedimentation*. Culverts and storm drains fill with silt, and streams flood and change course. Fish habitat is destroyed, vegetation sheltering stream banks is ripped away, and property many miles downstream from the forest is affected.

When a fire passes through timber it generally leaves pockets of green, although weakened, stands. Forest pests, such as the bark beetle, are attracted to the burned trees and soon move to the surviving trees, weakening them further. Healthy trees outside the burn area may also fall to pest infestation unless the burned trees are salvaged before pests can take hold. The ash and smoke from hot, fast-burning forest fires can be transported for

Image Not Available

miles, affecting air quality many miles from the actual fire.

Relationship to Timber Resources

Although a prescribed fire is an attempt to duplicate natural fire, it is not as efficient, because private and commercial property within the fire path must be protected. Once a fire has occurred, burned timber deteriorates quickly, either through insect infestation or blueing—a mold that stains the wood. Private landowners can move quickly to salvage fire-damaged trees and plant new seedlings to harness erosion. On federal land, regulations governing the salvage of trees can delay logging of the burned snags until deterioration makes it uneconomical to harvest them.

Fire Fighting

In fire fighting, bulldozers are used to cut fire lines ahead of the approaching fire, and fuels between fire lines and the fire are backburned. Helicopters and tanker planes drop water with a fire-retardant additive, or bentonite, a clay, at the head of the fire to smother fuels. Firefighters are equipped with fire shelters in the form of aluminized pup tents, which they can pull over themselves if a fire outruns them. Despite technological advances, one of the best tools for fighting fires—along with the shovel—remains the pulaski, a combination ax and hoe, first produced commercially in 1920. This tool, in the hands of on-the-ground firefighters, is used to cut fire breaks and to throw dirt on smoldering debris.

Public Policy and Public Awareness

Since the early twentieth century, forest fires have engendered public policy in the United States. In the aftermath of major fires in 1903 and 1908 in Maine and New York, state fire organizations and private timber protective associations were formed to provide fire protection. These, in turn, contributed to the Weeks Act of 1911, which permitted cooperative fire protection between federal and state governments.

People who make their homes in woodland settings in or near forests face the danger of forest fire, and government agencies provide information to help people safeguard themselves and their property. Homes near forests should be designed and landscaped with fire safety in mind, using fire-resistant or noncombustible materials on the roof and exterior. Landscaping should include a clear safety zone around the house. Hardwood trees, less flammable than conifers, and other fire-resistant vegetation should be planted.

FOREST MANAGEMENT

Categories: Disciplines; economic botany and plant uses; forests and forestry

Forest management includes reforestation programs as well as techniques to manage logging practices, provide grazing lands, support mining operations, maintain infrastructure networks, or slow the destruction of rain forests.

Forests provide lumber for buildings, wood fuel for cooking and heating, and raw materials for making paper, latex rubber, resin, dyes, and essential oils. Forests are also home to millions of plants and animal species and are vital in regulating climate, purifying the air, and controlling water runoff. A 1993 global assessment by the United Nations Food and Agriculture Organization (FAO) found that three-fourths of the forests in the world still have some tree cover, but less than one-half of these have intact forest ecosystems. *Deforestation* is occurring at an alarming rate, and management practices are being sought to try to halt this destruction.

Thousands of years ago, forests and woodlands covered almost 15 billion acres of the earth. Approximately 16 percent of the forests have been cleared and converted to pasture, agricultural land, cities, and nonproductive land. The remaining 11.4 billion acres of forests cover about 30 percent of the earth's land surface. Clearing forests has severe environmental consequences. It reduces the overall productivity of the land, and nutrients and biomass stored in trees and leaf litter are lost. Soil once covered with plants, leaves, and snags becomes prone to erosion and drying. When forests are cleared, habitats are destroyed and biodiversity is greatly diminished. Destruction of forests causes water to drain off the land instead of being released into the atmosphere by transpiration or percolation into groundwater. This can cause major changes in the hydrologic cycle and ultimately in the earth's climate. Because forests remove a large amount of carbon dioxide from the air, the clearing of forests causes more carbon dioxide to remain, thus upsetting the delicate balance of atmospheric gases.

Rain Forests

Rain forests provide habitats for at least 50 percent (some estimates are as high as 90 percent) of the total stock of plant, insect, and other animal species on earth. They supply one-half of the world's annual harvest of hardwood and hundreds of food products, such as chocolate, spices, nuts, coffee, and tropical fruits. Tropical rain forests also provide the main ingredients in 25 percent of prescription and nonprescription drugs, as well as 75 percent of the three thousand plants identified as containing chemicals that fight cancer. Industrial materials, such as natural latex rubber, resins, dyes, and essential oils, are also harvested from tropical forests.

Tropical forests in Asia, Africa, and Latin America are rapidly being cleared to produce pastureland for large cattle ranches, establish logging operations, construct large plantations, grow narcotic plants, develop mining operations, or build dams to provide power for mining and smelting operations. In 1985 the FAO's Committee on Forest Development in the Tropics developed the Tropical Forestry Action Plan to combat these practices, develop sustainable forest methods, and protect precious ecosystems. Fifty nations in Asia, Africa, and Latin America have adopted the plan.

Several management techniques have been successfully applied to slow the destruction of tropical forests. *Sustainable logging* practices and *reforestation* programs have been established on lands that allow timber cutting, with complete bans of logging on virgin lands. Certain regions have set up extractive reserves to protect land for the native people who live in the forest and gather latex rubber and nuts from mature trees. Sections of some tropical forests have been preserved as *national reserves*, which attract tourists while preserving trees and biodiversity.

Developing countries have been encouraged to protect their tropical forests by using a combination of *debt-for-nature swaps* and *conservation easements*. In debt-for-nature swaps, tropical countries act as custodians of the tropical forest in exchange for foreign aid or relief from debt. Conservation easement involves having another country, private organization, or consortium of countries compensate a tropical country for protecting a specific habitat.

Another management technique involves putting large areas of the forest under the control of indigenous people who use *slash-and-burn agriculture* (also known as swidden or milpa agriculture). This traditional, productive form of agriculture follows a multiple-year cycle. Each year farmers clear a forest plot of several acres in size to allow the sun to penetrate to the ground. Leaf litter, branches, and fallen trunks are burned, leaving a rich layer of ashes. Fast-growing crops, such as bananas and papayas, are planted and provide shade for root crops, which are planted to anchor the soil. Finally, crops such as corn and rice are planted. Crops mature in a staggered sequence, thus providing a continuous supply of food. Use of mixed perennial *polyculture* helps prevent insect infestations, which can destroy *monoculture* crops. After one or two years, the forest begins to take over the agricultural plot. The farmers continue to pick the perennial crops but essentially allow the forest to reclaim the plot for the next ten to fifteen years before clearing and planting the area again. Slash-and-burn agriculture can, however, post hazards: A drought in Southeast Asia in 1997 caused fires to burn for months when monsoon rains did not materialize, polluting the air and threatening the health of millions of Indonesians. In 1998, previous abuse of the technique resulted in flooding and mudslides in Honduras after the onset of Hurricane Mitch.

U.S. Forest Management

Forests cover approximately one-third of the land area of the continental United States and comprise 10 percent of the forests in the world. Only about 22 percent of the commercial forest area in the United States lies within national forests. The rest is primarily managed by private companies that grow trees for commercial logging. Land managed by the U.S. Forest Service provides inexpensive grazing lands for more than three million cattle and sheep every year, supports multimillion-dollar mining operations, and consists of a network of roads eight times longer than the U.S. interstate highway system. Almost 50 percent of national forest land is open for commercial logging. Nearly 14 percent of the timber harvested in the United States each year comes from national forest lands. Total wood production in the United States has caused the loss of more than 95 percent of the old-growth forests in the lower forty-eight states. This loss includes not only high-quality wood but also a rich diversity of species not found in early-growth forests.

National forests in the United States are required by law to be managed in accordance with principles of *sustainable yield*. Congress has mandated that forests be managed for a combination of uses, including grazing, logging, mining, recreation, and protection of watersheds and wildlife. Healthy forests also require protection from pathogens and insects. *Sustainable forestry*, which emphasizes biological diversity, provides the best management. Other management techniques include removing only infected trees and vegetation, cutting infected areas and removing debris, treating trees with antibiotics, developing disease-resistant species of trees, using insecticides and fungicides, and developing integrated pest management plans.

Two basic systems are used to manage trees: even-aged and uneven-aged. *Even-aged management* involves maintaining trees in a given stand that are about the same age and size. Trees are harvested, then seeds are replanted to provide for a new even-aged stand. This method, which tends toward the cultivation of a single species or monoculture of trees, emphasizes the mass production of fast-growing, low-quality wood (such as pine) to give a faster economic return on investment. Even-aged management requires close supervision and the application of both fertilizer and pesticides to protect the monoculture species from disease and insects.

Uneven-aged management maintains trees at many ages and sizes to permit a natural regeneration process. This method helps sustain biological diversity, provides for long-term production of high-quality timber, allows for an adequate economic return, and promotes a multiple-use approach to forest management. Uneven-aged management also relies on selective cutting of mature trees and reserves *clear-cutting* for small patches of tree species that respond favorably to such logging methods.

Harvesting Methods

The use of a particular tree-harvesting method depends on the tree species involved, the site, and whether even-aged or uneven-aged management is being applied. *Selective cutting* is used on intermediate-aged or mature trees in uneven-aged forests. Carefully selected trees are cut in a prescribed stand to provide for a continuous and attractive forest cover that preserves the forest ecosystem.

Shelterwood cutting involves removing all the mature trees in an area over a period of ten years. The first harvest removes dying, defective, or diseased trees. This allows more sunlight to reach the healthiest trees in the forest, which will then cast seeds and shelter new seedlings. When the seedlings have turned into young trees, a second cutting removes many of the mature trees. Enough mature trees are left to provide protection for the younger trees. When the young trees become well established, a third cutting harvests the remaining mature trees, leaving an even-aged stand of young trees from the best seed trees to mature. When done correctly, this method leaves a natural-looking forest and helps reduce soil erosion and preserve wildlife habitat.

Seed-tree cutting harvests almost every tree at one site, with the exception of a few high-quality seed-producing and wind-resistant trees, which will function as a seed source to generate new crops. This method allows a variety of species to grow at one time and aids in erosion control and wildlife conservation.

Clear-cutting removes all the trees in a single cutting. The clear-cut may involve a strip, an entire stand, or patches of trees. The area is then replanted with seeds to grow even-aged or tree-farm varieties. More than two-thirds of the timber produced in the United States, and almost one-third of the timber in national forests, is harvested by clear-cutting. A clear-cut reduces biological diversity by destroying habitat. It can make trees in bordering areas more vulnerable to winds and may take decades to regenerate.

Forest Fires

Forest fires can be divided into three types: surface, crown, and ground fires. *Surface fires* tend to burn only the undergrowth and leaf litter on the forest floor. Most mature trees easily survive, as does wildlife. These fires occur every five years or so in forests with an abundance of ground litter and help prevent more destructive crown and ground fires. Such fires can release and recycle valuable mineral nutrients, stimulate certain plant seeds, and help eliminate insects and pathogens.

Crown fires are very hot fires that burn both ground cover and tree tops. They normally occur in forests that have not experienced fires for several decades. Strong winds allow these fires to spread from deadwood and ground litter to treetops. They are capable of killing all vegetation and wildlife, leaving the land prone to erosion.

Ground fires are more common in northern bogs. They can begin as surface fires but burn peat or partially decayed leaves below the ground surface. They can smolder for days or weeks before anyone notices them, and they are difficult to douse.

Natural forest fires can be beneficial to some plant species, including the giant sequoia and the jack pine trees, which release seeds for germination only after being exposed to intense heat. Grassland and coniferous forest ecosystems that depend on fires to regenerate are called fire climax ecosystems.

They are managed for optimum productivity with prescribed fires.

The Society of American Foresters has begun advocating a concept called *new forestry*, in which ecological health and biodiversity, rather than timber production, are the main objectives of forestry. Advocates of new forestry propose that any given site should be logged only every 350 years, wider buffer zones should be left beside streams to reduce erosion and protect habitat, and logs and snags should be left in forests to help replenish soil fertility. Proponents also wish to involve private landowners in the cooperative management of lands.

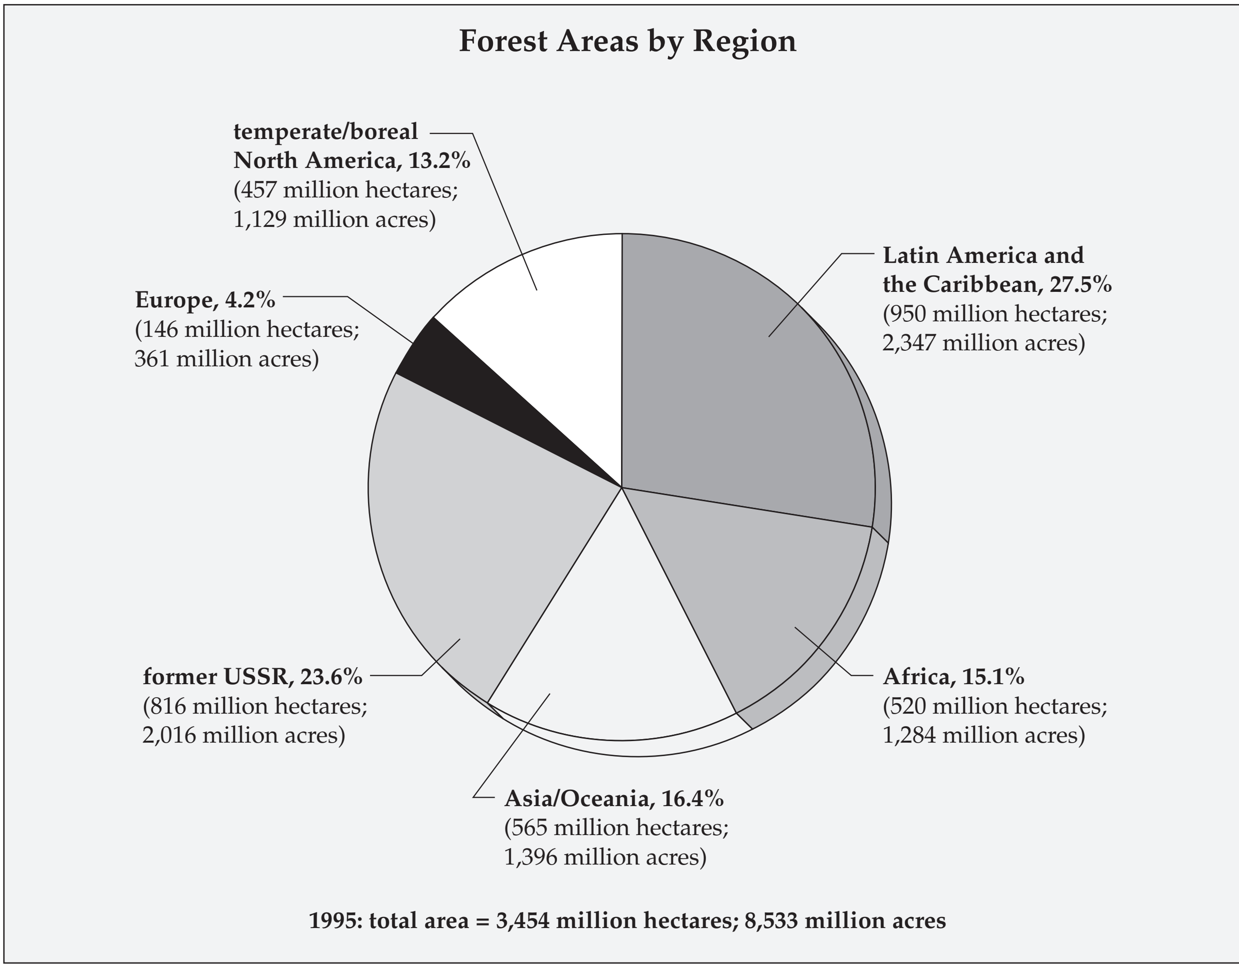
FORESTS

Categories: Ecosystems; forests and forestry

Forests are complex ecosystems in which trees are the dominant type of plant. There are three main forest biomes: tropical, temperate, and boreal.

Both humans and animals depend on forests for food, shelter, and other resources. Forests once covered much of the world and are still found from the equator to the Arctic regions. A forest may vary in size from only a few acres to thousands of square miles, but generally any natural area in which trees are the dominant type of plant can be considered a forest. For a plant to be called a tree, the standard



Source: Data are from United Nations Food and Agriculture Organization (FAOSTAT Database, 2000).

definition requires that the plant must attain a mature height of at least 8 feet (about 3 meters), have a woody stem, and possess a distinct crown. Thus, size makes roses shrubs and apples trees, even though apples and roses are otherwise close botanical relatives. Foresters generally divide the forests of the world into three general categories: *tropical*, *temperate*, and *boreal*.

Tropical Rain Forest

The tropical rain forest is discussed in depth elsewhere (see "Rain-forest biomes"). In brief, it is a forest consisting of a dizzying variety of trees, shrubs, and other plants that remain green year-round. The growth is lush and usually includes both a dense *canopy* formed by the crowns of the largest trees and a thick *understory* of smaller trees and shrubs. Growth is often continuous, rather than broken into periods of dormancy and active growth, so that fruiting trees are occasionally seen bearing blossoms and mature fruit simultaneously.

Temperate Forest

The temperate forest lies between the tropical forest and the boreal, or northern, forest. The forests of the Mediterranean region of Europe as well as the forests of the southern United States are temperate forests. Trees in temperate forests can be either *deciduous* or *coniferous*. Although coniferous trees are generally thought of as evergreen, the distinction between types is actually based on seed production and leaf shape. Coniferous trees, such as spruces, pines, and hemlocks, produce seeds in cones and have needle-like leaves. Deciduous trees, such as maples, poplars, and oaks, have broad leaves and bear seeds in other ways. Some conifers, such as tamarack, do change color and drop their needles in the autumn, while some deciduous trees, particularly in the southerly regions of the temperate forest, are evergreen.

Deciduous trees are also referred to as *hardwoods*, while conifers are *softwoods*, a classification that refers more to the typical density of the wood than to how difficult it is to nail into it. Softwoods are lower in density and will generally float in water while still green. Hardwoods are higher in density on average and will sink.

Like tropical forests, temperate forests can be quite lush. While the dominant species vary from area to area, depending on factors such as soil types and available rainfall, a dense understory of shade-tolerant species often thrives beneath the canopy. Thus, a mature temperate forest may have thick stands of rhododendrons 20 to 30 feet (6 to 9 meters) high thriving in the shade of 80-foot (24-meter) oaks and tulip poplars. As the temperate forest approaches the edges of its range and the forest makes the transition to boreal, the understory thins out, disappearing almost completely or consisting only of low shrubs. Even in temperate forests, the dominant species may prevent an understory from forming. Stands of southern loblolly pine, for example, often have a parklike feel, as the thick mulch created by fallen needles chokes out growth of other species.

Digital Stock

A rain forest in Washington State.

Boreal Forest

The boreal forest, which lies in a band across the northern United States, Canada, northern Europe, and northern Asia, is primarily a coniferous forest. The dominant species are trees such as white spruce, hemlock, and white pine. Mixed stands of northern hardwoods, such as birch, sugar maple, and red oak, may be found along the southern reaches of the boreal forest. As the forest approaches the Arctic, trees are fewer in type, becoming primarily spruce, birch, and willows, and smaller in size. The understory is generally thin or nonexistent, consisting of seedlings of shade-tolerant species, such as maple, and low shrubs. Patches of boreal-type forest can be found quite far south in higher elevations in the United States, such as the mountains of West Virginia. The edge of the temperate forest has crept steadily northward following the retreat of the glaciers at the end of the Ice Age twenty thousand years ago.

Forest Ecology and Resources

In all three types of forest a complex system of interrelationships governs the ecological well-being of the forest and its inhabitants. Trees and animals have evolved to fit into particular environmental niches. Some wildlife may need one resource provided by one species of tree in the forest during one season and a resource provided by another during a different time of year, while other animals become totally dependent on one specific tree. Whitetail deer, for example, browse on maple leaves in the summer, build reserves of fat by eating acorns in the fall, and survive the winter by eating evergreens. Deer are highly adaptable in contrast with other species, such as the Australian koala, which depends entirely on eucalyptus leaves for its nutritional needs. Just as the animals depend on the forest, the forest depends on the animals to disperse seeds and thin new growth. Certain plant seeds, in fact, will not sprout until being abraded as they pass through the digestive tracts of birds.

Humans also rely on the forest for food, fuel, shelter, and other products. Forests provide wood for fuel and construction, fibers for paper, and chemicals for thousands of products often not immediately recognized as deriving from the forest, such as plastics and textiles. In addition, through the process of transpiration, forests regulate the climate by releasing water vapor into the atmosphere while removing harmful carbon compounds. Forests play an important role in the hydrology of watersheds. Rain that falls on a forest will be slowed in its passage downhill and is often absorbed into the soil rather than running off into rivers and lakes. Thus, forests can moderate the effects of severe storms, reducing the dangers of flooding and preventing soil erosion along stream and river banks.

Threats to the Forest

The primary threat to the health of forests around the world comes from humans. As human populations grow, three types of pressure are placed on forests. First, forests are cleared to provide land for agriculture or for the construction of new homes. This process has occurred almost continuously in the temperate regions for thousands of years, but it did not become common in tropical regions until the twentieth century. Often settlers level the forest and burn the fallen trees to clear land for farming (*slash-and-burn agriculture*) without the wood itself being used in any way. Tragically, the land thus exposed can become infertile for farming within a few years. After a few years of steadily diminishing crops, the land is abandoned. With the protective forest cover removed, it may quickly become a barren, eroded wasteland.

Second, rising or marginalized populations in developing nations often depend on wood or charcoal as their primary fuel for cooking and for home heat. Forests are destroyed as mature trees are removed for fuel wood faster than natural growth can replace them. As the mature trees disappear, younger and younger growth is also removed, and eventually the forest is gone completely.

Finally, growing populations naturally demand more products derived from wood, which can include everything from lumber for construction to chemicals used in cancer research. Market forces can drive forest products companies to harvest more trees than is ecologically sound as stockholders focus on short-term individual profits rather than long-term environmental costs. The challenge to foresters, ecologists, and other scientists is to devise methods that allow humanity to continue to utilize the forest resources needed to survive without destroying the forests as complete and healthy ecosystems.

FOSSIL PLANTS

Categories: Evolution; paleobotany

Fossil plants are remnants, impressions, or traces of plants from past geologic ages preserved in the earth's crust.

The rise of land-dwelling animals paralleled the rise of plants, which have always been the basis for animal life. Fossil plants are a valuable source of information regarding such phenomena as changes in climate, ancient geography, and the evolution of life itself.

Thallophytes

The earliest fossil plants are represented by a phylum called the *thallophytes*. The geological record of the thallophytes is incomplete. Of seven large groups, only a few are represented by fossils. Although some records from the Paleozoic era have been found, the earliest identifiable specimens found are from the Jurassic period. The dearth of fossils from this group of plants can be attributed to their minute size and the fragile nature of their remains.

The thallophytes are in the most primitive plants, lacking roots, stems, leaves, and conducting cells. The simplest thallophytes are in the subphylum of *autophytic thallophytes*, which include blue-green bacteria (or cyanobacteria, formerly known as blue-green algae), diatoms, and algae. All these plants produce chlorophyll. Cyanobacteria are unicellular organisms occurring in colonies held together by a jellylike material. Diatoms are one-celled plants enclosed in a wall consisting of two overlapping valves. The next class, called simply algae, consists of several different types of seaweed, such as chara, or stonewort, which secretes lime with which it encrusts its leaves and is responsible for many freshwater limestones of the past. Many fossils that have been described as algae were actually molds of burrows or tracks of animals.

The second subphylum of the thallophytes is called the *heterophytic thallophytes*. These plants are distinguished by the absence of chlorophyll; as in animals, their principal source of energy is organic. The heterophytic thallophytes are subdivided into three classes. *Bacteria*, one-celled plants without definite nuclei, are the chief agents of the decomposition of organic matter; without bacteria, more prehistoric plant and animal remains would have been preserved. The next class, *slime fungi*, are sticky masses enclosing many nuclei but without cell walls. Slime fungi have never been found as fossils. The final class is the *fungi*, which are composed essentially of a branching mass of threads called the mycelium, which penetrate the cell walls of their "host"—plant or animal—and live upon its substance. *Lichens* are made up of a fungus and an alga living together in symbiosis. Fossil lichens have been recognized only from very recent formations.

Bryophytes

The next phylum to emerge, the *bryophytes*, exhibits a distinct advance over the thallophytes: Bryophytes adapted more successfully to the terrestrial environment. They were able to take water and other necessary substances from the soil by means of rootlike hairs called rhizoids. The most distinct advance of the bryophytes over the thallophytes is in their method of reproduction. The spores produced by these plants germinate by sending out a mass of green threads, the protonema.

The simplest bryophytes are the *liverworts*. The *mosses*, which are more abundant today than the liverworts, possess leaves consisting of many small chlorophyll-bearing cells. Because the ancient members of the bryophyte group were more delicate than the modern forms, they have been preserved only under exceptional conditions, such as those provided by the silicified peat beds at Rhynie, Scotland, which contain fossils from the Devonian period.

Pteridophytes

The *pteridophytes* were much more advanced than the bryophytes. While the structure of the bryophytes was primarily cellular, that of the fern plant is vascular. Unlike the bryophytes, the pteridophytes originate from a fertilized egg and produce spores. Pteridophytes are well represented by the ferns, which have existed from the Devonian period. Another class of pteridophytes is the horsetails (*Equisetales*), which also have existed from the Devonian to the present.

The third class of pteridophytes is the club mosses, which are largely creeping, many-branched plants with numerous tiny, mosslike leaves spirally arranged on the stem. The final class of pteridophytes, *Sphenophyllales*, consisted of slender plants with jointed stems and leaves in whorls. These climbing plants are known from the Devonian to the Permian periods.

Spermatophytes: Gymnosperms

The fourth phylum, the *spermatophytes*, are distinguished by the production of seeds, although the lower groups have the same alternation of the vegetative (asexual) and reproductive (sexual) generations as is seen in the pteridophytes. The chief distinguishing characteristics of the spermatophytes are the formation of a pollen tube and the production of seeds.

The first class, the *gymnosperms*, are typified by the pines, mostly evergreens. Members of one order of gymnosperms, *Cycadofilicales*, were fernlike in habit but were not actually ferns. Because the leaf and stem remained practically unchanged, it is very easy to mistake the early seed plants for ferns. One of the most familiar of the fernlike fronds of the Pennsylvanian coal deposits is *Neuropteris*, which had large, compound leaflets.

The stem in most forms was thick and short and covered with an armor of leaf bases. It represents an advance over previous plants in that it had a true flower because both male and female organs were borne on the same axis and were arranged in the manner of later flowering plants. Thus *Cycadales* is an intermediary in the line of development of the angiosperms (flowering plants) from their fern ancestors. This order formed the dominant vegetation of the Mesozoic, ranging from the Triassic into the Lower Cretaceous.

The next order of gymnosperms, *Cordaitales*, is an extinct group of tall, slender trees that thrived throughout the world from the Devonian to the Permian period. The leaves of these trees were swordlike and distinguished by their parallel veins and great size, reaching up to 1 meter. The *Cordaitales* were the dominant members of the gymnosperm forests during the Devonian period. The fourth order of gymnosperms, *Ginkgoales*, resembles the conifers in general appearance. The leaves, however, are fanlike and are shed each year. Like the cycads and ferns, the male cells are motile in fertilization.

The order *Coniferales* includes mostly evergreen trees and shrubs, with needles or scalelike leaves and with male and female cones. Derived from *Cordaitales* of the Paleozoic, *Coniferales* possesses fewer primitive characters than *Ginkgoales*. The yews, which are comparatively modern, have fruit with a single seed surrounded by a scarlet, fleshy envelope. Another family, *Pinaceae*, having cones with woody or membranous scales, are represented by *Araucaria*, which is very common in the Petrified Forest in eastern Arizona.

The *Abietae*, one of the more common families of evergreens, includes pines, cedars, and hemlocks dating back to the Lower Cretaceous. One of the most extraordinary members of the conifers was the family *Taxodiaceae*, which includes the genus *Sequoia*, represented today only by the redwood and the *Sequoia gigantea*, which grow in California. These species' twigs, cones, and seeds were abundant in the Lower Cretaceous of North America. Finally, the family *Cupressaceae* includes the junipers and is known from the Jurassic.

Spermatophytes: Angiosperms

The second class of spermatophytes is the *angiosperms*, commonly known as flowering plants. The angiosperms contain the plants of the highest rank. This group comprises well over one-half of all known living species of plants. The typical flower is composed of an outer bud-covering portion, the stamens, and the pistil. When the wind or an insect brings the pollen into contact with the pistil, the pollen is held in place by a sugary solution. After the pollen penetrates an ovule, the nucleus divides several times. This fusion is called fertilization. The embryo, consisting of a stem with seedling leaves, is called a seed.

Both subclasses of the angiosperms first appeared in the upper part of the Lower Cretaceous. *Dicotyledoneae* (the dicotyledones, or dicots) comprises a primitive subclass that begins with two seedling leaves that are usually netted-veined. The stem is usually thicker below than above, with the vascular bundles arranged to form a cylinder enclosing a pith center. As growth proceeds, new cylinders are formed. The last of the dicots to appear was the sassafras tree, flourishing throughout North America and Europe since the Lower Cretaceous.

The second subclass, *Monocotyledoneae* (monocotyledones, or monocots), descended from the dicots. These plants are distinguished by the fact that they begin with a single leaflet, or *cotyledon*. The veins of the leaves are parallel, the stem is cylindrical, and the roots are fibrous. This subclass is represented by the grasses and grains. Fossils from this subclass date back to the upper part of the Lower Cretaceous of eastern North America. The fossil record of the palm goes back to the mid-Cretaceous.

Evolution of Plants

The evolution of plants is the story of their struggle to adapt themselves to land. One of the changes necessary in the development of land flora was the change from a cellular structure to a vascular one, which opened up possibilities for increase in size and laid the foundation for the trees. In order to adapt to land, plants also had to develop a resistance to the dehydrating quality of the air.

The earliest plants, the thallophytes, were closely tied to water. One of the first examples of flora adapting to land were the freshwater algae. The change from a cellular to a vascular structure led to the development of roots; the pteridophytes were the first plants to take this step. The mosses and ferns adapted to land but still required rain or dew for the union of the gametes. It is only the spermatophytes that developed a device that freed them from the necessity of external water for fertilization to occur. This ability permitted the spermatophytes to proliferate throughout the earth.

FRUIT CROPS

Categories: Agriculture; economic botany and plant uses; food

Fruits are mature, or ripened, ovaries of angiosperms, their contents, and any accompanying accessory structures. From a botanical point of view, common foods such as grains, nuts, dried beans, squash, eggplant, and tomatoes are fruits, but in common usage the term is usually restricted to fleshy fruits that are commonly grown commercially as crops and are eaten, primarily raw, for their fleshy and juicy pulp.

Fertilization of ovules and the initiation of seed development lead to hormone production that triggers fruit development. Consequently, fruits usually contain seeds, but seeds can form without fertilization (*parthenogenesis*), and fruits can develop without seeds (*parthenocarpy*). Many fruits that are cooked or eaten as part of a main course are usually classed as vegetables. This dichotomy is reflected in the origins of the two words: fruit, from the Latin *fruor*, "to enjoy," and vegetable, from the Latin *vegetare*, "to enliven."

Ecology of Fruits

In nature, fleshy fruits serve as a reward for seed-dispersing animals. In keeping with the evolutionary principle that selection tends to minimize the cost of structures while maximizing their function, the flesh of these fruits contains comparatively few calories and basically consists of colored, flavored sugar water. Using animals as dispersal agents carries a risk, however, of seed destruction. Consequently, fleshy fruits that are dispersed by animals exhibit a number of mechanisms that protect seeds. One of these is the production of a large, hard seed that an animal cannot eat, such as a peach pit or a mango seed. Another protective characteristic is small seeds that go through an animal's digestive system without being crushed or digested, such as strawberry seeds. Over the last ten thousand years that humans have been practicing agriculture, many fleshy fruited species have been domesticated and bred for improved fruit production and quality. Several of the most marketed fruits worldwide are discussed below.

Temperate Fruits

The rose family (*Rosaceae*) contains a wide array of fruits grown in the cool regions of the world: apples, pears, plums, peaches, cherries, strawberries, and raspberries. Apples are the most important fruit tree crop of temperate regions. Apple and pear fruits are known as *pomes* because the edible fleshy part of the fruit is a combination of the outer ovary wall and the basal part of the flower. Cultivated apples are believed to have originated in western Asia and were enjoyed in prehistoric times. Apples were brought to North America about 1620 and are now the most widely grown fruit in the United States. Most of the apples grown today are diploids, but many are triploids. Orchards are usually planted with grafted trees, to ensure uniformity of the crop. Literally thousands of varieties of apples have been developed over the centuries since the species was domesticated.

Plums, peaches, and cherries come from different species of the genus *Prunus*. They share a fruit type known as a *drupe*, consisting of a fleshy mesocarp and a single seed inside of a hard endocarp. While there are native species of *Prunus* in the New World, the domesticated species are native to Eurasia.

The modern cultivated strawberry is a hybrid that apparently formed spontaneously in a European garden between a species of *Fragaria* from Chile and one from Virginia. Europeans had eaten native strawberries for centuries before the discovery of the New World, but the hybrid (*Fragaria ananassa*) was larger in size, as flavorful, and produced more fruit. A strawberry is actually an aggregation of fruits, or *aggregate fruit*. Each tiny seed is itself a fruit. The large, succulent, mass is the swollen top of the stem on which the flower was borne. Raspberries are also aggregated fruits, but each globular segment of the raspberry is itself a fruit, called a *drupelet*. The caps of drupelets pull free of the stem tips when the berry is picked.

Grapes are the second most widely cultivated fleshy fruit (on a tonnage-produced basis). However, the majority of grapes are not eaten as fruit but are turned into other foods, such as vinegar, liqueurs, raisins, and wine. The most widely cultivated species of grape is *Vitis vinifera* (*Vitaceae*), a woody perennial vine native to middle Asia. There are hundreds of varieties of grapes that vary in the color of the skin, flesh, flavor, and sweetness of the berries.

Nuts are dry fruits, each of which contains a single seed that is free inside the ovary wall, except for an attachment at one end called the funiculus. The pericarp (the walls of the ovary) is hard and fibrous. Commercially grown nuts include filberts, pecans, walnuts, and macadamia nuts, sold both for eating and for cooking.

Tropical Fruits

Many species of the genus *Citrus* (including sweet orange, tangerine, grapefruit, lemon, and lime) are grown for their edible fruits. Sweet oranges (*Citrus sinensis*) are the most widely grown fruit in the world, but in the nineteenth century they were considered luxuries and prescribed as cold remedies by physicians. Like other citrus fruits, the fruit of an orange is technically a *hesperidium*, a berry with a leathery rind and a juicy pulp that is formed of juice sacks borne on the inner layer of the fruit wall. The juice sacks fill the sections of the fruit and surround the seeds. The watery solution in the sacks is high in vitamin C. There are three main classes of oranges: Valencias, navels, and blood oranges. Valencias, with their deep orange color and rich flavor, are the source of most or-

ange juice. Navel oranges, favored for eating, are the result of a mutation that produces a second ovarylike structure (the navel) instead of seeds. Because they are seedless, navel oranges are all propagated by grafting. Blood oranges are seeded oranges named for the patches of deep red-purple color in the fruit.

Bananas became a major fruit crop in the twentieth century; prior to the use of refrigerated ships, bananas spoiled before they could reach markets outside the tropics. Wild bananas, native to eastern Asia, have seeds, but the common domesticated banana (*Musa paradisiaca*) is seedless and is the product of several cycles of hybridization followed by increases in chromosome number. Whether the fruit will be a tender and sweet yellow or red or a tough, starchy green plantain depends on the particular combination of chromosomes in the hybrid. Banana plants are giant herbs, not trees, and are propagated vegetatively by planting a piece of stem. Over the course of a year, the stem grows and produces a long terminal inflorescence of many clusters of female flowers along the flowering stalk and male flowers at the tip. The female flowers spontaneously mature, with each cluster forming a hand, or bunch, of bananas. An entire inflorescence can produce more than three hundred bananas, weighing 110 pounds. After fruiting, the shoot dies and is cut, allowing a sprout from the base to produce the next flowering stem.

Mangoes (*Mangifera indica*) are extremely common and important fruits in tropical areas, particularly in their native region of Southeast Asia, where the fruit pulp and even the seeds have been used for food. Mangoes are borne on trees that can grow only within tropical regions where there is adequate water in the summer. The fruit is a berry with musky yellow flesh surrounding a single large seed. Mangoes belong to the poison ivy family; some people are allergic to the latex produced in the skins. Mangoes were introduced into Brazil by the Portuguese in the early 1700's and subsequently spread to other areas of the New World tropics.

Melons, both common melons (*Cucumis melo*) and watermelons (*Citrullus lanatus*) belong to the same family (*Cucurbitaceae*) as squashes, but the latter are all native to the New World and the former to the Old World. All these species share the same kind of fruit, a *pepo*, which consists of a hard rind derived in part from the basal parts of the flower, and an edible fleshy layer of inner ovary tissue. Melons are monoecious vines with showy male and female flowers that require pollination to set fruit. Melons are native to Africa, where they were undoubtedly prized for their high water content and fresh flavor. Selection has led to numerous varieties, including cantaloupe, Crenshaw, honeydew, Persian, musk, and a variety of other melons that differ in the color and surface of the rind, color of the flesh, taste, and degree of sweetness.

Watermelons are native to sub-Saharan Africa, but they can be grown in temperate regions because they are annuals. The flesh is 87-92 percent water and is acidic enough to curdle milk. Recently, seedless types have been produced by artificially making triploid plants. The pollen of these triploids is sterile, and the seeds abort early. Farmers plant the triploids with fertile diploids. Pollen from the diploids fertilizes the ovules of the triploids and triggers fruit production. The seeds quickly die, but the fruit continues to mature into a seedless watermelon.

FRUIT: STRUCTURE AND TYPES

Categories: Anatomy; angiosperms; economic botany and plant uses; reproduction and life cycles

Fruits are the seed-containing reproductive organs, including nuts and grains, produced by angiosperms (flowering plants).

When most people think of a fruit, what typically comes to mind is a juicy, edible object, such as an apple, orange, or banana. To botanists, however, fruit includes many plant-derived structures, such as grains, nuts, and many vegetables. In essence, a fruit is an enlarged *ovary*, often with some accessory tissue, that develops after a flower has been pollinated. After pollination, seed development begins, and soon the peripheral parts of the flower fall away, leaving the immature fruit. The fruit subsequently enlarges and then ripens to maturity. It is then often edible.

Fruit Structure

Almost all fruits have a general structure that consists of an outer layer called the *pericarp*. The pericarp, in turn, encloses the *seed* or seeds. Usually there is a space between the seed and the pericarp, called a *locule*. The pumpkin is a good illustration of this structure, with orange rind as the pericarp, the hollow space within the locule, and the seeds inside the locule.

There are many different kinds of fruits. Some, such as cherries, tomatoes, and apples, have fleshy, juicy pericarps. Others, such as peanuts, milkweed pods, and acorns, have dry pericarps. The variability in fruits represents different seed dispersal strategies. In some plants, the seeds are dispersed while still enclosed within the fruit. Seeds in fleshy fruits are often dispersed by animals that eat the fruit and then either discard the seeds or later defecate them. Other fruits have barbs or hooks that catch on to fur or feathers and then travel with an animal until they are removed or drop off. Still other seeds, such as those of maple and ash, have "wings" for wind dispersal. A few, such as those of the coconut palm and many sedges, have fruits that float and are dispersed by water. In most instances, the fruit merely opens, and the seeds drop onto the ground. Some plants, such as witch hazel and the touch-me-not, produce fruits that open explosively and can disperse their seeds great distances.

Fruit Types

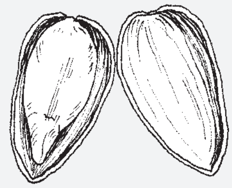
Fruits can be classified, based on the nature of the pericarp, into two groups: fleshy and dry. Fleshy fruits, in turn, are classified into several types, including *drupes*, *berries*, *pomes*, *hesperidia*, and *pepos*. Dry fruits are also subdivided into several categories, including *follicles*, *legumes*, *capsules*, *achenes*, *nuts*, *samaras*, *schizocarps*, and *caryopses*.

The three most familiar types of *fleshy fruits* are drupes, berries, and pomes. A drupe is a fleshy fruit that contains a single seed surrounded by a hard, bony inner wall of the pericarp (called the *endocarp*). The middle and outer walls of the pericarp (called the *mesocarp* and *exocarp*, respectively) are juicy and often sweet. Drupes include all the pitted fruits, such as cherries, plums, peaches, and olives. A berry typically has several seeds, and the pericarp is fleshy throughout. Familiar examples include tomatoes, eggplants, and grapes. A pome is a fleshy fruit, often with many seeds, that has a thick layer of *accessory tissue* immediately surrounding the pericarp. The accessory tissue is generally juicy, sweet, and often edible. Representative pomes include apples and pears.

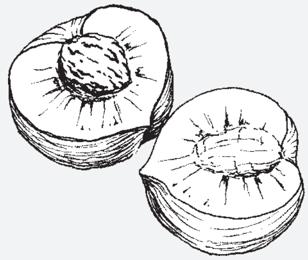
Two other fleshy fruits, the hesperidium and the pepo, are characterized by a leathery rind. Hesperidia, also known as a citrus fruits, have rinds rich in aromatic oils surrounding a juicy interior composed of wedge-shaped segments that have a sugary, acidic sap. Hesperidia include oranges, grapefruits, lemons, and limes. The pepo has a tough exocarp which is either smooth or variously sculptured and normally contains many seeds. Examples include cucumbers, cantaloupes, and squash.

Some common *dry fruits* are follicles, legumes,

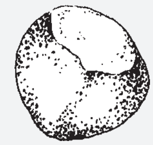
Fruit Types



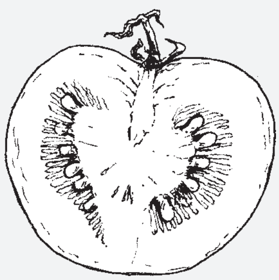
Achene: small, dry, indehiscent, single locule, single seed



Drupe: fleshy, indehiscent, stony endocarp around single seed; e.g., peach, cherry

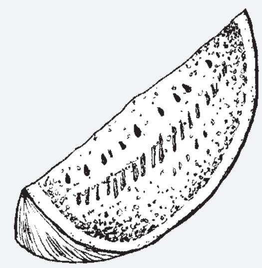


Nut: hard, dry, indehiscent, usually a single seed

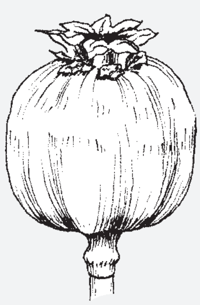


Berry: fleshy, from a single pistil, several seeds; e.g., tomato

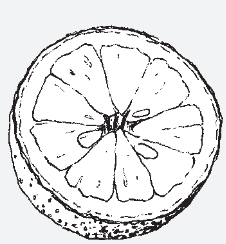
Follicle: dry, dehiscent with single-sided opening, single carpel; e.g., milkweed pod



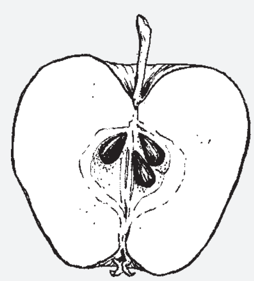
Pepo: fleshy, indehiscent, many-seeded, tough-rinded; e.g., melon, cucumber



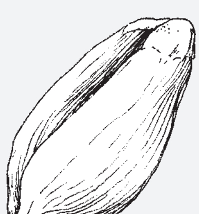
Capsule: dry, dehiscent, more than one carpel



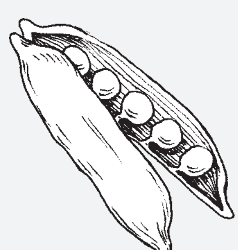
Hesperidium: fleshy fruit with tough rind; e.g., orange



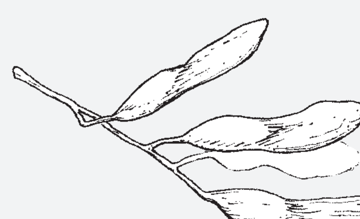
Pome: fleshy, indehiscent, growing from compound ovary, modified floral tube around core; e.g., apple



Caryopsis: dry, indehiscent, single seed with coat fused to pericarp—a grain



Legume: dry, dehiscent with two sides, single carpel; e.g., pea pod



Samara: dry, indehiscent, winged

Kimberly L. Dawson Kurnizki

capsules, achenes, nuts, samaras, schizocarps, and caryopses. Follicles are podlike fruits that open up along one side, revealing numerous seeds. Examples include milkweed pods and the aggregate follicles of magnolias. In contrast, legumes are podlike fruits that open up along two lines, releasing several seeds. They are produced by many members of the legume family, such as peas, beans, and peanuts.

The capsule opens along three or more lines or by pores at the top of the fruit. Lilies and poppies are good examples of plants that produce capsules. Achenes each contain a single seed that is free inside the cavity, except for an attachment at one end called the *funiculus*, and are typically small. A good example is a sunflower "seed." A nut is similar to an achene, except that the pericarp is hard and fibrous and is derived from a compound ovary. Representative nuts include acorns, hazelnuts, and hickory nuts. A samara is a modified achene that has part of the pericarp flattened to form a wing. Examples of plants that produce samaras include ashes and elms.

Maples have a winged fruit, called a *schizocarp*, which is often mistaken for a samara. Close observation reveals that the schizocarps come in attached pairs that later split into single-seeded portions. Schizocarps, which are generally not winged, also occur in the parsley family, where they may split into more than two parts. Finally, a *caryopsis* is a single-seeded fruit whose seed coat is fused to the

Fruit Types and Characteristics

Classification	*Examples*	*Type*[1]	*Fleshy/ Dry*[2]	*Dehiscent/ Indehiscent*[3]	*Comments*
Accessory	Strawberry	Accessory	F	—	Develops from receptacle; ovaries are achenes on surface.
Achene	Dandelion, sunflower	Simple	D	I	Single locule with single seed; not especially hard.
Aggregate	Raspberry	Aggregate	F	—	Drupelets from several pistils on a single flower.
Berry	Grape, tomato	Simple	F	—	Not enclosed by a receptacle, many seeds, soft skin.
Capsule	Lily, poppy	Simple	D	D	Formed by two or more carpels not separated by a septum.
Caryopsis (grain)	Wheat, corn, other grains	Simple	D	I	Single seed fused to pericarp.
Drupe	Peach, plum, cherry	Simple	F	—	Larger fruit with single seed (stone).
Drupelet	Raspberry drupelet	Simple on aggregate	F	I	Small, single seeded; occurs as a segment of an aggregate fruit.
Follicle	Milkweed pod	Simple	D	D	Single carpel opening on one side.
Hesperidium	Orange, other citrus	Simple	F	—	Berry-shaped, with several seeds and a tough rind.
Hip	Rose hips	Simple	F/D	—	Enlarged hypanthium surrounding many achenes.
Legume	Bean, pea pod	Simple	D	D	Composed of one carpel with seeds.

pericarp. Caryopses are produced only by plants in the grass family and include the familiar grains wheat, corn, rice, and oats.

The fruits listed above commonly fall under the category of *simple fruits*. In other words, they are identifiable as individual structures. Other plants produce fruits in dense clusters, and these are termed either *aggregate fruits* or *multiple fruits*. Aggregate fruits are produced by a single flower that has numerous pistils. One example is a raspberry, which is an aggregate of drupes which are often referred to as drupelets because of their small size. Another is the strawberry, not a berry in the botanical sense, which is an aggregate of tiny achenes attached to the surface of a swollen, juicy, *receptacle* (originally the base of the flower where all the flower parts were attached). In contrast, multiple fruits are produced by clusters of small flowers, each of which produces a single fruit. Representative multiple fruits include mulberries, figs, and pineapples.

Development and Maturation

In nature, fruits develop only after the flower is effectively pollinated. If pollination does not occur, the entire flower shrivels up, and no fruit is formed. Fruit development is apparently stimulated when the developing seeds produce hormones that diffuse into the ovary wall, causing it to enlarge. Two hormones are particularly implicated in fruit for-

Classification	*Examples*	*Type*[1]	*Fleshy/ Dry*[2]	*Dehiscent/ Indehiscent*[3]	*Comments*
Loment	Tick trefoil, sweet vetch	Simple	D	I	Legume but with individual seeds constricted by the pod.
Multiple	Pineapple, mulberry	Multiple	F	—	Formed by many flowers and ovaries on one receptacle.
Nut, nutlet	Acorn, hazelnut	Simple	D	I	Usually single seed inside a hard, woody pericarp.
Pepo	Melon, cucumber	Pepo	F	—	Not enclosed by receptacle; many seeds; tough rind.
Pome	Apple	Simple	F	—	Floral tube (core) containing multiple seeds, surrounded by fruit.
Samara	Maple, ash, elm fruits	Simple	D	I	Not splitting; winged.
Schizocarp	Carrot, geranium fruits	Simple	D	I	Fruit splitting but not releasing seeds.
Silicle (silique)	Mustard (*Brassicaceae*) fruits	Simple	D	D	Two carpels separated by septum, less than twice longer than wide.
Synconium	Fig	Multiple	F	—	From entire inflorescence (many flowers) with inverted receptacle bearing flowers internally; fruit formed of ripened ovaries (receptacle tissue).

— Not applicable.

1. Four main types: Simple (formed from a single mature ovary from a single flower); aggregate (several mature ovaries from a single flower); multiple (several mature ovaries from several flowers united on one receptacle, forming a mass); accessory (from tissues surrounding the ovary or ovaries, generally from flowers with inferior ovaries).
2. All fruits are either dry or fleshy, characterizing the pericarp at maturity.
3. Dehiscent fruits are dry fruits that split open when mature to release their contents, along either one or two sides. Indehiscent fruits are dry fruits that do not split open at maturity; often they are single-seeded.

mation: *auxin* and *gibberellin*. Many fruit growers routinely spray their plants with auxin to induce the formation of seedless, or *parthenocarpic*, fruits.

Fruit ripening is an important process that must occur properly in order for the seeds to be effectively dispersed. In fleshy fruits, such as tomatoes, cherries, apples, oranges, and bananas, fruit ripening involves several important changes in the pericarp that make the fruit more visible and palatable to a potential animal disperser. Perhaps the most visible change is in the color of the fruit. Immature fruits are green because of the presence of the pigment *chlorophyll* in the cells of the outer layer. Potential dispersers fail to notice the immature fruit because it blends in with the surrounding leaves. As fruits ripen, the chlorophyll breaks down, and other colors, such as orange, yellow, red, or blue, become evident. Those colors are the result of pigments that either are present in the unripe fruit and masked by the chlorophyll or develop as the fruit ripens. The texture and chemical composition of the pericarp change as well. Most fruits soften as they ripen, a result of the degradation of the cell walls in the pericarp. At the same time, starches or oils in the pericarp are chemically transformed into simple sugars such as *fructose*. That change causes the fruit to become better-tasting, more digestible, and thus more attractive to a hungry animal.

The physiology of fruit ripening has been well studied. Fruits such as grapes, citrus fruits, and strawberries ripen gradually. Others, such as tomatoes, apples, and pears, exhibit a transitional event called *climacteric*, which is marked by a dramatic increase in the rate at which oxygen is absorbed by the fruit, followed by a rapid change in the color and physical nature of the pericarp. Studies of climacteric fruit have shown that the onset of ripening can be delayed by storing the fruit at low temperatures or in an atmosphere devoid of oxygen. On the other hand, climacteric can be induced by exposing the fruit to *ethylene*, a plant hormone. Interestingly, ethylene is produced by ripening fruits, and thus a ripe fruit promotes the development of any unripe fruits nearby.

Finally, many plants drop their fruits at some point after they become ripened. Botanists use the term *abscission* to refer to the dropping process. Fruit abscission, like leaf abscission, occurs when a layer of cells at the base of the *pedicel* (the stem that attaches to the plant) become weakened. Studies have shown that abscission is influenced by two hormones: ethylene and auxin. Ethylene promotes abscission of fruits in many plant species, such as cherries, blueberries, and blackberries. Auxin, on the other hand, has effects that vary depending on the dose: Low concentrations promote fruit retention, while high doses cause fruits to drop.

A highly readable and informative account concerning the numerous uses of plants by various societies since the advent of recorded history. The book is copiously illustrated throughout, with photographs and line drawings. Chapters 4 and 5 provide an excellent account of fruits and nuts from temperate and tropical regions.

FUNGI

Categories: Fungi; taxonomic groups

The kingdom of nonphotosynthetic eukaryotic organisms, fungi are heterotrophic organisms, feeding on other materials rather than making their own food. They live on dead organisms by secreting digestive enzymes and absorbing the breakdown products. Although these organisms are stationary like plants and thus traditionally studied in botany courses, the heterotropic fungi are fundamentally different from plants, which are autotrophic organisms.

Although some unicellular forms of fungi exist, most fungi are characterized by a mycelial growth form; that is, they generally are made up of a mass of *hyphae* (tubular filaments). All fungi live in their food and have an absorptive mode of nutrition by which they secrete digestive enzymes and absorb the breakdown products. They are therefore heterotrophs. Fungi are also characterized by possession of cell walls made of chitin, synthesis of the amino acid lysine via the amino adipic acid (AAA) pathway, and possession of a ribosomal DNA sequence that classifies them more closely with other fungi than with any other group of organisms. Fungi produce spores by either asexual or sexual means. The way they produce their spores constitutes one of the main taxonomic criteria for classifying them within the kingdom *Fungi*.

Ecology and Habitats

Because of their absorptive, heterotrophic mode of acquiring nutrients, fungi are important members of the *decomposer* community in ecosystems. Because fungi break down dead organic matter (that is, because they live as *saprophytes*), they simultaneously release nutrients that are taken up by other members of their ecosystem. Fungi exist in terrestrial and aquatic habitats. Because the saprophytic fungi grow in a radial fashion from a point of origin, the mushroom types of fungi sometimes form so-called fairy rings: At the advancing edge of the mycelia, mushroom fruiting bodies appear in the shape of an irregular ring. One mass of mycelia, for example, became so large that it occupied 37 acres (15 hectares) in the Upper Peninsula of Michigan and became known as the Humongous Fungus.

Fungi are major *parasites*, living on live plants, animals, and other fungi. Fungal plant pathogens have evolved a variety of mechanisms to enable the fungus to penetrate the host plant and overcome the host's defenses. Next, the pathogen absorbs food from the host by establishing *haustoria*, which form a highly specialized absorbing system. These structures do not actually penetrate the host plasma membrane, but they reside within pockets of the host cell, where they secrete extrahyphal enzymes and absorb the soluble result. Consequently, the host plant develops a series of symptoms characteristic of the infection. Farmers can suffer severe loss of crops if an infestation is left unchecked. Plant breeders attempt to breed disease resistance into crop plants as a means of combating fungal diseases.

In contrast to plant fungal pathogens, some fungi grow within plants and do not cause disease symptoms. These fungi are called *endophytes*. They appear to protect host plants from herbivores and from certain pathogenic microbes.

Interactive Associations

Mycorrhizae are mutualistic associations between fungi and vascular plants whereby both members of the association benefit. A fungus that grows on plant roots facilitates nutrient and water uptake for the plant, and the plant provides organic nutrients to the fungus. About 90 percent of higher

PhotoDisc

Mushrooms are some of the best-known representatives of the kingdom Fungi.

plants have mycorrhizal associates. The fungus will form one of two types of associations with the plant. *Endotrophic mycorrhizae* penetrate cortical root cells with specialized hyphae that are finely branched. Other fungi grow around the root and between the cortical cells but never penetrate the cells. More than 80 percent of fungal genera that form mychorrizae are in the phylum *Basidiomycota*.

Lichens are an association that appears to be a controlled parasitism of an alga partner by a fungal partner. Ninety percent of lichens have one of three genera of algae as the photosynthetic partner: *Trebouxia*, *Trentepohlia*, and *Nostoc*. The first two are *Chlorophyta* (green algae), and the latter is a cyanobacterium (blue-green bacteria, formerly thought to be blue-green algae). Of all fungal partners, 98 percent are members of the phylum *Ascomycota*. In this controlled parasitism, the fungus obtains minerals and water and develops a physical structure to house the algal partner. The algal partner provides photosynthetic products to the fungal partner. These organisms can live in extreme environments such as deserts or Arctic regions. Because they have no way to eliminate toxic materials, they are extremely sensitive to air pollution. Indeed, the condition of lichens is sometimes used as an indicator of air pollution.

Some fungi have trapping mechanisms that allow them to prey upon invertebrate organisms such as nematodes, rotifers, and copepods. These trapping mechanisms involve networks of adhesive hyphae, adhesive branches, adhesive nets, adhesive knobs, nonconstricting rings, and constricting rings.

Chytrids

The type of sexually produced spore determines the taxonomy of fungal phyla. *Chytridiomycota*, or chytrids, reproduce sexually by a variety of means, including isogamy, anisogamy, oogamy, contact between gametangia (structures that contain the gametes), and contact between vegetative structures. However, the chytrids are better defined by their asexually produced, motile, uniflagellated zoospores; in fact, the chytrids are the only phylum of fungi that produce such spores. There are about 790 species in this phylum.

Zygomycota

Zygomycota reproduce sexually by producing zygospores within a zygosporangium. These fungi have a mycelial growth form that forms crosswalls only at reproductive structures. The zygomycetes produce spores asexually within a sporangium. Sexual reproduction leads to the production of a zygospore within a zygosporangium.

Mycelial cultures of a single strain may mate (in homothallic species) or may require a different mycelial strain (in heterothallic species) in order to mate. In both cases, copulation of two multinucleated gametangia occurs. Two lateral branches grow toward each other, sometimes attracted by the hormone trisporic acid. When these branches touch, a wall is laid down near the tip of each branch, creating the multinucleated gametangia. The wall separating the two gametangia at the point of contact breaks down, the protoplasmic contents mix, and the nuclei pair up and fuse. As the nuclei pair, a wall surrounding the fused gametangia develops into the zygosporangium. This thick-walled structure is resistant to environmental abuse. At or just prior to germination, the nuclei within the zygospore undergo meiosis. A stalk grows out of the zygospore bearing a sporangium. Included in this phylum of about 1,060 species are *Rhizopus*, the black bread mold; *Pilobolus*, the "cap" throwing fungus; and *Entomophthora*, the fly fungus.

Ascomycota

The ascomycetes reproduce sexually by producing ascospores within an ascus. Ascomycetes have a mycelial growth form with incomplete crosswalls. The septal hole permits the migration of cellular contents from cell to cell. *Yeasts* are single-celled ascomycetes that normally do not produce mycelial forms. Asexually, the *Ascomycota* reproduce by budding, fission, or production of chlamydospores or conidiospores. The unicellular yeasts reproduce using fission and budding methods. The majority of ascomycetes reproduce asexually, using conidiospores. A cell that is going to generate a conidium grows directly from hyphae or at the end of a stalk. The conidiogenous cell produces a swelling at the tip, into which protoplasm and a nucleus migrate. The nucleus is produced by mitotic means and is haploid. After swelling is complete and migration finishes, a wall is formed, separating the conidiospore from the conidiogenous cell.

Sexual reproduction occurs by gametangial contact between the female structure (the ascogonium) and the male structure (the antheridium). Usually, opposite mating types are required for sexual reproduction to occur. When contact between the gametangia occurs, nuclei from the antheridium migrate into the ascogonium and pair up with nuclei in the ascogonium. Alternatively, conidia or microconidia may land on the ascogonium and fuse with it. In both cases, fusion of paired nuclei is delayed until development of the ascus. Instead, special hyphae grow out from the ascogonium and will eventually generate the ascus. These ascogenous hyphae possess two nuclei, one of each mating type, in each cell.

Frequently the development of the ascogenous hyphae and ascus is associated with the development of a fruiting body. When the fruiting body is at the appropriate developmental stage, a hooklike structure develops at the end of the ascogenous hyphae. At this time the nuclei fuse, producing the only diploid cell in the life cycle of these organisms. As the saclike ascus elongates, the diploid nucleus undergoes meiosis, producing four haploid nuclei. Usually one mitotic division then occurs, resulting in eight nuclei in the elongated sac. Eventually walls are formed around each nucleus, creating the ascospore. As noted above, many *Ascomycota*—but not the yeasts—produce a fruiting body, called the ascoma. The ascoma may take a variety of shapes, from a closed, ball-like structure (cleistothecium) to a pear-shaped structure with an opening at the top (perithecium) to a cup-shaped open structure (apothecium) or a stromatic structure containing cavities (ascostroma). In all cases, the asci with the ascospores are contained within these structures. The type of ascoma, the number of walls in the ascus, and the presence or absence of a fertile layer from which the asci arise are criteria used to distinguish among the about 32,300 species of *Ascomycota*.

Basidiomycota

Basidiomycota reproduce sexually by producing basidiospores on a basidium. Like the *Ascomycota*, the *Basidiomycota* fungi also have a mycelial growth form with incomplete crosswalls. However, the structure of these crosswalls is different in that there is a swelling surrounding the pore where the wall is incomplete. There is also a curved membrane on each side of the hole, together looking much like parentheses. This septal structure is called the dolipore septum and is a secondary characteristic of the *Basidiomycota*.

The mycelia of most *Basidiomycota* pass through three stages. The primary mycelium has cells with a single nucleus, all derived from the germinated basidiospore; it is said to be *homokaryotic*. Later in development, fusion of hyphae of opposite mating types occurs, establishing the secondary mycelium, in which each cell has two nuclei; the secondary mycelium is therefore *dikaryotic*. Clamp connections occur on the secondary mycelium to facilitate division of the two nuclei in limited space. *Clamp* *connections* are another secondary characteristic of the *Basidiomycota*. Tertiary mycelium develops in the specialized organized tissues of the fruiting bodies, the *basidioma*.

Asexual reproduction takes place by means of budding, fragmentation of mycelium, production of chlamydospores, or conidia. Chlamydospores are fragmented sections of mycelia that have rounded up and formed thick walls. Sexual reproduction in the *Basidiomycota* occurs primarily by fusion of genetically compatible hyphae, thus establishing the secondary mycelium. Fusion of these nuclei is delayed until the production of the basidium. Nuclei of the dikaryotic cell that is to become the basidium fuse to produce one diploid nucleus that immediately undergoes meiosis, resulting in four haploid nuclei. Depending on the type of basidiomycete fungus, the haploid nucleus and associated cytoplasm migrate into a swelling that develops at the tip of the basidium. When full-sized, a wall separates the basidiospore from the basidium. Eventually the basidiospore falls off or is shot off the basidium. Classification of the approximately 22,250 species of *Basidiomycota* depends on the presence or absence of a fruiting body, septation, and the number of cells in the basidium.

Fungi: Phyla and Characteristics

Group	*Species*	*Characteristics*
Ascomycota	32,000+	Members of this phylum produce sexual spores in a specialized cell called an ascus. Includes *Neospora* (powder mildew), *Morchella* (morels), and *Tuber* (truffles). Causes mildews, fruit rots, chestnut blight, Dutch elm disease.
Basidiomycota	22,000+	Members of this phylum produce sexual spores on a specialized cell called a basidium. Includes three classes: *Basidiomycetes* (mushrooms, stinkhorns, puffballs, bird's nest fungi), *Teliomycetes* (rusts), and *Ustomycetes* (smuts). Causes rusts and smuts; includes poisonous varieties of mushrooms such as *Amanita*.
Chytridiomycota	800+	Members of this phylum are mainly aquatic organisms with motile spores with a whiplike flagellum. Includes gut chytrids, which live in the rumina of herbivores. Includes *Allomyces*, *Batrachochytrium* (parasite of frogs), and *Coelomomyces* (parasite of various insect hosts). Causes corn spots, crown wart in alfalfa, black wart in potatoes.
Zygomycota	750+	Members of this phylum are recognized by their rapidly growing hyphae. Includes bread molds and fruit rots (*Rhizopus stolonifer*); *Glomus versiforme* is often involved in mycorrhizae ("fungus roots").
Deuteromycetes	15,000+	Also called "fungi imperfecti," an artificial group based on the members' purely asexual form of reproduction. Includes fungi in the genus *Penicillium*, involved in cheese making and in the antibiotic penicillin. Also cause rots, molds, diseases of grains, vegetables, and fruits. *Aspergillus flavus* produces the carcinogenic toxin found on peanuts, aflatoxin.
Lichens	17,000+	Symbiotic relationships of fungal (mycobiont) and algal (photobiont) partners, familiar on substrates such as rocks, wood, tree trunks. Most of the mycobionts are members of *Ascomycota* or *Basidiomycota*. Some species live more than a century. Important as environmental indicators, food for tundra animals, sources of dyes, potential medicinal properties.
Yeasts	600+	Not a formal taxon but an artificial group of unicellular fungi that grow by budding. Yeasts in genus *Saccharomyces* are used in food manufacturing (bread dough, alcohol fermentation); also cause disease, such as fungal infections (*Candida albicans*) and pneumonia (*Pneumocystis carini*). Most are members of *Ascomycota*; a quarter are from *Basidiomycota*.

Source: Data on species are from Peter H. Raven et al., *Biology of Plants*, 6th ed. (New York: W. H. Freeman/Worth, 1999).

Deuteromycota

Deuteromycota are fungi that reproduce only asexually, by production of conidiospores. The majority of these fungi are thought to be derived from the *Ascomycota* by evolutionary loss of sexual stages; either that, or the sexual stages have yet to be discovered. Because the sexual stages, also called the "perfect" stages, have been lost, these fungi are also referred to as the "imperfect fungi," or "fungi imperfecti." About fifteen thousand form-species are grouped into larger form-genera and form-classes, based on the morphological characteristics of their asexual reproductive structures. Because this is an artificial classification (not based on evolutionary relationships), no basis for conclusions about relatedness within groups can be implied or inferred.

Evolutionary History

Because of a lack of sufficient fossil evidence, phylogenetic relationships have been inferred based on morphological features associated with cell structure and sexually produced structures. With the advent of sequencing analysis of proteins and nucleic acids, observations of some relationships have been confirmed, and new relationships are being discovered.

Small subunit rDNA sequence analysis shows that the fungi are derived from a flagellated animal ancestor. These data show fungi to be a *monophyletic* group, with the *Chytridiomycota* and *Zygomycota* as the earliest branches within the group. The facts that all fungi utilize the AAA synthetic pathway for lysine and possess cell walls of chitin support this monophyletic view of all fungi. Sequence analysis supports a relationship between the *Ascomycota* and *Basidiomycota*, perhaps both being derived from yeasts. The evidence for the monophyletic evolution of the *Basidiomycota* is strong, based on sequence analysis and morphological features such as ballistospores, basidia, and clamp connections. Sequence analysis, however, appears to contradict morphologically based phylogeny groupings, which use structure and number of cells in the basidium and presence or absence of a fruiting body as key features. Within the *Ascomycota*, phylogeny appears to be monophyletic, but the evidence is not strong.

GARDEN PLANTS: FLOWERING

Categories: Angiosperms; economic botany and plant uses; gardening

The most popular flowering garden plants worldwide include roses, lilies, tulips, irises, and daffodils. These plants range in form from herbs to bushes to trees. Their leaves, flowers, and optimum growth needs differ greatly.

Flowering plants (*angiosperms*) are grown in gardens for their beauty and their fragrant aromas. They and their relatives can also be grown for food. Myriad flowering plant types are grown in the world's gardens. Most popular flowering garden plants are in the rose family (*Rosaceae*, about three thousand species) and the lily family (*Liliaceae*, about forty-five hundred species), which together make up a wide variety of herbs, bushes, and trees. Also quite popular are members of the iris family, *Iridaceae*, which includes crocuses. Lilies and irises belong to the order *Liliales* (about eight thousand species) of herbaceous flowering plants. Other well-known plants of this order are tulips, daffodils, and hyacinths.

Roses and Lilies

The most popular garden plants are roses and lilies. Rose is the common name for members of the family *Rosaceae*, a family of one hundred genera and three thousand species. Included are important fruit and ornamental species, including the familiar genus *Rosa* (true roses). *Rosaceae* and more than twenty other families belong to the order *Rosales*. *Rosaceae* grow as trees, shrubs, or perennial herbs. Within this family, food is produced by apple, pear, peach, plum, cherry, apricot, almond, and nectarine trees. Many berries, including raspberries, blackberries, and strawberries, are *Rosaceae*.

Since antiquity, the true rose has been among the most popular garden flowers in the world. Roses evolved from sweetbriers (wild roses). This genus of perennials, with about one hundred species, is mostly native to the north temperate zone. Experts recognize two main classes of the approximately thirteen thousand cultivated rose varieties (*cultivars*) which have arisen from hybridization of a few original species, mostly from Asia. Members of the original class, such as brier, damask, and moss roses, bloom once a year, in early summer. The others, called *perpetual roses*, bloom more than once a season. They include the tea roses, polyanthas, and rugosas. Tea roses smell like tea or fruit. Other roses have the distinctive rose smell or no smell at all. True rose flowers are white or various shades of yellow, orange, pink, or red. A perpetual rose bush can grow up to 6 feet (2 meters) tall. Polyantha bushes are low and bear flower clusters; shrub roses grow up to 15 feet (4.5 meters) tall. The leaves of rose plants have stipules (leaflike appendages) at stalk bases and are most often compound.

The name "lily" indicates any of forty-five hundred species of the family *Liliaceae*. This is one of the largest, most important plant families in the order *Liliales*. The herbaceous flowering plants have beautiful, showy flowers. True lilies, *Liliaceae* of the genus *Lilium* (one hundred species), are native to temperate areas of the Northern Hemisphere and are among the oldest of cultivated plants. Examples are Colchis, tiger, Madonna, and Easter lilies. Within the same family are onions, garlic, and asparagus. Also included in *Liliales* are tulips, daffodils, hyacinths, and amaryllis. Among the eight thousand *Liliales* species are herbs, climbing shrubs, succulents, and trees. Their thick, fleshy stems grow from underground storage organs, and all have narrow, upright leaves with parallel veins. Most grow worldwide but flourish only in temperate and subtropical areas. These perennials bloom once yearly and store food and water in scaly bulbs, corms, or rhizomes. Stems and leaves may be storage organs, too, and have thick bark to prevent water loss. Many plants in the group can carry out asexual reproduction via bulblets on parent bulbs or flower clusters (for example, garlic).

Tulips, Daffodils, and Irises

Tulips and irises share some characteristics. The *Liliaceae* genus *Tulipa* contains about one hundred tulip species. They are native to Asia and the eastern Mediterranean region, and thousands of tulip cultivars are popular garden flowers. A tulip plant produces two to three thick, blue-green leaves, clustered at its base.

Irises, also in the *Liliales* order, belong to the family *Iridaceae*, which includes some of the world's most popular garden flowers. Irises are indigenous to the north temperate zone, Asia, and the Mediterranean region. "Iris" is the common name for spring-flowering, bulbous herbs. The leaves of iris plants rise directly from the bulb or rootstock; they are very narrow, erect, and swordlike. Iris plants arise from rhizomes (stems underground) or bulbs and have large flowers. *Iris*, the Greek word for "rainbow," refers to the flowers' rainbowlike color combinations.

"Iris" is the common name for spring-flowering, bulbous herbs. Irises are indigenous to the north temperate zone, the Mediterranean region, and Asia.

Another interesting and popular group of flowering garden plants is daffodils, of the genus *Narcissus*. They are sold as bulbs. Daffodils are so popular that they have been widely hybridized. A daffodil plant usually produces five to six lance-shaped leaves grouped about the base of its stem. Each plant has one large flower.

Blooming Habits: Roses and Lilies

Wild rose plants have regular, single flowers, with five petals. In most cultivars *double flowers*, having petals numbered in multiples of five, are produced. The flower also has a calyx with five lobes, many stamens, and one or more carpels. Rose sprouts have two seed leaves, so the plants are eudicots. Flowers of most cultivars bear few seeds, and the majority of them are sterile. The number of seeds is small because in double roses, flower parts that would otherwise produce seeds become extra petals. Therefore, most roses are grown from cuttings. All new rose varieties begin as seedlings, raised from fertile seeds.

Lily flowers grow one per stalk or in clusters. In contrast to roses, they have six petal-like segments, causing the flowers to resemble trumpets or cups. The flowers range from white to shades of almost all other colors except blue. Lily flowers all have three-chambered ovaries with nectaries between the chambers. They produce large, well-developed seeds which hold plenty of food-storage tissue and embryos. Plants of most species are 1 to 4 feet (0.3 to 1.3 meters) tall, though a few grow up to 8 feet (nearly 3 meters) tall. Lilies are usually raised from bulbs but can be grown from seed. Most species of these perennials bloom once, in July or August. However, flowering periods of some species begin in May or late autumn.

Blooming Habits: Tulips, Irises, and Daffodils

Tulip flowers can be single or double, and most, called "self-colored," grow in a huge range of solid colors, from pure white to many shades of yellow, red, brown, and purple. Some, called "broken tulips," have varicolored flowers caused by a harmless virus carried by aphids. The garden tulip, introduced into Western Europe from Turkey in the 1600's, is commercially cultivated most in the Netherlands and the United States, especially Michigan and Washington. Bell-shaped lilies are usually solitary. They have three petals and three sepals, six stamens, and a triple ovary that ends in a three-lobed stigma. A tulip fruit holds numerous seeds, but many of the four thousand tulip cultivars can be propagated only via their scaly bulbs.

Iris flowers are more asymmetric than those of roses, lilies, or tulips. They possess six petallike floral segments: three inner, erect *standards* forming an arch atop the flower and three outermost, drooping, often multicolored *falls*. A set of three petallike stigmas also cover the stamens. Iris colors include white, yellow, bronze, mauve, purple, and red. Best-known are rhizomatious bearded (German) irises, which have multicolored falls. These cultivars arose from European species. They have stems up to 3 feet (1 meter) tall and yearly bear at least three flowers per plant. The twentieth century saw the development dwarf bearded irises and fragrant cultivars. The best-known beardless, rhizomatous irises are Japanese and Siberian irises, which have clusters of blooms. English and Spanish irises grow from bulbs.

Daffodils, the best-known members of the genus *Narcissus*, are indigenous to northern Europe and have been widely cultivated there and in North America. Usually daffodil plants grow to heights of about 1.5 feet (about 0.5 meter). Each plant produces one large blossom on its centrally located stem. The blossom has a corolla split into six lobes and a centrally located trumpet, the *corona*. The corona is frilled at its edges, contains flower stamens, and leads to its pistil. The flowers were originally yellow; however, they have been hybridized into cultivars in which the trumpet and petals are often of contrasting yellows, whites, pinks, or oranges.

Rose and Lily Cultivation

Although found all over the world, roses grow best in mild climates, such as southern France and the U.S. Pacific coast. Roses' excellent growth in many different kinds of soil and climate is a result of the availability of myriad cultivars. A rose garden should be protected from cold wind and be exposed to sunlight for several hours a day. Deep, rich loam is best for roses, but most cultivars grow in sandy and gravelly soil. The soil must be well drained. Roses are planted in spring, about 2 feet (0.6 meter) apart. In the United States, about sixty-five million commercial rose plants are cultivated yearly. About 35 percent are grown for cut flowers, and the rest are used in gardens or landscaping. For the best growth, rose plants require severe pruning, which is adapted to the intended use of the flowers. Most varieties are grown by budding on understocks. Roses are susceptible to diseases such as rust and black-spot disease, so pests should be watched for and discouraged.

Lilies grow best in well-drained, deep, sandy loam, sheltered from winds and hot sunlight. Their bulbs are planted 6 or more inches (15 or more centimeters) underground, in late fall. This deep placement is used because they send out their roots well above the bulbs. As soon as blooms wilt, their seed pods should be removed. Lilies can be made to bloom early by putting the bulbs in pots and covering them with peat moss or soil. When kept at 50 degrees Fahrenheit for two weeks and then stored at 60 degrees Fahrenheit, they bloom in three months. Lilies are susceptible to a number of diseases. The most serious is mosaic, carried from plant to plant by aphids. Infected plants should be uprooted at once and burned to prevent an epidemic. A second severe disease of lilies is botrytis blight.

Tulip, Daffodil, and Iris Growth

Tulips are early bloomers, flowering in early spring; mid-season-bloomers; or late bloomers. Late bloomers are the largest group, with the widest range of growth habits and colors. Tulips flourish in any good soil but, like roses, do best in well-drained loam. The bulbs are planted in autumn at depths of 6 or more inches. These perennial plants flower annually for a few years, but eventually flowering diminishes. For best flower yields, after four to five years it is necessary to dig up bulbs after the flowers are gone and the foliage yellows. The bulbs should then be stored in a cool, dry place and replanted in autumn. Tulips are rarely attacked by garden pests.

Daffodil bulbs are planted in the fall, in loose soil, about 4 inches (10 centimeters) deep. The plants appear in mid-February. Their blossoms open in early April, announcing spring. Like tulips, the plants flower well, annually, for a few years and then diminish. For best flower yields, it is useful to store the bulbs every four to five years in the manner described above for tulips.

Irises bloom from March to July and may be planted in the spring before blooming or in the autumn. These perennials give the best flowers if plants are replanted every four to five years to eliminate the problem of overcrowding. Bearded irises do best in sunny areas where the soil is not too rich, but beardless ones prefer damp, rich soil. Iris diseases include crown rot, soft rot, and leaf spot. If the disease is serious, roots and soil may have to be treated. The worst iris insect enemy is the iris borer. Its larvae eat through leaves and roots, bringing on soft rot.

GARDEN PLANTS: SHRUBS

Categories: Angiosperms; economic botany and plant uses; gardening

Shrubs are perennial, woody plants that have multiple ecological uses and are economically important for a variety of landscape purposes. Like trees, the shrubs consist of both primary and secondary cambium (cells that ultimately form wood or bark), but unlike trees, shrubs typically have multiple stems and are somewhat shorter in height.

Native and nonnative shrubs have many uses, both in private gardens and as elements in commercial and civic landscaping. Shrubby willows and alders function as soil stabilizers, preventing erosion naturally along waterways. Other shrubs are natural windbreaks that reduce wind flow over open soils. Farmers value shrubby windbreaks that preserve barren farm soils during fall and winter months, when the land is barren and topsoil is especially liable to be blown away during winter storms. For much the same reason, homeowners may plant certain types of shrubs at strategic locations along the boundaries of the yard to reduce air flow.

Many shrubs are economically important as landscape ornamentals. They are prized for the beauty, variety, pattern, and color of their leaves, buds, flowers, or fruits. The color, shape, and texture of their leaves are all valued qualities for which shrubs are appreciated and used. Their shape, texture, pattern, and even the intricate contrast and pattern of their leafless twigs in winter can enhance the beauty and interest of a garden landscape.

Food Sources

In addition to their uses in gardens, many shrubs are important sources of foods for wildlife and for humans. Fruits of blackberries, blueberries, huckleberries, currents, gooseberries, plums, and hazelnuts are but a few of the foods obtained from shrubs. Many, such as blueberries and raspberries, are made into pies. Some currents and gooseberries are key components of jams and spreads. Still others, such as plums, cherries, and grapes, are eaten as fruits or used in the preparation of jams, jellies, pies, as cooking ingredients, or used for other baked goods. Some fruits are gathered only in the wild, but many others are cultivated. Cranberries, blueberries, and blackberries are cultivated varieties derived from hundreds of years of selecting and cultivating wild native shrubs. Fruits of plums, cherries, and especially the serviceberries, or Juneberries, are used to make fine and natural wines, and it may be that serviceberries were named because they provided the earliest fruits that could be made into wines for the Eucharist during church services.

Ecologically, shrubs are also important for wildlife. They provide food, shelter, and resting and nesting areas for a wide variety of birds. For example, at least forty-six species of birds feed on elderberry fruits.

Medicinal Uses

By 1812 Johann Jacob Paul Moldenhawer had shown that plant tissue was composed of independent cells, and in 1826 Henri Milne-Edwards determined that all animal tissues were formed from globules. From time immemorial, humans have enjoyed the medicinal advantages of many species of shrubs. An extract derived from the bark of willows, called salicin, is the active ingredient in one of the most important and useful of all household drugs: aspirin. The distilled liquid from the bark of witch hazel is sold as a skin ointment. A soothing ointment is made of the oil of teaberry. Tannic acid, used for tanning leather and for medicinal purposes, was for many years obtained from the fruits of native sumacs.

Barberries

The barberries (*Berberis*) are a worldwide group of deciduous shrubs best known for their thorns and bright red berries. They have yellow wood and simple alternate or whorled leaves clustered on short spurs. Barberries were very popular landscape ornamentals, but their reputation and use drastically decreased when they were found to be the alternate host for the black stem rust, a fungus that infects wheat. The use of hybrid varieties eliminates this ecological problem, and the barberries have once again become common as interesting and colorful ornamentals that provide good hedges, ground covers, and living barriers. The bright red leaves make them an attractive fall shrub, while the persistent, bright red berries attractively color a yardscape through the winter months. The berries are also an important wildlife food used by a variety of birds and small mammals through the winter months.

Burning Bushes and Dogwoods

The various species of burning bushes, or *Euonymous*, are attractive and bushy shrubs that offer good landscape contours and contrast, but they are probably best known for their gorgeous scarlet, fire-red, or fire-pink colors during the fall season. Dogwoods (*Cornus*) are shrubs or small trees that have opposite deciduous leaves and branching. A number of dogwood shrubs are useful and colorful as garden ornamentals. Chief among these are the silky dogwood (*Cornus amomum*) and red-osier dogwood (*Cornus stolonifera*), which grow in moist soil conditions. Red-osier dogwood is the more colorful of the two shrubs, with bright red branches that provide attractive year-round landscape color, especially in winter. Almost all of the dogwoods are valuable garden shrubs for wildlife, both as nesting cover and for their fruits.

Dwarf Trees as Evergreen Shrubs

Evergreen shrubs add beauty, texture, and year-round cover as ornamentals. Many species are noted for their broad leaves and showy flowers, others for the protective cover that they offer wildlife. Many dwarf varieties of trees have also become landscape shrubs that offer year-round color, variety, and cover. Another of their properties is their remarkably slow growth, usually only a few inches a year. Dwarf trees are used as ground covers, creeping along the ground and over stone walls and fences. Some of the many types include the cypress (*Chamaecyparis*), which provides dense and colorful foliage; junipers (*Juniperus*), which range from low growth forms to spreading forms and are able to tolerate urban and suburban conditions of low moisture and poor soils; dwarf pines (*Pinus*), whose long needles offer landscape and rock garden diversity; and yews (*Taxus*), which are commonly used for hedges and topiaries.

Of these, the prostrate or ground junipers are especially useful. These low-growing evergreen shrubs rarely reach a height greater than 3 feet but may spread in a circular mat several feet in diameter. The horizontal stems of ground juniper burrow into the soil surface to send up numerous upright-arching stems that form a dense ground cover. The sharp and prickly points of the leaves also make this shrub useful as a protective mat or hedge.

Fruiting Shrubs

In addition to cover and color, many species and varieties of shrubs offer fruits for humans and for wildlife. These include the blueberries (*Vaccinium*), which occur in ornamental forms and also in low, spreading varieties, and the currants and gooseberries (*Ribes*), which offer black, purple, red, and white berries, depending on variety or species, that can be harvested and made into jellies and jams or simply left on the shrub to attract wildlife. The blackberries and raspberries (*Rubus*) are a diverse group of fruiting shrubs famous for their fruits but less desirable as garden shrubs because of their tenacious ability to spread if left untended. However, the fruits are harvested for preserves, pies, wines, and as ingredients in breads and other baked goods. The tangled thickets or briar patches that they form can be useful both as living hedges and as wildlife cover for quail, songbirds, and a variety of mammals.

Hollies and Hydrangeas

The hollies (*Ilex*) and inkberries are reasonably hardy shrubs that offer year-round beauty, color, and texture as landscape ornamentals. They are best known for their lustrous, bright green leaves, intricate spiny leaf shapes, and bright red berries, and they are especially desirable as plants during the winter holidays, when holly sprigs and berries brighten both outdoor yards and indoor holiday festivities. Many species offer cover and seasonal nesting habitat for a variety of bird species. Another favorite shrub is the hydrangea (*Hydrangea*), with its large clusters of flowers; it is available in both a compact growth form and larger varieties. Hydrangeas are most often used as decorative shrubs for shady or semishady and moist corners of lots and buildings.

Rhododendrons and Azaleas

Taking their name from two Greek words, *rhodo* for "rose" and *dendron* for "tree," the rhododendrons and azaleas (*Rhododendron*) are best known for their bright and showy flowers, but these shrubs also offer glossy green leaves. The large and showy flowers of rhododendrons come in purple, pink, red, and white, while azalea flowers offer additional yellow, orange, and apricot shades. Many rhododendrons are huge shrubs that are especially valuable as wildlife cover and as nesting habitat for desired species, such as cardinals.

Roses

Roses (*Rosa*) have been cultivated for centuries and celebrated in poetry, songs, and artwork for an equally long time. They occur in an enormous number of species and varieties and in every shade of flower color except blue. Roses have been bred into many varieties, from miniatures to ground-covering polyanthas to bush roses and floribundas to tall hybrid teas, grandifloras, and climbers. "Old roses" and wild roses have returned to commercial markets in recent years. Prolific and relatively easy to grow in most climates, roses fill many landscape needs, from garden color to cut flowers and even living fences to protect property.

Spireas and Sumacs

Spireas (*Spirea*) are deciduous shrubs with small, alternate, toothed, or lobed leaves. They are popular deciduous shrubs because they are generally easy to grow and make useful hedges, mass plantings, and borders. They are also popular for their dainty clusters of spring flowers. Many varieties are desired for their long blooms from spring through most of summer, while others are sought for their fall colors or yellowish-green foliage. Some of the spirea varieties offer low, spreading ground covers, while others are compact decorative shrubs. The sumacs (*Rhus*) are shrubs or small trees that often grow in thickets. Although infrequently used in gardens, several species offer both rapid growth cover in poor soils and rich fall colors.

GAS EXCHANGE IN PLANTS

Categories: Photosynthesis and respiration; physiology

Gas exchange is the process whereby water vapor and oxygen leave and carbon dioxide enters plant leaves. The gaseous balance in plants is quite complex because plant cells carry on both respiration and photosynthesis.

All living organisms continually produce gases via metabolic and cellular activities, and the vast majority of living things are in one way or another in intimate contact with a gaseous medium. In most instances, therefore, there is ample opportunity for all organisms to exchange gases with the environment. The gaseous balance in plants is quite complex because plant cells carry on both *respiration* and *photosynthesis*. Plants respire in much the same way as animals; oxygen is used to oxidize carbohydrates, and carbon dioxide and water are produced as waste products. The photosynthetic process requires an input of carbon dioxide and water. These two *reactants* are used to produce carbohydrates, and oxygen is released as a waste product. Under normal conditions, photosynthetic rates are higher than respiration rates; thus, there is a net increase in oxygen production, accompanied by a net increase in the usage of carbon dioxide. On balance, therefore, plants use carbon dioxide and produce oxygen.

Stomata and Guard Cells

The gases move into and out of the plants through specialized openings located along the lower surface of the leaf. These openings, called *stomata*, are of optimum size, shape, and distribution for the efficient diffusion of gases. Each stoma (or stomate) is surrounded by two specialized structures called *guard cells*. These two cells are attached together at each end of both cells. The lateral edges of the two cells are not attached to each other, but, when flaccid, the sides of the guard cells do touch each other and effectively close the stomate. Specialized structural components prevent the guard cells from increasing in diameter as expansion occurs. Hence, when guard cells take up water, expansion takes place only along the longitudinal axis. Because the ends of the cells are connected to each other, the expanding of the cells forces the sides apart and results in the opening of the stomate.

Role of Water

The opening of stomata is dependent on how well hydrated the plant is. The water initially comes from the soil. The water enters the root by *osmotic* processes, then moves across the root and into the *xylem* tissues, which transport it up the stem to the leaves. From the xylem in the leaves, the water moves into the *palisade* and spongy *parenchyma cells*, which make up the bulk of the leaf tissue. The water then moves into the subsidiary cells that immediately surround the guard cells.

When the leaf is exposed to light, the process of photosynthesis begins. As the photosynthetic reactions proceed in the guard cells, the residual carbon dioxide is converted to carbohydrates. The disappearance of carbon dioxide from the cytosol of the guard cell results in an increase in the cellular pH. As the pH rises, the activity of the enzymes that convert starch and sugars to organic acids increases. The higher concentration of organic acids results in a higher concentration of hydrogen ions. The hydrogen ions of the guard cells are then exchanged for potassium ions in the subsidiary cells. This increased concentration of potassium, combined with the higher levels of organic acids, lowers the osmotic potential of the guard cells, and, since water moves from regions of high osmotic potential to regions of lower osmotic potential, water will move from the subsidiary cells into the guard cells. This movement of water increases the *turgor pressure* (inner pressure) of the guard cells and causes them to swell. Thus, the stomata open.

Oxygen Out, Carbon Dioxide In

Once the stomata open, the intercellular free space around both the palisade and spongy parenchymas is put into continuous contact with the outside atmosphere. As the water within the parenchyma cells moves across the cellular membranes, it evaporates into the free space and diffuses through the stomata into the atmosphere. Oxygen produced during photosynthesis exits the plant in much the same manner as the water vapor.

Carbon dioxide, however, follows the reverse path. It enters through and across cell membranes into the parenchyma tissues. In each case, the gas involved moves down a concentration or pressure gradient. The pressure of water vapor and oxygen is higher inside the leaf's free space than in the atmosphere, whereas the partial pressure of carbon dioxide is greater in the atmosphere than within the free space. Thus, the impetus is for the former two gases to move out of the plant and for the latter to enter it.

This exchange will take place as long as the stomata remain open and the pressure gradient is in the right direction. As a general rule, stomata close in the dark. Without an input of solar energy, the light-mediated reactions of photosynthesis stop. In the absence of these reactions, the carbon dioxide level increases, thus decreasing the pH. The lower pH activates the enzymatic conversion of organic acids to sugars and starch. This causes the potassium ions to move from the guard cells into the subsidiary cells. As a result, the osmotic potential of the guard cells is raised, the water moves out, the cells become flaccid, and the stomata close.

External Influences

Environmental conditions can affect stomatal openings. Drought conditions, which induce water stress, can affect gas exchange because the lack of water moving through the plant causes the guard cells to lose turgor and close the stomata. When the temperature becomes too warm, stomata also tend to close. In some instances, the higher temperature causes water to leave the leaf more rapidly, which leads to water stress.

In other cases, the increase in temperature causes an increase in cellular respiration that, in turn, increases carbon dioxide levels. Internal high carbon dioxide concentrations both reverse the carbon dioxide pressure gradient and cause the stomata to close.

The percentage of relative humidity can drastically affect the rate of water evaporating from the leaf surface. As the humidity increases, the higher water content of the air decreases the rate of water loss from the leaf because the water pressure gradient no longer favors evaporation from the leaf surface. The amount of solar radiation can also influence gas exchange. As the amount of light increases, the stomata open faster and wider, resulting in a more rapid rate of gas exchange. Wind currents will also increase gas exchange rates: As the wind blows across the leaf, it carries water vapor away and, in a sense, reduces the humidity at the leaf surface. Because of this lower humidity, the water evaporates from the leaf surface more rapidly.

Ecological Impact

The exchange of gases between living plants and the atmosphere is critical to the survival of all living organisms. Without the release of the oxygen produced during photosynthesis, the atmosphere would contain very little of this necessary gas. Furthermore, the vast majority of organisms on earth depend on the organic materials supplied by plants. The carbon dioxide taken from the atmosphere is photosynthetically fixed into the more complex carbon molecules that eventually serve as food not only for the plants but also for all those organisms that consume plants. The amount of carbon dioxide fixed in this fashion is tremendous: It is estimated that an average of approximately 191 million metric tons of carbon dioxide is fixed daily.

The flux of oxygen out of and carbon dioxide into the plant is possible only because of the opening of the stomata, which in turn is dependent on the flow of water through the plant. Studies have shown that for every kilogram of grain (such as corn) produced, as much as 600 kilograms of water will transpire through the stomata in a process called *transpiration*. This represents tremendous water loss and raises the question: What is the selective advantage of transpiration that outweighs its wastefulness?

The most logical explanation is that water loss by transpiration is the price plants pay to absorb carbon dioxide, essential to the life of the plant. There is the additional possibility that transpiration may serve some purpose beyond opening the stomata, such as mineral transport. Plant cell growth appears to be partially dependent on the existence of turgor pressure within the cell. Hence, the transpirational flow of water through the plant could supply the turgidity necessary for plant cell growth. Transpiration may also serve the same purpose in plants that perspiration does in humans—that is, to cool the leaf surface through water evaporation.

Gas exchange and transpiration in plants are very dynamic and interrelated processes. A thorough knowledge of both processes and of the interaction between them could one day lead to increasing maximum crop production while decreasing the amount of water required for the process.

Discusses structure and function of the stomata along with theoretical aspects of gas exchange and environmental factors affecting the process.

GENE FLOW

Categories: Ecology; genetics

Gene flow represents a recurrent exchange of genes between populations. This exchange results when immigrants from one population interbreed with members of another.

Charles Darwin published *On the Origin of Species by Means of Natural Selection* in 1859. Since then, scientists have modified and added new concepts to the theory of evolution by natural selection. One of those concepts, which was only dimly understood in Darwin's lifetime, is the importance of genetics in evolution, especially the concepts of migration and gene flow.

Genes

Genes are elements within the cells of a living organism that control the transmission of hereditary characteristics by specifying the structure of a particular protein or by controlling the function of other genetic material. Within any species, the exchange of genes via reproduction is constant among its members, ensuring genetic similarity. If a new gene or combination of genes appears in the population, it is rapidly dispersed among all members of the population through inbreeding. New *alleles* (forms of a gene) may be introduced into the *gene pool* of a breeding population (thus contributing to the evolution of that species) in two ways: *mutation* and *migration*. Gene flow is integral to both processes.

A mutation occurs when the DNA code of a gene becomes modified so that the product of the gene will also be changed. Mutations occur constantly in every generation of every species. Most of them, however, are either minor or detrimental to the survival of the individual and thus are of little consequence. A very few mutations may prove valuable to the survival of a species and are spread to all of its members by migration and gene flow.

Separation and Migration

In nature, gene flow occurs on a more or less regular basis between *demes*, geographically isolated populations, races, and even closely related species. Gene flow is more common among the adjacent demes of one species. The amount of migration between such demes is high, thus ensuring that their gene pools will be similar. This sort of gene flow contributes little to the evolutionary process, as it does little to alter gene frequencies or to contribute to variation within the species.

Much more significant for the evolutionary process is gene flow between two populations of a species that have not interbred for a prolonged period of time. Populations of a species separated by geographical barriers (as a result, for example, of seed dispersal to a distant locale) often develop very dissimilar gene combinations through the process of natural selection. In isolated populations, dissimilar alleles become fixed or are present in much different frequencies. When circumstances do permit gene flow to occur between populations, it results in the breakdown of gene complexes and the alteration of allele frequencies, thereby reducing genetic differences in both. The degree of this homogenization process depends on the continuation of interbreeding among members of the two populations over extended periods of time.

Hybridization

The migration of a few individuals from one breeding population to another may, in some instances, also be a significant source of genetic variation in the host population. Such migration becomes more important in the evolutionary process in direct proportion to the differences in gene frequencies—for example, the differences between distinct species. Biologists call interbreeding between members of separate species *hybridization*. Hybridization usually does not lead to gene exchange or gene flow, because hybrids are not often well adapted for survival and because most are sterile. Nevertheless, hybrids are occasionally able to breed (and produce fertile offspring) with members of one or sometimes both the parent species, resulting in the exchange of a few genes or blocks of genes between two distinct species. Biologists refer to this process as *introgressive hybridization*. Usually, few genes are exchanged between species in this process, and it might be more properly referred to as "gene trickle" rather than gene flow.

Introgressive hybridization may, however, add new genes and new gene combinations, or even whole chromosomes, to the genetic architecture of some species. It may thus play a role in the evolutionary process, especially in plants. *Introgression* requires the production of hybrids, a rare occurrence among highly differentiated animal species but quite common among closely related plant species. Areas where hybridization takes place are known as *contact zones* or *hybrid zones*. These zones exist where populations overlap. In some cases of hybridization, the line between what constitutes different species and what constitutes different populations of the same species becomes difficult to draw. The significance of introgression and hybrid zones in the evolutionary process remains an area of some contention among life scientists.

Speciation

Biologists often explain, at least in part, the poorly understood phenomenon of *speciation* through migration and gene flow—or rather, by a lack thereof. If some members of a species become geographically isolated from the rest of the species, migration and gene flow cease. Such geographic isolation can occur, for example, when populations are separated by water (as occurs on different islands or other landmasses) or valleys (different hillsides). The isolated population will not share in any mutations, favorable or unfavorable, nor will any mutations that occur among its own members be transmitted to the general population of the species. Over long periods of time, this genetic isolation will result in the isolated population becoming so genetically different from the parent species that its members can no longer produce fertile progeny should one of them breed with a member of the parent population. The isolated members will have become a new species, and the differences between them and the parent species will continue to grow as time passes. Scientists, beginning with Darwin, have demonstrated that this sort of speciation has occurred on the various islands of the world's oceans and seas.

GENE REGULATION

Categories: Cellular biology; genetics

Genetic regulation is the manner in which a cell carries out transcription of its DNA (by copying it to messenger RNA) and the production of corresponding protein, called translation.

When a gene is expressed, one strand of that gene's double helical deoxyribonucleic acid (DNA) is copied, in the process of *transcription*, by an enzyme called RNA (ribonucleic acid) polymerase to make a *messenger RNA* (mRNA). The mRNA then associates with a *ribosome* (formed by specific ribosomal RNAs and proteins), where the nucleic acid base sequence is read, to produce the corresponding protein in a process called *translation*. A section of three nucleotides, called a *codon*, codes for one amino acid. Small RNA molecules called *transfer RNAs* (tRNAs) carry specific amino acids to the ribosome during translation. That amino acid is added to the growing polypeptide chain when the anticodon part of the tRNA pairs with a codon of the mRNA being translated.

Prokaryotic vs. Eukaryotic Regulation

Prokaryotes (*Bacteria* and *Archaea*) and eukaryotes (all other life-forms, including plants and animals) carry out transcription and translation in very similar ways, but there are some differences. The RNA polymerases and ribosomes differ between the two types of cell. In a prokaryote, such as a bacterium, translation of an mRNA can begin as soon as the first part of the mRNA molecule has been made from the DNA template. This is said to be "coupled" transcription and translation. In the eukaryotic cell, mRNA is transcribed in the nucleus and crosses the nuclear envelope to go to the cytoplasm, where the mRNA is translated into proteins on ribosomes.

Promoters

Transcription begins at a *promoter*, which is a DNA sequence at the start of a gene that tells the RNA polymerase where to start transcribing the DNA to make mRNA. The promoter includes the site where transcription begins (the initiation site) as well as sequences upstream, which are not transcribed. In eukaryotes, RNA polymerase II recognizes a DNA sequence called the TATA box (because it contains many thymine (T) and adenine (A) bases) that is about thirty nucleotides upstream of the initiation site. Another element often found in promoters is the CAAT box (which includes cytosine (C) bases).

Other regulatory elements include *enhancer* sequences, which can be in either orientation in the chromosome and far from the coding region of the gene. Enhancers may be involved in regulating the specificity of expression of a gene in a particular tissue or organ. *Silencer sequences* are structurally similar to enhancers but function to decrease gene expression. Other proteins, called *transcription factors*, aid the RNA polymerase in locating and binding to the promoter. The DNA-binding domains of eukaryotic transcription factors may have one of several types of structural motifs, such as a helix-turn-helix structure, a zinc finger (a cysteine- and histidine-rich region of the protein that complexes zinc), or a leucine zipper. Once the polymerase binds, it separates the two strands of DNA at the initiation site, and transcription begins. Transcription ends at a termination site on the DNA. In eukaryotes, a common termination sequence is AATAAA.

Other Regulatory Elements

Genes with related functions often have similar regulatory elements. A number of environmentally induced genes in plants contain the G-box with the sequence 5'CCACGTGG3'. Genes that respond to light, ultraviolet radiation, cold, and drought have the G-box and at least one additional regulatory element. For example, genes that respond to the hormone abscisic acid also have an abscisic acid-responsive element.

Role of Chromatin

The chromosomes of eukaryotes consist of unique, single-copy genes among a complex pattern of repetitive DNAs. In addition, there are DNAs in organelles outside the nucleus, such as mitochondria and chloroplasts. Each eukaryotic chromosome contains a single long DNA molecule that is coiled, folded, and compacted by its interaction with chromosomal proteins called *histones*. This complex of DNA with chromosomal proteins and chromosomal RNAs is *chromatin*. The DNA of higher eukaryotes appears to be organized into looped domains of chromatin by attachment to a nuclear scaffold. The loops are anchored at matrix-attachment regions that function in the structural organization of the DNA and may increase transcription of certain genes by promoting the formation of a less-condensed chromatin.

Transcription and mRNA Processing in Eukaryotes

In the eukaryote, as mRNA makes its way from the nucleus to the ribosomes in the cytoplasm, the mRNA molecule is modified (RNA processing). Both ends of the mRNA are altered. The 5′ end (the end that is first formed during transcription) is capped by the addition of a modified guanine (G) residue (7-methylguanosine). The 5′ cap protects the mRNA from degradation by nucleases and serves as a signal for the attachment of small ribosomal subunits to the mRNA. While still in the nucleus, the 3′ end of the mRNA is also modified. An enzyme adds thirty to two hundred adenine nucleotides (called a poly-A tail). The poly-A tail inhibits mRNA degradation and may aid in mRNA transport to the cytoplasm.

In addition, many eukaryotic mRNAs are spliced in a cut-and-paste process in which a large part of the RNA molecule initially synthesized is removed. The parts of the DNA that code for the RNA that will be discarded are the intervening sequences, or introns. The DNA that codes for the parts of the RNA that will be translated are exons.

GENETIC CODE

Categories: Genetics; reproduction

The genetic code defines each amino acid in a protein, or polypeptide, in terms of a specific sequence of three nucleotides, called codons, in the DNA. The genetic code is therefore the key to converting the information contained in genes into proteins.

The genetic code defines each amino acid in a protein, or *polypeptide*, in terms of a specific sequence of three *nucleotides*, called codons, in the deoxyribonucleic acid (DNA). Therefore, the genetic code is called a *triplet code*. The four different nucleotides in DNA can form sixty-four different triplet codons. Because there are only twenty amino acids found in proteins, some amino acids are encoded by more than one codon. Therefore, the genetic code is said to be redundant, or *degenerate*. Three of the triplet codons do not encode any amino acids. These are *stop codons*, which identify the end of the message (similar to the period at the end of a sentence) encoded in genes. The genetic code is nearly universal; that is, specific codons code for the same amino acids in nearly all organisms. However, a few exceptions have been found, primarily in *mitochondrial DNA* (mtDNA), but also in a few protozoa and a single-celled algae, such as *Acetabularia*. (DNA is found in three places in eukaryotic cells: the nucleus, plastids, and mitochondria.)

Role of RNA

There are two distinct steps in the conversion of DNA sequences into protein sequences: *transcription* and *translation*. Transcription is the process by which the nucleotide sequence of a gene (in the DNA of a chromosome) is used to make a complementary copy of RNA (*ribonucleic acid*). DNA is a double-stranded molecule, and genes are arranged along DNA on each strand. Wherever there is a gene on one strand, called the *coding strand*, the other strand opposite the gene contains a nucleotide sequence that is complementary. The opposite strand is called the *non-coding strand*. When transcription of a gene occurs, it is the coding strand that is transcribed into a complementary stand of RNA. The transcribed RNA is complementary in the sense that for each adenine (A) in the DNA, a uracil (U) is incorporated into the RNA. Likewise, for each uracil, guanine (G), and cytosine (C) in the DNA, an adenine, cytosine, and guanine are incorporated into the RNA, respectively. Thus, for the codon AGT in the DNA, it becomes UCA in the RNA.

In *prokaryotes* (bacteria), the RNA resulting from transcription is called *messenger RNA* (mRNA), and it is immediately ready for the next step, translation. In the subsequent translation process, the mRNA is translated into a protein sequence by a *ribosome*. Ribosomes are macromolecular assemblies composed of various proteins and a second type of RNA, *ribosomal RNA* (rRNA). Ribosomes bind to mRNA molecules near the 5′ end and scan along the nucleotides until they reach an *initiation* or *start codon*, which indicates where translation should begin and establishes the *reading frame*. The start codon is always AUG and is the first translated codon in all mRNAs. Translation ends when a stop codon is reached. Most organisms have three stop codons (UAA, UGA, and UAG), and each gene ends with one of these. A stop codon does not code for an amino acid but simply identifies the end of the gene. Because nucleotide bases are read three at a time along a continuous chain of nucleotides, shifting the reading frame by inserting or deleting a single nucleotide within a gene can dramatically alter the amino acid sequence of the protein it can produce.

Although ribosomes are essential for translating mRNAs, they are not directly responsible for interpreting the codons. *Transfer RNA* (tRNA) molecules are single-stranded RNA molecules that exhibit extensive intramolecular base-pairing such that the tRNA has a two-dimensional structure with a stem and three loops resembling a three-leaf clover. The middle loop contains a region, composed of three nucleotides, called the *anticodon*, which is complementary to a specific codon. The tRNA molecules directly decode the mRNA sequence or translate it into a correct amino acid sequence by their ability to bind to the right codon. Each tRNA carries a specific amino acid to the ribosome where protein synthesis occurs. The binding of amino acids to tRNAs occurs at a place on the tRNA called the *amino acid attachment site*. Amino acids are added to tRNAs by special enzymes called *aminoacyl-tRNA synthetases*. Each tRNA has a special region on the stem below the amino acid attachment site whose nucleotide sequence determines which amino acid needs to be attached to the tRNA. This code is often called the second genetic code, and geneticists have discovered that if the nucleotide region is changed in this region, the wrong amino acid gets attached.

There are at least one type of tRNA for each of the twenty amino acids. It is the pairing of the codons of the mRNA molecules and anticodons of tRNA molecules that determines the order of the amino acid sequence in the polypeptide chain. The third base of the anticodon does not always properly recognize the third base of the mRNA codon. The third base is called the *wobble* position because nonstandard base pairing can occur there. This phenomenon, together with the degeneracy of the genetic code means that cells do not have to have sixty-one different tRNA types (one for each codon that specifies an amino acid). For example, only two tRNAs are needed to recognize four different codons for the amino acid glycine. Consequently, most organisms have about forty-five different tRNA types.

Polypeptide Sorting

A typical plant cell contains thousands of different kinds of proteins. For the cell to function properly, each of its numerous proteins must be localized to the correct cellular membrane, or cellular compartment. The process of protein sorting, or protein targeting, is critical to the organization and functioning of plant cells. Protein sorting relies upon the presence of special *signal sequences* at one end of the protein molecule. These signal sequences direct proteins to various sites. For example, some proteins synthesized on ribosomes in the cytoplasm are targeted to organelles, such as the mitochondria or chloroplasts. Other proteins, such as those found in the plant cell wall, are targeted to the cytoplasmic membrane for transport out of the cell to the cell wall. The signal sequences are frequently removed once the protein has reached its intended destination.

GENETIC DRIFT

Categories: Ecology; genetics; reproduction and life cycles

Genetic drift refers to random changes in the genetic composition of a population. It is one of the evolutionary forces that cause biological evolution, the others being selection, mutation, and migration, or gene flow.

Drift occurs because the genetic variants, or *alleles*, present in a population are a random sample of the alleles that adults in the previous generation would have been predicted to pass on, where predictions are based on expected migration rates, expected mutation rates, and the direct effects of alleles on fitness. If this sample is small, then the genetic composition of the offspring population may deviate substantially from expectation, just by chance. This deviation is called genetic drift. Drift becomes increasingly important as population size decreases. The key feature of drift that distinguishes it from the other evolutionary forces is the unpredictable direction of evolutionary change.

Anything that generates *fitness variation* among individuals (that is, variation in the ability of individuals to survive and reproduce) will increase the magnitude of drift for all genes that do not themselves cause the fitness variation. Because of their indeterminate growth, plants often vary greatly in reproductive potential because of local environmental variation, and this magnifies genetic drift. For example, the magnitude of drift in most annual plants is more than doubled by size variation among adults. This makes sense if one considers that larger individuals contribute a larger number of offspring to the next generation, so any alleles they carry will tend to be overrepresented.

Fitness variation caused by selection will also increase the magnitude of drift at any gene not directly acted upon by the selection. If an individual has high fitness because it possesses one or more favorable alleles, then all other alleles it possesses will benefit. This is called *genetic hitchhiking*. This is a potent source of evolution because the direction of change at a hitchhiking gene will remain the same for multiple generations. However, it is not possible to predict in advance what that direction will be because where and when a favorable mutation will occur cannot be predicted.

The opportunities for drift to occur are greatly influenced by *gene flow*. Most terrestrial plants are characterized by highly localized dispersal. Thus, even in large, continuous populations, the pool of potential mates for an individual, and the pool of seeds that compete for establishment at a site, are all drawn from a small number of nearby individuals known as the *neighborhood*. If the neighborhood is sufficiently small, genetic drift will have a significant impact on its genetic composition.

For these and other reasons, population size alone is not sufficient to predict the magnitude of drift. The *effective size* of a population, N_e, is a number that is directly related to the magnitude of drift through a simple equation. Thus, N_e incorporates all characteristics of a population that influence drift.

Loss of Variability

The long-term consequence of drift is a loss of genetic variation. As alleles increase and decrease in frequency at random, some will be lost. In the absence of mutation and migration, such losses are permanent. Eventually, only one allele remains at each gene, which is said to be fixed. Thus, all else being equal, smaller populations are expected to harbor less genetic variation than larger populations.

An important way in which different plant populations are not equal is in their reproductive systems. With self-fertilization (selfing), or asexual reproduction, genetic hitchhiking becomes very important. In the extreme cases of 100 percent selfing or 100 percent asexual reproduction, hitchhiking will determine the fates of most alleles. Thus, as a new mutation spreads or is eliminated by selection, so too will most or all of the other alleles carried by the individual in which the mutation first arose. This is called a *selective sweep*, and the result is a significant reduction in genetic variation. Which alleles will be swept to fixation or elimination cannot be predicted in advance, so the loss of variation reflects a small N_e. Consistent with this expectation, most populations of flowering plants that reproduce partly or entirely by selfing contain significantly less genetic variation than populations of related species that do not self-fertilize.

Extinction

Mutations that decrease fitness greatly outnumber mutations that increase fitness. In a large population in which drift is weak, selection prevents most such mutations from becoming common. In very small populations, however, alleles that decrease fitness can drift to fixation, causing a decrease in average fitness. This is one manifestation of a phenomenon called *inbreeding depression*. In populations with very small N_e, this inbreeding depression can be significant enough to threaten the population with extinction. If a population remains small for many generations, mean fitness will continue to decline as new mutations become fixed by drift. When fitness declines to the point where offspring are no longer overproduced, population size will decrease further. Drift then becomes stronger, mutations are fixed faster, and the population heads down an accelerating trajectory toward extinction. This is called *mutational meltdown*.

Creative Potential

By itself, drift cannot lead to adaptation. However, drift can enhance the ability of selection to do so. Because of diploidy and sexual recombination, some types of mutations, either singly or in combinations, will increase fitness when common but not when rare. Genetic drift can cause such genetic variants to become sufficiently common for selection to promote their fixation. A likely example is the fixation of new structural arrangements of chromosomes that occurred frequently during the diversification of flowering plants. New chromosome arrangements are usually selected against when they are rare because they disrupt meiosis and reduce fertility. The initial spread of such a mutation can therefore only be caused by strong genetic drift, either in an isolated population of small effective size or in a larger population divided into small neighborhoods.

GENETIC EQUILIBRIUM: LINKAGE

Categories: Cellular biology; genetics

Genetic equilibrium is the tendency for genes located close together on the same chromosome to be inherited together. The farther apart the genes, the less likely it is that they will be passed along together.

The genetic complement of any organism is contained on one or more types of *chromosomes*. Whether there are only a few chromosomes or many (such as in a diploid organism), each type occurs as a set of two, called *homologs*. Each gene at a particular *locus*, or site, along the chromosome occurs twice in the same cell (except for some loci which only occur on one of the two sex chromosomes), one copy of each homolog. The particular information at each locus may be different because genes can exist in several forms.

An alternative form of a particular gene is called an *allele*. For example, one of the genes for flower color in pea plans can exist as a white allele or a purple allele. A given pea plant could have a white allele on one homologous chromosome and a purple allele on the other. Each homologous chromosome, therefore, contains an allele at a locus which may or may not be the same as the allele on its homolog.

During reproduction, this chromosomal material is copied, thereby duplicating the individual genes which lie along the chromosome. During *mitosis*, a copy of each chromosome is distributed to each of the two new nuclei. In *meiosis*, however, during gamete production, the chromosome copies are separated so that only a single chromosome from each pair of homologous chromosomes is distributed to each of four new nuclei. Before this happens, however, the homologs and their duplicates, called *sister chromatids*, become aligned. The arms of sister chromatids undergo crossover near the beginning of the first part of meiosis, which results in the exchange of homologous regions of these chromosomes.

The result of this *crossing over* is that alleles that were once on one homolog are now on the other. In mitosis, genes on the same chromosome exhibit linkage and tend to remain together and be inherited by the daughter cell together; in meiosis, these linked genes can become recombined in new associations so that linkage is partial. Individuals with chromosomes exhibiting these new combinations of alleles are called *recombinants*.

Discovery of Linkage

Mendelian genetics (named for Gregor Mendel) predicts a 3:1 phenotypic ratio in a monohybrid cross (a cross involving only one gene having two alleles, one dominant and one recessive) and a 9:3:3:1 phenotypic ratio in a dihybrid cross (a cross involving two genes on different chromosomes, each having two alleles, one dominant and one recessive). Early in the twentieth century, geneticists began to notice that not all crosses produced offspring in the proportions predicted by Mendel's *law of independent assortment*. Cytologists also discovered that occasionally homologous chromosomes did not look exactly alike. Geneticists used these differences in chromosomes as cytological markers and associated them with genetic markers or alleles with specific effects.

In 1911 T. H. Morgan concluded that during segregation of alleles at meiosis, certain genes tend to remain together because they lie near each other on the same chromosome. The closer genes are located to each other on the chromosome, the greater their tendency to remain linked.

In 1909 *chiasmata* had been described. Chiasmata represent the locations of exchanges (crossover) between maternal and paternal homologous chromosomes. Morgan hypothesized that partial linkage occurs when two genes on the same chromosome are separated physically from each other by crossover during meiosis. Crossover provides new combinations of genes, genes which did not exhibit the linkage relationship in the parents but which were recombined. In these kinds of crosses, the parental phenotypic classes are most frequent in the offspring, while the recombinant classes occur much less frequently.

Genetic recombination results from physical exchange between homologous chromosomes that have become tightly aligned during meiotic prophase. A chiasma is the site of crossing over and is where homologs have lined up touching each other where they are homologous. Crossing over itself is the exchange of parts of nonsister chromatids of homologous chromosomes by symmetrical breakage and crosswise rejoining. Two papers providing convincing evidence of this were published within weeks of each other in 1930.

Harriet Creighton and Barbara McClintock worked with corn (*Zea mays*). They studied individuals in which the two copies of chromosome 9 had a strikingly different appearance. They studied two loci on chromosome 9, one affecting seed color (colored and colorless, dominant and recessive, respectively) and the other affecting endosperm composition (waxy or starchy, dominant and recessive, respectively). One homolog was dominant for both traits (colored and waxy) and lacked the knob and the extension. Plants with these two homologs of chromosome 9 had colored, waxy seeds. Recombinant offspring would have either colored and starchy seeds or colorless and waxy seeds and their copies of chromosome extension but no knob. Offspring that were like the parents showed no change in chromosome structure. This provided visual evidence that crossover had occurred.

Genetic Maps

The frequency of crossover can be used to construct a *genetic map*. The more closely linked genes are, the less frequently crossing over will take place between them. The recombinants will occur much less frequently than when linked genes are more widely separated.

With widely separated genes, the chances of double crossovers increases, so that the recombination frequency may actually underestimate the crossover frequency and, hence, the *map distance*. The map distance is a relative distance based on the percent of recombination and is not a precise physical distance. The presence of a chiasma in one region often prevents the occurrence of a second chiasma nearby. This phenomenon is called *interference*.

In many large, randomly mating natural populations, the genotype frequencies at each locus will typically be found at a mathematically determined *equilibrium*. In a single generation of random mating, unlinked loci separately attain equilibrium of genotype frequencies. This is not true of linked loci. If loci are unlinked, equilibrium occurs very rapidly, but if the loci are on the same chromosome, the speed of approach to equilibrium is proportional to the map distance between them.

Once equilibrium is attained, repulsion and coupling gamete frequencies do not depend on the degree of linkage. Another way of saying this is that the characters produced by alleles at linked loci show no particular association in an equilibrium population. When characters happen to be associated in a population, the association may form because alleles at separate loci that are in genetic disequilibrium result from recent population immigrations. They may also be the result of selection for certain allelic combinations. Like dominance, linkage can be confirmed only in controlled breeding experiments.

Mutations

Mutations are the ultimate source of variation. In populations, mutant alleles may accumulate over time because they are recessive to the normal allele. Recessive lethal alleles, as well as beneficial alleles, persist in populations because recessive alleles are hidden when in the heterozygous state (that is, in individuals who have one normal, dominant allele and one mutant, recessive allele). It is only when the mutant becomes widely distributed in the population that they are revealed.

With ten loci and four alleles at each locus, ten billion different possible genotypes will occur with equal frequency if all the alleles occur with equal frequency and segregate independently. This describes a state of linkage equilibrium. In a natural population, however, these conditions are rarely met. The probability is that some genotypes will be more common than others, even if the allele frequencies are all the same.

Diploid organisms typically have tens of thousands of gene loci. Because they have only a small number of chromosomes, usually less than forty, many loci lie on the same chromosome. The genotypes are highly biased toward already existing combinations. This does not alter the theoretical possibilities of particular genotypes, only the probability of their occurrence. It does ensure that variation is present in the population for adaptability to changing conditions, while maintaining large numbers of individuals that are adapted to existing conditions.

Functions of Linkage

Linked genes may control very different functions. For example, enzymes vary depending on climate. Northern species may possess an enzyme which functions at a lower temperature than the variant of the southern species. Linked to the gene which controls this highly adaptive allele may be an allele of another gene whose adaptive value is lower or neutral. This less adapted allele hitchhikes on the chromosome with the adaptive allele.

Linkage disequilibrium is decreased by recombination. The maintenance of favorable allelic combinations in linkage disequilibrium is enhanced by reducing recombination between the loci involved. This is achieved by inversions and translocations that include the loci involved. The genes included in these in the translocated or inverted region are sometimes called supergenes, because of their strong tendency to be inherited as a large unit of many genes. Inversions and translocation do not completely inhibit crossover in the regions involved, but they do reduce it. They also reduce the occurrence of recombinant chromosomes, because if a crossover does occur in one of these regions, most of their resulting recombinant chromosomes are either lethal or cause varying levels of sterility. Whenever linkage disequilibrium is favored by natural selection, chromosomal rearrangements increasing linkage among loci will also be favored by natural selection.

GENETICALLY MODIFIED BACTERIA

Categories: Bacteria; biotechnology; economic botany and plant uses; genetics

Bacteria may be genetically modified through the introduction of recombinant DNA molecules into their cells. Such bacteria may be used to produce human insulin or introduce disease-resistant genes into plants, as well as numerous other applications.

The ability to genetically engineer bacteria is the outcome of several independent discoveries. In 1944 Oswald Avery and his coworkers demonstrated gene transfer among bacteria using purified DNA (deoxyribonucleic acid), a process called *transformation*. In the 1960's the discovery of *restriction enzymes* permitted the creation of hybrid molecules of DNA. Such enzymes cut DNA molecules at specific sites, allowing fragments from different sources to be joined within the same piece of genetic machinery.

Restriction enzymes are not specific in choosing their target species. Therefore, DNA from any source, when treated with the same restriction enzyme, will generate identical cuts. The treated DNA molecules are allowed to bind with one another, while a second set of enzymes called *ligases* are used to fuse the fragments together. The recombinant molecules may then be introduced into bacteria cells through transformation. In this manner, the cell has acquired whatever genetic information is found in the DNA. Descendants of the transformed cells will be genetically identical, forming *clones* of the original.

Bacterial Plasmids

The most common forms of genetically altered DNA are bacterial *plasmids*, small circular molecules separate from the cell chromosome. Plasmids may be altered to serve as appropriate *vectors* (carriers of genetic material) for genetic engineering, usually containing an *antibiotic* resistance gene for selection of only those cells that have incorporated the DNA. Once the cell has incorporated the plasmid, it acquires the ability to produce any gene product encoded on the molecule.

The first such genetically altered bacteria used for medical purposes, *Escherichia coli*, contained the gene for the production of human insulin. Prior to creation of the insulin-producing bacterium, diabetics were dependent upon insulin purified from animals. In addition to being relatively expensive, insulin obtained from animals produced allergic reactions among some individuals. Insulin obtained from genetically altered bacteria is identical to that of human insulin. Subsequent experiments also engineered bacteria able to produce a variety of human proteins, including human growth hormone, interferon, and granulocyte colony-stimulating factor.

Use in Plants

Genetically modified bacteria may also serve as vectors for the introduction of genes into plants. The bacterium *Agrobacterium tumefaciens*, the cause of the plant disease called crown gall, contains a plasmid called *Ti*. Following infection of the plant cell by the bacterium, the plasmid is integrated into the host chromosome, becoming part of the plant's genetic material. Any genes that were part of the plasmid are integrated as well. Desired genes can be introduced into the plasmid, promoting pest or disease resistance.

In April of 1987 scientists in California sprayed strawberry plants with genetically altered bacteria to improve the plants' freeze resistance, marking the first deliberate release of genetically altered organisms in the United States to be sanctioned by the Environmental Protection Agency (EPA). The release of the bacteria climaxed more than a decade of public debate over what would happen when the first products of biotechnology became commercially available. Fears centered on the creation of bacteria that might radically alter the environment through elaboration of gene products not normally found in such cells. Some feared that so-called super bacteria might be created with unusual resistance to conventional medical treatment. Despite these concerns, approval for further releases of genetically altered bacteria soon followed, and the restrictions on release were greatly relaxed. By 2002, permits for field tests of hundreds of genetically altered plants and microorganisms had been granted.

GENETICALLY MODIFIED FOODS

Categories: Agriculture; biotechnology; economic botany and plant uses; food; genetics

Foods derived from living organisms that have been modified using gene-transfer technology are known as genetically modified foods. Many of these foods are plant crops.

Applications of genetic engineering in agriculture and the food industry could increase world food supplies, reduce environmental problems associated with food production, and enhance the nutritional values of certain foods. However, these benefits are countered by food-safety concerns, the potential for ecosystem disruption, and fears of unforeseen consequences resulting from altering natural selection. Humans rely on plants and animals as food sources and have long used microbes to produce foods such as cheese, bread, and fermented beverages. Conventional techniques such as cross-hybridization, production of mutants, and selective breeding have resulted in new varieties of crop plants or improved livestock with altered genetics. However, these methods are relatively slow and labor-intensive, are generally limited to intraspecies crosses, and involve a great deal of trial and error.

Genetically Modified Crop Plants Unregulated by the U.S. Department of Agriculture

Crop	*Patent Holder*	*Genetically Engineered Trait(s)*

Transgenic Technology

Recombinant DNA techniques, which manipulate cells' deoxyribonucleic acid (DNA), developed in the 1970's enable researchers rapidly to make specific, predetermined genetic changes. Because the technology also allows for the transfer of genes across species and kingdom barriers, an infinite number of novel genetic combinations are possible. The first animals and plants containing genetic material from other organisms (*transgenics*) were developed in the early 1980's. By 1985 the first field trials of plants engineered to be pest-resistant were conducted. In 1990 the U.S. Food and Drug Administration (FDA) approved chymosin as the first substance produced by modified organisms to be used in the food industry for dairy products such as cheese. That same year the first transgenic cow was developed to produce human milk proteins for infant formula. The well-publicized Flavr Savr tomato, modified to delay ripening and rotting, obtained FDA approval in 1994.

Goals and Uses

By the mid-1990's, more than one thousand genetically modified crop plants were approved for field trials. The goals for altering food crop plants by genetic engineering fall into three main categories: to create plants that can adapt to specific environmental conditions to make better use of agricultural land, increase yields, or reduce losses; to increase nutritional value or flavor; and to alter harvesting, transport, storage, or processing properties for the food industry. Many genetically modified crops are sources of ingredients for processed foods and animal feed.

Herbicide-resistant plants, such as the Roundup Ready soybean, can be grown in the presence of glyphosphate, an *herbicide* that normally destroys all plants with which it comes in contact. Beans from these plants were approved for food-industry use in several countries, but there has been widespread protest by activists such as Jeremy Rifkin and environmental organizations such as Greenpeace. Frost-resistant fruit containing a fish antifreeze gene, insect-resistant plants with a bacterial gene that encodes for a pesticidal protein (*Bacillus thuringiensis*), and a viral disease-resistant squash are examples of other genetically modified food crops that have undergone field trials.

Scientists have also created plants that produce healthier unsaturated fats and oils rather than saturated ones. Genetic engineering has yielded coffee plants whose beans are caffeine-free without processing and tomatoes with altered pulp content for improved canned products. Genetically modified microbes are used for the production of food additives such as amino acid supplements, sweeteners, flavors, vitamins, and thickening agents. In some cases, these substances had to be obtained from slaughtered animals. Altered organisms are also used for improving fermentation processes in the food industry.

Food and Environmental Issues

Food safety and quality are at the center of the genetically engineered food controversy. Concerns include the possible introduction of new toxins or allergens into the diet and changes in the nutrient composition of foods. Proponents argue that food sources could be designed to have enhanced nutritional value.

A large percentage of crops worldwide are lost each year to drought, temperature extremes, and pests. Plants have already been engineered to exhibit frost, insect, disease, and drought resistance. Such alterations would increase yields and allow food to be grown in areas that are currently too dry

Seeds of Dissent

Creation of transgenic crops has been alleged to create the risk of new allergenic proteins. Despite these risks, as of 2001, both giant agribusiness and the United States Department of Agriculture resisted informational labeling of genetically modified (GM) food products, arguing that GM foods are as safe as conventional foods and that there is no evidence they cause allergic reactions. Because GM products are often mixed with conventional products, unlabeled foods make it hard to trace individuals' allergic reactions. Similarly, people with culturally based dietary restrictions do not know whether produce they eat contains proteins derived from beef, pork, fish, or other animals.

Other potential risks of transgenic crops include increases in toxins and decreases in nutritional value. Accidental crossbreeding with wild species of plants has caused critics of "genetic pollution" to raise the specter of a steady stream of animal and microbial genes entering the gene pools of plants in wild ecosystems.

Additionally, herbicide-resistant weeds remind activists that soybeans dubbed Roundup Ready Soybeans have been bred to tolerate glyphosphate, enabling that herbicide's wider use. Development of pesticide resistance among insects was feared when U.S.-grown transgenic corn was shipped, unlabeled, to Europe in 1996. Situations like this could lead to increased application of chemicals already in use by farmers or a switch to different, more toxic chemicals.

These and other controversies and fears have caused many European nations and Japan to prohibit agricultural production of GM crops. Some nations have banned imports of all GM products.

or infertile, positively impacting the world food supply.

Environmental problems such as deforestation, erosion, pollution, and loss of biodiversity have all resulted, in part, from conventional agricultural practices. Use of genetically modified crops could allow better use of existing farmland and lead to a decreased reliance on pesticides and fertilizers. Critics fear the creation of "superweeds"—either the engineered plants or new plant varieties formed by the transfer of recombinant genes conferring various types of resistance to wild species. These weeds, in turn, would compete with valuable plants and have the potential to destroy ecosystems and farmland unless stronger poisons were used for eradication. The transfer of genetic material to wild relatives (*outcrossing*, or "genetic pollution") might also lead to the development of new plant diseases. As with any new technology, there may be other unpredictable environmental consequences.

GENETICS: MENDELIAN

Categories: Disciplines; genetics; history of plant science

Mendelian genetics is the classical mechanistic explanation of heredity in sexually reproducing organisms. It explains how genetic information is passed from one generation to another.

In 1866 the Augustinian monk Gregor Mendel (1822-1884) published a paper titled "Versuch über Pflanzenhybriden" (*Experiments in Plant-Hybridisation*, 1910), describing the heredity of mutant characteristics of garden peas. Mendel founded the modern science of genetics with these experiments, because they led him to propose the existence of hereditary factors, now called *genes*, and rules describing their inheritance, now referred to as *Mendel's laws*. The importance of Mendel's work was not recognized until 1900, sixteen years after his death, when the movements of *chromosomes* during cell division were carefully studied. Since then, Mendel's laws have been shown to hold true throughout nature. The biochemical nature of genes has been discovered, the genetic code has been broken, and genetics has assumed a central role in modern biology, medicine, and agriculture.

Mendel's Experiments

Mendel was not the only researcher interested in genetics, or inheritance, as it was called in his day. The prevailing theories of his time, though, differed considerably from his final conclusions. It was believed by most biologists that inheritance involved the blending of some sort of element from each parent. The result is offspring that are intermediate between the parents. This process, as understood, was analogous to blending two colors of paint. Experiments by others made it difficult to challenge this theory, because they often studied numerous complex traits simultaneously, only analyzed offspring from a single generation, and worked with small numbers of organisms.

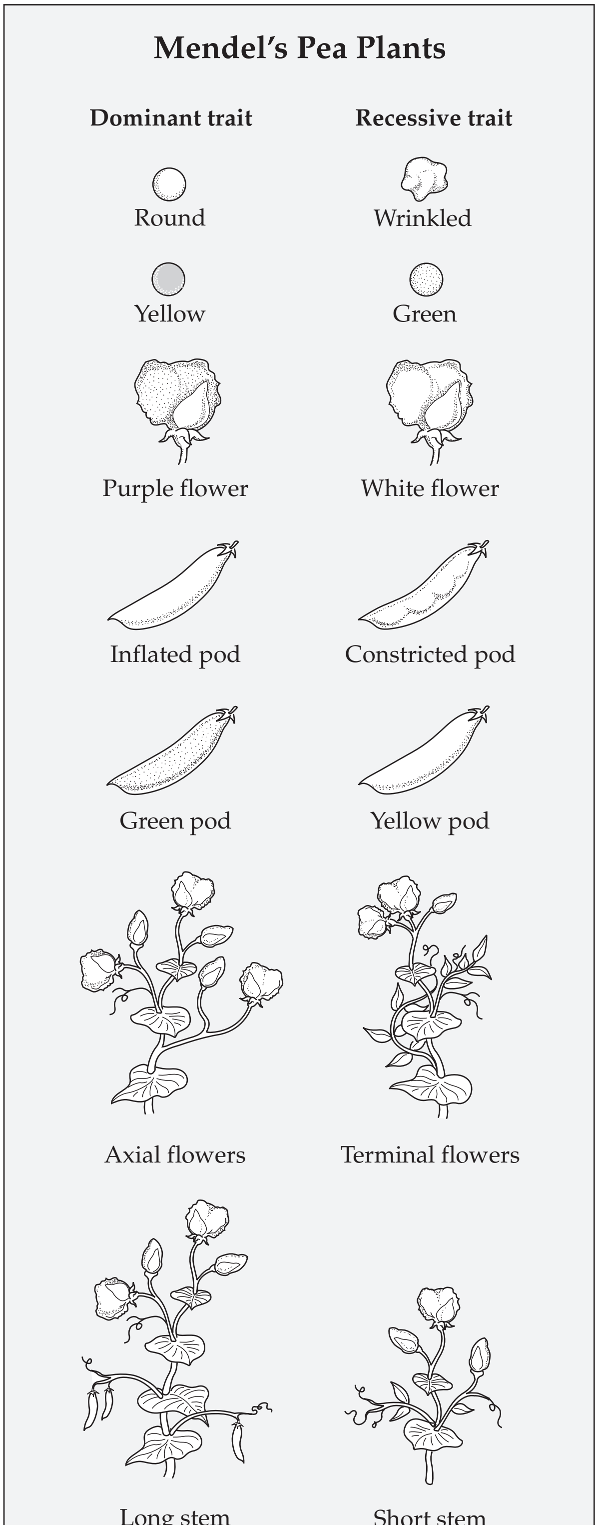
One of the reasons for Mendel's success was that he simplified the problem of heredity by analyzing a few simple, easily distinguishable, hereditary differences among a species that was easy to breed. He also initially studied one trait at a time and followed the inheritance of each trait for several generations, using large enough numbers to solidify his conclusions.

He began by selecting strains of garden peas that differed by a single trait from normal strains, such as wrinkled versus smooth, green peas versus yellow, and tall plants versus short. Once each strain bred true for a mutant variation, he crossed it with a different strain to see which trait was passed on to the offspring. Mendel observed that all the hybrid offspring of each individual cross resembled one of the parent types and not the other, rather than a mixture of the two types or an intermediate form (the conventional "mixed-paint" theory). Crosses between tall and short parent strains, for example, produced hybrids that were tall only. Mendel defined this phenomenon as *dominance* of one trait over the alternate trait, which he called the *recessive* trait.

Mendel then discovered that crossing two hybrids resulted in the reappearance of the recessive trait but only in one-fourth of the offspring. A cross between two tall hybrids, for example, produced about three-fourths tall plants and one-fourth short plants. Mendel proposed that hereditary factors (now called genes) existed for each of the traits with which he was working. He also proposed that hereditary factors exist in pairs, such that each individual inherits one from the pair carried by each parent. Mendel hypothesized that the pairs of factors would be separated, and one would be randomly included in each *gamete* (male or female germ cell—pollen or ovule, in the case of plants).

Testing the Theory

Mendel tested this theory with further crosses. (Because Mendel did not know of the existence of genes, he did not have a clear way to refer to the ge-



Electronic Illustrators Group

Mendel evaluated the transmission of seven paired traits in his studies of garden peas.

netic factors responsible for his results. The word "gene" is used in this discussion for convenience.)

He predicted, for example, that the original tall parent had two tall genes for height (symbolized as *TT*), and the original short parent had two short genes for height (*tt*). The hybrid would inherit one of each (*Tt*), but because the tall gene is dominant, the hybrid's appearance would be tall. Mendel predicted that crossing a *Tt* hybrid with one of the short (*tt*) plants should produce half tall (*Tt*) offspring and half short ones (*tt*). That is exactly what Mendel observed. He was also able to predict the outcomes of other crosses involving different traits. Mendel concluded that his theory worked: Paired hereditary factors must exist, and only one of the two, chosen at random, could be passed on to each offspring by each parent. Mendel labeled this phenomenon *segregation*, meaning that the parent's two hereditary factors are physically segregated into different cells during the production of gametes. This principle of segregation is now called Mendel's first law of inheritance.

Mendel's second law of inheritance describes the principle of *independent assortment*, which states that different hereditary factors segregate independently of one another. Mendel observed, for example, that if he crossed a tall and purple parent (*TT-PP*) with a short and white one (*tt-pp*), the hybrid offspring were tall and purple, as these genes are dominant. Then, when he crossed the tall and purple hybrid (*Tt-Pp*) with another, identical hybrid, the progeny showed an "assortment" of the two traits (tall and purple, tall and white, short and purple, short and white) in a 9:3:3:1 ratio, respectively. This is the ratio expected if each trait's genes segregate independently. Stated another way, whether a parent passes on a tall or short factor does not influence whether that parent also passes on the purple or white factor.

These two laws of heredity summarize Mendel's discovery of discrete genetic factors and their patterns of inheritance: Mendel had proposed that discrete genetic factors exist, had explained how they are passed on, and had supported his theories with experimental evidence. Mendel's discovery, however, was virtually ignored. He died in 1884 without receiving recognition for his work. Mendel's laws were independently rediscovered in the year 1900, and then their fundamental importance and general applicability were widely recognized.

Results of Mendel's Pea-Plant Experiments

Parental characteristics	*First generation*	*Second generation*	*Second generation ratio*
Round × wrinkled seeds	All round	5,474 round : 1,850 wrinkled	2.96 : 1
Yellow × green seeds	All yellow	6,022 yellow : 2,001 green	3.01 : 1
Gray × white seedcoats	All gray	705 gray : 224 white	3.15 : 1
Inflated × pinched pods	All inflated	882 inflated : 299 pinched	2.95 : 1
Green × yellow pods	All green	428 green : 152 yellow	2.82 : 1
Axial × terminal flowers	All axial	651 axial : 207 terminal	3.14 : 1
Long × short stems	All long	787 long : 277 short	2.84 : 1

Morgan's Contributions

Microscopic bodies in the nuclei of cells, called chromosomes, had been discovered by the end of the nineteenth century, and in 1901 it was proposed that chromosomes are the physical structures that contain Mendel's hereditary factors, or genes. Chromosomes were a likely structure for the location of genes because chromosomes occur in pairs, duplicate when the cell divides, and segregate into sperm and egg cells such that only one of the two chromosomes in each pair is passed on to any single offspring by each parent. The chromosomal theory of heredity made it easier for biologists to think of genes as physical objects of analysis, and studies of Mendelian patterns of inheritance and their chromosomal basis progressed rapidly.

A geneticist named Thomas Hunt Morgan at Columbia University made several key discoveries using fruit flies between 1910 and 1920. He and his colleagues discovered mutations in flies that showed different patterns of inheritance in males and females, which led to association of these genes with the sex-determining X and Y chromosomes. Traits affected by genes on these chromosomes show a sex-linked pattern of inheritance in which recessive traits appear more often in males than in females. Human sex-linked traits, for example, include hemophilia, color-blindness, and baldness.

Fruit flies have three pairs of chromosomes besides the sex chromosomes, and Morgan's laboratory team showed that traits could be grouped together in "linkage groups" corresponding to their four pairs of chromosomes. They realized that Mendel's second law describing the principle of independent assortment corresponded to the assortment of chromosomes being passed from parent to offspring. Any genes on different chromosomes would be passed on independently, while genes linked together on the same chromosome would be passed on together as a unit. The discovery of linkage groups supported the idea that chromosomes were made up of collections of a large number of genes linked together.

Sturtevant's Contributions

Morgan's laboratory group, however, also observed occasional exceptions to this pattern of linkage, when offspring showed unexpected new combinations of linked genes that did not exist in either parent. Alfred H. Sturtevant, a student in Morgan's laboratory, proposed that the paired chromosomes carrying different forms of the same genes (one carrying recessive forms, for example, *a-b-c*, versus the other, carrying dominant forms *A-B-C*) could undergo a reciprocal exchange of part of the chromosome. One chromosome pair could exchange, for example, *C* for *c*, resulting in new *a-b-C* and *A-B-c* combinations of the linked genes.

Sturtevant also discovered that such recombination events occur with different frequencies between different genes. Only 1 percent of the *A* and *B* genes might be switched in each cross, for example, but 20 percent of the *A* and *C* genes might recombine in the same cross. Sturtevant proposed that the genes are linked together in a linear sequence and that the frequency of recombination between them is a function of the physical distance separating them on the chromosome. Two genes that are far apart should recombine more frequently than two genes close together, since there would be a greater opportunity for the breakage and the exchange of different chromosomal material to occur between them.

Sturtevant proposed that differences in the frequency of recombination among linked genes on the same chromosome could be used to "map" the genes in a linear sequence that would reveal their order and relative positions on the chromosome. This principle turned out to be universal, and it allows genes to be mapped to specific locations on each chromosome in all organisms that can be systematically bred. Mendel's genes had, by the 1920's, been associated with chromosomes, and individual genes on each chromosome could be ordered and mapped using recombination analysis.

Mid-Twentieth Century Developments

The following two decades were marked by two important parallel developments in genetics. The first was a mathematical and experimental synthesis of Mendel's genetic theory with Charles Darwin's theory of natural selection. It was shown that the genetic mechanism described by Mendel provided the hereditary mechanism required for Darwin's theory of natural selection. The revision of Darwin's work that resulted is often referred to as the neo-Darwinian synthesis.

The second development was progress in identifying the biochemical nature of genes, primarily by the extension of genetic analysis to bacteria and viruses. These studies led to the identification of *deoxyribonucleic acid* (DNA) as the hereditary molecule and to the identification of its biochemical structure by James Watson and Francis Crick in 1953. Once the biochemical structure of genes was identified, an understanding of how DNA replicates and carries a genetic code that directs the synthesis of proteins followed rapidly.

One more revolutionary breakthrough that set the stage for the current era of genetics was the rapid development of *recombinant DNA technology* in the 1970's and its refinement and broad application in the 1980's. Recombinant DNA technology is a collection of methods that allows DNA sequences of one organism to be recombined with those of another. The application of these techniques is commonly referred to as "genetic engineering." The fact that the chemical structure of DNA and the genetic code for protein synthesis are virtually the same for all organisms makes recombinant DNA a powerful technology. Recombinant DNA techniques, together with an understanding of the genetic code and the ability to identify and map specific genes, have opened up a new era of biological investigation and applications to medicine and agriculture.

GENETICS: MUTATIONS

Categories: Cellular biology; evolution; genetics

A mutation is a heritable, sudden change in the structure of a gene, which has no relation to the individual's ancestry. The change can occur spontaneously or can be the result of exposure to ultraviolet radiation or chemicals.

In 1901 Hugo de Vries coined the term *mutation* to describe changes in the hereditary material of evening primrose (*Oenothera*). "Mutation" is a derivative of the Latin verb *mutare*, meaning "to move or change." The word was first used to describe spontaneous, heritable changes in the phenotype of an organism.

In the modern era of genomics, mutations can be defined as changes in DNA (deoxyribonucleic acid) sequences, that is, changes in the structure of a gene. The changes can occur spontaneously or can be induced via ionizing radiation (ultraviolet radiation) or chemicals, such as aflatoxin B_1 and ethylmethane sulfonate. A common cause of spontaneous mutations is *deamination*, in which the amino group on the number 2 carbon of cytosine (C) is removed, converting C to uracil (U) in DNA. Another cause is copying errors during DNA replication: slippage or shifting of the translational reading frame. Spontaneous mutations also may be caused by *depurination*, in which the bond between deoxyribose sugar and a purine base, adenine (A) or guanine (G), is hydrolyzed, or by *depyrimidination*, the hydrolization of the bond between deoxyribose sugar and a pyrimidine base, either C or thymine (T). Depyrimidination is less common than depurination. The sites where a base is missing are called apurinic sites (when a purine base is missing) or apyrimidinic sites (when a pyrimidine base is missing) or simply *AP sites*.

An individual with a mutation is called a *mutant*. When a mutation occurs in the reproductive tissue of an individual plant, it can be transmitted to the next generation. When a mutation occurs in the somatic tissue, it will be limited only to that generation and affects only the cells in which it occurs.

Heredity vs. Genetic Combinations

Mutation is the only process that creates new genetic variation that results from a change or changes in the structure of a gene or genes. Genetic variability also can arise from new genetic combinations produced through the processes of crossing over, gene segregation, and chromosome assortment. In the case of recombination, all the genes are already present in an individual, and new variation simply results from the shuffling of those genes during gamete formation; there are no structural changes in genes.

Sites and Types of Mutation

Gene mutation involves a change in a single base pair or a deletion of a few base pairs. It usually affects the function of a single gene. The substitution of one base (or nucleotide) for another base (or nucleotide) is called a *point mutation* or a *substitution mutation*. The replacement of a pyrimidine (cytosine and thymine) with another pyrimidine or the replacement of a purine (adenine and guanine) with another purine is termed *transition*. The replacement of a pyrimidine with a purine or the replacement of a purine with a pyrimidine is termed *transversion*.

Base pair or nucleotide changes can produce one of the following types of mutation:

- *Missense mutation*, which results in a protein in which one amino acid is substituted for another amino acid.
- *Nonsense mutation*, in which a stop codon is substituted for an amino acid codon, which results in premature termination of a protein.
- *Frameshift mutation*, which causes a change in the reading frame. These mutations can introduce a different amino acid into the protein and have a much larger effect on protein structure. Small deletions also have effects similar to those of frameshift mutations. A nonfunctional protein

may be produced, unless the frameshift is near the terminal end of a gene.

- *Chromosomal mutations* or *abnormalities*, which involve deletions or insertions of several contiguous genes, inversion of genes on a chromosome, or the exchange of large segments of DNA between nonhomologous chromosomes.

Effects of Mutations

Gene flow is the exchange of genes between different populations of the same species, produced by migrants and commonly resulting in changes in gene frequencies at many loci (locations) in the recipient gene pool. The effect of a mutation carried into a new population will depend upon the number of migrants that were mutants and the size of the recipient population.

Genetic drift is the random fluctuations of gene frequencies as a result of sampling errors. Drift occurs in all populations, but its effects are most striking in small populations. Due to periodic reductions in population size, genetic drift can affect gene frequencies. A large population may contract and expand again with an altered gene pool (called the *bottleneck effect*). A consequence of genetic drift is reduced variability. A mutation has a better chance of spreading faster in a smaller population than in a larger population.

The "founder effect" is a term first coined by Ernest Mayr in 1942, who referred to small groups of migrants that succeed in establishing populations in a new place as "founders." Two founders could carry only four alleles at each gene locus. If a rare (mutant) allele were included among them, its frequency would be considerably higher (0.25) than it was in the parental population.

Nonrandom mating, also called *assortative mating*, occurs when male and female plants are not crossed at random. If the two parents of each pair tend to be more (or less) alike than is to be expected by chance, then positive (or negative) assortative mating occurs. Positive assortative mating promotes *homozygosity*, whereas negative assortative mating tends to promote *heterozygosity*. Mating of similar homozygotes would increase their frequency at the expense of heterozygotes. A mutation should spread more quickly under assortative mating than under nonassortative mating.

Inbreeding is defined as the coming together, at fertilization, of two alleles that are identical by descent. This is the result of mating between closely related plants. A mutation has a better chance of establishing under mating systems in which close relatives are involved than under those where inbreeding is prevented. Assortative mating represents the mating of individuals with similar *phenotypes*, whereas inbreeding represents the mating of individuals of similar *genotypes*.

Autogamy, or self-fertilization, is the strictest form of inbreeding. A mutation would spread more quickly under self-pollination than under cross-pollination.

If a mutation occurs at a homozygous locus (*aa* × *Aa*, or *AA* × *Aa*), the result would be greater diversity. If a mutation occurs at a heterozygous locus (*Aa* × *AA* or *aa*), it would result in more uniformity. Depending on the size of the population, gene frequency will change.

GENETICS: POST-MENDELIAN

Categories: Disciplines; genetics; history of plant science

Thirty years after the work of Gregor Mendel in the nineteenth century, several rediscoveries of his work in genetics brought his theories to the fore. At about the same time, the discovery of chromosomes, coupled with the earlier knowledge, took genetics in a new direction.

Gregor Mendel (1822-1884) is often considered the founder of the science of genetics. Though his experiments with pea plants became the basis for understanding genetics in all plants and animals, he died unknown. In 1900 three simultaneous "rediscoveries" of Mendel's studies put his name at the forefront of biology. With the reintroduction to the world of Mendel's genetic laws, biologists began to look more closely at genetic phenomena. These researchers used Mendel's laws as the basis for more in-depth studies of genetics, which led to the modern understanding of genes, chromosomes, and their inheritance.

Rediscovery of Mendel

In 1900, working independently of one another, biologists Erich Tschermak, Hugo de Vries, and Karl Erich Correns each published data that reasserted Mendel's historic principles of heredity. Each scientist came to this rediscovery from a slightly different perspective.

Tschermak, an Austrian botanist, coincidentally started pea plant breeding experiments in 1898. He performed these experiments for two years before he accidentally discovered a reference to Mendel's work from thirty years earlier. When he read Mendel's papers, Tschermak found that he had duplicated many of Mendel's breeding experiments, and, embarrassingly, his own work was not as thorough. The Austrian published his own findings and gave credit to Mendel for performing the original breeding work. Tschermak is known for applying the genetic principles he helped rediscover to developing wheat-rye hybrids and a disease-resistant oat hybrid.

Hugo de Vries, whose primary concern was understanding how evolution worked, was a professor at the University of Amsterdam. De Vries wanted to find a genetic basis for Charles Darwin's theory of natural selection to understand how species could change over time. De Vries studied the evening primrose and found that, after cultivating the plant for years, several varieties arose through abrupt, unexplained genetic changes. Based on these changes, he came up with a theory of *mutation* in which he hypothesized that rapid alterations in organisms could explain how evolution could quickly produce new species. For eight years, starting in 1892, de Vries conducted breeding experiments that led him to the same laws of heredity that Mendel had discovered. When he reported his own work, de Vries was very careful to attribute his concepts to Mendel.

Karl Correns was a German botanist at the University of Tübingen in the 1890's. By coincidence, Correns conducted breeding experiments with peas that reproduced Mendel's experiments. In a survey of the literature, Correns found Mendel's papers, published many years earlier. Much of Correns's life work was spent in developing additional evidence to support Mendel's hypotheses. Correns was the first researcher to suggest that if certain genes were physically close to each other, they might be "coupled" in some way and be consistently inherited in offspring. His concept explained why some traits did not seem to follow Mendel's *law of independent assortment*, which stated that all traits separated independently of one another when inherited by offspring.

Chromosomes

Chromosomes were not discovered until the end of the nineteenth century, so Mendel was never able to suggest any physical basis for his genetic theories. It was not until the science of cytology (the study of cells) was founded that scientists started to

Image Not Available

examine cells and their replication more closely. They discovered that *somatic cells* (that is, nonreproductive cells) consistently went through a pattern of division in which chromosomes were duplicated and separated between two new *daughter cells*.

Walter Sutton and Theodore Boveri, working with grasshopper cells, were the first scientists to notice that chromosomes in somatic cells occur in pairs. Sutton and Boveri suggested a connection between the pairs of chromosomes and Mendelian genetics. They believed that chromosomes carried the units of inheritance and that the way chromosomes divided accounted for how Mendel's laws functioned. Their work formed the basis for the *chromosomal theory of inheritance*.

The chromosomal theory of inheritance suggested that Mendel's genes reside on chromosomes and that when plants and animals reproduce, half their genetic material comes from each parent, forming sets of chromosomes. For example, barley has fourteen chromosomes in each somatic cell. Seven of those chromosomes are contributed from the "mother" plant and seven from the "father" plant, to make a total of fourteen chromosomes in the offspring. Therefore, half of the genes from all organisms come from each parent to determine the progeny's genetic makeup.

Each chromosome is essentially one long, linear strand of deoxyribonucleic acid (DNA), wrapped up and compacted for easy duplication and transport by the cell. There are two copies of each chromosome (called homologous pairs or homologs) in every somatic cell of an organism, each with the same physical appearance.

Such a cell with two copies of each chromosome type is called a *diploid* cell. Reproductive cells, known as *gametes*, have half the number of chromosomes and are known as *haploid* cells. It is these haploid cells from each parent that comprise the new diploid cells of the offspring. Half the chromosomes in each diploid cell come from each parental haploid cell.

Copies of the same gene on each chromosome pair are found at the same location (called a *locus*) and control traits of the organism. The copies of the same gene at a locus are called *alleles*. For example, one copy of chromosome #1 might be from the male parent and have a *dominant allele* (symbolized by *A*), and the other copy of chromosome #1 might be from the female parent and have a *recessive allele* (symbolized by *a*). These two alleles together (*Aa*), each on a separate chromosome, would constitute the *genotype*, and the expression of these alleles produces the *phenotype* (physical traits of an organism).

Linkage

In 1905 William Bateson and Reginald Punnet were the first to show clear evidence that Correns's theory of "genetic coupling" was correct. They crossed sweet peas having purple flowers and long pollen grains with sweet peas having red flowers and round pollen grains. According to Mendel's rules, the offspring in the second sweet pea generation should have *segregated* (genetically separated) into four phenotype combinations (purple/long, purple/short, red/long, and red/short) in a ratio of 9:3:3:1, because the two genes controlling these traits should have separated independently of each other. Bateson and Punnet did not obtain a 9:3:3:1 ratio. Instead, the parental traits stayed together in the offspring more often than expected, and more offspring looked like the parents than expected: purple/long or red/short. Bateson and Punnet called this phenomenon *linkage*, and any genetic traits that followed this pattern were said to be linked to each other.

In 1910 American geneticist Thomas Hunt Morgan explained the physical basis for linkage. Through his experiments with fruit flies, Morgan found that alleles for different traits only followed Mendel's law of independent assortment if they were on different chromosomes or if they were very far apart when they were on the same chromosome. If the genes for two traits were on the same chromosome, they were often passed down to the next generation jointly and stayed together consistently from generation to generation. Morgan further found that the physically closer that two alleles were to each other on a chromosome, the more closely "linked" they were to each other, staying together in offspring a greater percentage of the time.

Incomplete Dominance

Linkage was one of the first phenomena to break the Mendelian laws, but there were many additional conditions that Mendel would have puzzled over, such as *incomplete dominance*. Usually in a heterozygous organism (one with a dominant allele and a recessive allele at the same locus), the phenotype is controlled by the dominant allele, and the trait from the recessive allele will be masked. When incomplete dominance occurs, the dominant trait is weakened, and the heterozygotes look as though they have a trait partway between the recessive and dominant traits. For example, if a red-flowered snapdragon, *RR*, is crossed with a white-flowered snapdragon, *rr*, all the first-generation offspring are heterozygous, *Rr*. If the trait were dominant, then all the flowers in the offspring would be red. However, the trait displays incomplete dominance, and all the flowers are pink.

Multiple Alleles

Although an individual can have only up to two alleles at a locus, more than two alleles can exist in a population. For example, some populations of red clover are estimated to have hundreds of alleles at a locus for self-sterility. As a result, most individuals have alleles that are different from those of other members of the population, thus preventing self-pollination and making out-crossing with other plants successful. Some plants can also have more than two alleles at a locus if they are *polyploid*.

A polyploid plant has more than two homologous chromosomes of each type. The most common type of polyploid is a tetraploid, which has four homologous chromosomes of each type. With four chromosomes of each type, a locus has four alleles instead of just two. Other levels of polyploidy exist in plants, even as much as cases with ten, twenty, or more homologous chromosomes of each type.

Gene Interactions

Gene interactions occur when two or more different loci (gene locations) affect the outcome of a single trait. The most common type of gene interaction is known as *epistasis*. Epistasis describes a situation where an allele at one locus masks the phenotypic effects of a different locus. The gene being masked is called the *hypostatic* gene, while the gene doing the masking is called the *epistatic* gene.

Bateson and Punnet discovered this phenomenon during their sweet pea breeding experiments.

They crossed purple-flowered plants with white-flowered plants. In the first generation, they got all purple-flowered offspring—so they concluded that purple was the dominant gene. In the next generation, they did not get a 3:1 ratio of purple-flowered to white-flowered plants, as would be expected if purple was dominant. They got a ratio of 9:7 purple to white-flowered plants. It turned out that there were two different loci involved in the control of petal color: at the first locus *C* (purple) was dominant to *c* (white), and at the second locus *P* (purple) was dominant to *p* (white). When either locus was homozygous recessive, either *cc* or *pp*, the flowers were white, regardless of the genotype of the other locus. The recessive alleles were epistatically affecting (or masking) the dominant alleles.

Polygenic Inheritance

Certain traits are too complex to be controlled by a single locus. These traits are controlled by a complex of two or more loci, a phenomenon known as *polygenic inheritance*. In humans, multiple loci control height, intelligence, and skin coloration. These multiple genes lead to *continuous variation*, meaning that one observes a wide range of phenotypic variation. The first experiment demonstrating continuous variation was conducted by Swedish scientist Herman Nilsson-Ehle in 1910. He studied the inheritance of the red pigment on the hulls of wheat. He found that red-hulled wheat crossed with white-hulled wheat for several generations gave him plants ranging in pigment from white, light-pink, and pink to medium, basic, and dark-red. Nilsson-Ehle found that three loci control this color variation in the wheat.

Pleiotropy

Pleiotropy also breaks Mendel's laws. Usually, one locus controls a single trait. A pleiotropic gene is a single locus that controls multiple traits. If there is a loss of function mutation in a pleiotropic gene, the organism is affected in multiple ways. One example of such a trait can be found in the plant *Arabidopsis thaliana*. This plant has a mutant allele known as tu8. This gene was originally isolated as a mutant in the biochemical pathway that makes glucosinolate, a chemical used against pathogens. This tu8 mutation also causes the plant to be dwarfed, late-flowering, and heat-sensitive. Genetic experiments by researchers James Campanella and Jutta Ludwig-Mueller have shown that all these traits are controlled by a mutation in a single gene.

Cytoplasmic Inheritance

Finally, *cytoplasmic inheritance*, often known as *maternal inheritance* or *extranuclear inheritance*, is a phenomenon referring to any genetic traits not inherited from nuclear genes. For example, both chloroplasts and mitochondria contain their own genetic information that is inherited by every generation. This information is inherited in a different fashion from that of nuclear genes. Nuclear genes, in the form of chromosomes, are donated equally by each parent. The genetic information from chloroplasts and mitochondria is not donated equally. Offspring come from the joining of the male and female gametes, but the size of these gametes differs drastically. Male gametes, both animal sperm and plant pollen, are often one-one hundredth the volume of an egg cell. Because of their small size, male gametes often have little cytoplasm. Because the chloroplast and mitochondria reside in the cytoplasm, it is usually the case that none of the organellar DNA of the male gamete is included in the offspring. The female parent alone donates the chloroplast and mitochondrial alleles. Although maternal inheritance is the rule in most plants, a few groups, such as some members of the evening primrose family (*Onagraceae*) have displayed biparental inheritance of organellar DNA.

GERMINATION AND SEEDLING DEVELOPMENT

Categories: Anatomy; physiology; reproduction and life cycles

With germination, the growth of a seedling, spore, or bud begins. Seedling development begins with the close of germination.

To germinate, seeds must be nondormant and in a suitable environment. Seeds germinate within a restricted range of temperatures, moisture, oxygen, light, and freedom from chemical inhibitors. Wild seeds display many *adaptations* that predispose germination within specific habitats and seasons. By contrast, seeds of crops and other cultured plants usually lack controls that prevent germination. The control system was lost because some seeds in the population lacked controls and were chosen when they germinated in the care of a culturist. For that reason, most cultivated plants that start from seeds show little or no germination control. Most of the information on germination control, therefore, covers wild species of plants.

Seeds and Dormancy

Seeds are the exclusive means of regeneration for the annual flowering plants. In other plants, seeds are an alternative strategy to regeneration by *buds*, *bulbs*, *rhizomes*, *stolons*, or *tubers*. In those plants, the primary roles of the seed are to disperse the population and to reinvigorate the genetic diversity of the germ line.

Seed *dormancy* occurs in most plants, and when a seed is dormant it will not germinate, even if it is in the right environmental conditions. The dormant state may begin with maturation of the seed embryo, or it may develop in climate extremes after the seed falls from its parent. Dormancy prevents immediate germination when the mature seed is in an inappropriate environment, and it is a programmed phase in the life cycle. Dormancy's function ends, and a *germination window* opens, at a time when the emerging seedling will have the optimum chance for survival.

After-ripening removes the dormancy and allows the seed to respond to germination stimuli. Seeds of summer annuals after-ripen when exposed to winter and early spring temperatures, a treatment called *stratification*. Exposure to cold temperatures can also promote dormancy in some seeds.

Not all nongerminating seeds are innately dormant. There are also nondormant and conditionally dormant seeds. Neither type may germinate when the seeds mature, simply because the parent prevents contact with the soil and absorption of water or because the temperature range is below that necessary for germination. Wild seeds may experience a deepening of dormancy as a result of exposure to the temperatures of the dormant season. Nondormant seeds may simultaneously experience biochemical reactions that deepen dormancy and cause them to after-ripen.

Dormancy is caused by one or more conditions of the seed. Physiological dormancy of the embryo is the most common. It may be caused by the presence of an *inhibitor molecule*, an inadequate level of a growth hormone, or some other internal factor. Examples of the latter include blockages in membrane function or in synthesis of an enzyme or its nucleic acid messenger.

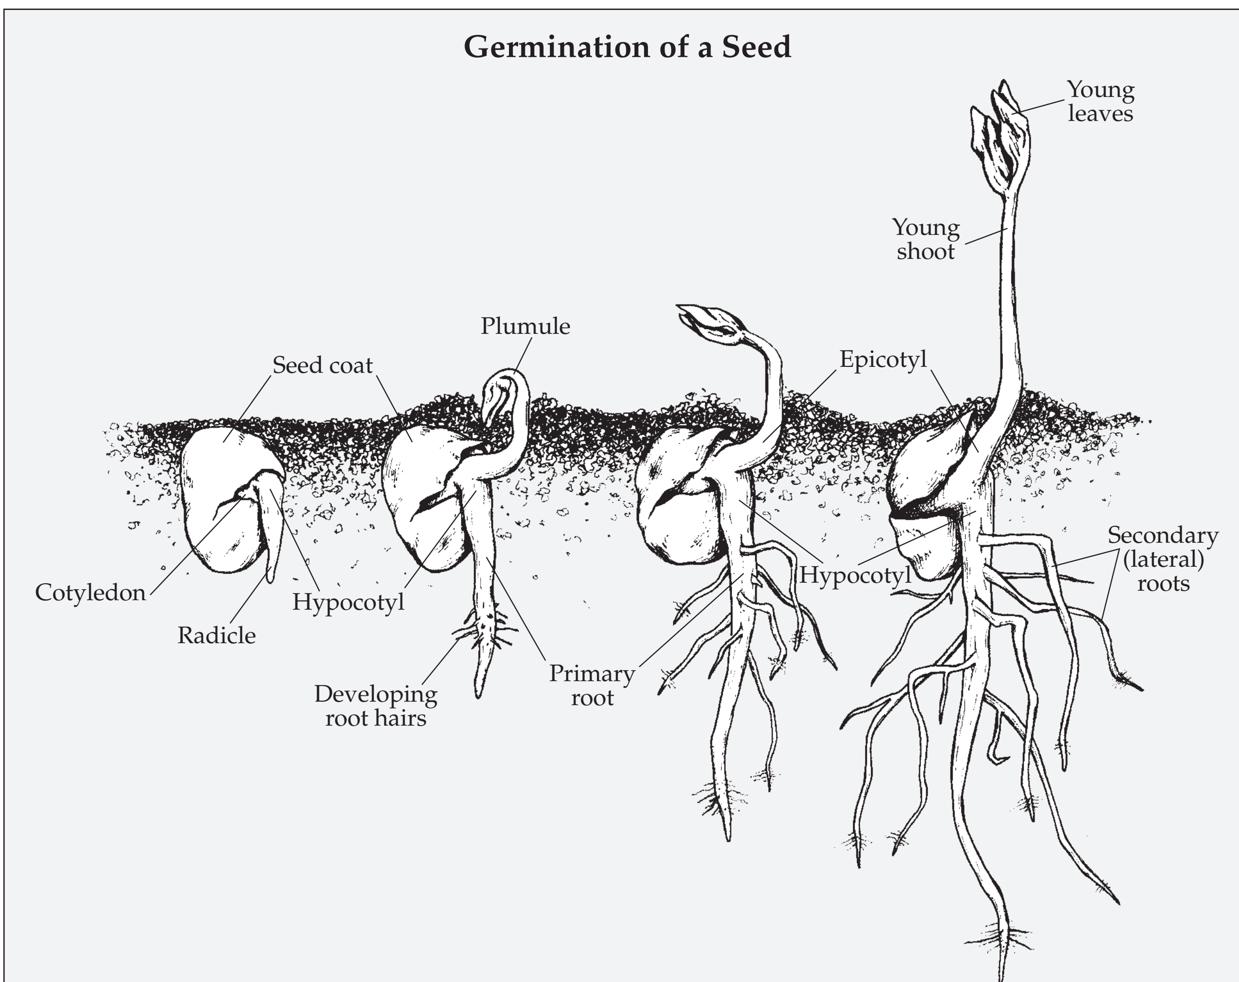
Other causes of dormancy are a hard or impervious seed coat, an underdeveloped embryo, or some combination of those factors. Some hard-coated seeds require physical scraping, such as tumbling down a swift-flowing stream and being scraped on the streambed. Others may require exposure to a forest fire or passage through the gut of an animal to weaken the seed coat.

Germination

The seeds from the previous year's crop of summer annuals wait to germinate in spring. Seeds of many species will germinate when soil temperatures reach a threshold constant. Others require daily fluctuations of temperature, waiting until the daily fluctuation becomes sufficiently large.

Seeds of most species require a light stimulus to germinate. The light is absorbed by the pigment *phytochrome*, which is positioned in the cotyledons of the embryo. Phytochrome acts as a shade detector. White light and, especially, red light, convert the phytochrome molecule to an active form. The rearrangement of the molecule causes it to attach a different part of itself to a new location on a cell membrane within the cotyledons of the seed. Transformed phytochrome allows seeds to germinate. By contrast, far-red light, which is absorbed by the transformed phytochrome molecule, transforms the molecule back to its original shape—that is, it deactivates it. When sunlight is transmitted through green leaves to the forest floor, much of the visible light with wavelengths shorter than 700 nanometers is absorbed or scattered. This *shade light* is rich in far red, and it tends to deactivate phytochrome.

Not all seeds germinate at the beginning of the following growing season. Light-demanding seeds that have become buried or have fallen into the shade will be stressed by the absence of an activat-



Kimberly L. Dawson Kurnizki

ing light signal, while the embryos experience an environment that is otherwise growth-promoting. Stressed seeds may enter a *secondary dormancy* and will need to undergo a second interval of after-ripening before again becoming nondormant. Seeds emerging from secondary dormancy may require a smaller light stimulus. Following primary dormancy, one or more complete light cycles may be necessary. By contrast, seeds may be fully activated by only a brief pulse of light when they emerge from secondary dormancy.

Many seeds become dry on the parent plant as a part of maturation. Drying is believed to end the seed-building phase and start the pregermination phase. Most domestic seeds require no after-ripening but will germinate if allowed to take up water. Water uptake is a first step in germination. Biochemical events that begin with water uptake in domestic seeds include metabolism along three separate pathways and an increased use of oxygen. Excessive moisture, even at temperatures too low for germination, may lower seed viability. Thus, seeds are best preserved under cold, dry conditions.

With proper storage, a reasonable percentage of seeds may live for many years. Record long-lived species include seeds of *Canna* (arrowroot, six hundred years), *Albizia* (mimosa and silk trees), and *Cassia* (about two hundred years). Seeds of *Verbascum* (mullein) have survived at 40 percent viability for one hundred years. Weed seeds in soil banks may need to wait for hundreds of years before the forest is cleared by catastrophe and the environment once again is favorable for such pioneer species. By contrast, recalcitrant seeds require their embryos to be kept moist, or viability is quickly lost; examples include trees with large seeds, such as walnut, oak, hazel, and chestnut. These seeds usually live less than one year.

Seedlings

Seedling development begins with the close of germination. Cells in the embryonic root (the *radicle*) begin to divide and grow. In some seeds, or in unusual environmental conditions, other parts of the embryo emerge before the radicle. Development of the seedling is marked by the growth and elongation of the embryo stem. Seeds are classified according to which part of the stem grows more rapidly. In the *epigeal* type, the *hypocotyl*, which is the basal part of the stem between the radicle and the embryonic leaves (the *cotyledons*), grows, thereby thrusting the cotyledons above the soil. In the *hypogeal* type, the *epicotyl* or upper part of the stem elongates, and the cotyledons remain underground.

Exposed to light, phytochrome in the cotyledons calls for an end to subterranean elongation, called *etiolation*, and the beginning of plantlike growth. Among its functions, phytochrome triggers the synthesis of chlorophyll; photosynthesis soon turns the cotyledons into sugar factories. At the same time, the epicotyl region of the embryo above the cotyledons is extending the *plumule* to form the first true, or foliage, leaves. In hypogeal seeds the first leaves emerge from the plumule.

Food reserves that are stored in the endosperm, cotyledons, and embryo will nourish the early growth of the plant until it can synthesize the necessary machinery for making its own food. Foods are stored in seeds as starch and other complex carbohydrates, fats, and proteins. Cereal grains contain large amounts (65-80 percent) of carbohydrates, which are stored in the endosperm. Seeds of legumes are famous for their high protein contents, which reach 37 percent in soybeans. The peanut, a legume, stands out by having both high protein (30 percent) and high fat content (50 percent). Legumes store food reserves in the embryonic leaves (cotyledons).

Food is transferred to the growing sites, primarily as sucrose and amino acids. Starches and other carbohydrates and fats are first converted to simple sugars and then to sucrose for transport. Synthesis of active phytochrome, second messengers, and the plant hormone gibberellin are involved in determining the rate of mobilization and transport. They promote synthesis of enzymes, such as those that break down food reserves into simple sugars.

The embryo selects one part of the root-stem axis for rapid growth, changing the relationship of the other parts to the external environment. The cotyledons are also versatile: They may act as first leaves or may remain attached to another part of the embryo, such as the endosperm. There, they act as absorptive organs to transport mobilized food reserves to the growing parts of the seedling. In onions, a single cotyledon performs both functions. The exposed part carries out photosynthesis, while the buried part absorbs foods from the endosperm.

GINKGOS

Categories: Evolution; gymnosperms; paleobotany; *Plantae*; taxonomic groups

The ginkgos, phylum Ginkgophyta, *constitute one of four phyla of the gymnosperms in the kingdom* Plantae. Ginkgo biloba, *the maidenhair tree, is the only living representative of the ginkgo family,* Ginkgoaceae, *a group of plants that have lived for millions of years and are identified by an abundant fossil record.*

The ginkgo is a hairless, deciduous tree with a straight trunk and pyramid-shaped foliage usually sparsely branched when young, becoming denser with age. Leaves are fan-shaped, 2 to 3 inches (5 to 7.5 centimeters) across, sometimes divided into two lobes. The ginkgo normally reaches heights of 80 to 100 feet (24 to 30 meters) and under favorable conditions grows to 125 feet (38 meters) or more. The bark is reddish-gray and corky, with irregular, wide fissures dividing rough plates. On old trees, the bark becomes gray, rough, and deeply furrowed.

Considerable diversity in branching habit occurs, sometimes with one side of the tree having erect branching and the other side spreading limbs. Young trees send out straight branches at a skyward angle and, until maturity, the sparse branching gives the tree an erratic appearance. Upon maturity, the branches round out and become widespread, yet retain an uneven crown.

As in many conifers, the long branches (shoots) and short, spurlike shoots of *Ginkgo biloba* are easily distinguished. The leaves are spirally arranged on both types but widely spaced on the long shoots, with leaves in crowded, rosettelike clusters on the short shoots. Branchlets (twigs) have a horizontal or drooping habit and are occupied with short, spurlike shoots. These shorter shoots increase in length only a fraction of an inch (2.5 centimeters) per year and may produce clusters of leaves annually for many years before abruptly lengthening out into long shoots bearing scattered leaves. The fan-shaped leaf has a marked resemblance to the fronds of the maidenhair fern, thus the common

Classification of Phylum *Ginkgophyta*

Class *Ginkgoopsida*
Order *Ginkgoales*
Family *Ginkgoaceae* (Ginkgo family)
Sole living species: *Ginkgo biloba* (maidenhair tree)

name: maidenhair tree. However, in its native China it is commonly called ducks-foot tree, also based on leaf shape.

The leaves, which grow on slender stalks up to 3 inches (7.5 centimeters) long, have numerous veins radiating out from the base to an irregularly notched leaf margin. There is no central midrib vein on the somewhat leathery, textured leaf. Stomata (breathing pores in the leaves) occur on both the upper and lower surfaces of the leaves. The leaves emerge yellow-green in spring but turn green toward midsummer and become golden in autumn. Leaves on vigorous young trees can grow up to 6 to 8 inches (15 to 20 centimeters) in width. There is a morphological distinction between leaves of long branches and short shoots, with the leaves of long branches generally bilobate to four-lobed and those of short shoots only fan-shaped to bilobate.

Elliptical, naked seeds resembling a small plum appear on female trees in early spring. Seeds range from 0.75 to 1 inch long (1.9 to 2.5 centimeters) and are covered by a thin, yellowish-orange, fleshy outer wall enveloping a woody shell which contains an edible kernel in the shell interior. When falling to the ground in autumn, the seed covering begins to diminish in thickness over several months, giving off the vile odor of butanoic and hexanoic acids (butter and Romano cheese fatty acids), and is eventually lost from most seeds. *Ginkgo biloba* wood is light, brittle, yellowish in color, and of little value. It is used as a base wood in highly lacquered furniture and small carved items.

Reproduction

The ginkgo is dioecious: Male and female reproductive structures are borne on separate trees. The male reproductive structures appear in May and are inch-long, catkinlike structures bearing numerous paired, pollen-bearing organs. The pollen grains are similar to the elliptical grain of cycads. The pollen organs and ovules are confined to the short shoots of each ginkgo tree and arise in the leaf axils or inner bud scales.

The female reproductive structure consists of a long stalk, bearing on each side an erect, naked ovule, which is surrounded at the base with a collarlike rim. The paired ovules are borne in groups of two to ten. The three-layered ovules include a fleshy exterior layer (sarcotesta), an inner flesh, and a stony shell (sclerotesta) between the two. This three-layered structure is called the integument. The nucellus (the central cellular mass of the body of the ovule containing the embryro) is mostly free from the surrounding integument, except at its base, where it develops a pollen chamber at its apex.

Similar to the cycads, the gingko reproduces by means of flagellated sperm cells, which are carried by the wind-borne pollen to the female reproductive structures within the ovule. In the ginkgo, the vascular system is weakly developed and consists of a pair of braided bundles in the interior fleshy layer of the integument. Upon maturation of the microgametophyte (male gametophyte), pollen tubes are produced, as are large, motile sperm cells similar to those of the cycads. Megagametophyte (female gametophyte) development is similar to that in cycads as well.

Natural Regeneration

Studies into the seedling development of *Ginkgo biloba* reveal a unique mechanism of clonal regeneration that may help explain the species' long survival in the natural setting. The organ of clonal regeneration in the gingko is called the *basal chichi*. These organs are part of aggregates of suppressed shoot buds and are located in embryonic tissue of *Ginkgo biloba* seedlings. When damage occurs to the seedling axis, one of these subsurface buds grows down from the tree trunk to form a woody, stemlike basal chichi. Regeneration of *Ginkgo biloba* by basal chichi promotes survival of the tree in the forests of China today and may have been a factor in the protracted survival of the order since the Mesozoic era.

Habitat and Range

Ginkgo biloba, a distinctive tree suited for use in singular or in group plantings on lawns or along streets, is widely cultivated in all temperate zones. It prospers in moderately moist, fertile soil in humid, temperate regions. It is extremely resistant to disease and pests, and it is highly tolerate of smoke, dust, wind, and ice.

Ginkgo biloba is apparently native in eastern China, with documented semiwild trees growing on the west peak of Tian Mu Mountain in the Tian Mu Reserve, Zhejiang Province. *Ginkgo biloba* is planted in the eastern United States, Europe, and along the Pacific coast.

Fossil Record

Among the plants, *Ginkgo biloba* is probably the best-known example of a "living fossil." Although the ancestors to the order *Ginkgoales* date to the Paleozoic era, it was at the close of the Triassic period when they became a dominant part of the Mesozoic flora. During the Jurassic period, especially the middle Jurassic, *Ginkgoales* reached zenith numbers of species and its widest distribution.

Jurassic and Cretaceous fossil localities reveal circumpolar *Ginkgophytes* sites, including Alaska, Greenland, Zemlya Frantsa Iosifa (Franz Joseph Land), and Mongolia, with the Siberian locations especially productive. Southern Hemisphere *Ginkgoales* localities include Patagonia at the southern tip of South America, South Africa, India, Australia, and New Zealand. European fossil sites are known in England, Scotland, Germany, Italy, Hungary, Turkestan, and Afghanistan. Western Canada and the United States have *Ginkgoites* leaf remains from the Upper Mesozoic and Lower Tertiary deposits. The presence of *Ginkgophytes* in high northern latitudes during the Early Cretaceous period and its presence in southern latitudes, such as Argentina, during the Jurassic, suggests that the dispersal of the plant was from the southern to northern latitudes during the Upper Mesozoic era.

During the Tertiary period, the decline of the *Ginkgophytes* was evident from the presence of only two of nineteen species remaining in the fossil record. One of the remaining two species is the *Ginkgo adiantoides*, which declined sharply during the Oligocene period. This decline continued into the Miocene period in North America, with *Ginkgo adiantoides* disappearing from the fossil record at the end of the Miocene. *Ginkgo adiantoides* did continue into the Pliocene in Europe, however. Since the Pliocene, the fossil record indicates that *Ginkgoales* have been represented by the extant living fossil, *Ginkgo biloba*.

Researchers propose that the decline of *Ginkgophyta* was a result of competition from the angiosperms (flowering plants) for similar plant habitats. Also, the *Ginkgophytes* became more restricted to northern temperate forests in the Tertiary period. When glaciation occurred in these areas during the Pleistocene, these forests were destroyed by climate change.

GLYCOLYSIS AND FERMENTATION

Category: Cellular biology

Glycolysis is the beginning of the process of extracting usable energy from food. The disposal of the products of glycolysis when there is no oxygen available is the process of fermentation.

The simple sugar *glucose* is generally considered the starting point for looking at glycolysis and fermentation. Glucose is a simple *carbohydrate*, consisting of carbon, hydrogen, and oxygen. Most glucose is produced by plants; organisms that cannot photosynthesize must obtain glucose (or more complex carbohydrates) from their surroundings. Animals obtain food molecules by eating. Simpler forms of life, such as bacteria and yeast, simply absorb their food from their environment.

Breaking Chemical Bonds

The energy in glucose is locked up in the chemical bonds that hold the molecule together. The process of glycolysis breaks these chemical bonds in a series of carefully controlled chemical reactions. Each reaction can be greatly accelerated by the appropriate *enzyme*. Generally, cells have sufficient quantities of the necessary enzymes present at all times.

Each chemical step is regulated by either the amount of raw materials present or the amount of finished product. If the raw materials are in short supply, the rate of reaction will be slow. Also, if the finished products build up to a high concentration, the reaction will slow down. The energy of the chemical bonds in glucose must be released gradually. During most of the chemical steps, small amounts of energy are released. The amount of energy released is often not enough to perform significant biological work, in which case it is simply wasted as heat. The energy released during some steps, however, is captured in the special high-energy bond of *adenosine triphosphate* (ATP). ATP is one of the most important of the short-term energy storage molecules in cells and is a coenzyme for many important chemical reactions.

Adenosine Triphosphate

ATP belongs to a class of organic molecules known as *nucleotides*. It has an important role in the energy reactions in the cell. The term "triphosphate" indicates that there are three phosphate groups attached to the base molecule. The last two of these phosphates are held by a special kind of chemical bond known as a *high-energy bond*. It takes a greater amount of energy to form one of these bonds than to form the normal kinds of bonds that hold the atoms of other molecules together. When this bond is broken, a large amount of energy is released and is available to the cell to do work. Examples of such work are production of heat, synthesis of complex molecules, and movement of molecules across a membrane. When energy is required in a cell, the third phosphate of ATP is released. While the third phosphate group is routinely split off to release energy, the second one is rarely split off in cellular reactions. The cell must maintain a supply of ATP by means of the reverse reaction. The energy required for this reaction may come from fermentation when oxygen is unavailable. When oxygen is available, other components of cellular respiration are used, which include the *Krebs cycle* and *electron transport*.

Glycolysis

Energy from glycolysis is used to make ATP by two different processes. During glycolysis the glucose molecules are each split into two smaller molecules. The initial glucose molecules contain six carbon atoms each. Each molecule of glucose produces two molecules of pyruvic acid, and each pyruvic acid molecule contains three carbon atoms. During glycolysis, energy is released from the bonds of glucose molecules and is used to join free phosphate ions (also called *inorganic phosphate* or P_i) with molecules of adenosine diphosphate (ADP) to make ATP. This type of ATP synthesis is called substrate-level phosphorylation.

As a by-product, however, electrons are also stripped from glucose. These electrons are immediately trapped and held by another very important molecule, the electron carrier *nicotinamide adenine dinucleotide* (NAD). By convention, the empty electron carrier is denoted as NAD^+. When the molecule is carrying a pair of electrons, it is denoted as NADH, since the molecule also picks up a hydrogen nucleus, or proton. The electrons held by NADH represent potential energy. In the presence of oxygen, these electrons can be passed to the electron transport system to make ADP by *oxidative phosphorylation*, while at the same time regenerating NAD^+, which is required to maintain glycolysis. This second process for making ATP results in about eight times as much ATP per glucose molecule than from substrate-level phosphorylation in glycolysis. Because fermentation is carried out in the absence of oxygen, this process cannot be used. Instead, the NADH must be relieved of its electrons by an alternative process. The NAD^+ regeneration mechanism varies according to the type of organism.

Glucose molecules are relatively stable and do not split readily. For glucose molecules to split, they must be energized by the addition of two phosphate groups to each glucose molecule from two ATP molecules. The third phosphate from each ATP molecule is transferred, along with its high-energy bond. Therefore, the initial steps of glycolysis actually use ATP, depleting some of the cell's energy stores. Once glucose is energized, it readily splits under the influence of the appropriate enzyme. Each half of the glucose molecule then attaches another phosphate group from the cell's pool of P_i. In a series of reactions, each half of the glucose molecule generates two ATP molecules by substrate-level phosphorylation. Therefore, glycolysis results in a net gain of two molecules of ATP per molecule of glucose. At the end of glycolysis there are two three-carbon molecules of pyruvate left over for each original glucose molecule.

Fermentation

Under aerobic conditions, further energy from the chemical bonds of pyruvic acid is harvested by the Krebs cycle and electron transport system. When oxygen is not available (*anaerobic* conditions), however, the electrons must be removed from the NADH to regenerate NAD^+. While there are many ways of accomplishing this, the most common methods are alcoholic fermentation, as observed in yeast, where the end products are ethyl alcohol and carbon dioxide, and lactic acid fermentation, as observed in the muscles of a mammal during strenuous physical exercise. In any event, no further energy is gained for the cell.

In yeast cells cultured in the absence of oxygen, a carbon atom and two oxygen atoms are first split from pyruvic acid, releasing a molecule of carbon dioxide (CO_2). This CO_2 gas is responsible for the bubbles that make bread rise and the carbonation in champagne. The remainder of each pyruvic acid molecule then receives a pair of electrons from NADH, producing a molecule of ethyl alcohol (ethanol). The alcohol evaporates from bread when it is baked but is retained for its mildly euphoric effect in alcoholic beverages. As far as the yeast is concerned, the alcohol is only produced as a way of regenerating NAD^+. It is not a desirable product and will eventually kill the yeast cells. Most yeast cells cannot tolerate an alcohol concentration greater than about 12 percent.

Cellular respiration is the process by which organisms harvest usable energy in the form of ATP molecules from food molecules. Fermentation is the form of respiration used when oxygen is not available. Fermentation is much less efficient than aerobic cellular respiration. Fermentation harvests only two molecules of ATP for every glucose molecule used. Aerobic respiration reaps a yield of more than thirty molecules of ATP. Additionally, the typical products of fermentation, alcohol or lactic acid, are toxic to the organism producing them. Most forms of life will resort to fermentation only when oxygen is absent or in short supply. These are described as *facultative anaerobes*.

While higher forms of life, such as animals, can obtain energy by fermentation for short periods, they enter an oxygen debt, which must eventually be repaid. The yield of two molecules of ATP for each glucose molecule used is simply not enough to sustain their high demand for energy. A few simple forms of life, mostly bacteria, rely solely on fermentation for their source of ATP. To some of these, oxygen is actually poisonous. These are described as *obligate anaerobes*, and they are only found under the completely anaerobic conditions of the deeper layers of mud in saltwater and freshwater marshes.

GNETOPHYTES

Categories: Evolution; gymnosperms; *Plantae*; taxonomic groups

The gnetophytes are a small group of vascular seed plants composing the phylum Gnetophyta*, which is one of four phyla of gymnosperms that have living representatives.*

The *Gnetophyta* include only three genera—*Ephedra*, *Gnetum*, and *Welwitschia*—each of which belongs to a separate family, in a single order, the *Gnetales*. The gnetophytes have a number of features in common with the flowering plants (phylum *Anthophyta*, the angiosperms), which has sparked scientific interest in the evolutionary relationships between the two groups; they are the only gymnosperms, for example, in which vessels occur. There are about ninety species of gnetophytes. They are diverse in form and size, and their distribution varies widely, from moist, tropical environments to extremely dry deserts. Most gnetophytes are shrubs or woody vines. The leaves occur oppositely or in whorls of three.

Like most other gymnosperms, the gnetophytes bear their reproductive structures in strobili, or cones. The gnetophytes differ from other gymnosperms in that both the seed-producing (ovulate or female) cones and the pollen-producing (male) cones are compound; that is, they are, in turn, composed of cones. Both male and female cones contain oppositely arranged bracts, or modified leaves, which bear short, fertile shoots at the axil (the angle between the bract and the stem that bears it). Most gnetophytes are *dioecious*, meaning that they bear their pollen and ovulate cones on separate plants.

Angiosperm-like Features

The gnetophytes share with the angiosperms a number of structural and developmental characteristics. One of these is the presence of water-conducting tubes, called *vessels*, in the secondary xylem, or wood. Vessels, although present in angiosperms, do not occur in gymnosperms other than gnetophytes. Another similarity is that *archegonia*—structures that protect the egg—which are typical of gymnosperms but absent from angiosperms, are not found in either *Gnetum* or *Welwitschia* (although they are present in *Ephedra*). In addition, the cones

Classification of Gnetophytes

Class *Gnetopsida*
- Order *Ephedrales*
  - Family *Ephedraceae* (Mormon tea family)
    - Genus *Ephredra*
- Order *Gnetales*
  - Family *Gnetaceae* (Gnetum family)
    - Genus *Gnetum*
  - Family *Welwitschiaceae*
    - Genus *Welwitschia* (tumboa)

of gnetophytes bear some resemblance to angiosperm flower clusters, and the leaves of *Gnetum* are similar in form, structure, and venation to those of the *Eudicotyledones* of the angiosperms.

Another feature common to angiosperms and gnetophytes—but not found in gymnosperms other than gnetophytes—is double fertilization. In double fertilization, there is union of each of two sperm nuclei with a nucleus in the female gametophyte (the gamete-producing generation in plants), rather than just a union of a single sperm and egg nucleus. Further, in at least some species of all three gnetophyte genera, the reproductive structures produce nectar that attracts insects, as in many angiosperms. Insects play a role in the pollination of gnetophytes, in contrast to the typical gymnosperm's reliance on the wind.

The similarities between gnetophytes and angiosperms have led scientists, who have long thought that the ancestor of the angiosperms is a gymnosperm, to look closely at the gnetophytes. The living gnetophytes are considered too specialized to include the angiosperm ancestor. In addition, evidence suggests that such shared features as similar-appearing vessels, similar-appearing reproductive structures, and the absence of archegonia were derived independently in the two groups. Scientists have still not determined, however, whether the gnetophytes and angiosperms share a close, common ancestor. Unfortunately, the fossil record for gnetophytes is too sparse to shed much light on this question. Although the gnetophytes were once more diverse than they are today, there is no indication that the group was ever rich in genera or abundant in individuals. The earliest known gnetophyte fossils date back 140 million years, to the Early Cretaceous period of the Mesozoic era, which is about as far back in time as the angiosperm fossil record goes.

Researchers have turned to cladistics (phylogenetic analyses) to study fossil, structural, and molecular evidence in an attempt to determine evolutionary relationships. The results of these studies have been inconsistent, and additional research will be needed. There is strong evidence, however, that, within the gnetophytes, *Ephedra* is the closest to the common ancestor of the group, and that *Gnetum* and *Welwitschia* are derived sister clades.

Ephedra

The genus *Ephedra* includes about sixty species, most of them adapted to semiarid and desert conditions. *Ephedra* is the only genus of gnetophyte that occurs in the United States, with twelve species growing in the desert Southwest, some of them ranging into Mexico. Another twelve species occur over a wide area in South America. The rest grow in the Eastern Hemisphere, from central Asia westward across southwest Asia and into Mediterranean Europe and North Africa.

Most species of *Ephedra* are scraggly, profusely branched shrubs. Some are vinelike, commonly climbing over other vegetation. The leaves of most species are small, dry, brown scales. Their reduced size may be related to the plants' need to minimize evaporative water loss in their dry environments. Photosynthesis is carried on mostly in the branches, which remain green while young. The branches are jointed, giving rise to the genus's common name, joint fir. Both the branches and the leaves are arranged two or three to a node. With its jointed stems and small leaves, *Ephedra* superficially resembles the horsetail, *Equisetum*. The stems of *Ephedra* form secondary xylem, or wood, as do the stems of conifers and many angiosperms. *Ephedra* wood is extremely hard.

The cones of *Ephedra* are borne in the leaf axils and are very tiny—the smallest in the gnetophyte group. The female cones have at their tips one or two ovules borne on very short stalks. The male cones are in spikelike clusters. Male and female cones are produced on the same plant or on different ones, depending on the species. The mature female cones are fleshy and berrylike and often brightly colored.

Stem extracts of *Ephedra* have a long history of use as folk medicines. Many Eurasian *Ephedra* species, especially *Ephedra sinica*, contain ephedrine, an alkaloid chemical that the Chinese have used for more than five thousand years as a decongestant drug, called Ma-huang, to treat asthma and hay fever. Ephedrine alkaloids have not been found in New World species of *Ephedra*, but Western countries manufacture synthetic ephedrine, which is used in cough medicines. European settlers in the American Southwest and Mexico brewed a beverage known as Mormon tea or Mexican tea from stem fragments of *Ephedra*.

Gnetum

The genus *Gnetum* includes approximately thirty species, which grow throughout the moist tropics. Most of these are woody vines that climb on trees in the rain forests of central Africa, Asia, and northern South America and on some Pacific islands. The best-known species, *Gnetum gnemon*, however, is a tree native to Indonesia that grows to 10 meters. It is cultivated for its edible seeds and tender young leaves.

Gnetum stems characteristically bear two broad, leathery leaves at each node and produce secondary xylem, or wood. In all *Gnetum* species, male and female reproductive structures are borne on separate plants. The cones, like those of *Ephedra*, look like berries, and the seeds may be brightly colored.

Welwitschia

The genus *Welwitschia* includes a single species, *Welwitschia mirabilis*. This low-growing, perennial plant is restricted to a 150-kilometer-wide strip of coastal desert in Angola, Namibia, and South Africa. In this extremely arid environment, where there may be no precipitation for several years at a time, *Welwitschia* may survive, at least in part, by using dew and condensate from fog that rolls in off the ocean at night. Young plants seem to become established mainly during rare wet years. Some living *Welwitschia* plants have been dated at fifteen hundred years old.

Described by some as the strangest living plant, *Welwitschia* bears little resemblance to other gymnosperms. Most of the plant is taproot, buried in sand to a depth of 1 to 1.5 meters. At its tip, the taproot divides into smaller roots that probably absorb water unavailable to less deeply rooted plants. The exposed part of *Welwitschia* includes a massive, squat stem that emerges only a short distance above the ground. The stem widens with age, becoming up to a meter across, and may develop a crusty, barklike covering on its surface. This broad, woody, concave disk, having ceased elongating from the tip, produces only two leaves during the plant's lifetime. The wide, strap-shaped leaves continue to grow from their bases at a rate of 8 to 15 centimeters per year, for the life of the plant. Battered by wind and hot sand, the leaves break off at their tips and split lengthwise, giving older plants the appearance of having numerous leaves. With their worn tips, the leaves seldom exceed 2 meters in length, although they may reach 6 meters.

The only real branches that *Welwitschia* produces are the branch systems of the pollen and ovulate cones, which are borne on separate plants. These branch systems develop in the axils of the leaves, although they appear to grow from around the rim of the stem cup. The pollen cones, which are red, are produced in groups of two or three at the end of each branch. Ovulate cones are also red. Droplets of nectar lure flies to pollinate the plant. The seeds, generally only one to a cone, have winglike extensions that may aid dispersal by the wind.

GRAINS

Categories: Agriculture; economic botany and plant uses; food

Grains are the fruits or seedlike fruits of plants, particularly members of the grass family, Poaceae. *Important cereal grain crops are all produced by annual grasses and are dry (desiccant) fruits with the ovary wall fused to the seed coat. Inside the fruit wall-seed coat covering (the bran) is a small embryo (germ) and a large amount of stored food (endosperm).*

Grains were the first domesticated crops and allowed the development of all of the great early civilizations. Several factors contribute to the importance of grains in agriculture: ease of growth, storage, and preparation; high yields; and high-energy, easily digestible content (starch). The wild relatives of cereal grains all disperse their seeds by the shattering, or breaking apart, of mature fruiting stalks. Harvesting these wild species is a problem because the seeds are flung everywhere when the fruiting stalk is disturbed. A first step in the domestication of all grains was the elimination of shattering so that inflorescences could be harvested. For grasses, such as wheat, that produce many stems, or tillers, arising from the base of the plant, selection led to synchrony in the production of the tillers so that all the inflorescences of a plant would set fruit at the same time. For grasses, such as corn, that had a thick main stem, selection led to the elimination of secondary branches and a concentration of seeds in one or a few large inflorescences. The second half of the twentieth century saw selection for shorter stature that allows grains to grow better in tropical regions. While thirty-five species of grasses have been domesticated, only five are major crops today: *wheat*, *rice*, *corn*, *sorghum*, and *barley*.

Wheat

Wheat is the most widely cultivated grain in the world and was among the earliest grains to be domesticated. Archaeological deposits from the Middle East, the native home of wheat, containing domesticated wheat seeds have been dated to ten thousand years ago. The first species of wheat domesticated was the diploid einkorn wheat (*Triticum monococcum*), soon followed by the tetraploid, free-threshing emmer wheat (*T. turgidum*), which made it easier for people to separate the fruits from the papery tissues, or chaff, in which they are enclosed. Today, emmer wheats are grown throughout the world and are especially well suited to making pasta and pastries. Bread wheat (*T. aestivum*) was the last to be domesticated. This species is a hexaploid, and its increased cell size has as an important secondary effect: the high production of proteins, known as glutens, that allow bread wheat to form an elastic dough that produces light, spongy bread.

While some wheat is eaten as a grain in such dishes as tabbouli, most wheat is used for flour: whole wheat if the bran and germ are ground along with the starchy endosperm and white if the bran and embryo are removed. Because white flour (even organic flour) lacks the vitamins present in whole wheat flour, federal law in the United States requires that it be enriched with five nutrients: riboflavin, niacin, folic acid, thiamin mononitrate, and iron.

Rice

The acreage devoted to rice (*Oryza sativa*) is less than that of wheat, but more rice is produced annually than wheat, and more people in the world depend on rice as their primary food. Rice was domesticated in the Yangtze River region of China, probably more than nine thousand years ago. In most of the world, rice is grown by germinating seeds and growing seedlings in a nursery. Seedlings are then planted by hand in fields covered with water. Rice does not need to grow in standing water, but it needs high rainfall if the fields are not irrigated. Because rice contains no gluten, it is not used for leavened bread, but it is well suited for cooking because the seeds retain their shape and have a soft, chewy consistency. The two major types of rice are long-grained *Indica*, preferred in India, and short-grained *Japonica*, preferred in China and Japan because of the sticky grains that adhere to one another upon cooking. Removing the bran produces white rice, which lacks the vitamins and fiber of brown rice. Consequently, rice is often enriched with vitamin B_1.

Corn

Corn (*Zea mays*) is the only major grain native to the New World. It was domesticated in southern Mexico about eight thousand years ago from an annual grass known as *teosinte*. Corn plants are monoecious (having both pistillate and staminate flowers on one plant), with male flowers forming the tassel on the top of a corn plant and the female flowers packed inside the ear. The silks of an ear are the styles, one leading to each kernel of corn. Much of the U.S. crop is used for animal feed, but a large portion is converted to cornstarch or corn syrup to be used in the brewing, paper making, and processed food industries. A by-product of the cornstarch industry is corn oil, extracted from the germs.

Sorghum

Sorghum (*Sorghum bicolor*) is native to sub-Saharan Africa, where it was domesticated by five thousand years ago. Grain sorghums are a major source of food for millions of people in Africa and India, but in the New World sweet sorghum (sorgo) is grown primarily for animal feed. The plants are robust, with modern cultivars having a single, thick stem bearing a mass of seeds at the apex. Sorghum is the most drought-tolerant of the major grains and is therefore widely grown in arid regions. In addition to the grain sorghums and sorgos, other varieties yield rough fiber for brushes and booms.

Barley

Barley (*Hordeum vulgare*) was probably the first grain to be domesticated; ancient cultivated fruits found in the Near East have been dated to 10,500 years ago. Initially, barley was preferred over wheat and was used to make flat breads, pastes, gruel, and beer. Barley became less popular after the domestication of emmer and then bread wheat. However, it has remained the grain of choice for brewing beer because of its superior flavor after malting. Malting consists of germinating the grain just enough for it to produce enzymes that break down the starch into simple sugars that yeast can then ferment.

GRASSES AND BAMBOOS

Categories: Agriculture; angiosperms; economic botany and plant uses; food; gardening; *Plantae*

Grasses are monocotyledonous flowering plants (phylum Anthophyta, the angiosperms*) belonging to the family* Poaceae, *formerly* Gramineae. *The family is widespread and economically very valuable. All the grasses are herbaceous except for the bamboos, some of which are treelike.*

Grasses arose seventy million to eighty million years ago, in the Late Cretaceous period of the Mesozoic era. They succeeded partly because they concentrate their growth lower down on the leaf and stem than other plants do and thus can regenerate quickly when fire or herbivores remove the top part of the plant. This makes them ideal for human uses such as lawns and pasture for domestic livestock. Grasses are a very important food source for humans. Grasses provide all cereal grains—barley, corn, millet, oats, rice, rye, and wheat. Other grasses used for food include sorghum, sugarcane, and bamboo.

The grass family is important botanically and ecologically, too. With about 650 genera and 7,500 to 10,000 species, it is the fourth largest angiosperm family. In number of individual plants, it far outranks any other flowering plant family, composing the natural vegetation of about one-quarter of the earth's land surface. The family is especially abun-

PhotoDisc

Grasses are a very important food source for humans and provide all cereal grains, including wheat.

dant in semiarid climates and has the widest range of all the angiosperm families. Grasses provide a vital food source for many grazing, wild animals. By binding the soil with their roots, grasses protect it from erosion. In addition, grasses build up the soil when they die and decompose.

Stems, Roots, and Leaves

The aboveground stems of grasses are called *culms*. The roundness of culms distinguishes grasses from similar-looking plants, the sedges and rushes, which have differently shaped stems. Grass culms are divided into *nodes*, or joints, which are solid, and internodes (the regions between the nodes), which are usually hollow. Elongation of the culm occurs mainly at the bases of the internodes, rather than at the stem tip as in most plants. Grasses range in height from only a few centimeters, in annual bluegrass, to 30 or 40 meters, in treelike bamboos. Grasses may have underground stems, or *rhizomes*. The roots are slender and fibrous and form an extensive system that may compose a large proportion of the plant's total biomass. This large root system helps grasses obtain water in dry regions.

The leaves of grasses are generally arranged alternately on the stem and have no petiole, or stalk. The lower part of the leaf, the *sheath*, is wrapped around the culm like a split tube and is attached at its base to a node. The upper part of the leaf, the *blade*, diverges from the culm and is slender and elongated, tapering to a point at the tip.

Flowers and Fruits

Pollinated by the wind, grass flowers are simple and inconspicuous individually. They have stamens and pistils—the essential male and female reproductive structures—but lack petals and sepals, which most other angiosperms use to lure insect pollinators. Many grass flowers have three stamens and a single pistil that has two stigmas. Long, dangling anthers in the stamens and long, feathery stigmas help the wind transfer pollen efficiently from stamen to pistil.

Identification of grass species is based to a considerable extent on flower arrangement and characteristics of modified leaves, called bracts, that surround the flowers. Individual flowers, called florets, are usually arranged in clusters, called spikelets. Each floret and spikelet typically has at its base a pair of bracts. The spikelets may be crowded on an unbranched stalk, forming a spike, or borne at the ends of stalks having many branches, in a panicle.

Common Grasses of the United States

Common Name	*Scientific Name*
American beachgrass	*Ammophila breviligulata*
Baltic rush	*Juncus balticus*
Basin wildrye	*Leymus cinereus*
Basket rush	*Juncus textilis*
Beaked panicgrass	*Panicum anceps*
Bermudagrass	*Cynodon dactylon*
Big bluestem	*Andropogon gerardii*
Billion-dollar grass	*Echinochloa frumentacea*
Bitter panicgrass	*Panicum amarum*
Blue grama	*Bouteloua gracilis*
Bluebunch wheatgrass	*Pseudoroegneria spicata*
Broomsedge bluestem	*Andropogon virginicus*
Buffalograss	*Buchloe dactyloides*
Bushy bluestem	*Andropogon glomeratus*
California bulrush	*Schoenoplectus californicus*
Canada wildrye	*Elymus canadensis*
Caucasian bluestem	*Bothriochloa bladhii*
Cereal rye	*Secale cereale*
Cheatgrass	*Bromus tectorum*
Common rush	*Juncus effusus*
Common threesquare	*Schoenoplectus pungens*
Cosmopolitan bulrush	*Schoenoplectus maritimus*
Crested wheatgrass	*Agropyron cristatum*
Deergrass	*Muhlenbergia rigens*
Deertongue doc	*Dichanthelium clandestinum*
Desert wheatgrass	*Agropyron desertorum*
Eastern gamagrass doc	*Tripsacum dactyloides*
Fall panicgrass	*Panicum dichotomiflorum*
Field brome	*Bromus arvensis*
Florida paspalum	*Paspalum floridanum*
Hard fescue	*Festuca trachyphylla*
Indian ricegrass	*Achnatherum hymenoides*
Indian woodoats	*Chasmanthium latifolium*
Indiangrass	*Sorghastrum nutans*
Inland saltgrass	*Distichlis spicata*
Intermediate wheatgrass	*Thinopyrum intermedium*
Italian ryegrass	*Lolium perenne* ssp. *multiflorum*

(continued)

Common Grasses of the United States *(continued)*

Common Name	*Scientific Name*
Kentucky bluegrass	*Poa pratensis*
Knotgrass	*Paspalum distichum*
Little bluestem	*Schizachyrium scoparium*
Maidencane	*Panicum hemitomon*
Nutgrass	*Cyperus rotundus*
Orchardgrass doc	*Dactylis glomerata*
Perennial ryegrass	*Lolium perenne*
Prairie cordgrass	*Spartina pectinata*
Purpletop tridens	*Tridens flavus*
Red fescue	*Festuca rubra*
Redtop	*Agrostis gigantea*
Reed canarygrass	*Phalaris arundinacea*
Salt rush	*Juncus lesueurii*
Saltmeadow cordgrass	*Spartina patens*
Sandberg bluegrass	*Poa secunda*
Santa Barbara sedge	*Carex barbarae*
Seashore paspalum	*Paspalum vaginatum*
Siberian wheatgrass	*Agropyron fragile*
Sideoats grama	*Bouteloua curtipendula*
Slender wheatgrass	*Elymus trachycaulus*
Slough sedge	*Carex obnupta*
Smooth brome	*Bromus inermis*
Smooth cordgrass	*Spartina alterniflora*
Snake River wheatgrass	*Elymus wawawaiensis*
Splitbeard bluestem	*Andropogon ternarius*
Streambank wheatgrass	*Elymus lanceolatus*
Switchgrass	*Panicum virgatum*
Tall fescue	*Lolium arundinaceum*
Tall flatsedge	*Cyperus eragrostis*
Tall oatgrass	*Arrhenatherum elatius*
Texas cupgrass	*Eriochloa sericea*
Timothy	*Phleum pratense*
Torpedo grass	*Panicum repens*
Tule	*Schoenoplectus acutus* var. *occidentalis*
Vanilla grass doc	*Hierochloe odorata*
Weeping lovegrass	*Eragrostis curvula*
Western wheatgrass	*Pascopyrum smithii*

The grass fruit, called a caryopsis, or grain, consists of a single seed with its seed coat firmly adherent to the thin fruit wall. Wind plays a major role in dissemination of the fruits. Grasses may germinate, grow, set seed, and die in the same year (*annuals*) or live and produce seed for many years (*perennials*).

Bamboos

The bamboos are perennial, often treelike, grasses belonging to the *Bambusoideae*, a subfamily that is thought to be an early offshoot in the grass family lineage. Bamboo taxonomy is poorly understood. One estimate holds that there are roughly 45 genera and 480 species.

Like other grasses, bamboos have jointed culms, which are hollow except at the nodes, where there are partitions. The culms, which originate from rhizomes, are often called *canes*. The canes are light and elastic. Their hardness is due not to secondary xylem, or wood, as in most trees and shrubs, but rather to scattered fibers in the outer walls of the cane internodes.

Canes of some bamboo species grow at rates as high as a meter a day. The upper nodes of fully elongated culms give rise to small, horizontal branches. Leaves are borne on these branches or on branches of these branches. The blades are narrow and often short. Although some bamboos flower every year, many bloom only at the end of their lifetimes, which may range from 10 to 120 years.

Bamboos are distributed mainly in tropical and subtropical regions, with large concentrations in Asia and South America. A few species reach mild temperate areas. In the United States, there is a single native species, *Arundinaria gigantea*, called cane. It forms canebrakes in southern bottomlands. Bamboos are grown as ornamentals in many parts of the world. Dense bamboo thickets are sometimes planted as living fences or barricades. In Asia, bamboos are very significant economically, providing materials for building, matting, and many other purposes. The young shoots are popular as food in eastern Asia.

GRASSLANDS

Category: Ecosystems

Grasslands are areas of intermittent rainfall which favor grass growth. The grass helps the soil become rich by facilitating the accumulation of nutrients and decaying plant material.

Grasslands once covered about a quarter of the world's land surface. Grasses' growth patterns help enrich the soil immensely. Because their soils become among the world's richest, grasslands are so intensely farmed and grazed that only small patches of natural grassland remain.

Climate and Geographic Location

Annual precipitation between 10 and 32 inches (25-80 centimeters), often with a dry period late in the growing season, supports grassland. Grassland temperature patterns vary. Fire and grazing favor grasses and often combine with climate to maintain grasslands.

Extensive grasslands generally are found in continental interiors. In North America, grasslands occur from the eastern foothills of the Rocky Mountains to the Mississippi River, from south central Canada to northeastern Mexico, in eastern Washington and Oregon, and in California's Central Valley. Grasslands on other continents include the steppes of Europe and Asia, areas fringing the major deserts of Africa and Australia, and the Pampas of South America.

Types of Grasslands

Extensive grasslands are often divided into *tall-grass*, *mixed-grass*, and *short-grass* regions. In prehuman settlement North American grasslands, the tall-grass prairie occurred in the moist eastern zone. Big bluestem, Indian grass, and switch grass grew 6-10 feet (2-3 meters) tall in this region. The short-grass prairie or plains occupied the drier western extreme. There, blue grama and buffalo grass seldom grew taller than 8 inches (20 centimeters). Mixed-grass prairie grew in between, with a mixture of tall, short, and middle-height grasses. Boundaries between regions were broad zones of gradual change.

Grasses and Grasslands

Grasses are well adapted to occupy regions with intermediate annual precipitation, fires, and grazing animals. Grasses have their main center of growth at or below the ground. Their slender, widespread roots compete intensely for nutrients and moisture, especially near the surface. The aboveground parts of the plants grow densely, and the entire aboveground plant dies every year, covering the ground with a dense mulch. These characteristics present difficulties for plants invading grasslands, as the grass roots usurp moisture and nutrients and the leaves and mulch intercept sunlight.

Under very dry conditions, when grasses cannot grow densely, shrubs and succulents (such as cacti) dominate, and deserts occur. With heavy rainfall and infrequent dry periods, trees compete well with grasses, and forests dominate the landscape. Grasslands are often bordered by forests at their moist edges and deserts at their dry boundaries. Under intermediate rainfall conditions, however, grasses are favored over all competitors.

Fire and grazing by animals tip the balance further in favor of the grasses. The late-season dry period typical of grasslands and the mulch built up after a year or more of growth are ideal conditions for the spread of fires. Whether started by lightning or by humans, fires spread quickly through the dried mulch. The tops of plants burn to the ground, but often little damage occurs underground. Because the primary growth center of most nongrass plants is above ground and that of grasses is below ground, fire is more harmful to woody plants and nonwoody, nongrass plants (*forbs*).

Because grazing removes the tops of plants, it does more damage to forbs and woody plants than to grasses. Many grasses actually increase growth after light grazing. Most extensive grasslands are occupied by large grazing animals, such as the bison and pronghorn of North American grasslands. These and other grazers played important roles in the maintenance of the native grasslands and in the lives of the people who lived there.

Grassland Soils

The presence of grasslands is determined by climate, fire, and grazing, but grasses impact their environment as well. In addition to their competitive role in excluding trees, shrubs, and forbs, grasses contribute to soil formation. All the aboveground parts of grass plants die each year, become mulch, and slowly decompose into the soil. Rainfall is generally insufficient to wash nutrients out of the reach of the grass roots, so the soil accumulates both nutrients and decaying plant material. The world's richest soils develop under these conditions.

Human Impact on Grasslands

Because of their soils, grasslands became agricultural centers. Domestic grasses became the predominant crops—corn in the tall-grass country and wheat in the mixed-grass region. The short-grass plains were too dry to support grain crops but became an important region for grazing domestic animals.

In the process of learning what activities the grasslands could and could not support, Americans changed the grasslands of the continent forever. Farming reduced native tall-grass prairie to one of the world's rarest habitats. Although grazing had less impact on the short-grass plains, vast areas have been *overgrazed* severely. Grasslands in other parts of the world have been similarly abused. Given the importance of grasslands to humanity, serious conservation measures must be taken to restore their productivity.

GRAZING AND OVERGRAZING

Categories: Animal-plant interactions; economic botany and plant uses; environmental issues; soil

Animals that eat grass, or graze, can actually help the earth produce richer land cover and soil. When the land suffers ill effects because of too much grazing, overgrazing has occurred.

The effects of overgrazing occur where there are more grazing animals than the land and vegetation can support. Overgrazing has negatively affected regions of the United States, primarily in the Southwest. Areas that have been severely damaged by overgrazing typically show declining or endangered plant and animal species.

Herbivores are animals that feed on plant material, and grazers are herbivores that feed specifically on grass. Examples are horses, cows, antelope, rabbits, and grasshoppers. Overgrazing occurs when grazer populations exceed the *carrying capacity* of a specified area (the number of individual organisms the resources of a given area can support). In overgrazing conditions, there is insufficient food to support the animal population in question. Depending on the grazer's strategy, emigration or starvation will follow. Grasslands can handle, and even benefit from, normal grazing; only overgrazing adversely affects them.

Grasses' Defenses Against Grazing

Grasslands and grazers coevolved, so grasses can withstand grazing within the ecosystem's carrying capacity. All plants have a site of new cell growth called the meristem, where growth in height and girth occurs. Most plants have the meristem at the very top of the plant (the apical meristem). If a plant's apical meristem is removed, the plant dies.

If grasses had an apical meristem, grazers—and lawn mowers—would kill grasses. Grasses survive mowing and grazing because the meristem is located at the junction of the shoot and root, close to the ground. With the exception of sheep, grazers in North America do not disturb the meristem, and sheep do so only during overgrazing conditions. At proper levels of grazing, grazing actually stimulates grass to grow in height in an attempt to produce a flowering head for reproduction. Grazing also stimulates grass growth by removing older plant tissue at the top that is functioning at a lower photosynthetic rate.

Grazers

Mammalian grazers have high, crowned teeth with a great area for grinding to facilitate opening of plants' cell walls as a means to release nutrients. The cell wall is composed of cellulose, which is very difficult for grazers to digest. Two major digestive systems of grazing strategies have evolved to accommodate grazing. *Ruminants*, such as cows and sheep, evolved stomachs with four chambers to allow regurgitation in order to chew food twice to maximize cellulose breakdown. Intestinal bacteria digest the cellulose, releasing fatty acids that nourish the ruminants. Other grazers, such as rabbits and horses, house bacteria in the cecum, a pouch at the junction of the small and large intestines. These bacteria ferment the plant material ingested. The fermented products of the bacteria nourish these grazers.

the ground. With the exception of sheep, grazers in North America do not disturb the meristem, and sheep do so only during overgrazing conditions. At proper levels of grazing, grazing actually stimulates grass to grow in height in an attempt to produce a flowering head for reproduction. Grazing also stimulates grass growth by removing older plant tissue at the top that is functioning at a lower photosynthetic rate.

Grazers

Mammalian grazers have high, crowned teeth with a great area for grinding to facilitate opening of plants' cell walls as a means to release nutrients. The cell wall is composed of cellulose, which is very difficult for grazers to digest. Two major digestive systems of grazing strategies have evolved to accommodate grazing. *Ruminants*, such as cows and sheep, evolved stomachs with four chambers to allow regurgitation in order to chew food twice to maximize cellulose breakdown. Intestinal bacteria digest the cellulose, releasing fatty acids that nourish the ruminants. Other grazers, such as rabbits and horses, house bacteria in the cecum, a pouch at the junction of the small and large intestines. These bacteria ferment the plant material ingested. The fermented products of the bacteria nourish these grazers.

Impacts in the Southwest

As previously mentioned, in the United States the negative effects of overgrazing are most intense in the Southwest. Some ecologists believe that one significant factor was the pattern of early European colonization of the area. Missions were abundant in the Southwest, and the missions owned cattle that were rarely slaughtered, except on big feast days. Because Catholic missionaries received some financial support from their religious orders in Europe, mission cattle were not restrained as strictly as were

Image Not Available

gions where certain species have been removed. Desertification is the intensification and expansion of deserts at the expense of neighboring grasslands. When overgrazing occurs along desert perimeters, plant removal leads to decreased shading. Decreased shading increases the local air temperature. When the temperature increases, the air may no longer cool enough to release moisture in the form of dew. Dew is the primary source of precipitation in deserts, so without it, desert conditions intensify. Even a slight decrease in desert precipitation is serious. The result is hotter and drier conditions, which lead to further plant loss and potentially to monocultures.

Overgrazing of grasslands, combined with the existence of nonnative species in an ecosystem, can result in the endangerment of species of native grasses. At one time, cattle in the Southwest fed exclusively on native grasses. Then nonnative plant species arrived in the New World in the guts of cows shipped from Europe. They began to compete with the native grasses. European grass species have seeds with prickles and burs; southwestern native grasses do not, making them softer and more desirable to the cattle. Hence European grasses experienced little, if any, grazing, while the much more palatable southwestern native grasses were grazed to the point of overgrazing. The result was drastic decline or loss of native grassland species. In such cases animals dependent on native grassland species must emigrate or risk extinction. For example, many ecologists conjecture that the Coachella Valley kit fox in California is threatened because of the loss of grassland habitat upon which it is dependent.

Solutions

Desertification is usually considered irreversible, but the elimination of grazing along desert perimeters can help to prevent further desertification. One kind of attempt to reestablish native grass species involves controlled-burn programs. Nonnative grassland species do not appear to be as fire-resistant as native grass species. Controlled burn programs are therefore being used in some overgrazed grassland areas to try to eliminate nonnatives and reestablish native grass species. If successful, such programs will improve the health of the ecosystem.

GREEN ALGAE

Categories: Algae; *Protista*; taxonomic groups; water-related life

The green algae are a diverse group of eukaryotic organisms classified in the phylum Chlorophyta. *They are considered eukaryotic because individual cells possess a prominent structural feature known as a nucleus, which houses the chemicals responsible for heredity and metabolic regulation. The phylum is one of several algal phyla in the kingdom* Protista, *where algae are grouped based upon pigmentation, carbohydrate storage reserves, and cell wall composition.*

Green algae are found in moist soils and freshwater and saltwater habitats; most are believed to be freshwater-dwelling. The phylum consists of at least eight thousand species. Some estimates place this number at seventeen thousand species. Several shared characteristics support the hypothesis that these organisms and terrestrial plants derived from a common ancestor.

General Characteristics

The green algae, or chlorophytes, may be unicellular, multicellular, colonial, or filamentous. Multicellular forms may demonstrate some tissue differentiation but not to the complexity displayed by terrestrial plants. Colonial algae tend to cluster in a pattern resembling a hollow sphere or disc. Some filamentous forms are coenocytic, meaning they have lost a portion or all of their cross walls.

The cell walls consist of cellulose. There are usually two layers of cellulose fortified by pectin. Some unicellular forms have a lorica (thin wall or cuticle), which is separated from the protoplast by a gelatinous matrix or water.

The phylum *Chlorophyta* is named for the prominent green chloroplast, a cell structure containing pigments that carry out photosynthesis, similar to that found in higher plants. The chloroplasts are green because the accessory pigments, which include xanthophylls and various carotenoids, do not mask the chlorophylls, the principal photosynthetic pigments, present. All classes contain chlorophylls *a* and *b*. Chlorophyll *c* has been found in a few species of the class *Prasinophyceae*. The chloroplasts are double-membraned structures with thylakoids (membranous folds) stacked in groups of from two to six.

The storage carbohydrate is starch. Starch grains can be found clustered around pyrenoids (protein bodies), if they are present. However, they are found generally scattered throughout the fluid portion of the chloroplast. Chlorophytes possess either two or four flagella (whiplike appendages for motility) at least once during their life cycle, although some forms have a single flagellum. In addition to providing motility, flagella may play a key role in the sexual process for some unicellular forms.

There is considerable debate over the classification of green algae. Most taxonomists currently classify *Chlorophyta* in the kingdom *Protista*. Because of the many similarities to terrestrial plants, many taxonomists feel that *Chlorophyta* should have its own kingdom. Living species of charophytes are grouped into three classes: *Chlorophyceae*, *Charophyceae*, and *Ulvophyceae*.

Chlorophyceae

The class *Chlorophyceae* is the largest in terms of the number of species listed. Members have two or more flagella; a diverse array of sexual and asexual reproductive strategies; production of a zygospore following sexual reproduction; and mitosis that involves phycoplasts (microtubules that separate daughter nuclei during division). Representative genera include *Chlamydomonas*, *Pandorina*, *Volvox*, and *Gonium*.

Chlamydomonas species are unicellular, with two apical flagella and a cup-shaped chloroplast. *Gonium* is a colonial species with four or more cells with no functional or morphological differentiation. *Pandorina* species form spherical colonies with limited differentiation and structural organization. Colonies of *Volvox* can consist of up to sixty thousand cells and demonstrate some structural specialization. Portions of the colony have cells with large flagella and stigmata. These cells appear to be specialized for colony motility. The posterior region consists of cells with small flagella and no stigmata. These seem to be responsible for reproduction.

Charophyceae

Charophyceae contains asymmetrical cells that may or may not be motile. Motile cells have two apical flagella. Sexual reproduction is characterized by the formation of a zygospore and zygotic meiosis. This class is similar to land plants in that nuclear envelopes dissolve during mitosis, which is not the case for the other two classes. The genus *Chara* includes members that resemble vascular plants. Chara species have a central axis and branchlike extensions. These organisms demonstrate apical growth that begins with an apical cell, which is analogous to the apical meristems of terrestrial plants. *Spirogyra* is a well-known filamentous genus that is distinguished by spiral chloroplasts. Sexual reproduction is characterized by the formation of a conjugation filament between two cells that allows for gamete transfer.

Ulvophyceae

Ulvophyceae is a diverse class of primarily marine organisms that can consist of small colonial forms, filamentous forms, thin sheets of cells, or coenocytic complexes. Reproduction is by alternation of generations, with meiosis occurring in spores. There may be two or more flagella, if flagella are present. The genus *Ulva*, also known as sea lettuce, displays a green sheet of cells that are found in intertidal waters. Reproduction involves an isomorphic alternation of generations. *Ulothrix* contains freshwater filamentous algae that can attach to surfaces via a holdfast. Ulothrix asexually generates zoospores and aplanospores. Species are able to reproduce sexually by formation of a heterothallic zygote/zygospore from isogamous gametes.

Reproductive Strategies

Chlorophytes reproduce sexually, which involves alternating haploid (organisms with half the complete chromosome set) and diploid stages. *Haplobiontic* haploid organisms consist of mature haploid forms that produce gametes by mitosis (division resulting in offspring cells identical to the parent form). Compatible gametes fuse and form a diploid zygote, which divides by meiosis (division resulting in four haploid offspring cells) to form four spores. A haplobiontic diploid organism consists of mature diploid forms that produce gametes by meiosis. *Diplobiontic* green algae are more complex, with a zygote undergoing mitosis. This results in the formation of a haploid and diploid thalli. The haploid thallus is referred to as the gametophyte, and the diploid thallus is referred to as the sporophyte. Gametophytes generate gametes, while sporophytes produce spores. This pattern is referred to as an alternation of generations.

The thalli may be identical (isomorphic) or different (heteromorphic). If a thallus produces both sperm and eggs, it is considered homothallic. If the egg and sperm are produced on separate thalli, the organism is heterothallic. Gametes may be isogamous (indistinguishable and motile) or heterogamous (two distinct types). Male gametes develop in gametangia known as antheridia. Female gametes develop in either oogonia (single-celled gametangia) or archegonia (multicelled gametangia). Zygotes often form thick-walled resting structures called zygospores.

The most common type of spore is the zoospore, which is a flagellated cell. Cells can form single zoospores or divide mitotically to produce many zoospores. Zoospores mature into vegetative cells within minutes or days, depending upon the species. Vegetative cells may or may not keep their flagella. Zoospores are typically formed in compartments called sporangia but may be formed following meiosis in a zygote. Most zoospores resemble members of the chlorophyte genus *Chlamydomonas*. Thick-walled, nonmotile spores called akinetes may be formed and can produce zoospores via mitosis or form filamentous structures. Some chlorophytes form aplanospores, which are nonmotile.

Ecology

Chlorophytes are found in diverse habitats all over the world. While most inhabit temperate, freshwater environments, marine and terrestrial forms also exist. Terrestrial forms include some living on moist soils, some on moist rocks, and some in snow-covered areas. Some terrestrial forms are specialized as *lichens*, a close association between an alga and a fungus, or living on animals such as turtles or sloths.

Because they are photoautotrophic, capable of making their own carbohydrates using sunlight energy, chlorophytes are critical to life on earth. Green algae are the planet's largest food source. They fix approximately 1,010 tons of carbon per year. As a result, they also contribute significantly to oxygen production.

GREEN REVOLUTION

Categories: Agriculture; economic botany and plant uses; food; history of plant science

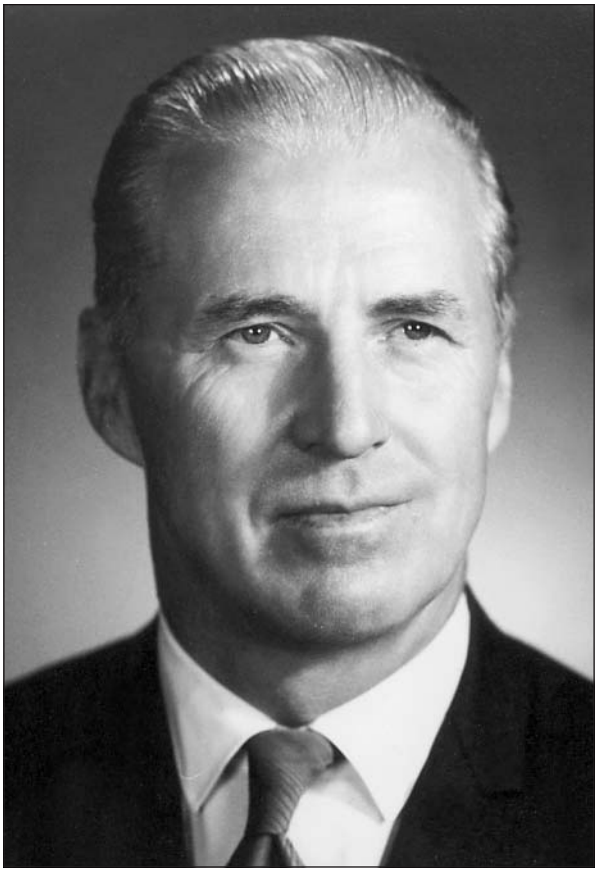
The Green Revolution implemented advances in agricultural science to raise food production levels, particularly in developing countries. These advances are associated with the spreading use of high-yield varieties (HYV) of wheat, rice, and corn developed through advanced methods of genetics and plant breeding.

Yield Increases

The Green Revolution can be traced back to a 1940 request from Mexico for technical assistance from the United States to increase wheat production. By 1944, with the financial support of the Rockefeller Foundation, a group of U.S. scientists were researching methods of adapting the new high-yield variety (HYV) wheat that had been successfully used on American farms in the 1930's to Mexico's varied environments. A major breakthrough is attributed to Norman Borlaug, who by the late 1940's was director of the research in Mexico. For his research and work in the global dissemination of the Mexican HYV wheat, Borlaug won the 1970 Nobel Peace Prize.

From wheat, research efforts shifted to rice production. Through the work of the newly created International Rice Research Institute in the Philippines, an HYV rice was developed. This so-called miracle rice was widely adopted in developing countries during the 1960's. Later research has sought to spread the success of the Green Revolution to other crops and to more countries.

Approximately one-half of the yield increases in food crops worldwide since the 1960's are attributable to the Green Revolution. Had there not been a Green Revolution, the amount of land used for agriculture would undoubtedly be higher today, as would the prices of wheat, rice, and corn, three crops that account for more than 50 percent of total human energy requirements. There is a concern, however, that the output benefits of the Green Revolution have had some negative equity and environmental effects.



Norman Borlaug was awarded the Nobel Peace Prize in 1970 for his research and work in the global dissemination of the Mexican high-yield varieties of wheat.

Equity and Environmental Issues

The Green Revolution has promoted input-intensive agriculture, which has, in turn, created several problems. In theory, a small-scale farmer will get benefits from planting the HYV seeds that are similar to those reaped by a large farm. In practice, however, small-scale farmers have had more difficulty in gaining access to Green Revolution technology. To use the new seeds, fields need adequate irrigation and the timely application of chemical fertilizers and pesticides. In many developing countries, small-scale farmers' limited access to credit makes the variety of complementary inputs difficult to obtain. Greater use of fertilizers is associated with rising nitrate levels in water supplies. Pesticides have been linked to community health problems. Long-term, intensive production has resulted in compaction and salinization of soil and other problems.

Because agriculture is increasingly dependent on fossil fuels, food prices have become more strongly linked to energy supplies of this type. This issue raises concerns about the sustainability of the new agriculture. Biotechnological approaches to generating higher yields, the expected future path of the Green Revolution, will raise an additional set of equity and environmental concerns.

GREENHOUSE EFFECT

Categories: Environmental issues; pollution

The greenhouse effect is a natural process of atmospheric warming in which solar energy that has been absorbed by the earth's surface is reradiated and then absorbed by particular atmospheric gases, primarily carbon dioxide and water vapor. Without this warming process, the atmosphere would be too cold to support life. Since 1880, however, the surface atmospheric temperature appears to be rising, paralleling a rise in the concentration of carbon dioxide and other gases produced by industrial activities.

Since 1880, carbon dioxide, along with several other gases—chlorofluorocarbons (CFCs), methane, hydrofluorocarbons (HFCs), perfluorocarbons (PFCs), sulfur hexafluoride, and nitrous oxide—have been increasing in concentration and have been identified as likely contributors to a rise in global surface temperature. These gases are called *greenhouse gases*. The temperature increase may lead to drastic changes in climate and food production as well as widespread coastal flooding. As a result, many scientists, organizations, and governments have called for curbs on the production of greenhouse gases. Since the predictions are not definite, however, debate continues about the costs of reducing the production of these gases without being sure of the benefits.

Global Warming and Human Interference

The greenhouse effect occurs because the gases in the atmosphere are able to absorb only particular wavelengths of energy. The atmosphere is largely transparent to short-wave solar radiation, so sunlight basically passes through the atmosphere to the earth's surface. Some is reflected or absorbed by clouds, some is reflected from the earth's surface, and some is absorbed by dust or the earth's surface. Only small amounts are actually absorbed by the atmosphere. Therefore, sunlight contributes very little to the direct heating of the atmosphere. On the other hand, the greenhouse gases are able to absorb long-wave, or infrared, radiation from the earth, thereby heating the earth's atmosphere.

Discussion of the greenhouse effect has been confused by terms that are imprecise and even inaccurate. For example, the atmosphere was believed to operate in a manner similar to a greenhouse, whose glass would let visible solar energy in but would also be a barrier preventing the heat energy from leaving. In actuality, the reason that the air remains warmer inside a greenhouse is probably because the glass prevents the warm air from mixing with the cooler outside air. Therefore the greenhouse effect could be more accurately called the "atmospheric effect," but the term greenhouse effect continues to be used.

Even though the greenhouse effect is necessary for life on earth, the term gained harmful connotations with the discovery of apparently increasing atmospheric temperatures and growing concentrations of greenhouse gases. The concern, however, is not with the greenhouse effect itself but rather with the intensification or enhancement of the greenhouse effect, presumably caused by increases in the level of gases in the atmosphere resulting from human activity, especially industrialization. Thus the term *global warming* is a more precise description of this presumed phenomenon.

A variety of other human activities appears to have contributed to global warming. Large areas of natural vegetation and forests have been cleared for agriculture. The crops may not be as efficient in absorbing carbon dioxide as the natural vegetation they replaced. Increased numbers of livestock have led to growing levels of methane. Several gases that appear to be intensifying global warming, including CFCs and nitrous oxides, also appear to be involved with *ozone depletion*. Stratospheric ozone shields the earth from solar ultraviolet (short-wave) radiation; therefore, if the concentration of these ozone-depleting gases continues to increase and the ozone shield is depleted, the amount of solar radiation reaching the earth's surface should increase. Thus, more solar energy would be intercepted by the earth's surface to be reradiated as long-wave radiation, which would presumably increase the temperature of the atmosphere.

However, whether there is a direct cause-and-effect relationship between increases in carbon dioxide and the other gases and surface temperature may be impossible to determine because the atmosphere's temperature has fluctuated widely over millions of years. Over the past 800,000 years, the earth has had several long periods of cold temperatures—during which thick ice sheets covered large portions of the earth—interspersed with shorter warm periods. Since the most recent retreat of the glaciers around ten thousand years ago, the earth has been relatively warm.

Problems of Prediction

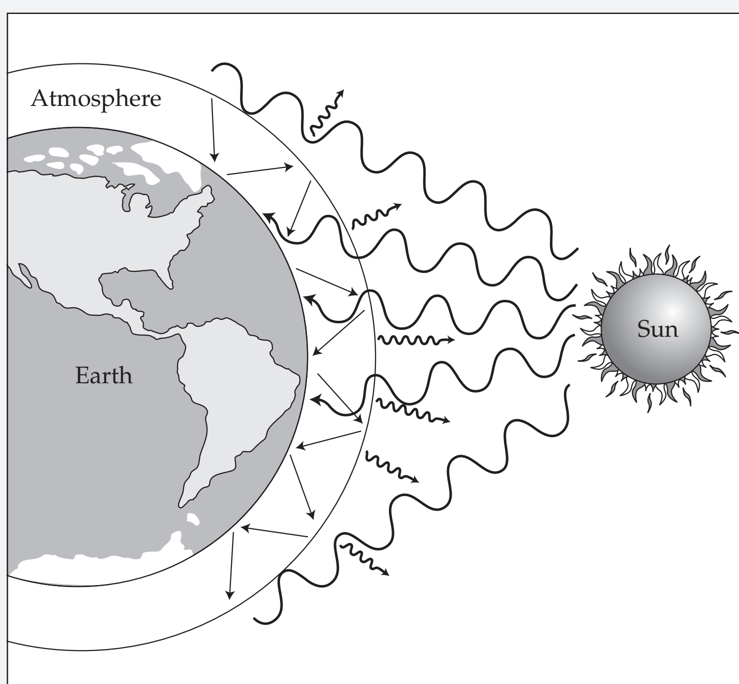
How much the temperature of the earth might rise is not clear. So far, the temperature increase of around 1 degree Fahrenheit is within the range of normal (historic) trends. The possibility of global warming became a serious issue during the late twentieth century because the decades of the 1980's and the 1990's included some of the hottest years recorded for more than one century. On the other hand, warming has not been consistent since 1880, and for many years cooling occurred. The cooling might have resulted from the increase of another product of fossil fuel combustion, sulfur dioxide aerosols, which reflect sunlight, thus lessening the amount of solar energy entering the atmosphere. Similarly, in the early 1990's temperatures declined, perhaps because of ash and sulfur dioxide produced by large volcanic explosions. In the late 1990's temperatures appeared to be rising again, thus indicating that products of volcanic explosions may have masked the process of global warming. The United States Environmental Protection Agency (EPA) states that the earth's average temperature will probably continue to increase because the greenhouse gases stay in the atmosphere longer than the aerosols.

Proper analysis of global warming is dependent on the collection of accurate temperature records from many locations around the world and over many years. Because human error is always possible, "official" temperature data may not be accurate. This possibility of inaccuracy compromises examination of past trends and predictions for the future. However, the use of satellites to monitor

The Greenhouse Effect

Clouds and atmospheric gases such as water vapor, carbon dioxide, methane, and nitrous oxide absorb part of the infrared radiation emitted by the earth's surface and reradiate part of it back to the earth. This process effectively reduces the amount of energy escaping to space and is popularly called the "greenhouse effect" because of its role in warming the lower atmosphere. The greenhouse effect has drawn worldwide attention because increasing concentrations of carbon dioxide from the burning of fossil fuels may result in a global warming of the atmosphere.

Scientists know that the greenhouse analogy is incorrect. A greenhouse traps warm air within a glass building where it cannot mix with cooler air outside. In a real greenhouse, the trapping of air is more important in maintaining the temperature than is the trapping of infrared energy. In the atmosphere, air is free to mix and move about.



U.S. Greenhouse Gas Emissions, 1990-1999

Type	*1990*	*1994*	*1995*	*1996*	*1997*	*1998*	*1999*
Carbon dioxide (carbon)[1]	1,350.5	1,422.5	1,434.7	1,484.1	1,505.2	1,507.4	1,526.8
Methane gas[1]	31.74	31.17	31.18	30.16	30.11	29.29	28.77
Nitrous oxide[2]	1,168	1,310	1,257	1,246	1,226	1,223	1,224

temperatures has probably increased the reliability of the data.

Predictions for the future are hampered in various ways, including lack of knowledge about all the components affecting atmospheric temperature. Therefore, computer programs cannot be sufficiently precise to make accurate predictions. A prime example is the relationship between ocean temperature and the atmosphere. As the temperature of the atmosphere increases, the oceans would absorb much of that heat. Therefore, the atmosphere might not warm as quickly as predicted. However, the carbon dioxide absorption capacity of oceans declines with temperature. Therefore, the oceans would be unable to absorb as much carbon dioxide as before, but exactly how much is unknown. Increased ocean temperatures might also lead to more plant growth, including phytoplankton. These plants would probably absorb carbon dioxide through photosynthesis. A warmer atmosphere could hold more water vapor, resulting in the potential for more clouds and more precipitation. Whether that precipitation would fall as snow or rain and where it would fall could also affect air temperatures. Air temperature could lower as more clouds might reflect more sunlight, or more clouds might absorb more infrared radiation.

To complicate matters, any change in temperature would probably not be uniform over the globe. Because land heats up more quickly than water, the Northern Hemisphere, with its much larger landmasses, would probably have greater temperature increases than the Southern Hemisphere. Similarly, ocean currents might change in both direction and temperature. These changes would affect air temperatures as well. In reflection of these complications, computer models of temperature change range widely in their estimates. Predicted increases range from 1.5 to 11 degrees Celsius (3 to 20 degrees Fahrenheit) over the early decades of the twenty-first century.

Mitigation Attempts

International conferences have been held, and international organizations have been established to research and minimize potential detriments of global warming. In 1988 the United Nations Environment Programme and the World Meteorological

Organization established the International Panel on Climate Change (IPCC). The IPCC has conducted much research on climate change and is now considered an official advisory body on the climate change issue. In June, 1992, the United Nations Conference on Environment and Development, or Earth Summit, was held in Brazil. Participants devised the Framework Convention on Climate Change, considered the landmark international treaty. It required signatories to reduce and monitor their greenhouse gas emissions.

A more advanced agreement, the Kyoto Accords, was developed in December, 1997, by the United Nations Framework Convention on Climate Change. It set binding emission levels for all six greenhouse gases over a five-year period for the developed world. Developing countries do not have any emission targets. It also allows afforestation to be used to offset emissions targets. The Kyoto agreement includes the economic incentive of trading emissions targets. Some countries, because they have met their targets, would have excess permits, which they might be willing to sell to other countries that have not met their targets.

GROWTH AND GROWTH CONTROL

Category: Physiology

The processes of primary and secondary growth take a plant from early cell division to its adult form. Growth control factors regulate these processes.

Plant growth is of two distinct types: *primary growth* and *secondary growth*. Primary growth results in increased length of stems or roots. Secondary growth increases the width of the plant and allows differentiation of cells into various distinct tissue types. Both types of growth occur in plant tissues called *meristems*. A meristem consists of tissue where extensive cell division takes place, and thus plant growth. There are two general types of meristems. Primary growth occurs at the *apical meristems*, and secondary growth occurs at the *lateral meristems*, which are known as the *vascular cambium* and the *cork cambium*.

Meristems

Apical meristems are located at the growing tips of the plant; there are apical meristems in the roots and in the buds on shoots of the aboveground part of the plant. New cells produced at the meristems are initially undifferentiated. They enlarge in the adjacent *zone of elongation*, mostly by increasing their water content. These cells eventually differentiate into the plant's primary tissue types: *dermal*, *vascular tissue*, and *ground tissues*.

Other meristematic tissue occurs along the stem, and lateral buds are capable of producing branches with their own meristems, but most elongation occurs from the apical meristem. Apical dominance prevents excessive branching and in some plants prevents all branching. If the apical meristem is removed by removing the end of the stem, the lateral buds will be released from apical dominance, and greater branching results. Eventually, one of the lateral meristems will grow more than the others and will impose apical dominance, becoming the new apical meristem.

Secondary growth increases the girth (diameter) of the stems and roots of woody plants. Lateral growth of the vascular cambium produces new vascular tissue, called secondary *xylem* and *phloem*. In trees and shrubs, this continual lateral growth produces wood. Cork cambium produces cells at the outer edges of roots and stems. At maturity these cells are dead and form the bark, their primary function being structural support and protection. The walls of cork cells contain a protective waxy substance called *suberin*.

Gametophytes and Sporophytes

All vascular plants, as well as mosses and liverworts and many algae, display a type of life cycle referred to as *alternation of generations*, which involves two distinct life-forms, the *gametophyte* and *sporophyte*. The sporophyte generation is genetically diploid and, as the name implies, produces spores by meiosis. Spores germinate and develop into gametophytes, which are genetically haploid and produce gametes (eggs and sperm) by mitosis. Sporophytes are larger than gametophytes and represent the dominant, or more noticeable, generation and typically live much longer than gametophytes. Trees, shrubs, herbs, and ferns all represent sporophytes. Gametophytes are extremely small by comparison and are therefore unknown to most nonscientists. They are free-living in ferns as tiny, heart-shaped masses of cells that grow on or just under the surface of the soil and are often smaller than the letters on this page. In flowering plants and gymnosperms, gametophytes are enclosed in the reproductive tissues of flowers and cones on the sporophytes that later develop into seeds. In mosses and liverworts, gametophytes are larger and represent the dominant generation, and the sporophyte grows from the structure on the end. Algae are more diverse. In some groups both gametophytes and sporophytes are indistinguishable, whereas in other groups one or the other is larger.

Both the gametophyte and the sporophyte develop from single cells—the *spores* and the *zygotes*, respectively. In seed plants, the first cell division of the zygote often defines the root cell line (or its equivalent) and the stem cell line (or its equivalent). The body produced by this early development is initially linear in many cases, laying out the primary axis of the plant body. The embryo grows from the zygote and as it matures is included in integuments that develop into the seed coat. A primary root and primary stem grow from a root apical meristem and a shoot apical meristem, respectively.

Primary and Secondary Tissue

In many species, the new cells in the sporophyte are produced primarily by the division of apical meristems, thus consisting almost exclusively of primary tissues. There are, however, some plants in which the sporophytes grow in girth. Some of these—such as the *calamites* (giant horsetails), the *Lepidodendron* (tree lycopods), and the seed ferns—are known only from the fossil record. Others are the trees and shrubs, so-called woody plants, that characterize the modern forests.

The wood of woody plants is composed almost entirely of secondary xylem—xylem that is not derived from the apical meristems but instead grows from the vascular cambium, a cylindrical meristem located under the bark. The bark of woody plants, also a secondary tissue, is composed of phloem and corky layers. The corky layers develop from a second cylindrical meristem, the cork cambium.

In addition to the secondary tissues, many plants as they grow produce secondary organs: branch stems and branch roots. These secondary organs are not derived from the original axis of the plant. In the early stages of their growth they are composed of primary tissues that are essentially identical to the primary tissues of primary organs. Cambial growth will produce secondary tissues in these branch stems and roots. The patterns of secondary tissue formation determine the form of the wood and bark of woody species. The patterns of secondary organ formation determine the architecture of the plant: the shape of the crown and the root system. This architecture plays an important role in the ability of the plant to compete for sunlight, water, and soil nutrients.

Growth Control

The patterns of secondary organ formation are controlled both by genetic factors and by environmental conditions. Horticulturists use plants as a source of dwarfing stocks that have a genetic predisposition to form branches early. In many cases, the dwarfing results from a failure of the stem to elongate in the *internodes* (the regions between the nodes, where leaves and lateral branches originate). Dwarfing appears to be particularly influenced by plant hormones called gibberellins, which stimulate internodal elongation in *dicots*. The effect of gibberellins is also influenced by the concentration of the other hormones within the plant.

Likewise, the architecture of columnar plants is under genetic and hormonal control. The Lombardy poplar, for example, has greatly reduced branching compared to the European poplar. This elongation

Digital Stock

Many plants as they grow produce secondary organs: branch stems and branch roots. These secondary organs are not derived from the original axis of the plant. The patterns of secondary organ formation determine the architecture of the plant: the shape of the crown and the root system. This architecture plays an important role in the ability of the plant to compete for sunlight, water, and soil nutrients.

of the principal axis is similar to that found in forest trees growing in the shade of the surrounding forest. The shaded environment stimulates the growth of the main axis of many tree species while inhibiting growth of the secondary stems. As a result, the stem reaches above the surrounding trees and is better able to compete for light.

The inhibition of secondary stem formation seems to be influenced primarily by hormones called auxins. High auxin concentrations inhibit the development of secondary stems, while low auxin levels stimulate the formation of branches. In some species, high cytokinin levels also stimulate secondary stem growth. Because cytokinins are produced in large quantities in the root tips, and auxins are produced in large quantities in the stem tip, the relationship between these two chemicals reflects the balance between the root system and the stem system.

Less is known about the mechanisms of control of branching in the root system. Some species, especially *monocots*, have many secondary roots of approximately equal size. Others have dominant primary roots, called *taproots*, with little development of secondary roots. Carrots carry this pattern to an extreme.

The pattern of secondary tissue formation is determined by an interplay between genetic factors and environmental conditions. Many plants complete their life cycles in a single year. This quick passage from seed to seed is under genetic control. Annuals rarely develop woody tissue; perennials survive many seasons and show increases in stem girth throughout their lives.

The annual rings seen in the cross-section of a tree are a result of seasonal variations in the production of secondary xylem. Variations in the thickness of annual rings are the result of genetic controls and environmental factors such as mean temperature, damage from insect pests or other pathogens, and water and nutrient availability. Even wind can have significant effects. Strong prevailing winds cause an effect called wind pruning, which results in reduced branching and shorter distances between the annual rings on the windward side.

Secondary tissues are extraordinarily complex. The patterns of cell division, apparently under genetic control, are influenced by a whole concert of hormones. Hormonal gradients and seasonal gradients of sugars and amino acids may play a role in these patterns of secondary tissue formation. The activity of mature phloem tissues and the concentrations of auxins, gibberellins, cytokinins, and perhaps of the gaseous hormone ethylene may all be important in regulating the activity of the cambia.
