Preface

The first edition of this book, a bestseller for Lewis Publishers/CRC Press, evolved from a series of articles on ecotoxicology authored by the editors and published in the journal *Environmental Science and Technology*. Ecotoxicology remains a rapidly growing field, with many components periodically being redefined or open to further interpretation. Therefore, this second edition of the *Handbook of Ecotoxicology* has expanded considerably in both concept and content over the first edition. The second edition contains 45 chapters with contributions from over 75 international experts. Eighteen new chapters have been introduced, and the original chapters have been substantially revised and updated. All of the content has been reviewed by a board of experts.

This edition is divided into five major sections: I. Quantifying and Measuring Ecotoxicological Effects, II. Contaminant Sources and Effects, III. Case Histories and Ecosystem Surveys, IV. Methods for Making Estimates, Predictability, and Risk Assessment in Ecotoxicology, and V. Special Issues in Ecotoxicology. In the first section, concepts and current methodologies for testing are provided for aquatic toxicology, wildlife toxicology, sediment toxicity, soil ecotoxicology, algal and plant toxicity, and landscape ecotoxicology. Biomonitoring programs and current use of bioindicators for aquatic and terrestrial monitoring are described. The second section contains chapters on major environmental contaminants and other anthropogenic processes capable of disrupting ecosystems including pesticides, petroleum and PAHs, heavy metals, selenium, polyhalogenated aromatic hydrocarbons, urban runoff, nuclear and thermal contamination, global effects of deforestation, pathogens and disease, and abiotic factors that interact with contaminants.

In order to illustrate the full impact of different environmental contaminants on diverse ecosystems, seven case histories and ecosystem surveys are described in the third section. The fourth section discusses methods and approaches used for estimating and predicting exposure and effects for purposes of risk assessment. These include global disposition of contaminants, bioaccumulation and bioconcentration, use of quantitative structure activity relationships (QSARs), population modeling, current guidelines and future directions for ecological risk assessment, and restoration ecology. The fifth section of this book identifies and describes a number of new and significant issues in ecotoxicology, most of which have come to the forefront of the field since the publication of the first edition. These include endocrine-disrupting chemicals in the environment, the possible role of contaminants in the worldwide decline of amphibian populations, potential genetic effects of contaminants on animal populations, the role of ecotoxicology in industrial ecology and natural capitalism, the consequences of indirect effects of agricultural pesticides on wildlife, the role of nutrition on trace element toxicity, and the role of environmental contaminants on endangered species.

This edition was designed to serve as a reference book for students entering the fields of ecotoxicology and other environmental sciences. Many portions of this handbook will serve as a convenient reference text for established investigators, resource managers, and those involved in risk assessment and management within regulatory agencies and the private sector.

David J. Hoffman

John Cairns, Jr.

The Editors

David J. Hoffman

David J. Hoffman is a research physiologist in the field of environmental contaminants at the Patuxent Wildlife Research Center, U.S. Geological Survey of the Department of the Interior. He is also an Adjunct Professor in the Department of Biology, University of Maryland at Frostburg. Dr. Hoffman earned a Bachelor of Science degree in Zoology from McGill University in 1966 and his Doctor of Philosophy Degree in Zoology (developmental physiology) from the University of Maryland in 1971. He was an NIH Postdoctoral Fellow in the Biochemistry Section of Oak Ridge National Laboratory from 1971 to 1973. Other positions included teaching at Boston College during 1974 and research as a Senior Staff Physiologist with the Health Effects Research Laboratory of the U.S. Environmental Protection Agency in Cincinnati from 1974 to 1976 before joining the Environmental Contaminants Evaluation Program of the Patuxent Wildlife Research Center.

Dr. Hoffman's research over the past 20 years has focused on morphological and biochemical effects of environmental contaminants including bioindicators of developmental toxicity in birds in the laboratory and in natural ecosystems. Key areas of study have included sublethal indicators of exposure to planar PCBs, lead, selenium, and mercury; embryotoxicity and teratogenicity of pesticides and petroleum to birds and impact on nestlings; interactive toxicant and nutritional factors affecting agricultural drainwater and heavy-metal toxicity; and measurements of oxidative stress for monitoring contaminant exposure in wildlife.

Dr. Hoffman has published over 120 scientific papers including book chapters and review papers and has served on eight editorial boards.

Barnett A. Rattner

Barnett A. Rattner is a research physiologist at the Patuxent Wildlife Research Center, U.S. Geological Survey of the Department of the Interior. He is also Adjunct Professor of the Department of Animal and Avian Science Sciences, University of Maryland. Dr. Rattner attended the University of Maryland, earning his Doctor of Philosophy degree in 1977. He was a National Research Council Postdoctoral Associate at the Naval Medical Research Institute in 1978 before joining the Environmental Contaminants Evaluation Program of the Patuxent Wildlife Research Center.

Dr. Rattner's research activities during the past 20 years have included evaluation of sublethal biochemical, endocrine, and physiological responses of wildlife to petroleum crude oil, various pesticides, industrial contaminants, and metals. He has investigated the interactive effects of natural stressors and toxic environmental pollutants, developed and applied cytochrome P450 assays as a biomarker of contaminant exposure, conducted risk assessments on potential substitutes for lead shot used in hunting, and compiled several large World Wide Web-accessible ecotoxicological databases for terrestrial vertebrates.

Dr. Rattner has published over 65 scientific articles and serves on four editorial boards and several federal committees including the Toxic Substances Control Act Interagency Testing Committee of the U.S. Environmental Protection Agency.

G. Allen Burton, Jr.

G. Allen Burton, Jr. is the Brage Golding Distinguished Professor of Research and Director of the Institute for Environmental Quality at Wright State University. He earned a Ph.D. degree in Environmental Science from the University of Texas at Dallas in 1984. From 1980 until 1985 he was a Life Scientist with the U.S. Environmental Protection Agency. He was a Postdoctoral Fellow at the National Oceanic and Atmospheric Administration's Cooperative Institute for Research in Environmental Sciences at the University of Colorado. Since then he has had positions as a NATO Senior Research Fellow in Portugal and Visiting Senior Scientist in Italy and New Zealand. Dr. Burton's research during the past 20 years has focused on developing effective methods for identifying significant effects and stressors in aquatic systems where sediment and stormwater contamination is a concern. His ecosystem risk assessments have evaluated multiple levels of biological organization, ranging from

microbial to amphibian effects. He has been active in the development and standardization of toxicity methods for the U.S. EPA, American Society for Testing and Materials (ASTM), Environment Canada, and the Organization of Economic Cooperation and Development (OECD). Dr. Burton has served on numerous national and international scientific committees and review panels and has had over \$4 million in grants and contracts and more than 100 publications dealing with aquatic systems.

John Cairns, Jr.

John Cairns, Jr. is University Distinguished Professor of Environmental Biology Emeritus in the Department of Biology at Virginia Polytechnic Institute and State University in Blacksburg, Virginia. His professional career includes 18 years as Curator of Limnology at the Academy of Natural Sciences of Philadelphia, 2 years at the University of Kansas, and over 34 years at his present institution. He has also taught periodically at various field stations.

Among his honors are Member, National Academy of Sciences; Member, American Philosophical Society; Fellow, American Academy of Arts and Sciences; Fellow, American Association for the Advancement of Science; the Founder's Award of the Society for Environmental Toxicology and Chemistry; the United Nations Environmental Programme Medal; Fellow, Association for Women in Science; U.S. Presidential Commendation for Environmental Activities; the Icko Iben Award for Interdisciplinary Activities from the American Water Resources Association; Phi Beta Kappa; the B. Y. Morrison Medal (awarded at the Pacific Rim Conference of the American Chemical Society); Distinguished Service Award, American Institute of Biological Sciences; Superior Achievement Award, U.S. Environmental Protection Agency; the Charles B. Dudley Award for excellence in publications from the American Society for Testing and Materials; the Life Achievement Award in Science from the Commonwealth of Virginia and the Science Museum of Virginia; the American Fisheries Society Award of Excellence; Doctor of Science, State University of New York at Binghamton; Fellow, Virginia Academy of Sciences; Fellow, Eco-Ethics International Union; Twentieth Century Distinguished Service Award, Ninth Lukacs Symposium; 2001 Ruth Patrick Award for

Environmental Problem Solving, American Society of Limnology and Oceanography; 2001 Sustained Achievement Award, Renewable Natural Resources Foundation, 2001.

Professor Cairns has served as both vice president and president of the American Microscopical Society, has served on 18 National Research Council committees (two as chair), is presently serving on 14 editorial boards, and has served on the Science Advisory Board of the International Joint Commission (United States and Canada) and on the U.S. EPA Science Advisory Board. The most recent of his 57 books are *Goals and Conditions for a Sustainable Planet*, 2002 and the Japanese edition of *Restoration of Aquatic Ecosystems: Science, Technology, and Public Policy*, 1999.

Contents

Chapter 1	
Introduction	1
David J. Hoffman, Barnett A. Rattner, G. Allen Burton, Jr., and John Cairns, Jr.	

Section I

Quantifying and Measuring Ecotoxicological Effects17

Chapter 2	
Aquatic Toxicology Test Methods	19
William J. Adams and Carolyn D. Rowland	

Chapter 3	
Model Aquatic Ecosystems in Ecotoxicological Research: Considerations of Design, Implementation, and Analysis.....	45
James H. Kennedy, Thomas W. LaPoint, Pinar Balci, Jacob K. Stanley, and Zane B. Johnson	

Chapter 4	
Wildlife Toxicity Testing	75
David J. Hoffman	

Chapter 5	
Sediment Toxicity Testing: Issues and Methods	111
G. Allen Burton, Jr., Debra L. Denton, Kay Ho, and D. Scott Ireland	

Chapter 6	
Toxicological Significance of Soil Ingestion by Wild and Domestic Animals	151
W. Nelson Beyer and George F. Fries	

Chapter 7	
Wildlife and the Remediation of Contaminated Soils: Extending the Analysis of Ecological Risks to Habitat Restoration.....	167
Greg Linder, Gray Henderson, and Elaine Ingham	

Chapter 8	
Phytotoxicity	191
Stephen J. Klaine, Michael A. Lewis, and Sandra L. Knuteson	

Chapter 9	
Landscape Ecotoxicology	219
Karen Holl and John Cairns, Jr.	

Chapter 10	
Using Biomonitoring Data for Stewardship of Natural Resources	233
Robert P. Breckenridge, Marilynne Manguba, Patrick J. Anderson, and Timothy M. Bartish	

Chapter 11	
Bioindicators of Contaminant Exposure and Effect in Aquatic and Terrestrial Monitoring.....	257
Mark J. Melancon	

Section II
Contaminant Sources and Effects.....279

Chapter 12	
Wildlife Toxicology of Organophosphorus and Carbamate Pesticides	281
Elwood F. Hill	

Chapter 13	
Organochlorine Pesticides.....	313
Lawrence J. Blus	

Chapter 14	
Petroleum and Individual Polycyclic Aromatic Hydrocarbons.....	341
Peter H. Albers	

Chapter 15	
Lead in the Environment	373
Oliver H. Pattee and Deborah J. Pain	

Chapter 16	
Ecotoxicology of Mercury	409
James G. Wiener, David P. Krabbenhoft, Gary H. Heinz, and Anton M. Scheuhammer	

Chapter 17	
Ecotoxicology of Selenium.....	465
Harry M. Ohlendorf	

Chapter 18	
Sources, Pathways, and Effects of PCBs, Dioxins, and Dibenzofurans.....	501
Clifford P. Rice, Patrick O’Keefe, and Timothy Kubiak	

Chapter 19	
Receiving Water Impacts Associated with Urban Wet Weather Flows	575
Robert Pitt	

Chapter 20	
Nuclear and Thermal	615
Linda Meyers-Schöne and Sylvia S. Talmage	

Chapter 21	
Global Effects of Deforestation	645
Richard A. Houghton	

Chapter 22	
Pathogens and Disease.....	667
Frederick A. Leighton	

Chapter 23	
Environmental Factors Affecting Contaminant Toxicity in Aquatic and Terrestrial Vertebrates.....	679
Barnett A. Rattner and Alan G. Heath	

Section III

Case Histories and Ecosystem Surveys701

Chapter 24	
The Chernobyl Nuclear Power Plant Reactor Accident: Ecotoxicological Update	703
Ronald Eisler	

Chapter 25	
Pesticides and International Migratory Bird Conservation.....	737
Michael J. Hooper, Pierre Mineau, María Elena Zaccagnini, and Brian Woodbridge	

Chapter 26	
Effects of Mining Lead on Birds: A Case History at Coeur d'Alene Basin, Idaho	755
Charles J. Henny	

Chapter 27	
White Phosphorus at Eagle River Flats, Alaska: A Case History of Waterfowl Mortality.....	767
Donald W. Sparling	

Chapter 28	
A Mining Impacted Stream: Exposure and Effects of Lead and Other Trace Elements on Tree Swallows (<i>Tachycineta bicolor</i>) Nesting in the Upper Arkansas River Basin, Colorado	787
Christine M. Custer, Thomas W. Custer, Andrew S. Archuleta, Laura C. Coppock, Carol D. Swartz, and John W. Bickham	

Chapter 29	
The Hudson River — PCB Case Study	813
John P. McCarty	

Chapter 30	
Baseline Ecological Risk Assessment for Aquatic, Wetland, and Terrestrial Habitats along the Clark Fork River, Montana.....	833
Greg Linder, Daniel F. Woodward, and Gary Pascoe	

Section IV

Methods for Making Estimates, Predictability, and Risk Assessment in

Ecotoxicology853

Chapter 31

Global Disposition of Contaminants855

Roy M. Harrison, Stuart Harrad, and Jamie Lead

Chapter 32

Bioaccumulation and Bioconcentration in Aquatic Organisms877

1.1 HISTORY

The term *ecotoxicology* was first coined by Truhaut in 1969 as a natural extension from toxicology, the science of the effects of poisons on individual organisms, to the ecological effects of pollutants.¹ In the broadest sense ecotoxicology has been described as toxicity testing on one or more components of any ecosystem, as stated by Cairns.² This definition of ecotoxicology can be further expanded as the science of predicting effects of potentially toxic agents on natural ecosystems and on nontarget species. Ecotoxicology has not generally included the fields of industrial and human health toxicology or domestic animal and agricultural crop toxicology, which are not part of natural ecosystems, but are rather imposed upon them. Yet there is a growing belief by some that humanity and its artifacts should be regarded as components of natural systems, not apart from them. More recently, Newman has defined ecotoxicology as the science of contaminants in the biosphere and their effects on constituents of the biosphere, which includes humans.³ Ecotoxicology employs ecological parameters to assess toxicity. In a more restrictive but useful sense, it can be defined as the science of assessing the effects of toxic substances on ecosystems with the goal of protecting entire ecosystems, and not merely isolated components.

Historically, some of the earliest observations of anthropogenic ecotoxic effects, such as industrial melanism of moths, date back to the industrial revolution of the 1850s (see Table 1.1). In the field of aquatic toxicology Forbes was one of the first researchers to recognize the significance of the presence or absence of species and communities within an aquatic ecosystem and to report approaches for classifying rivers into zones of pollution based on species tolerance.⁴ At the same

Table 1.1 Historical Overview: First Observations of Ecotoxic Effects of Different Classes of Environmental Contaminants

Date	Contaminant(s)	Effects
1850s	Industrial revolution; soot from coal burning	Industrial melanism of moths
1863	Industrial wastewater	Toxicity to aquatic organisms; first acute toxicity tests
1874	Spent lead shot	Ingestion resulted in death of waterfowl and pheasants
1887	Industrial wastewater	Zones of pollution in rivers established by species tolerance
1887	Arsenic emissions from metal smelters	Death of fallow deer and foxes
1907	Crude oil spill	Death of thousands of puffins
1924	Lead and zinc mine runoff	Toxicity of metal ions to fish
1927	Hydrogen sulfide fumes in oil field	Large die-off of both wild birds and mammals
1950s	DDT and organochlorines	Decline in American robins linked to DDT use for Dutch Elm disease; eggshell thinning in bald eagles, osprey, and brown pelicans linked to DDT; and fish-eating mammals at risk
1960s	Anticholinesterase pesticides	Die-offs of wild birds, mammals, and other vertebrate species
1970s	Mixtures of toxic wastes, including dioxins at hazardous waste sites	Human, aquatic, and wildlife health at risk
1980s	Agricultural drainwater containing selenium and other contaminants	Multiple malformations and impaired reproduction in aquatic birds in central California
1986	Radioactive substances from Chernobyl nuclear power station	Worst nuclear incident in peacetime, affecting a wide variety of organisms and ecosystems
1990s	Complex mixtures of potential endocrine disrupting chemicals, including PCBs and organochlorine pesticides	Abnormally developed reproductive organs, altered serum hormone concentrations, and decreased egg viability in alligators from contaminated lakes in Florida

Source: Adapted from: Hoffman, D. J., Rattner, B. A., Burton, G. A. Jr., and Lavoie, D. R., *Ecotoxicology, in Handbook of Toxicology*, Derelanko, M. J., and Hollinger, M. A., Eds., CRC Press, Boca Raton, FL, 2002.

time some of the earliest acute aquatic toxicity tests were first performed by Penny and Adams (1863)⁵ and Weigelt, Saare, and Schwab (1885),⁶ who were concerned with toxic chemicals in industrial wastewater. The first “standard method” was published by Hart et al. in 1945 and subsequently adopted by the American Society for Testing and Materials.⁷ In this manner it has become generally recognized that the presence or absence of species (especially populations or communities) in a given aquatic ecosystem provides a more sensitive and reliable indicator of the suitability of environmental conditions than do chemical and physical measurements alone.

In the field of terrestrial toxicology reports of anthropogenic contaminants affecting free-ranging wildlife first began to accumulate during the industrial revolution of the 1850s. These included cases of arsenic pollution and industrial smoke stack emission toxicity. One early report described the death of fallow deer (*Dama dama*) due to arsenic emissions from a silver foundry in Germany in 1887, and another described hydrogen sulfide fumes near a Texas oil field that resulted in a large die-off of many species of wild birds and mammals,⁸ thus affecting multiple species within an ecosystem. With the advent of modern pesticides, most notably the introduction of dichlorodiphenyltrichloroethane (DDT) in 1943, a marked decline in the population of American robins (*Turdus migratorius*) was linked by the early 1950s to DDT spraying to control Dutch Elm disease. It soon became evident that ecosystems with bald eagles (*Haliaeetus leucocephalus*), osprey (*Pandion haliaetus*), brown pelicans (*Pelecanus occidentalis*), and populations of fish-eating mammals were at risk.^{9,10}

More recent observations of adverse effects of environmental contaminants and other anthropogenic processes capable of disrupting ecosystems will be covered in subsequent chapters of this book. Exposure and adverse effects, sometimes indirect, of anticholinesterase and other pesticides used in agriculture, petroleum and polycyclic aromatic hydrocarbons (PAHs), manufactured and waste polyhalogenated aromatic hydrocarbons, heavy metals, selenium and other trace elements are included. Other processes and contaminants include nuclear and thermal processes, urban runoff, pathogens and disease, deforestation and global warming, mining and smelting operations, waste

and spent munitions, and released genotoxic and endocrine disruptive chemicals will be presented and discussed in detail.

This book is divided into five sections (I. Quantifying and Measuring Ecotoxicological Effects; II. Contaminant Sources and Effects; III. Case Histories and Ecosystem Surveys; IV. Methods for Making Estimates, Predictability, and Risk Assessment in Ecotoxicology; V. Special Issues in Ecotoxicology) in order to provide adequate coverage of the following general areas of ecotoxicology: (1) methods of quantifying and measuring ecotoxicological effects under controlled laboratory conditions and under natural or manipulated conditions in the field; (2) exposure to and effects of major classes of environmental contaminants and other ecological perturbations capable of altering ecosystems; (3) case histories involving disruption of natural ecosystems by environmental contaminants; (4) methods used for making estimates, predictions, models, and risk assessments; and (5) identification and description of a number of new and significant issues and methodologies, most of which have come to light since publication of the first edition of this book in 1995. The rationale and some of the key points and concepts presented in each of the five sections are presented below.

1.2 QUANTIFYING AND MEASURING ECOTOXICOLOGICAL EFFECTS

Current methodologies for testing and interpretation are provided for aquatic toxicology and design of model aquatic ecosystems, wildlife toxicology, sediment toxicity, soil ecotoxicology, algal and plant toxicity, and the concept of landscape. Identification of biomonitoring programs and current use of biomarkers and bioindicators in aquatic and terrestrial monitoring are also important chapters in this section.

Chapter 2, by Adams and Rowland, provides a comprehensive overview of aquatic toxicology with an emphasis on test methods to meet the requirements of various regulatory guidelines. The chapter describes recent efforts to develop protocols and identify species that permit full-life cycle studies to be performed over shorter durations (e.g., 7-day *Ceriodaphnia dubia* life cycle tests, two-dimensional rotifer tests) and to establish protocols that use sensitive species and life stages that generate accurate estimates of chronic no-effect levels. There has been an increasing need to assess the toxicity of various types of suspect samples in minutes to hours instead of days. The use of rapid assays during on-site effluent biomonitoring allows for the collection of extensive data sets. The expanded use of biomarkers in natural environments, where organisms are exposed to multiple stressors (natural and anthropogenic) over time, will allow better detection of stress and provide an early indication of the potential for population-level effects. Model aquatic ecosystems, known as microcosms and mesocosms, were designed to simulate ecosystems or portions of ecosystems in order to study and evaluate the fate and effects of contaminants. Microcosms are defined by Giesy and Odum¹¹ as artificially bounded subsets of naturally occurring environments that are replicable, contain several trophic levels, and exhibit system-level properties. Mesocosms are defined as larger, physically enclosed portions of natural ecosystems or man-made structures, such as ponds or stream channels, that may be self-sustaining for long durations. Chapter 3 by Kennedy et al. focuses on key factors in the experimental design of microcosm and mesocosm studies to increase their realism, reduce variability, and assess their ability to detect changes. The success in using such systems depends on the establishment of appropriate temporal and spatial scales of sampling. Emphasis is placed on the need to measure exposure as a function of life history using parameters of size, generation time, habitat, and food requirements. This chapter also addresses the utility of employing a suite of laboratory-to-field experiments and verification monitoring to more fully understand the consequences of single and multiple pollutants entering aquatic ecosystems.

With the advent of modern insecticides and the consequent wildlife losses, screening of pesticides for adverse effects has become an integral part of wildlife toxicology. Avian testing protocols

developed by the U.S. Fish and Wildlife Service and other entities include protocols required for regulatory and other purposes. These are described with respect to acute, subacute, subchronic, chronic, developmental, field, and behavioral aspects of avian wildlife toxicity (Hoffman, Chapter 4). Several unique developmental toxicity tests assess the potential hazard of topical contaminant exposure to bird eggs and the sensitivity of “neonatal” nestlings to contaminants, including chemicals used for the control of aquatic weeds, mosquitoes, and wild fires. Coverage of toxicity testing for wild mammals, amphibians, and reptiles is provided as well, although in somewhat less detail since development of such tests has been more limited in scope and requirement.

Sediments serve as both a sink and a source of organic and inorganic materials in aquatic ecosystems, where cycling processes for organic matter and the critical elements occur. Since many potentially toxic chemicals of anthropogenic origin tend to sorb to sediments and organic materials, they become highly concentrated. Sediment toxicity testing (Burton et al., Chapter 5) is an expanding but still relatively new field in ecological assessments. The U.S. Environmental Protection Agency has initiated new efforts in managing contaminated sediments and method standardization that will result in an even greater degree of sediment toxicity testing, regulation, and research in the near future. A number of useful assays have been evaluated in freshwater and marine studies in which the importance of testing multiple species becomes apparent in order to protect the ecosystem. The assay methods described are sensitive to a wide variety of contaminants, discriminate differing levels of contamination, use relevant species, address critical levels of biological organization, and have been used successfully in sediment studies.

The importance of soil ingestion in estimating exposure to environmental contaminants has been best documented in assessments of pesticides or wastes applied to land supporting farm animals. Soil ingestion tends to be most important for those environmental contaminants that are found at relatively high concentrations compared to concentrations in a soil-free diet. Chapter 6, by Beyer and Fries, is designed to relate the toxicological significance of soil ingestion by wild and domestic animals. Concepts covered include methods for determining soil intake, intentional geophagy in animals, soil ingestion by both domestic animals and wildlife, toxicity of environmental contaminants in soil or sediment to animals, relation of particle size of ingested soil to exposure to contaminants, bioavailability of organic and inorganic contaminants in soil, and applications to risk assessments.

Chapter 7, by Linder, Henderson, and Ingham, focuses on applications of ecological risk assessment (ERA) of contaminated soils on wildlife and habitat restoration, since at present there is little or no federal, state, or other guidance to derive soil cleanup values or ecological-based remedial goal options. Three components of this chapter include ERA tools used to characterize a lower bound, the role of bioavailability in critically evaluating these lower bound preliminary remedial goals, and remediation measures intended to address field conditions and modify soil in order to decrease a chemical’s immediate bioavailability, while increasing the likelihood of recovery to habitats suitable for future use by fish and wildlife.

Evaluation of the phytotoxicity of a chemical is an essential component of the ecological risk assessment, since primary producers form an essential trophic level of any ecosystem. Since most chemicals introduced into the environment ultimately find their way into aquatic ecosystems, aquatic algal and plant toxicity evaluations are particularly critical. Klaine, Lewis, and Knuteson (Chapter 8) discuss the current state of phytotoxicity testing with particular attention to algal and vascular (both aquatic and terrestrial) plant bioassays. The algal bioassay section not only focuses on test methods developed over the relatively long history of algal toxicity testing, but also includes many adaptations to traditional laboratory methods to provide more realistic phytotoxicity estimates. The vascular plant section focuses on different species used for bioassays and the various endpoints used. Bioassay systems described include soil, hydroponics, foliar, petri dish, and tissue culture.

In recent years ecologists have established a need for studying natural processes not only at the individual, community, or ecosystem level, but over the entire landscape,^{12–14} since quite often ecological studies may be too small both spatially and temporally to detect certain important natural

processes and the movement of pollutants across multiple ecosystems. Holl and Cairns (Chapter 9) discuss the concept of landscape ecology with a focus on (a) landscape structure, that is, spatial arrangement of ecosystems within landscapes; (b) landscape function, or the interaction among these ecosystems through flow of energy, materials, and organisms; and (c) alterations of this structure and function. Different types of landscape indicators in ecotoxicology are presented.

Biomonitoring data form the basis upon which most long-term stewardship decisions are made. These data often provide the critical linkage between field personnel and decision-makers. Data from biomonitoring programs have been very useful in identifying local, regional, and national ecotoxicological problems. Natural resource management decisions are being made that annually cost millions of dollars. These decisions should be supported by scientifically sound data. Chapter 10, by Breckenridge et al., discusses why monitoring programs are needed and how to design a program that is based on sound scientific principles and objectives. This chapter identifies many of the large-scale monitoring programs in the United States, how to access the information from the programs, and how this information can be used to improve long-term management of natural resources. Bioindicators are an important part of biomonitoring and reflect the bioavailability of contaminants, provide a rapid and inexpensive means for toxicity assessment, may serve as markers of specific classes of chemicals, and serve as an early warning of population and community stress. Melancon (Chapter 11) defines bioindicators as biomarkers (biochemical, physiological, or morphological responses) used to study the status of one or more species typical of a particular ecosystem. Systematically, the responses can range from minor biochemical or physiological homeostatic responses in individual organisms to major toxicity responses in an individual, a species, a community, or an ecosystem. Many currently used bioindicators of contaminant exposure/effect for environmental monitoring are discussed. Some of these bioindicators (e.g., inhibition of cholinesterase by pesticides, induction of hepatic microsomal cytochromes P450 by PAHs and polychlorinated biphenyls (PCBs), reproductive problems such as terata and eggshell thinning, aberrations of hemoglobin synthesis including the effects of lead on ALAD, and porphyria caused by chlorinated hydrocarbons) have been extensively field-validated. Other potentially valuable bioindicators undergoing further validation are discussed and include bile metabolite analysis, oxidative damage and immune competence, metallothioneins, stress proteins, gene arrays, and proteomics.

1.3 CONTAMINANT SOURCES AND EFFECTS

The purpose of this section is to identify and describe the effects of significant environmental contaminants and other anthropogenic processes capable of disrupting ecosystems. We have focused on major pesticides (including organophosphorus and carbamate anticholinesterases and persistent organochlorines), petroleum and PAHs, heavy metals (lead and mercury), selenium, polyhalogenated aromatic hydrocarbons, and urban runoff. Toxicity of other metals and trace elements is included in Chapter 40 on amphibian declines, Chapter 44 on trace element interactions, and in three of the case history chapters. Chapters in this section on other important anthropogenic processes include nuclear and thermal contamination, global effects of deforestation, pathogens and disease, and abiotic factors that interact with contaminants.

About 200 organophosphorus (OP) and 50 carbamate (CB) pesticides have been formulated into thousands of products that are available in the world's marketplace for control of fungi, insects, herbaceous plants, and terrestrial vertebrates following application to forests, rangelands, wetlands, cultivated crops, cities, and towns.^{15,16} Though most applications are on field crops and other terrestrial habitats, the chemicals often drift or otherwise translocate into nontarget aquatic systems and affect a much larger number of species than originally intended. Hill (Chapter 12) provides an overview of the fate and toxicology of organophosphorus and carbamate pesticides. More attention is given to practical environmental considerations than interpretation of laboratory studies, which were detailed in the first edition of this book. Invertebrates, fish, amphibians, and reptiles are

exemplified as ecosystem components and for comparison with birds and mammals. The focus is on concepts of ecological toxicology of birds and mammals related to natural systems as affected by pesticidal application in agriculture and public health. The environmental fate of representative OP and CB pesticides, their availability to wildlife, and toxicology as related to ambient factors, physiological cycles and status, product formulations and sources of exposure are discussed.

It is unlikely that any other group of contaminants has exerted such a heavy toll on the environment as have the organochlorine (OC) pesticides. Blus (Chapter 13) discusses the nature and extent of ecotoxicological problems resulting from the use of organochlorine pesticides for over a half century as well as the future relevance of these problems. Toxicity of OCs is described as influenced by species, sex, age, stress of various kinds, formulations used, and numerous other factors. The eggshell-thinning phenomenon, depressed productivity, and mortality of birds in the field led to experimental studies with OCs, clearly demonstrating their role in environmental problems. An assessment of the environmental impact of OCs leads to the conclusion that the ecotoxicologist must integrate data obtained from controlled experiments with those obtained from the field. In this manner through the use of the "sample egg technique" and other such innovative procedures, controversies over whether DDE or dieldrin were more important in causing a decline of peregrine falcons and other raptors in Great Britain could have been resolved. Although most of the problem OCs have been banned in a number of countries, exposure, bioaccumulation, and ecotoxicological effects will linger far into the future because of the environmental persistence of many compounds and their continued use in a fairly large area.

Petroleum and individual PAHs from anthropogenic sources are found throughout the world in all components of ecosystems. Chapter 14 (Albers) discusses sources and effects of petroleum in the environment. Less than half of the petroleum in the environment originates from spills and discharges associated with petroleum transportation; most comes from industrial, municipal, and household discharges, motorized vehicles, and natural oil seeps. Recovery from the effects of oil spills requires up to 5 years for many wetland plants. Sublethal effects of oil and PAHs on sensitive larval and early juvenile stages of fish, embryotoxic effects through direct exposure of bird eggs, and acute effects in vertebrates are discussed. Evidence linking environmental concentrations of PAHs to induction of cancer in wild animals is strongest for fish. Although concentrations of individual PAHs in aquatic environments are usually much lower than concentrations that are acutely toxic to aquatic organisms, sublethal effects can be produced. Effects of spills on populations of mobile species have been difficult to determine beyond an accounting of immediate losses and, sometimes, short-term changes in local populations.

Lead (Pb) is a nonessential, highly toxic heavy metal, and all known effects of lead on biological systems are deleterious. According to Pattee and Pain (Chapter 15), present anthropogenic lead emissions have resulted in soil and water lead concentrations of up to several orders of magnitude higher than estimated natural concentrations. Consequently, lead concentrations in many living organisms, including vertebrates, may be approaching adverse-effect thresholds. The influence of the chemical and physical form of lead on its distribution within the environment and recent technology to accurately quantify low lead concentrations are described. The chapter also discusses the most significant sources of lead related to direct wildlife mortality and physiological and behavioral effects detected at tissue lead concentrations below those previously considered safe for humans.

The widespread geographic extent and adverse consequences of mercury pollution continue to prompt considerable scientific investigation. Globally increasing concentrations of methylmercury are found in aquatic biota, even at remote sites, as a consequence of multiple anthropogenic sources and their releases of mercury into the environment. For example, in the marine food web of the North Atlantic Ocean, analysis of feathers of fish-eating seabirds sampled from 1885 through 1994 have shown a steady long-term increase in concentration of methylmercury.^{17,18} Wiener et al. (Chapter 16) characterize the environmental mercury problem, critically review the ecotoxicology of mercury, and describe the consequences of methylmercury contamination of food webs. Topics include processes and factors that influence exposure to methylmercury, the highly neurotoxic form.

This form readily accumulates in exposed organisms and can biomagnify in food webs to concentrations that can adversely affect organisms in upper trophic levels. Emphasis is given to aquatic food webs, where methylmercury contamination is greatest.

Reproductive impairment due to bioaccumulation of selenium in fish and aquatic birds has been an ongoing focus of fish and wildlife research, not only in the western United States but also in other parts of the world. Selenium is a naturally occurring semimetallic trace element that is essential for animal nutrition in small quantities, but becomes toxic at dietary concentrations that are not much higher than those required for good health. Thus, dietary selenium concentrations that are either below or above the optimal range are of concern. Chapter 17, by Ohlendorf, summarizes the ecotoxicology of excessive selenium exposure for animals, especially as reported during the last 15 years. Focus is primarily on freshwater fish and aquatic birds, because fish and birds are the groups of animals for which most toxic effects have been reported in the wild. However, information related to bioaccumulation by plants and animals as well as to effects in invertebrates, amphibians, reptiles, and mammals is also presented.

PCBs, dioxins (PCDDs), and dibenzofurans (PCDFs) are all similar in their chemistry and manifestation of toxicity, including a high capacity for biomagnification within ecosystems. Mammals, birds, and fish all have representative species that are highly sensitive, as well as highly resistant, to dioxin-like adverse effects, especially chronic reproductive and developmental/endocrine effects. Aquatic food chain species (seals, dolphins, polar bears, fish-eating birds, and cold-water fish species) with high exposure potential through biomagnification are particularly vulnerable. Rice, O'Keefe, and Kubiak (Chapter 18) review the fate of these environmentally persistent compounds and their toxicity, which is complex and often chronic rather than acute. As for PCBs the complexity begins with the large number of compounds, with varying toxicities, that are regularly detected in the environment (100 to 150). With dioxin- and dibenzofuran-related compounds there are fewer commonly measured residues (< 20). However, environmental problems are confounded since they are not directly manufactured but occur as unwanted impurities in manufacturing and incineration.

Urban runoff investigations, which have examined mass balances of pollutants, have concluded that this process is a significant pollutant source. Some studies have even shown important aquatic life impacts for streams in watersheds that are less than 10% urbanized. In general, monitoring of urban stormwater runoff has indicated that the biological beneficial uses of urban receiving waters are most likely affected by habitat destruction and long-term exposures to contaminants (especially to macroinvertebrates via contaminated sediment), while documented effects associated with acute exposures of toxicants in the water column are less likely. Pitt (Chapter 19) recommends longer-term biological monitoring on a site-specific basis, using a variety of techniques, and sediment-quality analyses to best identify and understand these impacts, since water column testing alone has been shown to be very misleading. Most aquatic life impacts associated with urbanization are probably related to long-term problems caused by polluted sediments and food web disruption.

In addition to natural background radiation, irradiation occurs from the normal operation of nuclear power plants and plutonium production reactors, nuclear plant accidents, nuclear weapons testing, and contact with or leakage from radioactive waste storage sites. Assessing the impacts of nuclear power facilities on the environment from routine and accidental releases of radionuclides to aquatic and terrestrial ecosystems is important for the protection of these ecosystems and their species component. The impacts of power-plant cooling systems — impingement, entrainment, elevated water temperatures, heat shock, and cold shock — on aquatic populations and communities have been intensively studied as well. Discussion in Chapter 20 (Meyers-Schone and Talmage) focuses on basic radiological concepts and sources as well as the effects of radiation on terrestrial and aquatic populations and communities of plants and animals. Radiation effects in this chapter focus on field studies, with supporting information from relevant laboratory investigations. Selected examples attempt to relate estimated doses or tissue levels to potential effects; however, dose estimates in the field are often imprecise, and observations are further confounded by the presence of other contaminants or stressors. Thermal toxicity is related to power-plant cooling systems.

Nearly 17 million ha of tropical forests are being cleared each year for new agricultural lands, equivalent to clearing an area the size of the state of Georgia or Wisconsin annually.¹⁹ Global effects of deforestation include irreplaceable loss of species, emissions into the atmosphere of chemically active and heat-trapping trace gases (carbon dioxide, methane, nitrous oxide, and carbon monoxide), and consequent global warming. Current emissions of greenhouse gases from deforestation account for about 25% of the global warming calculated to result from all anthropogenic emissions of greenhouse gases. Continued emissions of greenhouse gases from both deforestation and industrial sources will raise global mean temperature by an estimated 1 to 3.5°C by the end of this century. Houghton (Chapter 21) reviews the contribution of deforestation and subsequent land use with respect to the increasing concentrations of greenhouse gases in the atmosphere and projected global warming. Suggested remedial and preventative actions include (1) a large ($\geq 60\%$) reduction in the use of fossil fuels through increased efficiency of energy use and a much expanded use of renewable energy sources, (2) the elimination of deforestation, and (3) reforestation of large areas of land, either to store carbon or to provide renewable fuels to replace fossil fuels.

Pathogenic organisms are life forms that cause disease in other life forms; they are components of all ecosystems. Although ecotoxicology is often considered to be the study of chemical pollutants in ecosystems, pathogenic organisms and their diseases are relevant in this context in at least several different ways, as described by Leighton (Chapter 22). Pathogens can be regarded as pollutants when they are released by humans into ecosystems for the first time or when they are concentrated in certain areas by human activity. Four situations in which human activities can alter the occurrence of diseases in the environment include: (1) translocation of pathogens, including manmade ones, host species, and vectors, to new environments; (2) concentration of pathogens or host species in particular areas; (3) changes in the environment that can alter host-pathogen relationships; and (4) creation of new pathogens by intentional genetic modification of organisms.

Environmental factors have long been shown to influence the toxicity of pollutants in living organisms. Drawing upon controlled experiments and field observations, Rattner and Heath (Chapter 23) provide an overview of abiotic environmental factors and perspective on their ecotoxicological significance. Factors discussed include temperature, salinity, water hardness, pH, oxygen tension, nonionizing radiation, photoperiod, and season. Free-ranging animals simultaneously encounter a combination of environmental variables that may influence, and even act synergistically, to alter contaminant toxicity. It is not possible to rank these factors, particularly since they are oftentimes interrelated (e.g., temperature and seasonal rhythms). However, it is clear that environmental factors (particularly temperature) may alter contaminant exposure and toxicity (accumulation, sublethal effects, and lethality) by more than an order of magnitude in some species. Accordingly, it is concluded that effects of abiotic environmental variables should be considered and factored into risk assessments of anthropogenic pollutants.

1.4 CASE HISTORIES AND ECOSYSTEM SURVEYS

To illustrate the full impact of different environmental contaminants on diverse ecosystems, seven case histories and ecosystem surveys are presented. These include effects of the nuclear meltdown of Chernobyl, agricultural pesticides on migratory birds in Argentina and Venezuela, impact of mining and smelting on several river basins in the western United States, white phosphorus from spent munitions on waterfowl, and effects of PCBs on the Hudson River.

The partial meltdown of the 1000 Mw reactor at Chernobyl in the Ukraine released large amounts of radiocesium and other radionuclides into the environment, causing widespread contamination of the northern hemisphere, particularly Europe and the former Soviet Union. Eisler (Chapter 24) provides a concise review of the ecological and toxicological aspects of the Chernobyl accident, with an emphasis on natural resources. The most sensitive local ecosystems and organisms are

discussed, including soil fauna, pine forest communities, and certain populations of rodents. Elsewhere, reindeer in Scandinavia were among the most seriously afflicted by fallout since they are dependent on lichens, which absorb airborne particles containing radiocesium. Some reindeer calves contaminated with ^{137}Cs from Chernobyl showed ^{137}Cs -dependent decreases in survival and increases in frequency of chromosomal aberrations. The full effect of the Chernobyl nuclear reactor accident on natural resources will probably not be known for at least several decades because of gaps in data on long-term genetic and reproductive effects and on radiocesium cycling and toxicokinetics.

Hooper and co-authors (Chapter 25) describe how recent events in Argentina and Venezuela have shown that pesticide effects transcend national borders with respect to migratory birds exposed to potentially damaging pesticides throughout their range. Despite its withdrawal from the United States, monocrotophos, one of the most acutely toxic pesticides to birds, remained the second highest use OP throughout the world through the mid-1990s, resulting in the death of an estimated 20,000 Swainson's hawks (*Buteo swainsoni*) in Argentina. What has been learned since, as demonstrated by the risks that face many trans-border avian migrants, has clarified the need for greater international cooperation and harmonization of pesticide use. Where a large portion of a species population occupies a small geographical area, either in the course of its migration or on wintering grounds, any localized contaminant or noncontaminant impact can have potentially serious consequences for that population.

Studies conducted in the vicinity of mining operations and smelters have provided some of the most revealing examples of environmental damage caused by metals and associated contaminants. Metal-contaminated soils eroded from exposed and disturbed landscapes and tailings generated during processing may be released to the environment and are associated with increased metal concentrations in surface water and groundwater. Similarly, dispersed sediments often become deposited as alluvial materials in riparian areas and can result in soil metal concentrations greatly exceeding predepositional conditions. Henny (Chapter 26) reviews the history and cause of waterfowl mortality in the Coeur d'Alene (CDA) River Basin of Idaho related to mining sediment containing high concentrations of lead and other metals. Diagnostic procedures and techniques to assess lead poisoning are discussed. Beyer and co-workers²⁰ concluded that exposure of waterfowl to lead in the CDA River Basin was principally related to the amount of ingested sediment, since the relative amount of lead in vegetation and prey was small. Following this logic and the fact that most raptors neither ingest sediment nor digest bones of prey species that are a major storage site for lead, it becomes clear why the ospreys, hawks, and owls in the CDA River Basin were less contaminated than waterfowl with lead from mining sources. Along the Arkansas River, lead concentrations in livers of nestling tree swallows conclusively demonstrated that lead from sediments is bioavailable to this species prior to fledging (Custer and co-authors, Chapter 28). Lead was detected in most tree swallow livers at two sites along an 11-mile stretch, the most sediment-contaminated section of the Arkansas River. The proportion of livers with detectable lead was less both downstream and upstream of the 11-mile stretch, but with a site-related upstream/downstream gradient in lead concentrations. Additionally, the mean half-peak coefficient of variation of DNA content (HPCV) indicative of possible chromosomal damage was positively correlated with both liver and carcass cadmium concentrations. Linder, Woodward, and Pascoe (Chapter 30) summarize ecological risk-assessment studies focused on metal-contaminated soil, sediment, and surface water for a series of Superfund sites located in the Clark Fork River (CFR) watershed of western Montana. Aquatic, terrestrial, and wetland resources at risk including benthic invertebrates, fish, earthworms, plants, and animals are evaluated.

Eagle River Flats (ERF), located on the Cook Inlet of Anchorage, Alaska, is used by waterfowl and shorebirds throughout the spring and summer and is particularly important as a spring and fall staging or stopover area for more than 75 species of migratory ducks, geese, swans, raptors, gulls, shorebirds, and passerines. Massive waterfowl mortalities due to ingestion of particles of white phosphorus (P4) originating from the firing of munitions into the area occurred and involved over

2000 ducks and swans each year. Sparling (Chapter 27) provides a discussion on toxicity of white phosphorus, a hazard assessment model, efforts to remediate the problem, and how ERF serves as a model for the effects and remediation of P4 on at least 71 other sites where the contaminant has been found.

The Hudson River dominates the history and landscape of eastern New York and surrounding states and has come to symbolize the difficulties associated with finding solutions to the problems of widespread contamination by persistent organic compounds. McCarty (Chapter 29) reviews the history of PCB contamination in the context of the Hudson River ecosystem, describing the patterns of PCB contamination in the biota of the Hudson, the risk contaminants pose to fish and wildlife, and attempts to mitigate those risks.

1.5 METHODS FOR MAKING ESTIMATES, PREDICTABILITY, AND RISK ASSESSMENT IN ECOTOXICOLOGY

Ecological risk assessment is a process that evaluates the likelihood that adverse ecological effects will occur as a result of exposure to one or more stressors; it is receiving increasing emphasis in ecotoxicology. Suter²¹ defines risk assessment as the process of assigning magnitudes and probabilities to the adverse effects of human activities or natural catastrophes. Examples and uses of ecological risk assessment occur in chapters throughout all sections of this book. However, the fourth section of this book is focused on describing methods and approaches used for estimating and predicting the outcome of potentially ecotoxic events for purposes of risk assessment. These include global disposition of contaminants, bioaccumulation and bioconcentration of contaminants, use of quantitative structure activity relationships (QSARs) for predicting ecological effects of organic chemicals, and population modeling in contaminant studies. Another important part of this section is the current guidelines and future directions of the U.S. Environmental Protection Agency for ecological risk assessment, followed by an exemplary chapter of an ecological risk assessment. The final chapter of this section describes the relationship between restoration ecology and ecotoxicology and quantifies how damaged ecosystems can be restored.

The sources of many environmental contaminants are relatively easy to identify. While short-lived contaminants are most readily identified close to the source, the more persistent substances, such as heavy metals and PCBs, may achieve a truly global distribution due to atmospheric transport and deposition to soils and surface waters. The interim period between emission or discharge of an environmental contaminant and ultimate contact with a specific ecosystem or representative species often contains many varied and interesting processes. Harrison, Harrad, and Lead (Chapter 31) describe some of the more important processes involved in pollutant transport and removal from the environment and discuss how such processes influence the distribution of pollutants. Included are processes leading to the transfer of chemical substances between environmental compartments such as water to air and air to soil. Bioaccumulation and bioconcentration are terms describing the transfer of contaminants from the external environment to an organism. In aquatic organisms bioaccumulation can occur from exposure to sediment (including pore water) or via the food chain (termed trophic transfer). Bioconcentration is the accumulation of waterborne contaminants by aquatic animals through nondietary exposure routes. Biomagnification is defined as the increase in contaminant concentration in an organism in excess of bioconcentration. Biomagnification appears most significant for benthic-based food webs and for very hydrophobic contaminants resistant to biotransformation and biodegradation. As reviewed by Barron (Chapter 32) concern for the bioaccumulation of contaminants arose in the 1960s because of incidents such as toxicity from methyl mercury residues in shellfish and avian reproductive failure due to chlorinated pesticide residues in aquatic species. Bioaccumulation models were first developed in the 1970s to account for processes such as the partitioning of hydrophobic chemicals from water to aquatic organisms. To regulate new and existing chemicals laws such as the Federal Insecticide,

Fungicide and Rodenticide Act contain stringent requirements for bioaccumulation testing. This chapter presents an overview of the principles and determinants governing bioaccumulation from sediments and water and biomagnification in aquatic-based food webs. Organic and metal contaminants are discussed, with an emphasis on hydrophobic organics. The objective of this chapter is to elucidate concepts relating to bioaccumulation, rather than simply present an exhaustive review of the literature.

Structure activity relationships (SARs) are comparisons or relationships between a chemical structure, chemical substructure, or some physical or chemical property associated with that structure or substructure and a biological (e.g., acute toxicity) or chemical (e.g., hydrolysis) activity. When the result is expressed quantitatively, the relationship is a quantitative structure activity relationship (QSAR). Most SARs have been developed for predicting ecological effects of organic chemicals. For SARs that predict ecological effects Walker and Schulz (Chapter 33) provide examples, developmental approaches, universal principles, applications, and recommendations for new QSARs to predict ecotoxicological effects. Since most QSARS have been developed for freshwater aquatic organisms, it is recommended that additional QSARs be developed for predicting effects of chemicals on terrestrial and sediment-dwelling organisms. There is a critical need for these QSARs, especially given the high exposure potential of terrestrial wildlife to pesticides that are intentionally dispersed and to persistent industrial chemicals that are toxic and undergo long-range transport.

The inconvenience and hardship resulting from ecological failures in ecosystem services (e.g., waste processing, provision of potable water, and food production) motivated early attempts at proactive management of the environment, including prediction and mitigation of damage. Cairns and Niederlehner (Chapter 34) discuss the science of predictive ecotoxicology, emphasizing that prediction of environmental outcome is different from appraisal of existing damage and that prediction is solely dependent upon modeling. There is often no way to verify the accuracy of prediction through field survey, yet accuracy checks are essential in assuring that predictive techniques are adequate to management needs. Validation studies compare predictions to appraisals of damage in natural systems. Through these comparisons the magnitude and significance of predictive errors can be evaluated. Ways in which predictive models can be improved are discussed.

A population model is a set of rules or assumptions, expressed as mathematical equations, that describe how animals survive and reproduce. Ecology has a rich history of using models to gain insights into population dynamics. Population models provide a means for evaluating the effects of toxicants in the context of the life cycle of an organism. By developing a model and estimating demographic parameters effects of toxicants on demographic parameters of population growth rates and model stability can be assessed. Also, modeling allows one to identify what portions of the life cycle are most sensitive to toxicants and can guide future data collection and field experiments.

Chapter 35 (Sauer and Pendleton) reviews how population modeling has been used to provide insights into theoretical aspects of ecology and addresses practical questions for resource managers about how population dynamics are affected by changes in the environment. Specific concepts include (1) use of modeling procedures that group populations into discernible age classes, with survival and fecundity rates measured at various intervals for these groups; (2) methods for analyzing the stable population attributes of these models; (3) methods for assessing the effects of changes in the parameters of the models; and (4) applications of the models in evaluating the effects of changes in the demographic parameters.

ERA has been used to evaluate a wide variety of environmental issues of interest such as water-regime management, chemical and biological stressors used to control harmful insects, and toxic chemicals used in industrial processes or present at hazardous waste sites. Chapter 36 (Norton and co-authors) describes recent and ongoing guidelines established by the U.S. Environmental Protection Agency for ERA. Taken into consideration are effects on multiple populations, communities, and ecosystems and the need to consider nonchemical as well as chemical stressors. Problem formulation, characterization of exposure and ecological effects, risk characterization, and case

studies and interaction between risk assessment and risk management are discussed. Applications are described in terms of assessing ecological risks from chemicals using probabilistic methods, conducting ecological risk assessment of biological stressors, expanding concepts of exposure, developing management objectives for ERA (including watershed management), and integrating ecological risk assessment with economic, human health, and cultural assessments. This chapter is followed by an exemplary chapter (Byron and co-authors, Chapter 37) describing an actual ERA involving selenium exposure in waterfowl and shorebirds feeding in ephemeral pools in the vicinity of Kesterson Reservoir in central California.

Cairns (Chapter 38) concludes that the adoption of a no-net-ecological-loss policy will require ecological restoration of systems damaged by accidental spills, cumulative impact of anthropogenic stresses over a long period of time, and even ecoterrorism. Ecotoxicology as a scientific discipline will remain essential to ensure that the management practices associated with potentially toxic materials are well understood. Illustrative examples of where the relationship between restoration ecology and ecotoxicology might be most effective include rivers chronically and cumulatively impacted by hazardous materials or by unexpected spills of hazardous materials. For terrestrial systems the Superfund sites in the United States, where accumulations of hazardous materials pose a threat to the surrounding environment and human health, provide an example. Although this chapter emphasizes the relationship between restoration ecology and ecotoxicology, other disciplines should be engaged in order to generate a long-term solution to a complex multivariate problem.

1.6 SPECIAL ISSUES IN ECOTOXICOLOGY

The purpose of the fifth section of this book is to identify and describe a number of new and significant issues and approaches in ecotoxicology, most of which have come into focus since the publication of the first edition of this book. These include endocrine-disrupting chemicals and endocrine active agents in the environment, the possible role of contaminants in the worldwide decline of amphibian populations, potential genetic effects of contaminants on animal populations, the role of ecotoxicology in industrial ecology and natural capitalism, the consequences of indirect effects of agricultural pesticides on wildlife, the role of nutrition on trace element toxicity in fish and wildlife, and the role of environmental contaminants on endangered species.

Over the last 5 years there has been a surge of reports in wildlife of suspect endocrine-disruptor-related effects based primarily on adverse reproductive and developmental effects.²²⁻²⁴ Collectively, there is some evidence of altered reproductive and developmental processes in wildlife exposed to endocrine disruptors, and in the United States, Congress has passed legislation requiring the Environmental Protection Agency to develop, validate, and implement an Endocrine Disruptor Screening Program (EDSP) for identifying potential endocrine-disrupting chemicals. A wide variety of chemicals have been reported as potential endocrine disruptors and are described by Gross and co-workers in Chapter 39 of this book. This chapter reviews and selectively summarizes methods for screening and monitoring of potential endocrine disruptors, the current evidence for endocrine-disrupting effects, and chemical classes in vertebrate wildlife and their potential modes of action. Classes of chemicals include polycyclic aromatic hydrocarbons; polychlorinated and polybrominated biphenyls, dibenzo-*p*-dioxins, dibenzo-*p*-furans; organochlorine pesticides and fungicides; some nonorganochlorine pesticides; complex environmental mixtures; and a few metals.

Over the past decade widespread population declines of amphibians have been documented in North America, Europe, Australia, and Central and South America.²⁵⁻²⁷ Population declines in eastern Europe, Asia, and Africa have been suggested as well but are not as well documented. Based on comparative toxicities of organic compounds and metals between amphibians and fish, the overall conclusions were that there was great variation among amphibian species in their sensitivity to metal and organic contaminants, that amphibians generally were more sensitive than fish, and that water-quality criteria established for fish may not be protective of amphibians.

Contaminants may be involved with amphibian population declines, including their possible interaction with other factors discussed by Sparling in Chapter 40.

Understanding changes to the genetic apparatus of an organism exposed to contaminants in the environment is essential to demonstrating an impact on parameters of ecological significance such as population effects. Genetic ecotoxicology attempts to identify changes in the genetic material of natural biota that may be induced by exposure to genotoxicants in their environment and the consequences at various levels of biological organization (molecular, cellular, individual, population, etc.) that may result from this exposure. Shugart, Theodorakis, and Bickham (Chapter 41) describe two major classes of effects studied in genetic ecotoxicology: (1) direct exposure to genotoxicants that have the potential to lead to somatic or heritable (genotoxicological) disease states and that could lower the reproductive output of an affected population, and (2) indirect effects from contaminant stress on populations that lead to alterations in the genetic makeup, a process termed evolutionary toxicology.²⁸ These latter types of effects alter the inclusive fitness of populations such as by the reduction of genetic variability.

Industrial ecology is the study of the flows of materials and energy in the industrial environment and the effects of those flows on natural systems. Natural capitalism refers to the increasingly critical relationship between natural capital (i.e., natural resources), living systems and the ecosystem services they provide, and manmade capital. Natural capitalism and two of its subdisciplines, industrial and municipal ecology, are essential components in developing a sustainable relationship with natural systems and protecting both natural capital and the delivery of ecosystem services. Cairns (Chapter 42) discusses the role of ecotoxicologists in this sustainability.

Agricultural pesticides have been identified as contributing to the decline of farmland wildlife, although the impact is often exacerbated by other farm practices associated with intensive agriculture. Many species of farmland birds are in decline in the United Kingdom, and there is considerable evidence for the indirect effects of pesticides as the cause. Sotherton and Holland (Chapter 43) discuss how changes in chick survival drive the population size of the once common United Kingdom farmland grey partridge, and conclude that the timing and magnitude of changes in population size and chick survival are consistent with having been caused by the increased use of pesticides, which reduce the insect foods available for partridge chicks. Indirect effects are also likely to impact upon a wide variety of farmland wildlife that are dependent on the same food chain as the grey partridge, and evidence of this is starting to appear for some passerines.

Nutrition of test organisms is one of the most important variables in the conduct of any biological experiment. Deficiencies of vitamins, minerals, and other nutrients in the diet of captive and free-ranging fish and wildlife can result in skeletal deformities, cataracts, histological lesions, abnormal behavior, and many other abnormalities. Excessive amounts of vitamins and minerals have also resulted in abnormalities. The quality of commercial or experimentally prepared diets of captive animals as well as diets consumed by wild animals can influence the acute and chronic toxicity of test compounds. Chapter 44 (Hamilton and Hoffman) examines interactions between nutrition and potentially toxic trace elements and interactions among trace elements. Limited information from dietary studies with trace elements, especially selenium, reveals that diet can have a profound effect on toxicity observed in contaminated ecosystems, yet water-quality standards are rarely derived taking this factor into account. Incorporation of dietary criteria into national criteria for trace elements will occur only after a sufficient database of information is generated from dietary toxicity studies. Recent findings with environmentally relevant forms of mercury (methylmercury) and selenium (selenomethionine) in birds have shown that mercury and selenium may be mutually protective to the toxicity of each other in adult birds but synergistic in combination to the reproductive process in embryos. Further studies are needed to examine the relationship between selenium, nutrition, and other trace elements that may be toxic by compromising cellular antioxidative defense mechanisms. There is also a need for comparative interaction studies in species of wild mammals.

The speed, severity, and taxonomic diversity of declining species is a major concern to ecologists because extinctions are taking place at a rate of approximately 100 species per day.²⁹ Previously,

Wilson³⁰ projected the loss of species at more than 20% of the planet's total biodiversity in 20 years. The last chapter (45) of this section by Pattee, Fellows, and Bounds examines the role of contaminants/pollution in the decline of species. Habitat destruction is the primary factor that threatens species and is listed as a significant factor affecting 73% of endangered species. The second major factor causing species decline is the introduction of nonnative species. This affects 68% of endangered species. Pollution and overharvesting were identified as impacting 38% and 15%, respectively, of endangered species. No other contaminant has impacted animal survival to the extent of DDT, which remains one of the few examples of pollution actually extirpating animal species over a significant portion of DDT's range. Once a species is reduced to a remnant of its former population size and distribution, its vulnerability to catastrophic pollution events increases, frequently exceeding or replacing the factors responsible for the initial decline. Therefore, large-scale environmental events, such as global warming, acid rain, and sea-level rise, attract considerable attention as speciation events, adversely affecting some species populations while causing other species to flourish.

The editors of this book conclude that with increasing loss of habitat the quality and fate of the remaining habitat becomes increasingly critical to the survival of species and ecosystems. Species that are endangered or at risk and that occupy a very limited geographical area could be easily decimated by a single event such as an oil or chemical spill or misapplication of pesticides. Furthermore, on a temporal basis where a large portion of a species population occupies a small geographical area, either in the course of its migration or on wintering grounds, any localized impact, whether pesticide-related (e.g., as reported by Hooper and co-authors, Chapter 25) or not, has the potential for serious consequences to populations. For these reasons the balance between shrinking habitat and anthropogenic stressors becomes increasingly crucial to sustain both ecosystems and species diversity.

2.1 INTRODUCTION

Aquatic toxicology is the study of the effects of toxic agents on aquatic organisms. This broad definition includes the study of toxic effects at the cellular, individual, population, and community levels. The vast majority of studies performed to date have been at the individual level. The intention

of this chapter is to provide an overview of aquatic toxicology with an emphasis on reviewing test methods and data collection to meet the requirements of various regulatory guidance.

2.2 HISTORICAL REVIEW OF THE DEVELOPMENT OF AQUATIC TOXICOLOGY

Aquatic toxicology grew primarily out of two disciplines: water pollution biology and limnology. The development of these disciplines spanned about 130 years in Europe and the United States. Early studies included basic research to define and identify the biology and morphology of lakes, streams, and rivers. These studies included investigations on how plants, animals, and microorganisms interact to biologically treat sewage and thus reduce organic pollution. For example, the role of bacteria in the nitrification process was demonstrated in 1877 by Schoesing and Muntz. Stephen Forbes is generally credited as one of the earliest researchers of integrated biological communities (Forbes, 1887).¹ Kolwitz and Marsson^{2,3} and Forbes and Richardson⁴ published approaches for classifying rivers into zones of pollution based on species tolerance and their presence or absence. It has become an accepted belief that the presence or absence of species (especially populations or communities) living in a given aquatic ecosystem provides a more sensitive and reliable indicator of the suitability of environmental conditions than do chemical and physical measurements. Thus, a great deal of effort has been expended over many years in the search for organisms that are sensitive to environmental factors and changes in these parameters. This effort has been paralleled by similar attempts to culture and test sensitive organisms in laboratory settings. The underlying belief has been that organisms tested under controlled laboratory conditions provide a means to evaluate observed effects in natural ecosystems and to predict possible future effects from human-made and natural perturbations. The science of aquatic toxicology evolved out of these studies and has concentrated on studying the effects of toxic agents (chemicals, temperature, dissolved oxygen, pH, salinity, etc.) on aquatic life.

The historical development of aquatic toxicology up to 1970 has been summarized by Warren.⁵ Most early toxicity tests consisted of short-term exposure of chemicals or effluents to a limited number of species. Tests ranged from a few minutes to several hours and occasionally 2 to 4 days. There were no standardized procedures. Some of the earliest acute toxicity tests were performed by Penny and Adams (1863)⁶ and Weigelt, Saare, and Schwab (1885),⁷ who were concerned with toxic chemicals in industrial wastewaters. In 1924 Kathleen Carpenter published the first of her notable papers on the toxicity to fish of heavy metal ions from lead and zinc mines.⁸ This was expanded by the work of Jones (1939)⁹ and has been followed by thousands of publications over the years on the toxicity of various metals to a wide variety of organisms.

Much of the work conducted in the 1930s and 1940s was done to provide insight into the interpretation of chemical tests as a first step into the incorporation of biological effects testing into the wastewater treatment process or to expand the basic information available on species tolerances, metabolism, and energetics. In 1947 F.E.J. Fry published a classical paper entitled *Effects of the Environment on Animal Activity*.¹⁰ This study investigated the metabolic rate of fish as an integrated response of the whole organism and conceptualized how temperature and oxygen interact to control metabolic rate and hence the scope for activity and growth. Ellis (1937)¹¹ conducted some of the earliest studies with *Daphnia magna* as a species for evaluating stream pollution. Anderson (1944, 1946)^{12,13} expanded this work and laid the groundwork for standardizing procedures for toxicity testing with *Daphnia magna*. Biologists became increasingly aware during this time that chemical analyses could not measure toxicity but only predict it. Hart, Doudoroff, and Greenbank (1945)¹⁴ and Doudoroff (1951)¹⁵ advocated using toxicity tests with fish to evaluate effluent toxicity and supported the development of standardized methods. Using aquatic organisms as reagents to assay effluents led to their description as aquatic bioassays. Doudoroff's 1951 publication¹⁵ led to the first standard procedures, which were eventually included in *Standard Methods for the Examination of Water and Wastewater*.¹⁶ Efforts to standardize aquatic tests were renewed, and the Environmental

Protection Agency (EPA) sponsored a workshop that resulted in a document entitled *Standard Methods for Acute Toxicity Test for Fish and Invertebrates*.¹⁷ This important publication has been the primer for subsequent aquatic standards development and has been used worldwide.

The concept of water quality criteria (WQC) was formulated shortly after World War II. McKee (1952)¹⁸ published a report entitled *Water Quality Criteria* that provided guidance on chemical concentrations not to be exceeded for the protection of aquatic life for the State of California. A second well-known edition by McKee and Wolf (1963)¹⁹ expanded the list of chemicals and the toxicity database. WQC are defined as the scientific data used to judge what limits of variation or alteration of water will not have an adverse effect on the use of water by man or aquatic organisms.¹ An aquatic water quality criterion is usually referred to as a chemical concentration in water derived from a set of toxicity data (criteria) that should not be exceeded (often for a specified period of time) to protect aquatic life. Water quality standards are enforceable limits (concentration in water) not to be exceeded that are adopted by states and approved by the U. S. federal government. Water quality standards consist of WQC in conjunction with plans for their implementation.

In 1976 the EPA published formal guidelines for establishing WQC for aquatic life that were subsequently revised in 1985.²⁰ Prior to this time WQC were derived by assessing available acute and chronic aquatic toxicity data and selecting levels deemed to protect aquatic life based on the best available data and on good scientific judgment. These national WQC were published at various intervals in books termed the Green Book (1972),²¹ the Blue Book (1976),²² the Red Book (1977),²³ and the Gold Book (1986).²⁴ In some cases WQC were derived without chronic or partial life-cycle test data. Acute toxicity test results (LC_{50} — lethal concentration to 50% of the test organisms) were used to predict chronic no-effect levels by means of an application factor (AF). The acute value was typically divided by 10 to provide a margin of safety, and the resulting chronic estimate was used as the water quality criterion. It was not until the mid-1960s that chronic test methods were developed and the first full life-cycle chronic toxicity test (with fathead minnows) was performed.²⁵

The AF concept emerged in the 1950s as an approach for estimating chronic toxicity from acute data.²⁶ Stephan and Mount (1967)²⁷ formalized this AF approach, which was revised by Stephan (1987)²⁸ and termed the acute-to-chronic ratio (ACR). This approach provides a method for calculating a chronic-effects threshold for a given species when the LC_{50} for that species is known and the average acute-to-chronic ratio for two or more similar species is also available. Dividing the LC_{50} by the ACR provides an estimate of the chronic threshold for the additional species. The approach has generally been calculated as the $LC_{50} \div GMCV$, where GMCV = the geometric mean of the no-observed effect concentration (NOEC) and the lowest observed effect level (LOEC), termed the chronic value (CV). Before the ACR method was published, the AF concept was not used consistently. Arbitrary or “best judgment” values were often used as AFs to estimate chronic thresholds (CVs). Values in the range of 10 to 100 were most often used, but there was no consistent approach. The chronic value has also been alternatively referred to as the geometric mean maximum acceptable toxicant threshold (GM-MATC).

The passage of the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA, 1972), the Toxic Substances Control Act (TSCA, 1976), and the Comprehensive Environmental Compensation Liabilities Act (CERCLA, 1980) as well as the incorporation of toxicity testing (termed biomonitoring) as part of the National Pollution Discharge Elimination System (NPDES, 1989)²⁹ have increased the need for aquatic toxicological information. Standard methods now exist for numerous freshwater and marine species, including fishes, invertebrates, and algae, that occupy water and sediment environments.

2.3 TEST METHODS

The fundamental principle upon which all toxicity tests are based is the recognition that the response of living organisms to the presence (exposure) of toxic agents is dependent upon the dose

(exposure level) of the toxic agent. Using this principle, aquatic toxicity tests are designed to describe a concentration-response relationship, referred to as the concentration-response curve when the measured effect is plotted graphically with the concentration. Acute toxicity tests are usually designed to evaluate the concentration-response relationship for survival, whereas chronic studies evaluate sublethal effects such as growth, reproduction, behavior, tissue residues, or biochemical effects and are usually designed to provide an estimate of the concentration that produces no adverse effects.

2.3.1 Acute Toxicity Tests

Acute toxicity tests are short-term tests designed to measure the effects of toxic agents on aquatic species during a short period of their life span. Acute toxicity tests evaluate effects on survival over a 24- to 96-hour period. The American Society for Testing and Materials (ASTM), Environment Canada, and the U.S. EPA have published standard guides on how to perform acute toxicity tests for water column and sediment-dwelling species for both freshwater and marine invertebrates and fishes. A list of the standard methods and practices for water-column tests for several species is presented in Table 2.1. The species most often used in North America include the fathead minnow (*Pimephales promelas*), rainbow trout (*Oncorhynchus mykiss*), bluegill (*Lepomis macrochirus*), channel catfish (*Ictalurus punctatus*), sheepshead minnows (*Cyprinodon variegatus*), *Daphnia magna*, *Ceriodaphnia dubia*, amphipods (*Hyaella azteca*), midges (*Chironomus* sp.), duckweed (*Lemna* sp.), green algae (*Selenastrum capricornutum*), marine algae (*Skeletonema costatum*), mayflies (*Hexagenia* sp.), mysid shrimp (*Mysidopsis bahia*), penaid shrimp (*Penaeus* sp.), grass shrimp (*Palaemonetes pugio*), marine amphipods (*Rhepoinius aboroni* and *Ampleisca abdita*), marine worms (*Nereis virens*), oysters (*Crassostrea virginica*), marine mussel (*Mytilus edulis*), and marine clams (*Macoma* sp.). Use of particular species for different tests, environmental compartments, and regulations is discussed in the following sections.

Acute toxicity tests are usually performed by using five concentrations, a control, and a vehicle (i.e., solvent) control if a vehicle is needed, generally with 10 to 20 organisms per concentration. Most regulatory guidelines require duplicate exposure levels, although this is not required for pesticide registration. Overlying water quality parameters are generally required to fall within the following range: temperature, $\pm 1^\circ\text{C}$; pH, 6.5 to 8.5; dissolved oxygen, greater than 60% of saturation; hardness (moderately hard), 140 to 160 mg/L as CaCO_3 . For marine testing, salinity is controlled to appropriate specified levels. All of the above variables, as well as the test concentration, are typically measured at the beginning and end of the study and occasionally more often. This basic experimental design applies for most regulations and species.

2.3.2 Chronic Toxicity Tests

Chronic toxicity tests are designed to measure the effects of toxicants to aquatic species over a significant portion of the organism's life cycle, typically one tenth or more of the organism's lifetime. Chronic studies evaluate the sublethal effects of toxicants on reproduction, growth, and behavior due to physiological and biochemical disruptions. Effects on survival are most frequently evaluated, but they are not always the main objective of the study. Examples of chronic aquatic toxicity studies have included: brook trout (*Salvelinus fontinalis*), fathead and sheepshead minnow, daphnids, (*Daphnia magna*), (*Ceriodaphnia dubia*), oligochaete (*Lumbriculus variegatus*), midge (*Chironomus tentans*), freshwater amphipod (*Hyaella azteca*), zebrafish (*Brachydanio rerio*), and mysid shrimp (*Americamysis bahia*). Algal tests are typically 3 to 4 days in length and are often reported as acute tests. However, algal species reproduce fast enough that several generations are exposed during a typical study, and therefore these studies should be classified as chronic studies. Currently, many regulatory agencies regard an algal EC_{50} as an acute test result and the NOEC or the EC_{10} as a chronic test result.

Partial life-cycle studies are often referred to as chronic studies; however, frequently only the most sensitive life stages are utilized for exposure in these studies and they should therefore not be considered true chronic studies. Hence, they are often referred to as partial chronic or subchronic studies. Common examples of partial life-cycle studies are the fish early-life-stage studies with fathead and sheepshead minnows, zebrafish, and rainbow trout. These studies generally expose the most vulnerable developmental stage, the embryo and larval stage (30 to 60 days post-hatch), to a toxicant and evaluate the effects on survival, growth, and sometimes behavior. Recently, procedures have been developed for an abbreviated fathead minnow life-cycle test to assess the potential of substances to affect reproduction.³⁰ This test was developed in response to a need to screen for endocrine-disrupting chemicals. Likewise, a partial life-cycle test with *Xenopus laevis* that evaluates tail resorption as a screen for thyroid active substances was recently developed.³¹

2.3.3 Static Toxicity Tests

Effluent, sediment, and dredged-materials tests are often performed in static or static renewal systems. Static toxicity tests are assays in which the water or toxicant in test beakers is not renewed during the exposure period. Static toxicity tests are most frequently associated with acute testing. The most common static acute tests are those performed with daphnids, mysids, amphipods, and various fishes. Renewal tests (sometimes called static renewal tests) refer to tests where the toxicant and dilution water is replaced periodically (usually daily or every other day). Renewal tests are often used for daphnid life-cycle studies with *Ceriodaphnia dubia* and *Daphnia magna* that are conducted for 7 and 21 days, respectively. Renewal tests have also been standardized for abbreviated early-life-stage studies or partial life-cycle studies with several species (e.g., 7- to 10- day fathead minnow early-life-stage studies).

Static and renewal tests are usually not an appropriate choice if the test material is unstable, sorbs to the test vessel, is highly volatile, or exerts a large oxygen demand. When any of these situations is apparent, a flow-through system is preferable. Static-test systems are usually limited to 1.0 g of biomass per liter of test solution so as not to deplete the oxygen in the test solution. More detail on fundamental procedures for conducting aquatic toxicity bioassays can be found in Sprague, 1969, 1973 and Rand, 1995.^{32–34}

2.3.4 Flow-Through Toxicity Tests

Flow-through tests are designed to replace toxicant and the dilution water either continuously (continuous-flow tests) or at regular intermittent intervals (intermittent-flow tests). Longer-term studies are usually performed in this manner. Flow-through tests are generally thought of as being superior to static tests as they are much more efficient at maintaining a higher-level of water quality,

ensuring the health of the test organisms. Static tests designed to provide the same organism mass to total water test volume as used in a flow-through study can maintain approximately the same water quality. Flow-through tests usually eliminate concerns related to ammonia buildup and dissolved oxygen usage as well as ensure that the toxicant concentration remains constant. This approach allows for more test organisms to be used in a similar size test system (number of organisms/standing volume/unit time) than do static tests.

There are many types of intermittent-flow diluter systems that have been designed to deliver dilution water and test for chemical presence in intermittent-flow toxicity tests. The most common system is that published by Mount and Brungs.³⁵ Continuous-flow systems provide a steady supply of dilution water and toxicant to the test vessels. This is achieved with a diluter system that utilizes flow meters to accurately control the delivery of water and metering pumps or syringes to deliver the toxicant.³⁶

2.3.5 Sediment Tests

The science of sediment-toxicity testing has rapidly expanded during the past decade. Sediments in natural systems and in test systems often act as a sink for environmental contaminants, frequently reducing their bioavailability. Bioavailability refers to that fraction of a contaminant present that is available for uptake by aquatic organisms and capable of exerting a toxic effect. The extent to which the bioavailability is reduced by sediments is dependent upon the physical-chemical properties of the test chemical and the properties of the sediment. Past studies have demonstrated that chemical concentrations that produce biological effects in one sediment type often do not produce effects in other sediments even when the concentration is a factor of 10 or higher. The difference is due to the bioavailability of the sediment-sorbed chemical.

The ability to estimate bioavailability is a key factor in ultimately assessing the hazard of chemicals associated with sediments. Much progress has been made in this area recently. It is now widely recognized that the organic carbon content of the sediment is the component most responsible for controlling the bioavailability of nonionic (nonpolar) organic chemicals.^{37, 38} This concept has been incorporated into an approach termed the "Equilibrium Partitioning Approach" and is being used by the EPA for establishing sediment quality criteria.³⁹ For some metals (cadmium, copper, nickel, and lead, silver, and zinc) the acid volatile sulfide (AVS) content of the sediments has recently been shown to control metal bioavailability in sediments with sufficient sulfide. AVS is a measure of the easily extractable fraction of the total sulfide content associated with sediment mineral surfaces. Metal-sulfide complexes are highly insoluble, which limits the bioavailability of certain metals. When the AVS content of the sediment is exceeded by the metal concentration (on a molar ratio of 1:1), free metal ion toxicity may be expressed.⁴⁰ Recent research shows that toxicity is frequently not expressed when SEM exceeds AVS due to the fact that metal ions are sorbed to sediment organic carbon or other reactive surfaces such as iron and manganese oxides.⁴¹ Approaches for additional classes of compounds such as polar ionic chemicals have been proposed.⁴² Recently, an approach was developed for assessing the combined effects of multiple PAHs sorbed to sediments based on equilibrium partitioning, narcosis toxicity theory, and the concept that chemicals within a given class of compounds with the same mode of action act in a predictive and additive manner.^{43, 44}

The recognition that sediments are both a sink and a source for chemicals in natural environments has led to increased interest in sediments and to the development of standard testing methods for sediment-dwelling organisms. Until recently, most sediment tests were acute studies. Greater emphasis is now placed on chronic sediment-toxicity tests with sensitive organisms and sensitive life stages. For example, partial life-cycle test procedures are available for several species of amphipods and the sea urchin. Full life-cycle tests can be performed with the marine worm *Nereis virens*, freshwater midges (*C. tentans* and *Paratanytarsus disimilis*), and freshwater amphipods (*H. azteca*) (Table 2.2). Partial and full life-cycle tests can be performed with epibenthic species such

as *D. magna* and *C. dubia*. These species can be tested with sediments present in the test vessels. Porewater (interstitial water) exposures offer a potentially sensitive approach to the toxicity of the freely dissolved fractions of contaminants. The interstitial water is extracted from the sediment, usually by centrifugation, and subsequently used in toxicity tests with a wide variety of test organisms and life stages. The use of porewater allows for the testing of fish early-life stages as well as invertebrates. An extensive review of porewater testing methods and utility of the data was recently summarized at a SETAC Pellston Workshop.⁴⁵ Available sediment-assessment methods have been reviewed by Adams et al.⁴⁶ Guidance for conducting sediment bioassays for evaluating the potential to dispose of dredge sediment via open ocean disposal has been summarized in the EPA-Corps of Engineers (COE) Green Book.⁴⁷

Typical sediment bioassays are used to evaluate the potential toxicity or bioaccumulation of chemicals in whole sediments. Sediments may be collected from the field or spiked with compounds in the laboratory. Spiked and unspiked sediment tests are performed in either static or flow-through systems, depending on the organism and the test design. Flow-through procedures are most often preferred. Between 2 and 16 replicates are used, and the number of organisms varies from 10 to 30 per test vessel. Sediment depth in the test vessels often ranges from 2 to 6 cm and occasionally as deep as 10 cm. Test vessels often range from 100 to 4000 mL in volume. Sediment tests for field projects are not based on a set number of test concentrations but rely on a comparison of control and reference samples with sediments from sites of interest. Care must be exercised in selecting sites for testing, collecting, handling, and storing the sediments.^{48,49} Likewise, special procedures have been devised for spiking sediments with test substances. A reference sediment from an area known to be contaminant-free and that provides for good survival and growth of the test organisms is often included as an additional control in the test design. Guidance for selecting reference samples and sites can be found in the EPA-COE Green Book.⁴⁷

2.3.6 Bioconcentration Studies

Bioconcentration is defined as the net accumulation of a material from water into and onto an aquatic organism resulting from simultaneous uptake and depuration. Bioconcentration studies are performed to evaluate the potential for a chemical to accumulate in aquatic organisms, which may subsequently be consumed by higher trophic-level organisms including man (ASTM E 1022–94, Table 2.1). The extent to which a chemical is concentrated in tissue above the level in water is referred to as the bioconcentration factor (BCF). It is widely recognized that the octanol/water partition coefficient — referred to as K_{ow} , $\text{Log } K_{ow}$ or $\text{Log } P$ — can be used to estimate the potential for nonionizable organic chemicals to bioconcentrate in aquatic organisms. Octanol is used as a surrogate for tissue lipid in the estimation procedure. Equations used to predict BCFs have been summarized by Boethling and Mackay.⁵⁰ While the use of K_{ow} is useful for estimating the bioconcentration potential of nonpolar organics, it is not useful for metals or ionizable or polar substances. Additionally, it should be recognized that the use of BCFs have limited utility for metals and other inorganic substances that may be regulated to some extent and that typically have BCFs that are inversely related to exposure concentration. For these substances the BCF value is not an intrinsic property of the substance.^{51,52}

Methods for conducting bioconcentration studies have been described and summarized for fishes and saltwater bivalves by ASTM (Table 2.1) and TSCA (Table 2.3). To date, the scientific community has focused its efforts on developing methods for fishes and bivalves because these species are higher trophic-level organisms and are most often consumed by man. In general, the approach for determining the BCF for a given chemical and species is to expose several organisms to an environmentally relevant chemical of interest that is no more than one tenth of the LC_{50} (lethal concentration) for the species being tested. At this exposure level mortality due to the test chemical can usually be avoided. The test population is sampled repeatedly, and tissue residues (usually in the fillet, viscera, and whole fish) are measured. This is most often done with C^{14} chemicals to facilitate tissue residue measurements. The study continues until apparent steady state is reached (a plot of tissue chemical concentrations becomes asymptotic with time) or for 28 days. At this point the remaining fish are placed in clean water, and the elimination (depuration) of the chemical from the test species is measured by analyzing tissues at several time intervals.

Apparent steady state can be defined as that point in the experiment where tissue residue levels are no longer increasing. Three successive measurements over 2 to 4 days showing similar tissue concentrations are usually indicative of steady state. When steady state has been achieved, the uptake and depuration rates are approximately equal. It has been shown that 28 days is adequate for most chemicals to reach steady state. However, this is not true for chemicals with a large K_{ow} (e.g., DDT, PCBs). An estimate of the time required to reach apparent steady state can be made for a given species based on previous experiments with a similar chemical or using K_{ow} for nonionizable chemicals that follow a two-compartment, two-parameter model for uptake and depuration. The following equation is used: $S = \{\ln[1/(1.00 - 0.95)]\}/k_2 = 3.0/k_2$, where: S = number of days, \ln = logarithm to the base e , k_2 = the first-order depuration constant (day^{-1}) and where k_2 for fishes is estimated as $\text{antilog}(1.47 - 0.414 \log K_{ow})$.⁵³ The use of K_{ow} for estimating the BCF or time to equilibrium is not useful for polar substances or inorganic substances such as metals.

Two additional terms of interest are bioaccumulation and biomagnification. The first refers to chemical uptake and accumulation in tissues by an organism from any external phase (water, food, or sediment). Biomagnification is the process whereby a chemical is passed from a lower to successively higher trophic levels, resulting in successively higher residue at each trophic level. Biomagnification is said to occur when the trophic transfer factor exceeds 1.0 for two successive trophic levels (e.g., algae to invertebrates to fish). Biomagnification is generally thought to occur only with chemicals with a large K_{ow} (>4.0) and does not occur for inorganic substances.⁵⁴ Specific tests and standard guidelines have been developed for measuring bioaccumulation of sediment associated contaminants in the freshwater oligochaete *L. variegatus* (EPA and ASTM).^{55, 56}

2.4 TOXICOLOGICAL ENDPOINTS

Toxicological endpoints are values derived from toxicity tests that are the results of specific measurements made during or at the conclusion of the test. Two broad categories of endpoints widely used are assessment and measures of effect. Assessment endpoints refer to the population, community, or ecosystem parameters that are to be protected (e.g., population growth rate, sustainable yield). Measures of effect refer to the variables measured, often at the individual level, that are used to evaluate the assessment endpoints. The measures of effect describe the variables of interest for a given test. The most common measures of effect include descriptions of the effects of toxic agents on survival, growth, and reproduction of a single species. Other measures of effect include descriptions of community effects (respiration, photosynthesis, diversity) or cellular effects such as physiological/histopathological effects (backbone collagen levels, ATP/ADP levels, RNA/DNA ratios, biomarkers, etc.). In each case the endpoint is a variable that can be quantitatively measured and used to evaluate the effects of a toxic agent on a given individual, population, or community. The underlying assumption in making toxicological endpoint measurements is that the endpoints can be used to evaluate or predict the effects of toxic agents in natural environments. EPA risk-assessment guidelines provide information on how endpoints can be used in the environmental risk-assessment process.⁵⁶

2.4.1 Acute Toxicity Tests

Endpoints most often measured in acute toxicity tests include a determination of the LC or EC₅₀ (median effective concentration), an estimate of the acute no-observed effect concentration (NOEC), and behavioral observations. The primary endpoint is the LC or EC₅₀. The LC₅₀ is a lethal concentration that is estimated to kill 50% of a test population. An EC₅₀ measures immobilization

or an endpoint other than death. The LC and EC₅₀ values are measures of central tendency and can be determined by a number of statistical approaches.⁵⁷ The Litchfield-Wilcoxon approach is most often used⁵⁸ and consists of plotting the survival and test chemical concentration data on log-probability paper, drawing a straight line through the data, checking the goodness of fit of the line with a chi-squared test, and reading the LC or EC₅₀ directly off the graph. Various computer packages are also available to perform this calculation. Other common methods include the moving-average and binomial methods. The latter is most often used with data sets where the dose-response curve is steep and no mortality was observed between the concentrations where zero and 100% mortality was observed.

The NOEC (no-observed effect concentration — acute and chronic tests) is the highest concentration in which there is no significant difference from the control treatment. The LOEC (lowest observed effect concentration — acute and chronic tests) is the lowest concentration in which there is a significant difference from the control treatment. The NOEC and LOEC are determined by examining the data and comparing treatments against the control in order to detect significant differences via hypothesis testing. The effects can be mortality, immobilization, reduced cell count (algae), or behavioral observations. These endpoints are typically determined using t-tests and analysis of variance (ANOVA) and are most often associated with chronic tests. NOECs/LOECs are concentration-dependent and do not have associated confidence intervals. Sebaugh et al. demonstrated that the LC₁₀ could be used as a substitute for the observed no-effect concentration for acute tests.⁵⁹ This provides a statistically valid approach for calculating the endpoint and makes it possible to estimate when the lowest concentration results in greater than 10% effects. It should be noted, however, that the confidence in the estimated LC decreases as one moves away from 50%. Regression analysis, as opposed to hypothesis testing, is gaining favor as a technique for evaluating both acute and chronic data. The advantage is that it allows for the calculation of a percentage of the population of test organisms affected, as opposed to ANOVA, which simply determines whether or not a given response varies significantly from the control organisms. EC and LC values are readily incorporated into risk-assessment models and are particularly useful in probabilistic risk assessments.^{60,61}

2.4.2 Partial Life-Cycle and Chronic Toxicity Tests

In partial life-cycle studies the endpoints most often measured include egg hatchability (%), growth (both length and weight), and survival (%). Hatchability is observed visually; growth is determined by weighing and measuring the organisms physically at the termination of the study. Computer systems are available that allow the organisms to be weighed and measured electronically and the data to be automatically placed in a computer spreadsheet for analysis. In chronic studies, reproduction is also evaluated. Endpoints include all the parameters of interest, i.e., egg hatchability, length, weight, behavior, total number of young produced, number of young produced per adult, number of spawns or broods released per treatment group or spawning pair, physiological effects, and survival. In partial and full life-cycle studies, the endpoints of interest are expressed as NOEC/LOEC or LC_x values. The geometric mean of these two values has traditionally been referred to as the maximum acceptable toxicant concentration (MATC). More recently, the term MATC has been referred to as the chronic value (CV), which is defined as the concentration (threshold) at which chronic effects are first observed. Other endpoints (LC or EC₅₀) may be estimated in chronic and subchronic studies, but they are of lesser interest. It is the CV that is compared to the LC or EC₅₀ to determine the acute-to-chronic ratio for a given species and toxicant.

The approach for assessing the aforementioned endpoints is based upon selecting the appropriate statistical model for comparing each concentration level to the control. Dichotomous data (hatchability or survival expressed as number dead and alive) require the Fisher's exact or chi-square test.⁶² For continuous data (growth variables, e.g., length and weight; reproductive variables, e.g.,

number of spawns; hatchability or survival data expressed as percentages) the Dunnett's means-comparison procedure would be used based on an analysis of variance (ANOVA).⁶² The type of ANOVA, such as one-way or nested, and the error term used, such as between chambers or between aquaria, should correspond to the experimental design and an evaluation of the appropriate experimental unit. Typically, a one-tailed test is used because primary interest is in the detrimental negative effects of the compound being tested and not on both a negative and a positive effect (two tails). Although parametric ANOVA procedures are robust, a nonparametric Dunnett's test should be performed if there are large departures from normality within treatment groups or large departures from homogeneous variance across treatment groups.

For studies that provide continuous data that are analyzed by calculating a percent change from the control, the most appropriate approach is to plot the percent change against the logarithm of the test concentration. The resulting regression line can be used to calculate a percent reduction of choice along with its corresponding confidence interval. It is common to calculate a 25% reduction and express the value either as an IC_p (inhibition concentration for a percent effect) or as an EC. Probit analysis of these data is not appropriate. Expressing the data as an IC_p, as opposed to an EC, is probably a better approach because it does not have as its basis the concept of a median effect concentration, which is dependent on dichotomous data as opposed to continuous data.

2.5 REGULATORY ASPECTS OF AQUATIC TOXICOLOGY IN THE UNITED STATES

2.5.1 Clean Water Act (CWA)

The CWA was passed in 1972 and has been amended several times since then. A primary goal of this regulation was to ensure that toxic chemicals were not allowed in U.S. surface waters in toxic amounts. The passage of this act had a major impact on environmental engineering and aquatic toxicology, which led to formalized guidelines for deriving water quality criteria.²⁰ These criteria were used to develop federal water quality standards that all states adopted and enforced. To date, 24 WQC have been developed in the United States.⁶³ The aquatic tests required to derive WQC are listed in Table 2.4. Additionally, 129 priority pollutants have been identified, and discharge enforceable limits that cannot be exceeded have been set.

Under the authority of the Clean Water Act, the EPA, Office of Water, Enforcement Branch, established a system of permits for industrial and municipal dischargers (effluents) into surface waters. This permit system is termed the National Pollutant Discharge Elimination System (NPDES). Chemical producers are classified according to the type of chemicals they produce (organic chemicals, plastics, textiles, pesticides, etc.). Each chemical industry category has a list of chemicals and corresponding concentrations that are not to be exceeded in the industry's wastewater effluent. These chemical lists apply to all producers for a given category and are part of each producer's NPDES permit. Each producer also has other water-quality-parameter requirements built into their permit that are specific to their operations. These usually include limitations on the amount (pounds) of chemical that is permitted to be discharged per month and may include items such as total organic carbon, biochemical oxygen demand, suspended solids, ammonia, and process-specific chemicals.

The NPDES permit system incorporates biomonitoring of effluents, usually on a monthly, quarterly, or yearly basis.²⁹ A toxicity limit is built into the discharger's permit for both industrial and municipal dischargers that must be achieved. If the toxicity limit is exceeded, the permittee is required to identify the chemical responsible for the excess toxicity and take steps to eliminate the chemical, reduce the toxicity, or both. Effluent biomonitoring most often consists of acute toxicity tests with *daphnia* (*Ceriodaphnia dubia*) and fathead minnow (*Pimephales promelas*). Seven-day life-cycle and partial life-cycle studies are required in some cases. An extensive set of procedures (toxicity identification evaluation, TIE) for identifying the substance or substances responsible for

Table 2.4 Aquatic Toxicity Tests Required by U.S. EPA for the Development of Water Quality Criteria

Type of Testing	Recommended Aquatic Tests
Acute Toxicity Tests	<p>Eight different families must be tested for both freshwater and marine species (16 acute tests):</p> <p><i>Freshwater</i></p> <ol style="list-style-type: none"> 1. A species in the family Salmonidae 2. A species in another family of the class Osteichthyes 3. A species in another family of the phylum Chordata 4. A plankton species in class Crustacea 5. A benthic species in class Crustacea 6. A species in class Insecta 7. A species in a phylum other than Chordata or Arthropoda 8. A species in another order of Insecta or in another phylum <p><i>Marine</i></p> <ol style="list-style-type: none"> 1. Two families in the phylum Chordata 2. A family in a phylum other than Arthropoda or Chordata 3. Chordata 4. Either Family Mysidae or Penaeidae 5. Three other families not in the phylum Chordata (may include Mysidae or Penaeidae, whichever was not used above) 6. Any other family
Chronic Toxicity Tests	<p>Three chronic or partial life-cycle studies are required:</p> <p>One invertebrate and one fish</p> <p>One freshwater and one marine species</p>
Plant Testing	<p>At least one algal or vascular plant test must be performed with a freshwater and marine species.</p>
Bioconcentration Testing	<p>At least one bioconcentration study with an appropriate freshwater and saltwater species is required.</p>

toxicity in effluents and sediments has been developed over the past decade.⁶⁴⁻⁷⁵ Present tie research efforts are focused primarily on freshwater and marine sediments.

2.5.2 Toxic Substances Control Act (TSCA)

The Toxic Substances Control Act (TSCA) was established by Congress on October 8, 1976 as public law 94-469 to regulate toxic industrial chemicals and mixtures. The goal of Congress was to establish specific requirements and authorities to identify and control chemical hazards to both human health and the environment. The office of Pollution Prevention and Toxics (OPPT) is the lead office responsible for implementing the Toxic Substances Control Act, which was established to reduce the risk of new and existing chemicals in the marketplace.

There are approximately 80,000+ compounds listed on the TSCA Chemical Inventory that are approved for use in the United States.⁷⁶ The detection of polychlorinated biphenyls (PCBs), an industrial heat transformer and dielectric fluid found in aquatic and terrestrial ecosystems in many parts of the United States, emphasized the need for controlling industrial chemicals not regulated by pesticide or food and drug regulations. From the viewpoint of aquatic testing, this regulation has focused on two areas: test requirements for new chemicals and existing chemicals. Under TSCA Section 5, notice must be given to the Office of Pollution Prevention and Toxics (OPPT) prior to manufacture or importation of any new or existing chemical. No toxicity information is required for the Premanufacture Notification (PMN). OPPT has 90 days to conduct a hazard/risk assessment and may require generation of toxicity information. Toxicity testing is required only if a potential hazard or risk is demonstrated.⁷⁶

Existing chemicals listed on the TSCA inventory register prior to 1976 are not required to undergo a PMN review. However, the EPA, through the Interagency Testing Committee (ITC), reviews individual chemicals and classes of chemicals to determine the need for environmental and human health data to assess the safety of the chemicals. If the ITC determines that a potential exists for significant chemical exposure to humans or the environment, they can require the manufacturers

to provide additional data for the chemicals to help assess the risk associated with the manufacture and use of the product. TSCA empowers the EPA to restrict chemical production and usage when the risk is considered severe enough. Data collection is accomplished through Section 4 of TSCA by means of developing a legally binding consent order on a Test Rule. The Test Rule spells out the reasons for the testing and identifies which tests are required. Aquatic tests that are most often required for PMNs or by Test Rules are listed in Table 2.3.

The Chemical Right-to-Know Initiative was begun in 1998 in response to the finding that very little toxicity information is publicly available for most of the high production volume (HPV) commercial chemicals made and used (more than 1 million lbs/yr) in the United States. Without this basic hazard information, it is difficult to make sound judgments about what potential risks these chemicals could present to people and the environment. An ambitious testing program has been established, especially for those chemicals that are persistent, bioaccumulative, and toxic (PBT), or which are of particular concern to children's health.⁷⁷

2.5.3 Federal Insecticide, Fungicide and Rodenticide Act (FIFRA)

Under FIFRA the EPA is responsible for protecting the environment from unreasonable adverse effects of pesticides.⁷⁸ This legislation is unique among environmental protection statutes in that it licenses chemicals known to be toxic for intentional release into the environment for the benefit of mankind. Most regulatory statutes are designed to limit or prevent the release of chemicals into the environment. The FIFRA licensing process regulates three distinct areas: (1) labeling, (2) classification, and (3) registration. To fulfill its responsibility the EPA requires disclosure of scientific data regarding the effects of pesticides on humans, wildlife, and aquatic species.

By statutory authority the EPA assumes that pesticides present a risk to humans or to the environment. The pesticide registrant is responsible for rebutting the EPA's presumption of risk. To accomplish this the EPA recommends a four-tiered testing series.⁷⁹ The tests become progressively more complex, lengthy, and costly, going from Tier I to Tier IV.⁸⁰ Studies in Tiers I and II evaluate a substance for acute toxicity and significant chronic effects, respectively. Higher-tier tests evaluate long-term chronic and subchronic effects. In Tier IV, field and mesocosm studies can be required. The need to perform successively higher-tiered tests is triggered by the degree of risk the pesticide presents to the environment. Risk is determined by the quotient method, i.e., by comparing the expected environmental concentration with the measured levels of biological effect. The difference between the two levels is referred to as the margin of safety. When the margin of safety is small in Tiers I and II, additional higher-tier studies are required to rebut the presumption of risk to the environment.

2.5.4 Federal Food, Drug, and Cosmetics Act (FFDCA)

The FFDCA of 1980 is administrated by the Food and Drug Administration (FDA). This act empowers the FDA to regulate food additives, pharmaceuticals, and cosmetics that are shipped between states. The intent of this act is to protect the human food supply and to ensure that all drugs are properly tested and safe for use. The FDA enforces pesticide tolerance and action levels set by the EPA. This can result in a ban or food consumption advisory for fish and seafood from certain areas. The FDA also regulates drugs that are used for animals, including fish, as well as human drugs. The use of drugs to treat fish diseases has drawn national and international attention since the FDA has begun to restrict the use of certain drugs that have not been properly tested for potential environmental effects. These drugs are used in significant quantities in commercial fishery operations.

The U.S. FDA is responsible for reviewing the potential environmental impact from the intended use of human and veterinary pharmaceuticals, food or color additives, Class III medical devices, and biological products. To evaluate the potential effects of a proposed compound the FDA requires

the submission of an Environmental Assessment (EA). The National Environmental Protection Act, passed by Congress in 1969, provides the statutory authority for the FDA to conduct EA requirements.

EAs are required for all New Drug Applications as well as for some supplementary submissions and communications. Previously, an EA required little more than a statement that a compound had no potential environmental impact; however, changes within the FDA have increased and intensified the EA review and approval process. Under current policy the FDA requests quantitative documentation of a compound's potential environmental impact. The EA must contain statistically sound conclusions based on scientific data obtained through studies conducted under Good Laboratory Practices (GLPs). These changes have significantly impacted the content, manner of data acquisition, and preparation of an EA. Details relative to the FDA statutory authority and information required for an EA submission are contained in the Code of Federal Regulations.⁸¹ The specific aquatic toxicity tests recommended by the FDA for inclusion with the EA submission are shown in Table 2.3.

2.5.5 Comprehensive Environmental Response, Compensation, Liability Act

Superfund is the name synonymous with the Comprehensive Environmental Response, Compensation, Liability Act (CERCLA, 1980). This act requires the EPA to clean up uncontrolled hazardous waste sites to protect both human health and the environment. CERCLA provides the statutory authority for the EPA to require environmental risk assessment as part of the Superfund site assessment process. Part of risk assessment includes evaluating the potential for risk to aquatic species, if appropriate, for a given site. Additional authority comes from the National Oil and Hazardous Materials Contingency Plan, which specifies that environmental evaluations shall be performed to assess threats to the environment, especially sensitive habitats and critical habitats of species protected under the Endangered Species Act.

The Superfund program provides (1) the EPA with the authority to force polluters to take responsibility for cleaning up their own wastes; (2) the EPA with the authority to take action to protect human health and the environment, including cleaning up waste sites, if responsible parties do not take timely and adequate action; and (3) a Hazardous Substance Response Trust Fund to cover the cost of EPA enforcement and cleanup activities. The Superfund process consists of: site discovery, preliminary assessment (PA)/site assessment (SA), hazard ranking/nomination to National Priorities List (NPL), remedial investigation (RI)/feasibility study (FS), selection of remedy, remedial design, remedial action, operation and maintenance, and NPL deletion.⁸²

Environmental risk assessment is conducted as part of the PA/SA investigation and as part of the RI/FS studies. Sites that have the potential for contaminants to migrate to surface waters and sediments require aquatic assessment. Risk assessment procedures have been evolving, and guidance in the selection of tests and species is available.⁸³⁻⁸⁵ Many of the tests for TSCA and FIFRA assessments are acceptable (Table 2.3). Most often, aquatic tests are performed on soils/sediments, which are shipped to an aquatic testing facility for studies with amphipods, midges, and earthworms. Most studies are static acute or static renewal partial life-cycle studies.

2.5.6 Marine Protection, Research and Sanctuaries Act (MPRSA)

The MPRSA of 1972 requires that dredged material be evaluated for its suitability for ocean disposal according to criteria published by the EPA (40 CFR 220-228) before disposal is approved. The maintenance of navigation channels requires dredging, and the disposal of that dredged material is a concern. For ocean disposal the dredged material must be evaluated to determine its potential for impact to the water column at the disposal site. In 1977 the EPA and COE developed the manual, "Ecological Evaluation of Proposed Discharge of Dredged Material into Ocean Waters," which contains technical guidance on chemical, physical, and biological procedures to evaluate the acceptability of dredged material for ocean disposal.⁸⁶ A similar manual was developed

in 1998 for freshwater systems entitled “Evaluation of Dredged Material Proposed for Discharge in Waters of the U.S.”⁸⁷

The manual outlines a tiered testing procedure for evaluating compliance with the limiting permissible concentration (LPC) as defined by ocean dumping regulations. The liquid-phase or water-column LPC must not exceed applicable marine water quality criteria or a toxicity threshold (0.01 times the acutely toxic concentration). The suspended and solid-phase LPCs must not cause unreasonable toxicity or bioaccumulation. The document describes four levels (tiers) of evaluation. Tiers I and II utilize existing information, which is often available for recurring disposals of dredged materials from channel maintenance, to determine the appropriateness for ocean disposal. Tier III contains most laboratory bioassays, and Tier IV includes some tests of bioaccumulation and a range of possible field investigations. The evaluation also recommends using a reference site, specifically a site that is free of contamination, as a source of sediments for comparison testing with the dredged materials. Examples of aquatic marine species that are acceptable to evaluate the suitability of dredge materials for ocean disposal via water-column, solid-phase, and bioaccumulation tests are presented in Table 2.5 (taken from the Green Book).⁴⁷

2.5.7 European Community (EC) Aquatic Test Requirements

The European Community (EC) also requires toxicity testing as part of their chemical environmental assessment process. The EC is managed by four institutions — the Commission, the Council of Ministers, the Parliament, and the Court of Justice. The Commission proposes regulations to the Council of Ministers, who make final rulings. Actions taken by the Council have the force of law and are referred to as regulations, directives, decisions, recommendations, and opinions. Most actions taken relative to chemical environmental assessment have taken the form of directives. Directives are binding on member countries; however, member countries may choose the method of implementation.

Critical directives that mandate aquatic toxicity tests are the Pesticide Registration Directive⁸⁸ and the Sixth and Draft Seventh Amendments of Directive 67/548/CEE, Classification, Packaging, and Labeling of Dangerous Substances. Additionally, the Paris Commission was established to prepare guidelines to ensure that offshore (North Sea) oil exploration would not endanger the marine environment. The directives of the Paris Commission as well as the previously mentioned directives require aquatic toxicity tests as part of environmental assessments.

2.5.8 Organization for Economic Cooperation and Development (OECD)

The published list of aquatic test methods and species required to be used when fulfilling the data requirements of EC directives is shown in Table 2.3. Test guidelines are listed as EEC (European Economic Community) or OECD (Organization of Economic Cooperation and Development). The OECD operates as a methods-generating and standardization body, whereas the EEC formally adopts test guidelines that become the legally binding method to be used. Relevant internationally agreed-upon OECD test methods used by government, industry, and independent laboratories have been published and are available as a compendium of guidelines^{89, 90} (Table 2.6).

2.6 SUMMARY AND FUTURE DIRECTION OF AQUATIC TOXICOLOGY

The field of aquatic toxicology has grown out of the disciplines of water pollution biology and limnology. Aquatic toxicology studies have been performed for the past 120 years. Studies evolved from simple tests conducted over intervals as short as a few hours to standard acute lethality tests lasting 48 or 96 hours, depending on the species. Acute toxicity tests were followed by the

* Recommended species.

development of various short sublethal tests (e.g., behavior or biochemical studies) and tests with prolonged exposures such as partial life-cycle studies and full life-cycle studies. Early studies were performed in the absence of regulatory requirements by individuals with a high degree of scientific curiosity. Today, aquatic toxicology studies are done for research purposes or environmental risk assessments and are required by many regulatory agencies for product registration, labeling, shipping, or waste disposal.

The cost and length of time required to perform full life-cycle tests have encouraged scientists to search for sensitive test species and sensitive life stages. Full life-cycle fish studies have, for the most part, been replaced by embryo-larval studies (partial life-cycle studies).⁹¹ A major effort has been expended to identify species that allow full life-cycle studies to be performed in much shorter periods (e.g., 7-day *Ceriodaphnia dubia* life cycle tests,⁹² two-dimensional rotifer tests⁹³) or tests that use sensitive species and sensitive life stages. For example, a 7-day fathead minnow embryo-larval growth and survival study is used to evaluate effluents.⁹⁴ The goal of these tests is to quickly provide accurate estimates of chronic no-effect levels. It is important to remember that these tests estimate chronic results, not duplicate them. The estimated value is often within a factor of 2 to 4 of the chronic value and, depending on the use of these data, may provide adequate accuracy.

During the last decade significant effort has been expended in developing rapid toxicity assays. There has been an increasing need to assess the toxicity of various sample types in minutes to hours instead of days. For example, effluent toxicity identification evaluation (TIE) procedures require multiple toxicity tests on successive days. The use of assays (such as the Microtox⁹⁵ assay) can speed up the TIE process considerably. The use of rapid assays during on-site effluent biomonitoring allows for collection of a more extensive data set during the limited testing time available.

Table 2.6 Adopted and Draft OECD Test Guidelines Harmonized with OPPTS since 1990

Test Guideline No.	Guideline Title	Date of Adoption as an Original or as an Updated Version and Draft Date

202	<i>Daphnia</i> sp., Acute Immobilization Test	Draft
305	Bioconcentration; Flow-Through Fish Test	June 14, 1996

In recent years the increasing desire to link exposure to effect has drawn considerable attention to the “biomarker approach.” Because chemical contaminants are known to evoke distinct measurable biological responses in exposed organisms, biomarker-based techniques are currently being investigated to assess toxicant-induced changes at the biological and ecological levels.⁹⁶ Collectively, the term biomarker refers to the use of physiological, biochemical, and histological changes as “indicators” of exposure and effects of xenobiotics at the suborganism or organism level.⁹⁷ However, indicators or biomarkers can be defined at any level of biological organization, including changes manifested as enzyme content or activity, DNA adducts, chromosomal aberrations, histopathological alterations, immune-system effects, reproductive effects, physiological effects, and fertility at the molecular and individual level, as well as size distributions, diversity indices, and functional parameters at the population and ecosystem level. In the field of ecotoxicology, the use of biomarkers has emerged as a new and very powerful tool for detecting both exposure and effects resulting from environmental contaminants.^{97–104} Unlike most chemical monitoring, biomarker endpoints have the potential to reflect and assess the bioavailability of complex mixtures present in the environment as well as render biological significance. Biomarkers provide rapid toxicity assessment and early indication of population and community stress and offer the potential to be used as markers of specific chemicals.

Chemical effects are thought to be the result of the interaction between toxicant and biochemical receptor. Therefore, biochemical responses are expected to occur before effects are observed at higher levels of biological organization. Biomarker response frequently provides a high degree of sensitivity to environmental impacts, thereby providing an “early warning” to potential problems or irreversible effects. In natural environments, where organisms are exposed to multiple stresses (natural and anthropogenic) over time, biomarkers reflect this integrated exposure of cumulative, synergistic, or antagonistic effects of complex mixtures. A myriad of recent studies have demonstrated the utility of biomarker techniques in the assessment of contaminants ranging from single compounds to complex mixtures in both the laboratory and the field.^{105–109}

To date, biomarker assays have not been standardized or incorporated into regulatory guidelines as part of chemical environmental risk assessments. It is expected that in the future a variety of specific biomarkers will be sufficiently validated as predictors of whole organism and population effects; however, it is unlikely that they will therefore tell us if an ecosystem is in danger of losing its integrity or if compensation to a particular insult is possible. A more reasonable application would be use as either part of a tiered assessment or as measurement by some standard of predefined ecological health. The trend toward more sensitive, biologically relevant test methods predictive of early ecosystem stress will continue, and biomarkers are expected to play a role as surrogate measures or predictors of ecosystem well-being.

3.1 INTRODUCTION

A number of research studies have made use of model aquatic ecosystems of varying design and complexity for evaluating the fate and effects of contaminants in aquatic ecosystems. These systems are designed to simulate ecosystems or portions of ecosystems. As research tools, model ecosystems contribute to our understanding of the ways in which contaminants affect natural ecosystems.¹ These systems are a tool for allowing ecologists to address hypotheses on a manageable scale and with control or reference systems. They also provide ecotoxicologists with models of ecosystem functioning, in the absence of perturbation, so that direct and indirect effects might be better separated from natural events such as succession or inherent variation.²

Traditionally, model ecosystems have been categorized as either microcosms or mesocosms. The distinction between microcosms and mesocosms has been somewhat subjective, with researchers establishing their own criteria, but has mainly been a function of size.³ The degrees of organizational complexity and realism will often vary when these systems are established, depending largely on study goals and endpoints selected by the researchers.

Giesy and Odum⁴ define microcosms as artificially bounded subsets of naturally occurring environments that are replicable, contain several trophic levels, and exhibit system-level properties. Mesocosms are defined as either physical enclosures of a portion of a natural ecosystem or manmade structures such as ponds or stream channels.⁵ Voshell⁵ further specifies that the size and complexity of mesocosms are sufficient for them to be self-sustaining, making them suitable for long-term studies. In this regard they differ from microcosms, where smaller size and fewer trophic levels do not allow for long study durations, particularly in laboratory systems. Cairns,⁶ however, does not distinguish between microcosms and mesocosms because “both encompass higher levels of biological organization and have high degrees of environmental realism.” The lack of a defined distinction between microcosm and mesocosm systems has caused some confusion among researchers around the world. The organizing committee of the European Workshop on Freshwater Field Tests (EWOFFT) operationally described microcosms on the basis of size, defining outdoor lentic microcosms as those surrogate ecosystems whose volume contain less than 15 m³ of water and mesocosms as ponds of 15 m³ or larger. Experimental stream channels were also characterized on the basis of size, defining microcosms as smaller and mesocosms as larger than 15 m in length. Such designations are useful categories for standardizing terminology. These distinctions are often used when comparing studies conducted throughout the world, and this paper will define model systems based on the EWOFFT definitions, when needed.

The use of “model” systems in aquatic research has grown considerably since the use of replicated ponds in community structure analysis by Hall, Cooper, and Werner⁷ in the late 1960s and the pesticide studies of Hurlbert et al.⁸ Studies prior to or concurrent with these, such as Eisenberg’s⁹ studies of density regulation in pond snails, used experimentally manipulated natural systems. Aspects such as community composition and spatial heterogeneity can be controlled to a greater extent in model (constructed) systems relative to natural ones. Model ecosystems are logistically more manageable and replicable for statistical analyses. In addition, model systems are effective tools in aquatic research because they act as surrogates for important cause-and-effect pathways in natural systems^{6,10} yet retain a high degree of environmental realism relative to laboratory single-species bioassays.⁶ These tests should be viewed as part of a tiered testing sequence and not as replacements of single-species bioassays.¹¹ Single-species tests, however, are inadequate when chemical fate is altered significantly under field conditions, when organismal behavior can affect exposure to a toxicant, or when secondary effects occur due to alterations in competitive or predator-prey relationships.¹²

Model ecosystems in ecotoxicological research are used to study the fate and potential adverse effects of chemicals. The ability to detect and accurately measure these effects can be influenced by both system and experimental design that influence variability. This paper addresses key factors that can influence the ability of model systems to accomplish these tasks.

3.2 HISTORICAL PERSPECTIVE

The concept of the microcosm was introduced early in ecological thinking through the writings of Forbes.¹³ In his work on lake natural history the basic principles of ecological synergism, variability, and dynamic equilibrium as well as the complex interactions of predator and prey were discussed. Though speaking of the lake itself and not of the surrogate systems routinely employed in aquatic research today, Forbes¹³ touched upon the rationale for the use of artificial systems in both toxicological and ecological research: "It forms a little world within itself — a microcosm within which all the elemental forces are at work and the play of life goes on in full, but on so small a scale as to bring it easily within the mental grasp."

This assertion — that artificial systems simulate processes that occur in nature enough to be viable surrogates for natural systems — is central to the underlying basis for using microcosms (and mesocosms) in ecotoxicological research.

The initial applications of artificial aquatic systems, such as laboratory microcosms, artificial ponds, and various *in situ* enclosures, were historically utilized in ecological studies of productivity,^{7,14–16} community metabolism,^{17–19} and population dynamics.²⁰ The earliest of these experiments, using laboratory microcosms, were those of Woodruff²¹ and Eddy,²² who examined protozoan species succession in hay infusions, and the slightly later studies of Lotka,^{23,24} Volterra,^{25,26} and Gause,²⁰ which formed the basis of the now standard quadratic population models in competition and predator-prey interaction. Gause²⁰ conducted his classic experiments on protozoan competition in glass dish microcosms from which his mathematical theory of competitive exclusion was derived. Gause²⁰ sought to address important ecological issues in these systems while being cognizant of their (potential) limitations. In discussing earlier studies conducted in laboratory microcosms Gause writes:

However, in experiments of this type there exists a great number of different factors not exactly controlled, and a considerable difficulty for the study of the struggle for existence is presented by the continuous and regular changes in the environment. It is often mentioned that one species usually prepares the way for the coming of another species. Recollecting what we have said in Chapter II it is easy to see that in such a complicated environment it is quite impossible to decide how far the supplanting of one species by another depends on the varying conditions of the microcosm which oppress the first species, and in what degree this is due to direct competition between them.

The above-cited research helped lay the groundwork for understanding how biotic processes function in artificially bounded and maintained systems. A fundamental knowledge of the ecology of the systems is necessary if there is to be any understanding of how they may be altered by an introduced perturbation. There has been considerable concern and debate over whether model systems, such as microcosms, simulate natural systems closely enough to be used as ecosystem surrogates. Microcosms tend not to closely simulate natural systems at all levels of ecological organization. Traditionally, this has not been viewed as a problem, as the system selected will vary with the research goals and the endpoints of choice. The presence of higher levels of organization may not be necessary to demonstrate effects with some endpoints.

The use of surrogate systems in toxicological research, particularly those encompassing any appreciable scale and complexity, has been relatively recent (ca. 1960). Concern over the effects of insecticides used to control mosquito populations in California prompted a series of field studies on the consequences of chemical control methods on nontarget species such as mosquito fish and waterfowl. Keith and Mulla²⁷ and Mulla et al.²⁸ used replicated artificial outdoor ponds to examine the effects of organophosphate-based larvicides on mallard ducks. Hurlbert et al.⁸ conducted subsequent studies in the same systems, examining the impact on a greater number of species within several broad taxa (phytoplankton, zooplankton, aquatic insects, fish, and waterfowl). Essentially, system-level impacts were being assessed, with subsequent evaluation of indirect effects

(e.g., changes in prey species densities in the absence of a predator species or the effects of emigration from a system) attributable to the pesticide application.

The broad application of microcosms and mesocosms in toxicological studies largely followed the realization that single-species toxicity tests alone were inadequate for predicting effects at the population and ecosystem levels.^{29,30} Multispecies tests have the potential to demonstrate effects not evident in laboratory tests that use a single, presumably (most) sensitive, species.³¹ As the goals of environmental protection focus on ecosystem-level organization, testing within more complex systems involves less extrapolation, apparently enhancing the prediction of impacts on natural systems. Model ecosystems in ecotoxicological research are seen primarily as a way of studying potential contaminants in systems that simulate parts of the natural environment but that are amenable to experimental manipulations.¹

An assessment of the ecological risk of pesticides is required under the United States Federal Insecticide, Fungicide and Rodenticide Act (FIFRA). A tiered data-collecting process that results from a progression of increasingly complex toxicity tests is considered together with an estimation of environmental exposure to make an assessment of whether a chemical may pose an unacceptable risk to the aquatic environment. Following tests conducted for each tier, data are evaluated, and risk to the aquatic environment is determined. Based on the outcomes of testing at each tier, the decision is made whether to stop testing or to continue to the next tier. Initial tiers are in the form of laboratory bioassays. The final tier (Tier IV) involves field testing. A description of the tests required at each tier and criteria for their implementation by the Environmental Protection Agency (EPA) is given in the Report of the Aquatic Effects Dialogue Group (AEDG).³² Registrants may be required by the EPA to conduct higher-tier tests, or they may opt for this level of testing to refute the presumption of unacceptable environmental risk indicated by a lower-tier test.

Prior to the EPA's adoption of the mesocosm technique as part of the ecological risk assessment of pesticides, Tier IV tests were conducted in natural systems that were exposed to the agricultural chemical during the course of typical farming practices. Although these types of studies provided realism in terms of environmental fate of the compound and exposure to the aquatic ecosystem, they were difficult to evaluate, in part because of insufficient or no replication, a high degree of variability associated with the factors being measured, and influences of uncontrollable events such as weather. In the mid-1980s the EPA adopted the use of mesocosms (experimental ponds) as surrogate natural systems in which ecosystem-level effects of pesticides could be measured (Tier IV tests) and included in the ecological risk-assessment process.³³

Although no longer part of the regulatory requirements in the United States, mesocosm test requirements have stimulated an increased worldwide interest in the use of surrogate ecosystems for the evaluation of the fate and effects of contaminants in aquatic ecosystems, as evidenced by the number of symposia^{5,34-38} and workshops^{1,39-41} over the last decade.

3.3 BIOMAGNIFICATION

Barron⁴² presents an overview of the principles and determinants of biomagnification in aquatic food webs. Environmental contaminants affect organisms that are part of an aquatic food chain. Biomagnification is the increase in contaminant body burden (tissue contaminant) caused by the transfer of contaminant residues from lower to higher trophic levels.⁴³ Rasmussen et al.⁴⁴ showed that PCBs in lake trout increased with the length of benthic-based food web and with the lipid content of tissue. Simon et al.⁴⁵ have analyzed the trophic transfers of metals (cadmium and methylmercury) between the Asiatic clam *Corbicula fluminea* and crayfish *Astacus astacus*. Their experimental data suggest a small risk of Cd transfer between the crayfish and predators, humans included. However, methylmercury distribution in muscle and accumulation trends in this tissue represent an obvious risk of transfer.

3.4 MODEL ECOSYSTEMS

A wide variety of model ecosystems have been developed and used for fundamental and applied aquatic ecological research. Review articles describing these systems are available for microcosms,⁴⁶ freshwater mesocosms,^{47,48} marine mesocosms,⁴⁹⁻⁵¹ and artificial streams.³⁵ Kennedy et al.⁵² review and summarize in table format representative examples of experimental designs used by researchers to study the fate and effects of xenobiotic chemicals in freshwater and marine aquatic environments.

3.4.1 Microcosms

Microcosms have been employed extensively in studies of contaminant effects on community-level structure and function. These systems can be viewed as an intermediate to laboratory tests and larger-scale mesocosms. Microcosms — whether indoor or outdoor — may not accurately parallel natural systems at all levels of organization, but important processes such as primary productivity and community metabolism can be studied in them, even in cases where systems cannot support all of the trophic levels found in larger systems.

Outdoor microcosms have taken a variety of forms including small enclosures in larger ponds⁵³⁻⁵⁶ and free-standing tanks of sizes ranging from small aquaria (12 L)⁵⁷ suspended in a natural pond to vessels constructed of fiberglass,⁵⁸⁻⁶³ stainless steel,⁶⁴ or concrete⁶⁵⁻⁶⁷ or excavated from the earth.^{68,69} Other researchers have used plastic wading pools⁷⁰ and temporary pond microcosms.⁷¹

3.4.2 Mesocosms

Likewise, an assortment of mesocosm ecosystems have been devised. Most mesocosm systems can be categorized into one of several systems based on their construction.

3.4.3 Enclosures

Limnocorrals — large enclosure systems in open-water areas of lakes — have been used extensively by Canadian researchers. These are systems designed to partition and encompass natural planktonic populations in order to study their responses to perturbations. Kaushik et al.⁷² described limnocorral construction. The impact of pesticides on plankton populations has been a frequent focus of enclosure studies.⁷²⁻⁷⁹

Littoral enclosures, which border the edge of a pond or lake, have been developed and used by the U.S. EPA Research Laboratory at Duluth, MN. These systems (5 m × 10 m surface area) have been used to study the fate and effects of pesticides on water quality parameters, zooplankton, phytoplankton, macroinvertebrates, and fish.⁸⁰ Brazner et al.⁸¹ described littoral enclosure construction and endpoints studied and discussed variability (coefficients of variation) of different indicators.

3.4.4 Pond Systems

Replicated pond mesocosms have been used extensively to evaluate pesticide fate and toxicological effect relationships.⁸² Most ponds used for this purpose are dug in the earth and range in size from 0.04 to 0.1 hectares in surface area.

3.4.5 Artificial Streams

Unlike lentic mesocosms, there have been no attempts to standardize the conduct of lotic experimental systems, even though experimental stream ecosystems have been employed to test chemical effects (Tables 3.1 and 3.2). Invariably, the use of these constructed stream ecosystems

has involved studying the responses of macrobenthic communities to multiple chemicals, chosen to be “typical” of what might be expected in natural streams. Response variables have differed among previous lotic studies and depend on the research questions asked and approaches taken (Table 3.2). Presently, there are relatively few such systems in the world. Costs associated with building and operating lotic mesocosm systems often limit the number of experimental units. Thus, most stream mesocosm studies have evaluated single chemicals at multiple concentrations with or without treatment replication. The designs range from small recirculating streams⁸³ to large, in-ground flow-through streams of 520 m in length.⁸⁴ Most constructed streams are 3 or 4 m long and around 50 cm wide. Volume flows range considerably and are usually selected to approximate the regional conditions.

The endpoints selected for study are almost always functional and structural endpoints of algae or benthic invertebrate populations (Table 3.2). The size and scale of the artificial streams preclude the use of predator fish, except for the very large systems. For the short term, studies pools may be constructed downstream to place herbivorous minnows or larval predators such as bluegill or bass.

Regression designs are common and suggested for use in risk assessment when experimental units are scarce.^{85,86} Despite problems associated with pseudoreplication,⁸⁷ lack of replication may be justified because intraunit variability due to treatments can be substantially more important than interunit variability.⁸⁸ Limited experimental stream studies have used factorial designs or addressed issues of multiple stressors.^{89,90} Factorial designs use ANOVA (requires replication), are efficient, and allow investigation of multiple-factor interactions (multiple stressors).^{91,92} Tables 3.1 and 3.2 present representative examples of experimental designs and endpoints used in outdoor stream mesocosms.

3.5 DESIGN CONSIDERATIONS

There are many problems to be considered when designing and implementing studies using model systems. These range from the pragmatic (funding, time constraints, etc.) to the heuristic

(What are the study goals? What levels of realism are desired?). The physicochemical and biotic features of a model system will determine to what extent, if any, the system will represent a natural one. These factors also influence contaminant fate and effects in model ecosystems. System design is therefore important in defining what inferences may be drawn from the results of surrogate systems and extrapolated to natural aquatic ecosystems. Using results from the scientific literature on model ecosystems, the following sections seek to provide a synthesis of some key experimental design considerations.

3.5.1 Scaling Effects in Artificial System Research

The question of whether artificial aquatic systems are reliable surrogates for natural ones is strongly linked to system scale. Scale includes not only size and physical dimensions of a microcosm or mesocosm but also its spatial heterogeneity and attendant biotic components. Crucial physical and chemical processes behave differently as both a function of, and contributor to, scale. Thus, scaling effects can have implications for community structure and the resultant functional attributes of the system.

The choice of spatial and temporal scales in an experiment may determine whether changes in selected endpoints can be detected during a study and is, therefore, vital to the research methodology. Frost et al.¹¹⁴ stated that “typically scale has not been incorporated explicitly into sampling protocols and experimental designs.” The choice of appropriate time scales, for example, in model aquatic system research must be considered in the selection of both study duration and sampling frequency intervals between sampling events. Both temporal elements should consider life cycles and periodicities of important system species. Sampling intervals should also consider the temporal behavior of key physicochemical processes (often related to pesticide fates and half-lives) and, ultimately, the longevity of the surrogate system as well.

Microcosms, particularly laboratory ones, require little or no equilibration time prior to their use as test systems. Results can be observed quickly, but the systems are not self-sustaining and tend to become unstable over time. Because laboratory microcosms can sustain only a limited number of trophic levels, usually composed of small organisms with short lifespans (days to weeks) and rapid turnover times, frequent sampling regimes and short study durations are required. Unfortunately, frequent sampling in small systems may be damaging to the system and its biotic contingent.³²

The size and overall dimensions of systems in ecotoxicological research have idiosyncratic implications in the outcome of the project. Dudzik et al.¹¹⁵ cite the prevalence of biological and chemical activity on the sides and bottoms of microcosms as one of the most important problems in microcosm research. Edge effects have been noted and discussed in enclosure studies as well,^{116,117} but the ecological implications of such scaling ramifications in ecotoxicological and ecological studies have yet to be resolved. These concerns present a unique challenge in the toxicological arena, as scaling effects may ultimately hinder the validation process, which is becoming increasingly critical in decision-making, policy-making, enforcement, and litigation issues.

The cause of some edge effects in ecotoxicological work pertain to materials from which littoral and pelagic enclosures are constructed, since they may serve as sorption sites for some toxins (via adsorption).^{118–120} This problem was also linked to physical scale and system dimensions, as the ratio of the wall surface area to water volume is greater in smaller test systems. Smaller enclosures and microcosms may remove disproportionate amounts of pesticide from the water column via absorption to container walls.³²

A study investigating the role of spatial scale on methoxychlor fate and effects in three sizes of limnocorrals found pesticide dissipation was more rapid than expected in the smallest enclosures.⁷⁴ These findings were associated with less severe impacts and quicker recovery of zooplankton populations in the smallest enclosures. Such studies are, in part, contingent upon an understanding of the role of spatial factors in biotic organization.

In an attempt to address such concerns, Stephenson et al.¹¹⁶ studied the spatial distributions of plankton in limnocorrals of three sizes (equal depths) in the absence of perturbations to assess the viability of such systems in community-level toxicant research. The most predominant edge effects were reported in the largest enclosures, where macrozooplankton occurred in significantly higher numbers than microzooplankton. Perhaps differentially sized edge zones contributed to distributional differences (edge zones constituted 100% of the volume of the smallest enclosures), or circular currents that occurred only in the largest enclosures could have affected zooplankton distributions. The actual cause of the zooplankton distribution differences was not determined, but basic research of this type provides important “background” data to better recognize treatment effects once disturbance has been introduced.

The limited size and accompanying physical homogeneity of many microcosms creates additional problems: (1) they are particularly susceptible to stochastic, often catastrophic, events from which system recovery may be highly variable relative to mesocosms,³² and (2) the often limited species compositions of microcosms induce overly strong biotic couplings, resulting in drastic population oscillations and competitive exclusion events.¹¹⁴ This latter problem was established early in ecological study with the research of Lotka²⁴ and Gause²⁰ when only a limited number of population cycles could be established in small microcosms.

As discussed previously, large outdoor systems, such as pond mesocosms, require colonization and equilibration times of months to years because they may incorporate many trophic levels, and an extensive number of interactions occur as a function of greater physical scale. Frequent (i.e., daily) sampling for many selected parameters may not be logistically feasible or even necessary to detect effects at the population or community levels. Study durations are by necessity and design much longer, since impacts at higher levels of organization, particularly indirect effects, may not be immediately evident. Such systems are presumably self-sustaining enough to permit the study periods necessary for detecting effects at these higher levels.

A variety of scales are to be considered when designing studies using surrogate systems because the scales discussed herein will affect the outcome of research whether the experimenter acknowledges them or not. Most researchers are aware of the implications of system size in fate and effects research, though indirect results in these studies may not always be perceived or attributed to their actual causes. Temporal aspects are also recognized, though the interaction of timing and spatial factors is still not well understood. The treatment of these scaling considerations in a more integrated fashion will ultimately enhance the predictive value and ecological relevance of the results.

3.5.2 Variability

Variability is inherent in any biological system, but the limiting of variability is often critical to the scientific process wherein the ultimate goal is prediction. Variability occurs within and among systems such as microcosms or mesocosms. Replication of treatments and the use of controls are necessary to distinguish natural variation from the effects of treatment.⁸³ Sampling replication can assess intrasystem heterogeneity resulting from spatiotemporal variation in community structure and physicochemical parameters.

Studies of stream benthos, however, indicate that the number of samples required to obtain adequate representation of the community would be quite high and no doubt impractical.¹²¹⁻¹²³ There is also the risk that accepted sampling regimes in lentic and marine research may similarly underestimate inherent variability in these more “homogeneous” systems. Assessing variability through such methods as coefficients of variation¹²³ and determining the number of sampling replicates that would be adequate to ensure representative sampling become critical in ecological research. Green¹²⁴ emphasizes the importance of conducting pilot studies in ecological research and having adequate replication, both in treatment and sampling. Unfortunately, even though the number of replicates needed to detect changes of a given magnitude can be determined *a priori*,

such estimates do not always match the availability of research resource personnel, space, or time.¹²⁵ Therefore, sampling must be focused on those variables that convey scientific meaning and provide investigators with resolving power for detecting differences. At the present time these variables are primarily structural.¹²⁶

An alternative to increased sampling replication has been to employ less diverse systems as a means of reducing intrasystem variation. This approach may result in simplification to the extent that model systems will not resemble the natural systems they are attempting to “mimic,” thereby affecting predictability⁴ and applicability. However, mimicking natural systems may not provide the best experimental models, according to Maciorowski,¹²⁷ who further emphasizes that the challenge in ecotoxicological research is to find those phenomena that can be simplified to several salient interactions. Extrapolating the results of model system research to natural systems remains one of the major areas of contention regarding their use.

In any manipulative experiment the assumption is made that observed effects (i.e., significant differences) are due to the treatment. Often, however, observed differences among treatment levels, or even among replicates within a treatment level, may be influenced by factors other than those being tested.⁸⁷ When this occurs, it is impossible to separate the covariates, and the hypotheses being tested at the onset may be invalidated. Variability among systems is a frequent contributor to this phenomenon.

Sources of variability may be structural, physicochemical, or biotic. Biotic variability can occur at a variety of levels within the ecosystem and markedly affect system-level processes such as productivity and respiration. Variability can be due to differences among systems prior to study initiation, or it may result from changes that occur during the study. Hurlbert⁸⁷ discusses both initial or inherent variability among systems and the temporal changes that occur within systems.

The confounding influence of system variability in ecotoxicological studies involving microcosms and mesocosms has long been recognized,¹¹⁵ but no uniform approach to a solution has been reached. Some researchers^{128,129} have attempted to assess inherent variability and determine the amount of sampling replication required to detect treatment effects. Other solutions involve establishing more stable communities in the hopes that equilibrium within systems will occur, enhancing both similarity among systems and increasing system realism. Giesy and Odum⁴ suggest that higher trophic levels assert a controlling influence on lower trophic levels in microcosms being used for effects studies. Giddings and Eddlemon¹³⁰ have attempted to assess microcosm variability for the purpose of determining the validity of using such model systems in toxicological research.

Methods of limiting intersystem variability sometimes employ design features. One routinely applied method in mesocosm — and sometimes in microcosm — research circulates water among the systems prior to study commencement.^{60,131–134} Heimbach¹³⁵ developed outdoor microcosms in which three interconnected tanks were joined via wide locks (passageways). Water exchange was allowed during an acclimation period, followed by isolation prior to pesticide application. Systematic “seeding” of the systems with biota and sediments from mature ponds may minimize variability resulting from nonuniform distributions of macroinvertebrates and macrophytes.¹³⁶

3.5.3 Colonization and Acclimation

Ecological maturity of mesocosms affects the degree of variability of both physicochemical and biological parameters used to investigate the impact of contaminants.¹³⁷ The establishment of biological organism communities is a critical part of microcosm and mesocosm experiments. Adequate time is required to establish a number of interacting functional groups.⁴ The colonization methods used in microcosm and mesocosm research will vary predominantly as functions of system size, the type of study, whether it is fate- or effect-oriented, and the endpoints of interest.¹³⁸ Studies using limnocorrals and littoral enclosures usually have no acclimation period because it is assumed these systems enclose established communities.^{73,119,139} In stream mesocosms stabilization periods of 10 days,¹⁴⁰ 4 weeks,¹⁰⁹ or 1 year¹⁴¹ have been reported.

The duration of the maturation period for pond mesocosms varies from 1 to 2 months³⁹ to 2 years.⁷ Following initial system preparation a period of acclimation is usually required to allow the various biotic components to adjust to the new environment and establish interspecific and abiotic interactions. Duration of acclimation time depends on system size and complexity. Systems with more trophic levels will form more complex interactions that may require much more time to equilibrate than small systems with fewer species. The time needed to equilibrate will increase with initial system complexity, although the use of natural sediments usually shortens the duration of the stabilization period because natural maturation processes are enhanced.⁵² During this acclimation period in outdoor systems the initial preparation of the systems is typically controlled, and natural colonization by insects and amphibians will contribute to biotic heterogeneity and system realism. Continuous colonization, however, presents further problems in that each system tends to follow its own trajectory through time. These trends are most apparent in small-scale systems and in systems that have been in operation longer.³⁵ Circulation of water between the different systems has frequently been proposed as a way to limit intersystem variability during this period.^{142,143,68}

3.5.4 Macrophytes

Aquatic vascular plants play a key role in system dynamics within natural lakes, and their presence in model ecosystems makes them more representative of littoral zones in natural systems. However, once introduced into model ecosystems, macrophyte growth is difficult to control and may vary greatly among replicates. This is of particular concern in field studies because macrophytes can influence the fate of chemicals, the occurrence and spatial distribution of invertebrates, and, if present, the growth of fish. Thus, variations of plant density and diversity in model ecosystems can be a major contributor to system variability and subsequent inability to detect changes in ecosystem structure and function.

Macrophyte densities can affect chemical fate processes by increasing the surface area available for sorption of hydrophobic compounds. The pyrethroid insecticide deltamethrin accumulated rapidly in aquatic plants and filamentous algae during a freshwater pond chemical fate study.¹⁴⁴ Caquet et al.¹³⁷ reported the residues of deltamethrin and lindane in the macrophyte samples for 5 weeks after treatment but never in the sediment. A microcosm study with permethrin demonstrated similar results, with extensive partitioning to macrophytes.¹⁴⁵ Weinberger and others¹⁴⁶ evaluated fenitrothion uptake by macrophytes in freshwater microcosms and found that pesticide accumulation was two- to fivefold greater in the light compared with microcosms in the dark. They concluded that both uptake and degradation of fenitrothion appeared to be photocatalyzed.

Macrophytes can also affect physicochemical composition in surrounding waters, influencing the distribution and community structures of many aquatic organisms.¹⁴⁷ In addition, macrophytes provide three-dimensional structure within constructed ecosystems, which affects organism distribution and interactions. Brock et al.¹⁴⁸ in a study with the insecticide Dursban 4E observed considerable invertebrate taxa differences between Elodea-dominated and macrophyte-free systems. Other workers have shown that macroinvertebrate community diversity is influenced by patchy macrophyte abundance¹⁴⁹ and specific macrophyte types.^{150,151} Cladoceran communities are also associated with periphytic algae on aquatic macrophytes.¹⁵²

Impacts of chemicals on macrophytes densities may cause indirect effects on organisms by influencing trophic linkages such as predator-prey interactions between invertebrates and vertebrates. Bluegill utilization of epiphytic prey may be much greater than predation upon benthic organisms.¹⁵³ Excessive macrophyte growth may force fish that normally forage in open water to feed on epiphytic macroinvertebrates, where the energy returns may not be as great.¹⁵⁴ Fish foraging success on epiphytic macroinvertebrates depends on macrophyte density¹⁵⁵ and plant growth form (i.e., cylindrical stems vs. leafy stems).^{107,156-158} Dewey¹⁵⁹ studied the impacts of atrazine on aquatic insect community structure and emergence. Decreases in the number of insects in this study were

correlated with reductions in aquatic macrophytes and associated algae and were not a direct effect of the pesticide.

The wide range of chemical, structural, and biotic interactions dependent upon macrophyte type and density as outlined above emphasizes the central role of this part of the community in lentic systems. It is apparent that the design of surrogate ecosystems needs to consider plant density and diversity as a contributor to system variability and the inability to detect ecosystem changes.

3.5.5 Fish

Whether to include fish, what species or complex of species to select, the loading rates, and their potential for reproduction are critical factors to consider in experiment design. Fish populations are known to have direct and indirect effects on ecosystem functioning. Fish predation is known to alter plankton community composition,^{160–162} and the presence of fish in limnocorral or microcosm experiments may alter nutrient dynamics and cycling.^{163,164} For example, during an outdoor microcosm experiment, Vinyard and others¹⁶² found that filter feeding cichlids altered the “quality” of nitrogen (shifting dominant form) and decreased limnetic phosphorus levels via sedimentation of fecal pellets. Additionally, unequal fish mortality among replicate microcosms may influence nutrient levels independently of any other treatment manipulations.¹⁶⁵

In separate limnocorral studies Brabrand et al.¹⁶⁶ and Langeland et al.¹⁶⁷ both concluded that fish predation alters planktonic communities in eutrophic lakes and that the very presence of certain fish species may contribute to the eutrophication process. These studies offered a number of interesting hypotheses regarding fish effects in limnetic systems; unfortunately, the experimental designs of these studies lacked treatment replication, limiting their inferential capability.

Many studies completed in the United States from 1986 through 1992 under U.S. EPA guidelines³³ for pesticide studies require that mesocosms include a reproducing population of bluegill sunfish (*Lepomis macrochirus* Rafinesque). Presumably, these fish and their offspring are integrators of system-level processes, and differences in numbers, biomass, and size distribution between pesticide exposure levels provide requisite endpoints for risk-management decisions. Chemical registration studies by Hill et al.,^{47,168} Giddings et al.,¹⁶⁹ Johnson et al.,⁶⁵ Morris et al.,¹⁷⁰ and Mayasich et al.¹⁷¹ have determined that the abundance of young bluegill in mesocosm experiments obscured or complicated the evaluation of pesticide impacts on many invertebrate populations. This is consistent with Giesy and Odum's⁴ suggestion that higher trophic levels assert a controlling influence on lower trophic levels in microcosms being used for effects studies. Ecological research with freshwater plankton and pelagic fish communities indicates that both “top-down” and “bottom-up” influences affect planktonic community structure and biomass.^{172–174} These relationships have not been investigated to the same degree in littoral zone communities, and the role of benthic macroinvertebrates in these trophic relationships requires further study. Along these lines Deutsch et al.¹⁷⁵ stocked largemouth bass in pond mesocosms in order to control unchecked bluegill population growth, thereby potentially limiting intersystem variability and provide a more natural surrogate system. However, the desirability of adding bass to mesocosms must be balanced against possible increases in experimental error variances that may result from differential predation on bluegill if variable bass mortality occurs in the ponds.¹⁷⁶ The only way to control variability in predation of bluegill would be to maintain equal levels of predator mortality in all ponds.

The requirement of using a single test-fish species (bluegill sunfish) in mesocosm experiments may not be sufficiently protective of natural fish communities, for a number of reasons. First, the inherent sensitivity of other fishes compared with bluegill is not known with any degree of certainty. Second, due to a variety of life history adaptations, other fish might experience differential exposure to chemicals. For example, surface-dwelling fish, such as top-minnows, would potentially be exposed to high initial pesticide concentrations found in the surface layer following treatment. Alternatively, contaminants that sorb to sediments (including many pesticides) might be expected to impact bottom-feeding fish selectively. Drenner et al.¹⁷⁷ studied the effects of a pyrethroid

insecticide on gizzard shad, *Dorosoma cepedianum*, in outdoor microcosms. These fish are filter feeders and commonly have large amounts of bottom sediments and detritus in their digestive systems. This study¹⁷⁷ is unique in the use of “nonstandard” fish species. Similar field studies utilizing other fish species should be pursued in order to evaluate the influence of feeding behavior and habitat selection on chemical exposure. Following appropriate research it is conceivable that a multispecies assemblage (i.e., surface feeder, water-column planktivore, and bottom feeder) might eventually be used to better represent potential impacts to natural fish communities.

The reader is cautioned, however, that additional research in this area is needed. Scaling is an important consideration, and criteria for fish stocking levels are highly dependent on system size. The fish population should not exceed the “carrying capacity” of the test system.¹⁶⁸ Biomass densities should generally not exceed 2 g/m³.¹⁷⁸

It may be useful to stock the mesocosm with a low adult density and remove adults and larvae after spawning. However, the life stage, number, and biomass of fish added will depend on the purpose of the test. For example, should the emphasis be on an insecticide, larval fish may be added to monitor their growth in relation to the invertebrate food base.

3.6 DOSING CONTAMINANT EXPOSURE

3.6.1 Chemical Fate Considerations

The primary assessment of the potential that a chemical has to affect an aquatic ecosystem is the prediction of its environmental fate. This includes how it is transported, its persistence, its distribution or partitioning among various environmental compartments, and an estimation of its bioavailability and potential to bioaccumulate.¹⁷⁹ Various chemical characteristics affecting fate are currently measured in the laboratory such as solubility, octanol/water and soil/water partitioning, and bioaccumulation in different organisms. More comprehensive estimates of the fate of the chemical are manifested in mathematical and physical models of aquatic ecosystems. Boyle¹⁷⁹ provided a list of examples of different representative types of mathematical models from the literature used to determine the fate of a potential contaminant. Rand et al.⁶³ described the design, specific techniques, and fate of pyridaben in microcosms and discussed the usefulness of microcosms to study the fate of a chemical under environmental conditions that are more representative of the field.

3.6.2 Application Method and Dosing

Test chemicals, such as pesticides and other toxicants, are commonly applied to treatment mesocosms, with application method, frequency, and concentration of test chemical used being the major considerations.¹³⁷ The method used for application of the test chemical can have considerable effect on its fate and the exposure of organisms.¹³⁷

Because of their scale microcosms usually lend themselves to somewhat less complicated methods of chemical application compared to similar mesocosm experiments. Microcosm experiments have used systems to distribute the test material that range from simply pouring the solution into the test chamber and stirring,¹⁸⁰ to a continuous-flow system.¹⁸¹ Stay et al.¹⁸⁰ poured in the selected concentration of the chemical and used a magnetic stirring bar to thoroughly mix the contents of the microcosm before any measurements or samples were taken. Staples et al.¹⁸¹ used a flow-through system in which dilution water and the chemical mixture flowed into a mixing tube and dispensed at three subsurface levels. A stirring paddle was employed to consistently mix the chemical solution in the microcosm. In their edge-of-field runoff study Huckins et al.¹⁸² placed topsoil in a flask, spiked it with pesticide, and mixed it thoroughly. Then water was added, and mixing was achieved using a magnetic stirring bar.

Preparing a stock solution in a diluter or mixing chamber of some type and pumping it into the system is also common in these studies.^{181,183,184} For example, experiments by Cairns et al.¹⁸³ and Pratt et al.¹⁸⁴ demonstrated this application procedure in which the diluent flowed to a headbox, into a mixing chamber where the toxicants were added, and delivered to the microcosm test chambers with a peristaltic pump. Koerting-Walker and Buck¹⁸⁵ added their chemical to sediment samples to use in their 135 mm × 15 mm sediment tube microcosms.

Outdoor microcosm experiments also demonstrate a variety of dosing procedures. Pratt et al.¹⁸⁴ added and mixed chlorine in 130-L sediment, and water-filled polyethylene bags that were floating in a lake. Lehtinen et al.¹⁸⁶ used a continuous-flow system with 400-L fiberglass tanks to which effluent was continuously pumped. In his simulated wetland microcosms Johnson¹⁸⁷ prepared and poured a soil/water slurry onto the water surface to simulate field runoff. Similar methods were used by researchers at the University of North Texas Water Research Field Station,^{65,170} where a pesticide/water solution and pesticide/soil/water slurry were prepared and poured onto the water surface of concrete microcosms to simulate spray drift and runoff events, respectively.

Complexity of dosing methods for mesocosm studies varies with the purpose of the study. The contaminant may be added to the water surface or subsurface or on the sediments by pouring the active ingredient or a mixture of soil and toxicant surface,^{188–191} spraying with hand-held sprayers and spanners that release the solution onto the water surface,^{192–198} or pumping via a flow-through system.^{199–201} Subsurface dosing can also be achieved by placing the spray nozzle or hand-held sprayer below the water level.^{131,202}

Some application methodologies are quite innovative. Wakeham et al.²⁰³ spiked the water column of their fiberglass tank mesocosms with volatile organic compounds (VOCs), using Teflon tubing that released the VOC at about mid-tank depth, while the tank was mixed for several hours to ensure uniform VOC dispersal in the water column. Stephenson and Kane²⁰⁴ applied their stock solution by allowing it to run out a separating funnel through a diffuser that was raised and lowered within the water column. De Noyelles et al.¹⁹⁵ used a boat to achieve access to multiple portions of a pond and dispensed a herbicide through a fine screen just below the water surface so that undissolved portions would be finely dispersed. Lay et al.²⁰⁵ soaked strips of polyethylene in p-chloroaniline and placed these in the mesocosm to achieve a slow-release technique type of application. Giddings et al.¹⁶⁹ used a circulating system of reservoirs and tanks to simulate a typical runoff event. A stock-solution reservoir was metered to ensure the desired concentration passed into the mixing tank. The mesocosm water was then circulated into the mixing tank and pumped back into the mesocosm at three different places to ensure that each test system received a similar hydrologic treatment.

Reviewing the literature, one comes to realize that there are nearly as many application methods as there are researchers designing microcosm and mesocosm studies. It should be noted that the method chosen for the application of the test material can have considerable influence on its fate and subsequent exposure to organisms. For example, the size of droplets reaching the water surface from a spray nozzle held near the water surface of an experimental system may differ from that of droplets deposited on a natural body of water following agricultural application to adjacent land.¹ In turn, droplet size may be critical since volatilization from the water-surface microlayer can be a very rapid process and may be a major route of dissipation.²⁰⁶ Thus, the decision to either spray a chemical on the water surface or inject it underneath can have a major influence on its half-life. Clearly, the method of test material application must be chosen so that realistic exposures are obtained.

3.7 EXPERIMENTAL DESIGN AND STATISTICAL CONSIDERATIONS

3.7.1 Experimental Design Considerations

Key issues in designing microcosm and mesocosm tests that need attention are replication of treatments, sample size and power, optimization criteria in design selection, choice of number and

spacing of dose levels, inference on “safe dose,” and defining the dose-response curve.²⁰⁷ Biological variables measured in field studies have a large amount of variability associated both within and between test systems that can decrease our ability to detect ecosystem effects.²⁰⁸ One approach to improving designs is by reducing variation. While this may be done by increasing the number of microcosms, this is not always possible due to cost. Information that can be gathered through power analysis can be used to maximize manpower resources and project expenditures to produce the best possible sample design as well as to determine which biological parameters should be included in a study protocol.²⁰⁸

3.7.2 Endpoint Selection

Toxicological endpoints are values derived from toxicity tests that are the results of specific measurements made during or at the conclusion of the test.²⁰⁹ Two broad categories of endpoints are widely used: assessment and measurement endpoints. The determination, selection, and measurement of assessment and measurement endpoints are among the most critical factors in conducting an ecological risk assessment.²¹⁰ Assessment endpoints refer to the population, community, and ecosystem parameters that are to be protected, such as population growth rate, or something specific and quantifiable, such as eutrophication.^{209–211} Measurement endpoints refer to the variables measured, often at the individual level, that are used to evaluate the assessment endpoints.²⁰⁹ The measurement endpoints describe the variables of interest for a given test. The most common measurement endpoints include descriptions of the effects of toxic agents on survival, growth, and reproduction of a single species. Other measurement endpoints include descriptions of community effects (respiration, photosynthesis, or diversity) or cellular effects. In each case the endpoint is a variable that can be quantitatively measured and used to evaluate the effects of the toxic agent on a given individual, population, or community. Sometimes it is not possible to examine the assessment endpoint directly. In this case measurement endpoints are used to describe the organism or entity of concern.²¹⁰ The underlying assumption in making toxicological endpoint measurements is that the endpoints can be used to evaluate or predict the effects of toxic agents in natural environments. Suter²¹¹ discussed the endpoints for the different levels of organization: suborganismal endpoints, organismal endpoints, population endpoints, and ecosystem endpoints. EPA risk assessment guidelines provide information on how endpoints can be used in the environmental risk-assessment process.²¹²

3.7.3 Level of Taxonomic Analysis

Frost et al.¹¹⁴ discussed as a scale of concern the taxonomic or functional levels to which organisms are identified or the degree of resolution. In this context organisms may be analyzed in trophic levels or functional groups or at some taxonomic level depending on the research focus and the questions proposed. Theoretically, species-level identifications have the greatest potential for identifying impacts of chemicals on aquatic organisms.²¹³ However, from a practical and technological standpoint, our ability to identify many organisms to the lowest taxonomic levels is limited. Many endpoints measured in mesocosm and microcosm studies require the identification of invertebrates. Increasing the taxonomic resolution used in a study increases the expertise and time needed to complete a study. As a result, taxonomic resolution used in field monitoring studies has traditionally been determined by budgetary considerations, the familiarity of the researchers with critical taxa, and the availability of reliable identification guides.

Decisions regarding the appropriate level of identification should be made with some knowledge of an organism's habitat and life history, combined with information regarding the fate of the chemical. Coarser identifications may obscure results and failure to identify organismal responses to stressors. Taxonomic sufficiency has been defined as the highest level of identification where toxic response is similar to that occurring at the lower levels of identification.^{214,215} In a mesocosm

study Kennedy et al.²¹⁶ demonstrated that identification to the family level for a dominant macrobenthic group failed to detect statistical differences when compared to the reference populations that were evident if subfamily identifications were determined. However, identification of these invertebrates to the genus and species level failed to detect statistical differences. This observation demands that we consider the influence counts of organisms made at lower taxonomic levels can have on statistical tests. As diverse populations are identified to lower taxonomic levels progressively lower counts and greater variability result at each level. Lower counts and increased variability results in tests of lower statistical power, which compromises our ability to detect statistical differences between populations.^{208,217} If preliminary studies indicate that greater taxonomic resolution is needed, then specialized sampling methods and strategies need to be developed to increase sampling effectiveness, thereby increasing counts and reducing variability.

3.7.4 Species Richness, Evenness, Abundance, and Indicator Organisms

The presence of species and their relative abundance are used as a measure of the degree of contamination of an aquatic habitat.^{218,219} These parameters are often used to calculate diversity indices. Although diversity indices have been shown to be insensitive to slight to moderate perturbations,^{220,221} they are still reported in biological monitoring.^{222,223} Species richness (the number of different species) and evenness (the distribution of individuals among species present) have been shown to better reflect impacts to aquatic communities than diversity indices.²²⁴ The abundance of species has been a standard measure for “good quality” habitat since early studies of habitat perturbation.²²⁵

3.7.5 Univariate Methods

Univariate techniques, particularly analysis of variance (ANOVA) using parametric or log ($x + 1$) transformed data, are the most commonly used analysis method, with either Dunnett's or the Student-Newman-Keuls (SNK) being the most common post hoc test.²⁰⁸ Linear regression and correlation have also been used, but with less frequency.²²⁶ When the assumptions of parametric tests, normality, and homogeneity cannot be met, nonparametric tests, such as Spearman, Wilcoxon rank statistic, and the Kruskal-Wallis tests, have been employed.²⁰⁸

However, these univariate methods of hypothesis testing are inappropriate for multispecies toxicity tests. As such, these methods are an attempt to understand a multivariate system by looking at one univariate projection after another, attempting to find statistically significant differences. Often, the powers of the statistical tests are quite low due to the few replicates, the high inherent variance of many of the biotic variables, and the zero counts for some organisms that were eradicated during the experiment.²²⁷ Ammann et al.²¹⁷ and Kennedy et al.²⁰⁸ proposed a statistical program, TAX-ALLN.Q, that overcomes the problems of high variability and zero counts as well as provides a measurement of statistical power that is an important design criterion in experimental studies. Perhaps the greatest danger of the use of ANOVA and related univariate tools is the perpetuation of NOECs, LOECs, and related terms based on univariate hypothesis testing. NOECs and LOECs are so dependent upon the statistical power and the concentrations chosen by the experimenter that they are artifacts of the experimental design rather than reflections of the intrinsic hazard of the toxicant.²²⁸

3.7.6 Multivariate Methods

Highly variable data are common in aquatic mesocosm studies. This can be a problem when univariate statistical procedures are used to analyze these data. The statistical power to detect effect is so low that the usefulness of conducting the analysis is questionable because even if effects exist, they may not be detected.^{208,217,228} However, even if the univariate procedures are performed with satisfactory power, the interactions between species, populations, or communities are usually not

considered and are therefore inadequate to elucidate ecological effects.¹²⁴ Additionally, standard univariate statistical methods can only properly analyze the information on a limited number of taxa (usually the abundant ones).^{229,230} Furthermore, with the vast number of potentially confounding variables that can affect population dynamics, such approaches can lead to problems in determining cause and effect.²³¹

A variety of multivariate techniques offer potential solutions to these analytical and interpretational problems.²³² Analyzing ecotoxicological field studies with multivariate techniques has some clear advantages. Community-level approaches have more ecological relevance than studies at lower levels of biological organization, and so far no compelling evidence suggests that they are any less sensitive at detecting the biological effects of pollution, especially when multivariate analyses are applied. Multivariate statistics analyzes all available data, and it is more likely to discriminate between treatments than simple univariate summaries of the same data.²¹⁰ Consequently, these approaches may be more helpful in determining the ecological significance of toxicant impacts and may help the evaluator of the study reach conclusions based on ecologically important effects, a fundamental responsibility in field studies.²³³ Cost effectiveness is important, and costs can be reduced dramatically by considering taxonomic sufficiency and sampling design appropriate for the subsequent statistical analysis.²³⁴ Multivariate techniques are also ideal for handling large amounts of data and endpoints more effectively. Kedwards et al.⁶⁷ showed how multivariate techniques can aid in the interpretation of biological monitoring studies, which present difficulties related to the sometimes semiquantitative nature of the data and the unavailability of true control sites, replication, and experimental manipulation.

Ludwig and Reynolds²³⁵ provide an introduction to the assumptions, derivations, and use of several multivariate techniques commonly used for the analysis of ecological communities. Van Wijngaarden et al.²³⁶ compare DCA, PCA, and RDA and their usage in mesocosm research in more detail. Van den Brink et al.²³⁷ proposed a multivariate method based on redundancy analysis (RDA). Clarke²³⁸ showed the use of nonmetric multivariate analysis in community-level ecotoxicology, which does not require the restrictive assumptions of parametric techniques. Multivariate techniques have become more accessible and user-friendly with the availability of software such as the principle response curves method²³³ and the routines in the PRIMER software package.²³⁸ Major steps have also been taken to produce outputs readily interpretable by both ecologists and environmental managers and regulators. Multivariate techniques now provide ecotoxicologists with powerful tools to visualize and present impacts at the community and ecosystem level.

3.8 SUMMARY

This chapter has focused on key factors that need to be considered in the experimental design of outdoor model ecosystem studies to increase their realism, reduce variability, and ultimately assess the ability of these systems to detect changes. The success in using such systems depends on the establishment of appropriate scales of sampling, both temporal and spatial. As systems need to be sampled with response times for species taken into account, so sampling programs should reflect the variance in activities, life span, and reproductive potential of the species of interest. The failure to observe patterns (predicted or otherwise) or establish equilibrium conditions in experimental plots is often a result of the scales selected.

In performing a model ecosystem study it is important to determine the ecological relevance of effects identified in linked laboratory studies. The studies therefore include several species, functional groups, or habitat types. Interpretation of the field study focuses on effects at the community level, potential indirect effects, and the recovery potential of aquatic populations and communities. A second important reason for conducting a model ecosystem study is to measure consequences of the chemical under environmentally realistic exposure conditions (realistic fate and distribution). Such conditions could include partitioning to sediments and plants, photolysis, and other processes

that may influence the fate of the pesticide. Moreover, these studies incorporate natural abiotic conditions (temperature, light, pH, etc.) that may influence the response of certain organisms.⁴⁰

Based on the discussions and examples given in the previous pages it should be evident that there is no single “best” experimental design or test system.⁴⁶ There are a number of options that can be chosen depending on available budgets and facilities. The experimental design needs to address the objectives of the study and must consider the characteristics of the contaminant being studied and the ecosystem being impacted. Outdoor meso- or microcosm studies can be performed with artificial tanks or ponds or in parts of existing ecosystems that are enclosed in a way that causes minimal disturbance. The size of the mesocosm depends on the nature of the study and size and habitat of the organisms of interest. Typically, for “pond” studies, volumes of 1 to 20 m³ are usually regarded as appropriate for outdoor meso- or microcosm studies. In situations in which planktonic species are the main concern microcosms of 100 to 1000 L may also be appropriate. The size to be selected for a meso- or microcosm study will depend on the objectives of the study and the type of ecosystem that is to be simulated. In general, studies with smaller tanks (about 1 to 5 m³) are more suitable for shorter studies (up to about 1 month), and larger volumes are more suitable for longer studies (e.g., up to 6 months or longer). Benthic and planktonic invertebrates are often added to mesocosms with sediments and water. Invertebrates typically include rotifers, cladocera, copepods, annelids, benthic crustaceans, gastropods, and insect larvae.

In general, approaches to ecosystem-level testing using surrogate systems have been overly simplistic. Continued development of innovative approaches to data collection and analysis are needed. Historically, mesocosm tests have been viewed as a “series” of single-species tests (the ANOVA statistical approach is currently favored). Ecosystem-level studies often require the prediction of responses of many biological variables given information on the state of environmental or other biological variables.²³⁹

Methods that evaluate endpoints in a more integrated and holistic fashion should be applied to these studies. Multivariate statistics are one tool for viewing the “big picture.” Multivariate techniques, however, are not a panacea for data analysis²⁴⁰ but should be part of an integrated approach that encompasses both reductionist component analysis and other holistic approaches such as modeling.¹²⁷ Ultimately, the value of research using surrogate systems lies in their potential to provide prediction of and probabilities for ecosystem responses to contaminants.

A number of ecotoxicological studies with similar experimental designs have been completed in North America and Europe for purposes of pesticide registration. The existence of such a large number of similarly designed and conducted large-scale model ecosystem studies provides a unique opportunity for further research. If results of these studies were compiled into a common database, analysis of these data could help identify common results, allowing generalization for given classes of stressors. Evaluation of these results in the light of current ecological theory should allow for the formulation of alternative hypotheses, future study designs to test these hypotheses, and subsequent validation (or refutation) of these ideas. A clear-cut, systematic synthesis of the existing information will help enable model ecosystems to reach their full potential as a tool for predicting impacts (as opposed to simply effects assessment). Until this happens, regulators, the manufacturing industries, and researchers will continue to argue over the meaning of community and ecosystem responses measured in these studies. As Cairns²⁴¹ succinctly stated: “If environmental toxicology is to come of age, it must begin to ask more searching questions, develop broader hypotheses involving natural systems, and develop models that are validated in landscapes, not laboratories.”

4.1 INTRODUCTION AND HISTORICAL BACKGROUND

Wildlife toxicology is the study of potentially harmful effects of toxic agents on wild animals. Fish and aquatic invertebrates are usually not included as part of wildlife toxicology since they fall within the field of aquatic toxicology, but collectively both fields often provide insight into one another and both are integral parts of ecotoxicology. Wildlife toxicology endeavors to predict the effects of toxic agents on nontarget wildlife species and, ultimately, populations in natural environments. Wildlife toxicology has often focused on highly visible species, including certain birds and a few mammals, that are of aesthetic or economic interest to humans.¹ However, during the past decade wildlife toxicology has expanded to include the effects of environmental contaminants on reptiles, amphibians, and terrestrial invertebrates.

Reports of anthropogenic environmental contaminants affecting free-ranging wildlife began to accumulate during the industrial revolution of the 1850s. Early reports included cases of arsenic and lead-shot ingestion and industrial smokestack-emission toxicity. One report described the death of fallow deer (*Dama dama*) due to arsenic emissions from a silver foundry in 1887 in Germany,² with subsequent reports of widespread killing of game animals, including deer and foxes, by arsenic emissions from metal smelters.³ Another report described hydrogen sulfide fumes in the vicinity of a Texas oil field that resulted in a large die-off of many species of wild birds and mammals.² Mortality in waterfowl and ring-necked pheasants (*Phasianus colchicus*) from ingestion of spent lead shot was recognized as early as 1874 when lead-poisoned birds were reported in Texas and North Carolina.⁴ Waterfowl mortality in the vicinity of mining and smelting operations was first reported in the early 1900s and subsequently linked to metallic or lead poisoning.⁵ At about the same time the potentially devastating effects, including the death of seabirds such as puffins, of crude oil spills were noticed.⁶

Prior to World War II most agricultural and household pesticides were relatively simple derivations of naturally occurring minerals and plant products. The advent of synthetic organic insecticides evolved from World War II. Many of these post-war insecticides exhibited vast biological activity and were remarkably persistent in the natural environment. Initially, this persistence seemed desirable, especially from an economical perspective, i.e., long-term pest control. However, within a few years insects began to show resistance to many of these "modern" pesticides, and even trivial amounts of some impaired reproduction in certain wildlife species. For example, dichlorodiphenyltrichloroethane (DDT) was introduced in 1943, and by the end of the decade ecological problems other than incidents of acute mortality began to surface. Farsighted scientists, such as Lucille Stickel and others at the Patuxent Wildlife Research Center, Laurel, Maryland, cautioned users of the potential hazards of application of DDT to wildlife.^{7,8} Little attention was paid to ecological hazards of pesticides until Rachel Carson published *Silent Spring*⁹ in 1962. This seminal treatise effectively sensationalized many ecologically significant happenings such as a decline in the population of American robins (*Turdus migratorius*) by the early 1950s, which was linked to DDT spraying to fight Dutch Elm disease, and evidence that bald eagles (*Haliaeetus leucocephalus*), osprey (*Pandion haliaetus*), and populations of fish-eating mammals were at risk. Research then revealed that DDT and other chlorinated hydrocarbon insecticides, including dichlorodiphenyldichloroethane (DDD), endrin, aldrin, and dieldrin, when incorporated into the diets of pheasants and quail, impaired reproductive success without necessarily having other adverse effects on adults.¹⁰ Eggshell thinning, related to DDT and ultimately dichlorodiphenyldichloroethylene (DDE), was determined to be an important factor in reproductive failure in European and North American birds of prey¹¹⁻¹³ as well as in brown pelicans (*Pelecanus occidentalis*).¹⁴ This and similar research played a major role in the cancellation of many highly persistent pesticides in the United States.

Even pesticides that are comparatively labile in a natural system may be problematic. For example, many wildlife losses have been documented due to organophosphorus and carbamate insecticides.¹⁵⁻¹⁸ These poisonings of many species of birds and mammals are due to acute lethal toxicity from cholinesterase inhibition. Agricultural practices other than pesticide application that

have received focus due to adverse effects on wildlife include subsurface drainage of irrigation water, wherein bioaccumulation of selenium and other trace elements in the aquatic food chain has proven highly embryotoxic and teratogenic to numerous species of waterbirds.^{19–22}

Certainly, factors other than agricultural practices may pose toxic hazards to wildlife. For example, concern has arisen over globally increasing concentrations of methylmercury in aquatic biota, even evident at remote and semiremote sites, as a consequence of multiple anthropogenic sources and their emitting mercury into the environment.²³ A case in point — in the marine food web of the North Atlantic Ocean — is the steady long-term increase in concentration of methylmercury in feathers of fish-eating seabirds sampled from 1885 through 1994.²⁴ This increase has averaged 1.9% per year in Cory's shearwater (*Calonectris diomedea borealis*) and 4.8% per year in Bulwer's petrel (*Bulweria bulwerii*). These increases are attributed to global trends in mercury contamination rather than local or regional sources. Mercury concentrations have also increased over the past century in other species of seabirds.²⁵

Another concern is endocrine disruption in wildlife species.^{26–28} Many of the endocrine disruptor reports in wildlife are based upon observed adverse reproductive and developmental effects rather than direct evidence of endocrine-modified function or defined endocrine pathways. A wide variety of chemicals have been reported as potential endocrine disruptors and are described by Gross et al. in Chapter 39 of this book. These include polycyclic aromatic hydrocarbons; polychlorinated and polybrominated biphenyls, dibenzo-*p*-dioxins and dibenzo-*p*-furans; organochlorine pesticides and fungicides; some nonorganochlorine pesticides; complex environmental mixtures; and a few metals. Collectively, there is strong evidence of altered reproductive and developmental processes in wildlife exposed to endocrine disruptors. The U.S. Congress has passed legislation (listed in federal register notice, 63 FR 71542) requiring the U.S. Environmental Protection Agency (EPA) to develop, validate, and implement an Endocrine Disruptor Screening Program (EDSP) for identifying potential endocrine-disrupting chemicals.

Wildlife toxicology involves the integration of three principal strategies for understanding effects of toxic agents on wildlife.^{1,29} The first strategy is *chemical screening*. A variety of toxicological tests are performed in the laboratory or in outdoor pens. Representative species are tested to help predict potential effects of a given chemical in natural populations of the same or closely related species. The second strategy is the *controlled field* or *mesocosm study*. Wildlife species of interest are exposed to operational chemical applications in a confined environment, simulating a natural system. The third strategy is *field ecology assessment*. Natural populations are studied in environments subjected to high levels of contamination.

With the advent of synthetic insecticides as well as the release of industrial pollutants and consequent wildlife losses, screening of pesticides and other chemicals for adverse effects has become an integral part of wildlife toxicology. A wide variety of wildlife testing protocols have been developed for regulatory use by the U.S. EPA under the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA) and the Toxic Substances Control Act (TSCA). The U.S. EPA has established a unified library of test guidelines issued by the Office of Prevention, Pesticides and Toxic Substances (OPPTS), for the Series 850-Ecological Effects Test Guidelines. This document outlines testing requirements and protocols for review by the U.S. EPA under TSCA and FIFRA. The purpose of harmonizing these guidelines into a single set of OPPTS guidelines is to minimize variations among test procedures that must be performed to meet the U.S. EPA data requirements. These guidelines are a compilation of the testing guidance and requirements of the Office of Pollution Prevention and Toxics (OPPT; Title 40, Chapter I, Subchapter R of the Code of Federal Regulations), the Office of Pesticide Programs (OPP), and the Organization for Economic Cooperation and Development (OECD). Table 4.1 summarizes the guidelines for terrestrial wildlife in this series and the above sources from which they were derived.

This chapter provides a summary of the toxicity tests commonly used in wildlife toxicology. The focus is on avian studies because birds have served as primary models for terrestrial wildlife toxicology since the 1950s. In contrast, though mammalian wildlife species were considered

important, it was generally accepted that the array of baseline tests routinely conducted with laboratory mammals would usually suffice for at least provisional intertaxa comparisons. The main avian tests described herein are acute, subacute, subchronic, chronic, developmental, field, and behavioral (Figure 4.1). Coverage of toxicity testing for wild mammals, amphibians, and reptiles is also provided but in somewhat less detail since the present body of information on these is more limited in scope and requirement than avian wildlife toxicity testing.

4.2 SINGLE-DOSE ACUTE ORAL AND SHORT-TERM SUBACUTE DIETARY AVIAN TOXICITY TESTS

Basic protocols with lethality as the principal endpoint have been used for first-line toxicity testing with birds by the U.S. Fish and Wildlife Service, the U.S. Geological Survey, and the U.S. EPA. These include experiments designed to estimate the acute oral median lethal dosage (LD₅₀), the 5-day median lethal dietary concentration (LC₅₀), and relevant statistical parameters.³⁰

4.2.1 Single-Dose Acute Oral

Reports on single-oral-dose avian LD₅₀s contain data for adults of nearly 75 species of birds and more than 1000 chemicals tested.³¹⁻³³ Full-scale acute oral toxicity tests are required by

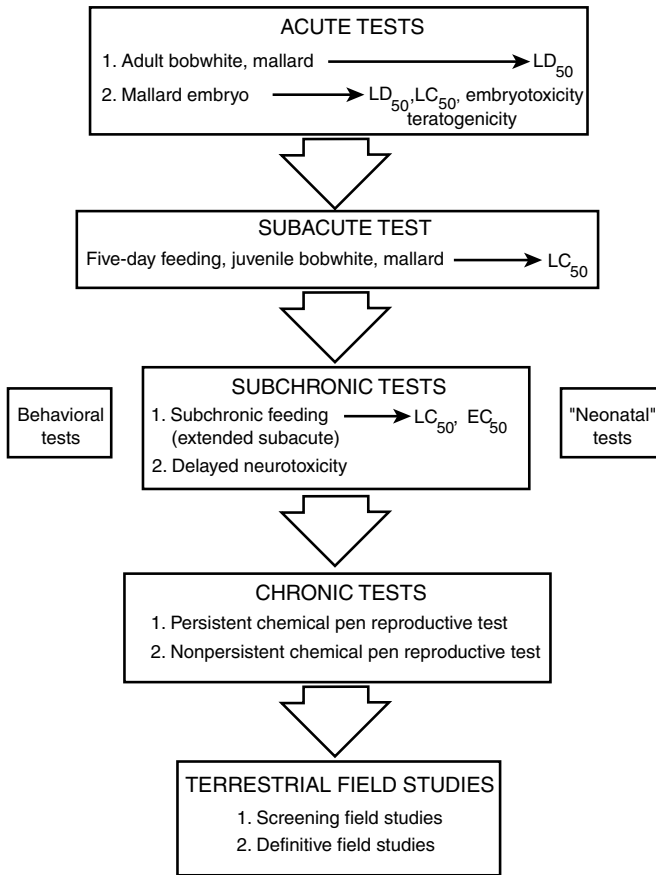

Figure 4.1 Protocols used in avian toxicity testing.

regulatory guidelines for pesticide registration in the United States (Table 4.1). Testing is with one of two species of birds, usually the mallard (*Anas platyrhynchos*) or the northern bobwhite (*Colinus virginianus*), and provides the LD_{50} and associated statistics including the dose-response curve.³⁴ Acute oral tests provide a preliminary indication of the lethal hazard of a substance.

These tests are rapid, uncomplicated, inexpensive, statistically reliable within the lethality curve (i.e., ± 1 SD of the LD_{50}), and, most importantly, provide insight necessary for further hazard evaluation.³⁵ Overnight-fasted birds receive a single dose of test substance at midmorning, usually administered by gavage or by capsule, at each of five or six geometrically arranged dosage levels that were predetermined from a preliminary study to span the expected 10 to 90% mortality levels.^{30,35} Feed is provided immediately postdosing, and observations for signs of intoxication are continued throughout the day. Special attention is given to the length of time to first evidence of toxicity, death, and recovery. Observations are continued twice daily, or more often as indicated, for 14 days posttreatment, or longer if toxic signs persist. Gross necropsy should be performed on all birds that die and on a subsample of survivors.

Optimal use of the acute test requires statistical estimation of the lethality curve and its midpoint and descriptive information on toxic response. The LD_{50} , expressed as mg (active ingredient)/kg of body mass, its 95% confidence interval, and the slope and error of the dose-response curve are derived by probit, logit, or other appropriate analysis. When only the general order of acute toxicity is desired for wide-scale initial comparisons of many species or finished product formulations, then a choice of several approximate tests of lethality may be used instead (e.g., up-and-down, moving averages).^{31,32,35}

Approximate tests conserve test animals. For example, as few as three groups of three to five birds are tested against a standardized fixed-dosage arrangement; toxicity statistics are derived from published tables.³¹ The up-and-down procedure may use even fewer animals and is based on dosing single subjects at a time and adjusting each subsequent dose up or down, depending on the response of the preceding subject. Approximate tests provide an estimate of the LD₅₀ and its 95% confidence interval but do not provide a statistical estimate of the dose-response curve.

The single acute oral test is best suited for substances whose principal action is lethality (e.g., insecticides, certain heavy metals, natural toxins), but (with less statistical confidence) the LD₅₀ can be used as a toxicity marker for any substance with substantial bioactivity. Thus, the LD₅₀ provides a statistical basis for comparisons among contaminants and species as well as with measured or estimated amounts of pesticide or other contaminant residue in the terrestrial or aquatic environment that could be consumed by wildlife in a single oral exposure.

However, care must be taken in how acute data are evaluated and whether the test is being used generally for regulatory purposes or specifically for risk assessment or research planning. For example, an avian database was compiled for 147 cholinesterase-inhibitor pesticides, with 837 acceptable LD₅₀ determinations, and 733 noncholinesterase-inhibitor pesticides with 1601 acceptable LD₅₀ values.³³ These authors found that when fitting a distribution to LD₅₀s expressed as mg/kg body weight, the LD₅₀ values were overestimated for small-body birds. Therefore, the use of scaling factors for body weight has been recommended to improve cross-species comparisons of acute toxicological sensitivity.³⁶ After the protection level had been arbitrarily fixed at the 5th percentile of the species distribution (termed HD₅; Hazardous Dose 5%), it was shown that of all of the above pesticides, 34 had an HD₅ less than 1 mg/kg, of which 24 were cholinesterase inhibitors. Of the remaining ten, two were insecticides (including the very new pyrrole insecticide chlorfenapyr), two were fungicides, and the others were rodenticides, including three of the coumarin anticoagulant products.

In another example generally similar acute toxicities between mallards and laboratory rats were reported for insecticides and herbicides.³⁷ However, subsequent evaluations have revealed important and major differences in acute sensitivity to pesticides between birds and mammals (laboratory rats) and have been reviewed by Walker³⁸ and by Hill.³⁵ To illustrate, the organophosphorus pesticides dimethoate, fenitrothion, and temephos have LD₅₀s of, respectively, 215, 740, and 8600 mg/kg of body mass in rats, but are extremely toxic to both pheasants and blackbirds with LD₅₀s of 7 to 42 mg/kg (Table 4.2.). It was concluded that the laboratory rat is not a good model for the prediction of acute toxicity to birds, even for chemicals that elicit their toxicity in the same manner.

Table 4.2 Acute Avian Toxicity Testing of Organophosphorus Pesticides of Widely Variable Mammalian Toxicity^a

Pesticide	Rat ^b	Pheasant ^c	Blackbird ^d
Single-Dose Oral LD₅₀			
Phorate	2	7	1
Azinphos-methyl	13	75	8
Ethion	65	1297	45
Dimethoate	215	20	7
Fenitrothion	740	26	25
Temephos	8600	35	42

^a Derived from reference 35.

^b Sherman strain male laboratory rats, 3 months old, n = 50–60 per test.

^c Farm-reared male and female ring-necked pheasants, 3 to 4 months old, n = 8–29 per test.

^d Wild-captured pen-conditioned male and female red-winged blackbirds, adult, n = 8–28 per test.

Such remarkable differences between birds and rats clearly justify the need for acute avian toxicity testing and confirm that reliance on widely existing rat data is not adequate for prediction of avian hazard. Wide variation in sensitivity to acute exposure to pesticides exists even among avian species. For example, the red-winged blackbird (*Agelaius phoeniceus*) was one of the most sensitive of seven species tested with ten different anticholinesterase pesticides.³⁵ In another study adult red-winged blackbirds were 137 times more sensitive to terbufos and 65 times more sensitive to diazinon than adult European starlings (*Sturnus vulgaris*).³⁹ Furthermore, a difference of nearly 70-fold in sensitivity was detected between American kestrels (*Falco sparverius*) and eastern screech owls (*Otus asio*) for the anticholinesterase insecticide EPN; screech owls were relatively tolerant ($LD_{50} = 274$ mg/kg), but kestrels were not ($LD_{50} = 4$ mg/kg).⁴⁰

LD_{50} tests have also been used to demonstrate practical differences in acute hazard of technical grade and liquid and granular formulations of pesticides.^{35,41–44} While the toxicity of liquid formulations was found to be equal or somewhat more toxic than the technical grade, granulars were generally less toxic than the technical grade. However, the hazard involved in risk assessment of granulars was more dependent upon which avian species (size and feeding behavior) was likely to inhabit a treated area rather than on actual application rate.⁴⁵ If ingestion is haphazard, then the application rate becomes more critical, but if ingestion is selective, then even the most stringent attempts to reduce granule availability may fail to reduce the hazard. Recent studies with bobwhite in planted enclosures have suggested that ground-feeding birds are more susceptible to granular insecticides than flowable applications.⁴⁶ The color, size, texture, granule base, taste, and application rate are all factors for consideration in reduction of granular hazard to wildlife.^{47–54}

4.2.2 Subacute Dietary

The subacute test (LC_{50}), a 5-day feeding trial, is required for two species, including upland game birds and waterfowl, to support registration of pesticides (Table 4.1). This guideline was modified from 40 CFR 797.2050 and OPP 71–2 to be harmonized with OECD guideline 205, allowing the use of coturnix (Japanese quail, *Coturnix japonica*) as an acceptable test species. This test serves as a composite indicator of vulnerability to a contaminated diet, allowing for metabolic changes that occur over time. The test was developed to quantify the toxicity of dietary residues that were considered an important source of exposure of wildlife to environmental contaminants.^{43,44,54} This test was optimized with young precocial birds, including ducks and quail, but almost any species can be tested provided it can be maintained in captivity in good health and cannot survive for 5 days without eating.³⁵ Mortality and signs of intoxication are monitored at least twice daily, and food consumption is measured at 24-hour intervals. After the fifth day, all feed is replaced with untreated feed, and the study is continued for at least 3 days or until complete remission of overt toxic signs.

The LC_{50} is expressed as mg (active ingredient)/kg of feed (or ppm) with its 95% confidence interval and slope with error of the dose-response curve as done for acute tests. Results of tests on more than 200 pesticides with young northern bobwhite, coturnix, ring-necked pheasants, and mallards have been published.^{43,44} When LC_{50} tests are compared with LD_{50} tests, subacute LC_{50} results often describe relationships among species and chemicals that are quite different from those for LD_{50} s because LC_{50} tests measure ability of birds to cope with toxic feed for a set duration.³⁵ LC_{50} s must be used carefully when comparing the toxicity of pesticides among species because there is no assurance that the species of interest have been equally challenged by the test protocol.³⁵ For example, if one species has a greater tendency to refrain from eating the test diet, or if a portion of the population can survive severely reduced nutriment for the duration of the test, then responses may vary considerably.

Age is an important consideration when evaluating LC_{50} s. In precocial species there is generally an increase in resistance to chemicals with increasing age during early growth.^{55,56} This increase occurs across a given class of chemical or pesticide and appears to be the result of changes in

ability to cope with a toxic diet for the exposure duration, where older (larger) chicks that eat less proportional to body mass are better able to survive the 5-day trial by reducing food consumption and hence toxic exposure.⁵⁶ During the first 21 days average increases in LC_{50} s in coturnix for nine pesticides (three organophosphorus and two each of carbamate, chlorinated hydrocarbon, and methylmercury) were 36% for days 1–7, 43% for days 7–14, and 28% for days 14–21.⁵⁶ This corresponded to reductions of normal food consumption in controls of about 35, 23, and 21% per week from hatch to 3 weeks of age. In contrast, acute oral LD_{50} s show a dichotomy of change with age. For example, mallard LD_{50} s for anticholinesterases that require activation for maximum potency tend to decrease between hatch and 7 days and then increase through adulthood, whereas the opposite pattern occurs for direct-acting organophosphorus and carbamate anticholinesterases.⁵⁷

4.3 AVIAN SUBCHRONIC DIETARY TOXICITY TEST

This test was developed as an extension of the subacute LC_{50} test but with greater emphasis on sublethal indicators of toxicity. The test was designed as a precursor to provide a biological indication of the necessity for conducting a full-scale reproductive trial and to provide a possible hazard index based on the ratio of sublethal to lethal toxicity values.³⁰ The first test of this kind was conducted to compare the effects of organic and inorganic mercury on various physiological parameters, including indicator enzymes and blood chemistries, in coturnix through 9 weeks of age, which is full maturity in this species; calculation of periodic EC_{50} s (median effective concentration) for each responding variable was used to develop hazard indices relating the EC_{50} to the oral LD_{50} and 5-day LC_{50} .

Other special studies of a subchronic nature (exposure period generally 1 to 3 months) have been conducted on pesticides and other environmental contaminants using farm-reared mallards and quail, as well as wild-captured species of birds. The emphasis of these studies has been on biochemical indicators of toxicity and toxicokinetics. For example, when studying the effects of an organic form of selenium, selenomethionine, implicated in agricultural drainwater toxicity to waterbirds in California, 2-year-old mallard drakes were fed diets containing supplementation of excess selenium from 1 to 32 ppm for 14 weeks.⁵⁸ Selenium accumulated readily in the liver in a dose-dependent manner. Mortality (10%) and histopathological effects, including bile duct hyperplasia and hemosiderin pigmentation of the liver and spleen, occurred at the highest level tested. These histopathological effects were accompanied by elevated plasma-alkaline-phosphatase activity, which is indicative of cholestatic liver injury. Other manifestations of hepatotoxicity included significant dose responses for hepatic oxidized glutathione (GSSG) concentrations and increased ratio of GSSG to reduced glutathione (GSH). Mean hepatic malondialdehyde (a measure of lipid peroxidation) concentration was elevated at the two highest levels tested. A number of these subchronic effects were similar to effects reported in wild waterfowl in a seleniferous location.

Subchronic studies have also been used for comparative purposes among species. For example, the potential hazard of ingestion of lead-contaminated sediment was assessed in mallard ducklings and goslings of Canada geese (*Branta canadensis*) from hatching for 6 weeks.^{59–61} At similar dietary concentrations of lead, blood and liver lead concentrations increased almost twice as much in mallards as in geese. Yet when species were compared for responses at similar blood and liver lead concentrations, manifestations of toxicity were greater in geese, as reflected by reduced survival and growth, hematological effects, and hepatic oxidative stress. Hepatic GSH-S-transferase activity was nearly three times higher in geese than in mallards and presumably had a role in the binding of lead to GSH and subsequent biliary excretion. In contrast, mallards showed higher hepatic levels of GSH and activities of GSH peroxidase (GPX) and GSSG reductase (GR). An increase of lipid peroxidation with lead exposure was more evident in geese than mallards. Hepatic GSH was inversely related to hepatic lipid peroxidation — only in mallards and in agreement with the differences observed in GPX and GR activities. This apparent lower resistance to lipid peroxidation

of Canadian geese compared to mallards may explain why geese found dead in the field by lead ingestion often have lower liver lead concentrations than mallards.

A third example of specialized subchronic testing comes from studying the potential of several organophosphorus insecticides to induce delayed neurotoxicity (OPIDN) in mallards.⁶² Here mallard hens received up to 270 ppm technical grade EPN in the diet for 90 days. Muscular incoordination, or ataxia, was first observed with 270 ppm in the diet after 16 days, with 90 ppm after 20 days, and with 30 ppm after 38 days; 10 ppm failed to produce ataxia. Brain neurotoxic esterase activity was inhibited by about 70% or more in groups experiencing ataxia. Brain and blood plasma cholinesterases and plasma alkaline phosphatase were significantly inhibited as well. Distinct histopathological manifestations of OPIDN were seen at concentrations as low as 30 ppm, which included demyelination and degeneration of axons of the spinal cord. Additional ducks exposed in a similar manner to leptophos experienced similar behavioral, biochemical, and histopathological alterations. These findings showed that adult mallards were sensitive to OPIDN but somewhat less so than chickens, which have served as the traditional model for screening substances for OPIDN.

4.4 AVIAN CHRONIC TOXICITY TESTS

Most avian chronicity tests are designed with reproduction as the primary endpoint. Such tests permit study of simulated field exposure under controlled conditions with a relevant species and exposure route. The Avian Reproduction Test guideline has been modified from 40 CFR 797.2130 and 797.2150 and OPP 71-4 to be harmonized with OECD guideline 206. The OECD guideline identifies Japanese quail as an acceptable species, but until several technical issues are resolved for this species the United States is listing only mallard and bobwhite as acceptable species for avian reproduction testing. For certain other tests, such as part of the Endocrine Disruptor Screening Program (EDSP, listed in federal register notice, 63 FR 71542), a two-generation test with Japanese quail is allowed. This test includes endocrine-specific endpoints in addition to the conventional fitness endpoints of existing avian reproduction test designs for identifying and characterizing endocrine effects of pesticides, industrial chemicals, and environmental contaminants.

Avian reproductive studies are required by the U.S. EPA^{63,64} with both waterfowl (mallards) and an upland game species (northern bobwhite) to support the registration of an end-use product that meets one or more of the following criteria: (1) the end-use product is intended for use where birds may be subjected to repeated or continuous exposure to the pesticide or any of its major metabolites or degradation products, especially preceding or during the breeding season; (2) the pesticide or its products may persist in the food at toxic levels; (3) the pesticide or its products accumulate in plant or animal tissues; and (4) the pesticide or its products cause adverse reproductive effects in mammals. The basic study usually required by the U.S. EPA is designed to elucidate reproductive effects of chemicals that persist in potentially toxic amounts in wildlife habitats throughout the reproductive season. Alternative studies have also been used to evaluate reproductive effects from pesticides that have a short life span in nature but may be applied repeatedly during the reproductive season. The basic reproductive study and an example of an altered reproduction study follow.

4.4.1 Reproduction Studies — Basic Protocol

This basic protocol was designed for testing environmentally persistent chemicals and may be required for pesticide registration (Table 4.1). Test concentrations for regulatory purposes are based on measured or calculated residues expected in the diet from the proposed use pattern, including an actual field exposure level and a multiple level, such as ten times the field level. Treatment commences at least 10 weeks in advance of breeding and continues through egg laying. Eggs are collected daily and set at weekly intervals for artificial incubation in the laboratory. Reproductive

endpoints in such studies include number of eggs laid, percent fertility, live 3-week embryos, hatchability, 14-day-old posthatch survivors, and eggshell thickness. Two examples of reproductive studies conducted with mallards include: (1) studies with endrin, a chlorinated hydrocarbon pesticide, and (2) studies with selenium, an agricultural drainwater contaminant. Both contaminants have been associated with avian mortality in the field.

In the early 1980s endrin was found to be quite toxic to birds as the cyclodiene insecticide was used in the western United States. Reproductive effects were suspected mostly in waterfowl. Therefore, studies were conducted in which concentrations of 0, 1, and 3 ppm endrin in dry feed were fed to mallards from late fall through the following breeding season; health and reproduction were monitored.⁶⁵ Endrin at 3 ppm increased adult mortality, reduced hatching success, and delayed hatching. In a comparative study screech owls were more sensitive than mallards to reproductive effects of endrin yet accumulated less endrin in eggs and tissues than mallards.⁶⁶ Eggshell thickness was not affected in either species.

Another example is from reproductive studies with mallards fed selenium. The purpose was to determine the form of selenium, dietary concentration, and concentration in eggs responsible for high embryonic mortality and teratogenicity in aquatic birds exposed to evaporation ponds receiving agricultural drainwater at the Kesterson Reservoir in central California and other western locations. Another facet of the studies was to examine the interaction of selenium and mercury. In summary, the organic form of selenium, selenomethionine, accumulated to levels in eggs comparable to those found in eggs of wild birds in contaminated locations; sodium selenite and selenocystine did not accumulate readily or produce reproductive impairment similar to selenomethionine.²² Characteristic malformations of the extremities occurred with selenomethionine, and included deformities of the bill, eyes, brain, and feet identical to those found at Kesterson.⁶⁷ Threshold concentrations for reproductive impairment from selenomethionine were 4 to 8 ppm in the diet (dry diet) and >3 ppm (wet weight) in the eggs. Studies of selenium and mercury interaction revealed antagonistic effects in adult mallards, but the two substances were synergistic in their effects on the reproductive process.⁶⁸ Individually, selenium and mercury lowered hatching success and survival of ducklings; the combination of mercury and selenium further reduced reproduction. Controls produced an average of 7.6 young per female — females fed 10 ppm selenium produced an average of 2.8 young, females fed 10 ppm mercury produced 1.1 young, and females fed both mercury and selenium produced 0.2 young. Furthermore, teratogenic effects were notably increased for the combined treatment; deformities were recorded in 6.1% of the embryos of controls, 16.4% for those fed methylmercury chloride, 36.2% for those fed selenomethionine, and 73.4% for those fed combined methylmercury chloride and selenomethionine.

4.4.2 Reproduction Studies: An Alternative Protocol

Several protocols have been used for testing comparative labile chemicals such as anticholinesterase pesticides.^{63,69–74} Because of use patterns the initial contact with these pesticides may occur at any time during reproduction but usually not in advance of nesting. Therefore, a shorter exposure period is initiated once the test population is in egg production. Northern bobwhite reproductive tests with organophosphorus insecticides have shown significant effects with treatment periods of 8 days,⁷⁰ 10 days,⁷¹ and 3 weeks.^{69,72–74} A mallard test of methyl parathion in the diet for 8 days resulted in reduced daily egg production, changes in incubation behavior of hens, and decreased number of hatchlings.⁷⁵

Test methods used in the above studies varied substantially and should be further considered if standardization is desired. There are many potential advantages to using short-term exposure tests including: (1) known layers of fertile eggs can be used, hence reducing variability in test data; (2) pretreatment values for each pen can serve as an additional control; and (3) timing of the test

can coincide with maximum egg production. However, the most important advantage may be to mimic actual exposure spikes as they may be encountered in nature.

4.5 SINGLE-DOSE AVIAN EMBRYOTOXICITY AND TERATOGENICITY TESTS

Toxic contaminants can enter the natural environment by numerous routes, including air pollution from mobile and stationary sources, pesticide spray applications, or aquatic translocation. All these routes have the potential to contaminate avian eggs, which are well known for susceptibility to direct applications of toxicant.^{30,76} Even a parent bird may be the source of contamination. For example, petroleum pollutants carried to the nest on breast feathers, feet, or nesting materials of sea birds caused reduced hatchability of contaminated eggs.⁷⁷ Laboratory studies showed that as little as 1 to 10 μL of crude or refined oil topically applied to eggs of various species was embryotoxic or teratogenic. The extent of toxicity was from egg penetration and the aromatic hydrocarbon composition, rather than from blockage of shell pores and interference with oxygen transfer as previously believed.^{78,79} Dose-dependent liver necrosis was one of the best indices of embryotoxicity dependent on petroleum composition and stage of development.⁸⁰

A variety of pesticides, including paraquat and parathion, have been shown to be embryotoxic and teratogenic to several avian species. Embryos did not develop normally when eggs were sprayed with or immersed in chemical formulations at concentrations encountered in nature.^{76,81}

With this background, routine test methods were developed for embryotoxicity and teratogenicity with mallard eggs. Measurement of embryo lethality was modeled after the avian acute toxicity test, that is, the median lethal effect (LD_{50} or LC_{50}) is derived by exposure of eggs or embryos to at least three geometrically arranged treatments. Treatment has been by egg immersion (LC_{50}) or topical application by spraying or pipetting (LD_{50}).

An evaluation of the potential hazard of external exposure of mallard eggs to petroleum, pesticides, and industrial effluents was carried out; tests conducted on more than 70 environmental contaminants indicated that 8 of 30 pesticides tested caused teratogenic effects at exposure levels well below the calculated LC_{50} or LD_{50} .⁸¹ Other measurements of embryotoxicity included presence of subcutaneous edema, blisters, hemorrhages, and stunted growth. Studies with different species (e.g., northern bobwhite) but the same classes of pesticides often lead to similar conclusions.⁷⁶ Several studies with insecticides and herbicides are summarized below.

The order of toxicity of commercial formulations was determined for 14 insecticides in aqueous emulsion, as reflected by LC_{50} values in mallard eggs.⁸¹ The LC_{50} values for these insecticides ranged from 30 g/L to greater than 600 g/L, and order of toxicity was endrin > sulprofos > parathion > acephate > lindane > temephos > diazinon > dimethoate > toxaphene > malathion > carbaryl, permethrin, phosmet, and methomyl. However, the order of potential hazard in terms of the highest permissible field level of application in the United States was toxaphene > malathion > endrin = dimethoate > lindane > sulprofos > diazinon > parathion > acephate > temephos > carbaryl, phosmet, methomyl, and permethrin. Apparent differences between the ranking based on toxicity and potential hazard were due to differences in maximum permissible levels of application, which, for example, were extremely high for toxaphene and malathion. Insecticides with LC_{50} values that occurred at approximately ten times the highest permissible field level of application or less included dimethoate, endrin, malathion, and toxaphene. Of these, all were teratogenic but only dimethoate and endrin were teratogenic at levels below the LC_{50} . Subsequent observations have shown that many of these abnormal embryos are unable to hatch, and this would have lowered the calculated LC_{50} if hatching success had been included.

The order of toxicity of herbicides in aqueous emulsion (LC_{50} values) was paraquat = trifluralin > propanil, bromoxynil with MCPA (Bronate[®]) > methyl-diclofop > prometon > picloram > 2,4,5-T > amitrole > glyphosate > 2,4,-D > atrazine, dicamba, and dalapon.⁸¹ However, the order of

potential hazard in terms of the highest permissible field level of application in the United States was trifluralin > paraquat > prometon > methyldiclofop = propanil > bromoxynil with MCPA (Bronate®) > picloram > amitrole > 2,4,5,-T > 2,4,-D > glyphosate > atrazine and dicamba. Herbicides with LC₅₀ values that occurred at ten times the field level of application or less included bromoxynil with MCPA, methyldiclofop, paraquat, prometon, propanil, and trifluralin.

Embryotoxicity testing has also involved hazard evaluations of aquatic weed control,⁸² mosquito control,^{83,84} and wildfire control agents.⁸⁵ Some examples follow. (1) Diquat dibromide, a bipyridylium compound, is commonly used as an aquatic weed control. Tests with mallard eggs indicated that concentrations of diquat in aqueous solutions as used for aquatic weed control would probably have little impact on mallard embryos. This is, of course, dependent upon the dilution effect of average water depth of the application area. However, concentrations applied above ground to weeds and cattails along ditches could affect the survival and normal development of mallard embryos and presumably other avian species nesting in such habitats.⁸²

(2) Golden Bear Oil or GB-1111 (also GB-1313) is a petroleum distillate that is used throughout the United States as a larvicide for mosquito pupae. External application of the product to mallard, bobwhite, and red-winged blackbird eggs reduced hatching success but at different levels of treatment. Hatching was significantly reduced in mallards treated on day 4 or day 11 at three and ten times the maximum field application; the LD₅₀ was 1.9 times the maximum field application.^{83,84} Hatching success of bobwhite and red-winged blackbirds was only reduced at ten times the maximum field application. Recommended rates of field application of GB-1111 were potentially toxic to mallard embryos, especially under conditions of spray overlap but unlikely to impair the survival or development of bobwhite or red-winged blackbird embryos.

(3) Eggs of nesting birds situated in peripheral areas serving as fire breaks are at risk of being sprayed with fire-control chemicals. Acute toxicity tests were conducted with northern bobwhite quail eggs using different water-based concentrations of Silv-Ex® (S-E), a fire suppressant chemical, and Phos-Chek® G75-F (P-C), a fire-retardant chemical, on day 4 or day 11 of incubation.⁸⁵ Mortality appeared higher in most groups exposed on day 11 than on day 4, suggesting that on day 11 the extensive chorioallantoic vascular network permitted greater uptake of chemical. A combination of S-E and P-C was synergistic (202 g/L P-C and 50 g/L S-E) at day 11 of incubation resulting in a large decrease in hatching success. However, lower combined concentrations of S-E (10 g/L or 30 g/L) with 202 g/L of P-C appeared antagonistic. This may be due to S-E, as a surfactant, altering the ability of P-C to penetrate. It was concluded that Phos-Chek G75-F could pose a potential threat to developing galliform species, especially during heavy application in densely wooded areas (the LC₅₀ was 220 g/L compared to the standard application concentration of 135 g/L).

Other studies have utilized egg injections as a short cut for initial comparison of relative toxicities of environmental contaminants that could be ingested by birds in nature to an array of avian species.⁸⁶⁻⁸⁸ For example, the effects of polychlorinated biphenyl (PCB) congeners, PCB 126 and PCB 77, were examined in chicken (*Gallus gallus*), American kestrel, and common tern (*Sterna hirundo*) embryos through hatching following air cell injections on day 4.⁸⁷ PCB 126 caused malformations and edema in chickens starting at 0.3 ppb, in kestrels at 2.3 to 23 ppb, but in terns only at levels affecting hatching success (44 ppb). The estimated LD₅₀ for PCB 126 in chickens, kestrels, and terns was 0.4, 65 and 104 ppb, respectively, and for PCB 77 it was 2.6 and 316 ppb, respectively, for chickens and kestrels. High concentrations of PCB 126 found in bald eagle eggs in nature are nearly 20-fold higher than the lowest toxic concentration detected in kestrel eggs suggesting potential for toxicity in nature. In contrast, concentrations of PCB 126 causing low-level toxic effects in common tern eggs are comparable to highest levels in common terns and Forster's terns found in nature, suggesting additional involvement of other compounds causing toxicity in areas such as the Great Lakes.

Another example of using egg injections as a short cut for comparing relative embryotoxicities among species involves the evaluation of mercury in the environment, which is especially hazardous

to fish-eating birds since it accumulates in the food chain. Therefore, studies were conducted by injecting methylmercury (dissolved in corn oil) into eggs of several species.⁸⁸ When mallard eggs were injected, hatching success was 76% for controls, and 56, 62, 53, 44, and 29% for eggs injected with 0.1, 0.2, 0.4, 0.8, and 1.6 ppm mercury, respectively. With white ibis (*Eudocimus albus*) eggs, hatching success was 62% for controls and 10, 25, and 20% for eggs injected with 0.2, 0.4, and 0.8 ppm mercury, respectively. For tricolored herons success was 60% for controls and 10% for eggs injected with 0.4 ppm mercury. For great egrets (*Casmerodius albus*) success was 60% for controls and 0% for eggs injected with either 0.4 or 1.3 ppm mercury. These results indicate that the embryos of some fish-eating birds may be more sensitive to methylmercury than mallard embryos and that estimates of toxic levels of mercury in eggs, based on reproductive trials with mallards, may have to be re-evaluated.

4.6 "NEONATAL" TOXICITY TESTING IN ALTRICIAL NESTLING BIRDS

Neonatal mammals are especially susceptible to accumulation and toxicity of many environmental contaminants. With this as a guide, studies with altricial and semi-altricial nestling birds were conducted and have shown that nestlings of different species including American kestrels, European starlings, red-winged blackbirds, herring gulls (*Larus argentatus*), and great egrets are considerably more sensitive to oral ingestion of contaminants, such as heavy metals, herbicides, OP insecticides and PCBs, than are adults of the same species or the young of fully precocial species such as northern bobwhite, mallards, and ring-necked pheasants.⁸⁹ Following are examples of the effective use of nestlings of various species in elucidation of contaminant hazard to birds.

4.6.1 American Kestrels

Studies have been conducted with American kestrel nestlings that were orally intubated daily for the first 10 days posthatching. Environmental contaminants administered were lead, herbicides (paraquat, nitrofen, bifenox, and oxyfluorfen), and PCB congeners (Table 4.3). Endpoints have included survival; body, organ, and skeletal growth; and blood and organ biochemistry.

Overt toxicity of metallic lead was manifested by 40% nestling mortality at the dose level of 625 mg/kg, with significant impairment of growth occurring at 125 mg/kg.⁹⁰ Since nestling kestrels consume approximately their own body weight in food per day, 625 mg/kg of lead daily can be considered equivalent in daily lead intake to approximately 625 ppm lead in the diet, and 125 mg/kg equivalent to 125 ppm in the diet. Lead ingestion was considerably more toxic to nestlings than previously reported for adults and young precocial species, where LC₅₀s were greater than 5000 ppm. Biochemical and hematological alterations in nestlings were also more severe than those reported in adult kestrels or precocial young birds exposed to lead.⁹¹

Paraquat ingestion by nestling American kestrels was also more toxic than previously reported for adults and young precocial species.⁹² For northern bobwhite, coturnix, ring-necked pheasants, and mallards, the LC₅₀s varied from nearly 1000 ppm to over 4000 ppm after a 5-day feeding trial. In kestrels 60 mg/kg of paraquat resulted in 44% mortality on days 4 to 8 of the experimental treatment period.

Diphenyl ether herbicides, including bifenox, nitrofen, and oxyfluorfen, were examined for developmental toxicity in kestrels. Bifenox was found to be more toxic than reported for precocial species; for ducks and pheasants, the 5-day LC₅₀s for bifenox were reported to be greater than 5000 ppm in the diet.⁹³ Precocial young also appear to be less sensitive than nestling kestrels to nitrofen ingestion. Bifenox at 500 mg/kg caused 66% mortality in nestling kestrels, whereas 500 mg/kg nitrofen caused 100% mortality within 5 days. Levels of bifenox or nitrofen at 250 mg/kg caused 9% mortality within 7 days. In addition to reduced growth and survival, nitrofen caused some

Table 4.3 "Neonatal" Toxicity Testing of Environmental Contaminants in Nestling Birds

Species	Exposure Method	Chemical	Observation Period	Effects	References
American kestrel	Daily oral	Lead, metallic	Days 1–10	525 mg/kg, high mortality; 125 mg/kg, reduced growth; 25 mg/kg, altered physiology	90, 91
American kestrel	Daily oral	Paraquat	Days 1–10	60 mg/kg, high mortality; 10 to 25 mg/kg, reduced growth, altered physiology	92
American kestrel	Daily oral	Bifenox	Days 1–10	500 mg/kg, high mortality, 250 mg/kg, reduced growth, altered physiology	93
American kestrel	Daily oral	Nitrofen	Days 1–10	500 mg/kg, complete mortality; 250 mg/kg, reduced growth; 50 mg/kg, altered physiology	93
American kestrel	Daily oral	Oxyfluorfen	Days 1–10	500 mg/kg, few effects	93
American kestrel	Daily oral	PCB 126	Days 1–10	50 ug/kg, onset of lymphoid depletion, decreased thyroid content, hepatic necrosis	94
European starling	Single oral (day 5 or 15)	Dicrotophos	24 h postdose	Day 5 LD ₅₀ = 4.9 mg/kg Day 15 LD ₅₀ = 9.0 mg/kg, reduced growth, brain cholinesterase	95
European starling	Single oral	Diazinon	24 h postdose	Day 1 LD ₅₀ = 13 mg/kg fledgling LD ₅₀ = 145 mg/kg	96, 39
European starling	Single oral	Terbufos	24 h postdose	Day 2 LD ₅₀ = 2.3 mg/kg fledgling LD ₅₀ = 61 mg/kg	39
Red-winged blackbird	Single oral	Diazinon	24 h postdose	Day 0–3 LD ₅₀ = 2.4 mg/kg fledgling LD ₅₀ = 8.3 mg/kg	39
Red-winged blackbird	Single oral	Terbufos	24 h postdose	Day 0–3 LD ₅₀ = 0.4 mg/kg fledgling LD ₅₀ = 3.3 mg/kg	39
Herring gull	Single oral (3–4 weeks old)	Crude oil	For 9 days	0.3 mg/kg reduced growth, altered physiology	97
Herring gull	Single i.p. injection (day 2 or 6)	Lead nitrate	19 days of age or older	100 mg/kg on day 6 was a critical period for disruption of behavior	99, 100
Herring gull	Single i.p. injection (day 2 or 6)	Chromium nitrate	50 days of age	50 mg/kg on day 2 affected growth and 12 of 14 behaviors	101
Herring gull	Single i.p. injection (day 2 or 6)	Manganese acetate	50 days of age	50 mg/kg on day 2 affected growth and 12 of 14 behaviors	101
Black guillemot	Single oral	Crude oil (weathered)	For 22 days	0.1–0.2 mL reduced growth, altered physiology	98
Great egret	Dosed orally from 1 to 14 weeks	Methylmercury chloride	Through 14 weeks of age	0.5 mg/kg affected immune system and behavior; 5 mg/kg caused severe ataxia and neural lesions	103–105

hepatotoxicity, including an increase in liver weight relative to body weight with significant increases in activities of several plasma enzymes. Hepatic tissue GSH peroxidase activity was significantly higher in all nitrofen-treated groups and in the two treated with the highest doses of bifenoxy (50 mg/kg and 250 mg/kg). Other alterations included an increase in plasma total thyroxine concentration (T4) by nitrofen, which may indicate thyromimetic activity, as suggested for mammals.

The developmental toxicity of the planar PCB 126 was also studied in the posthatching kestrel as a model for the eagle.⁹⁴ Nestlings were dosed with 5 μ L/g body weight of corn oil (controls) or PCB 126 at concentrations of 50, 250, or 1000 ng/g body weight. Dosing with 50 ng/g of PCB 126 resulted in a hepatic concentration of 156 ng/g wet weight, liver enlargement and mild coagulative necrosis, over tenfold increases in hepatic microsomal ethoxyresorufin-O-dealkylase and benzyloxyresorufin-O-dealkylase, and a fivefold increase in methoxyresorufin-O-dealkylase. At this dose mild to moderate lymphoid depletion of the spleen was apparent, as were decreased follicle size and content of the thyroid. At 250 ng/g concentration of PCB 126 in the liver was 380 ng/g, with increasing multifocal coagulative necrosis, decreased bone growth, decreased spleen weight with lymphocyte depletion of the spleen and bursa, and degenerative lesions of the thyroid. At 1000 ng/g the liver concentration was 1098 ng/g, accompanied by decreased bursa weight, decreased hepatic thiol concentration, and increased plasma enzyme activities (ALT, AST, and LDH-L), in addition to the previous effects. Highly significant positive correlations were noted between liver concentrations of PCB 126 and the ratio of oxidized to reduced glutathione. These findings indicated that nestling kestrels are more susceptible to PCB 126 toxicity than are adults but less sensitive than embryos.

4.6.2 European Starlings and Red-Winged Blackbirds

Acute oral LD₅₀s for European starlings were determined for nestlings from hatching until fledging. The LD₅₀ of dicotophos for free-living 5-day-old nestlings was about half that obtained for 15-day-old nestling and adults.⁹⁵ Brain cholinesterase activity was depressed by 74 to 94% in all birds that died, but neither the degree of inhibition nor the baseline cholinesterase activity varied with age. In another study of anticholinesterase pesticides to starlings newly hatched young were 20 times more sensitive to a single dose of diazinon than were fledglings of about 21 days of age.⁹⁶ Nestling sensitivity was supported by decreased plasma and brain cholinesterase activities. Acute age-dependent toxicity of terbufos and diazinon was evaluated in nestling starlings and red-winged blackbirds.³⁹ In brief, for starlings, LD₅₀s for turbufos increased from 2 days of age to 9 days by nearly ninefold and by 26-fold at 19 days and fledging; whereas for diazinon the increases between 2 days and 9 and 19 days were 7- and 11-fold. In comparison, blackbird nestlings were tested at 0 to 3 days and about halfway to fledging (8 to 11 days). The LD₅₀ increased during this period by ninefold for turbufos and threefold for diazinon. At both ages the red-winged blackbird was substantially more sensitive to turbufos and diazinon than was the European starling. Baseline cholinesterase activities in both brain and plasma increased with age in both species and may have contributed to the changes in sensitivity between hatching and fledging. It was also noted that fledgling starlings (19 days) were about three to four times more sensitive than adults to turbufos and diazinon.

4.6.3 Herring Gulls and Black Guillemots

Nestling birds are quite sensitive to exposure of petroleum hydrocarbons containing an aromatic fraction. For example, a single small oral dose of Kuwait Crude Oil (KCO) or South Louisiana Crude Oil (SLCO) at approximately 0.3 mL/kg body weight caused reduced growth, osmoregulatory impairment, and hypertrophy of hepatic, adrenal, and nasal gland tissue in herring gull nestlings living in a simulated marine environment.⁹⁷ Weathered SLCO caused similar effects in black guillemot (*Cephus grylle*) nestlings in nature.⁹⁸ This suggests that ingestion of oil by nestlings could reduce a fledgling's ability to survive at sea.

Another example is a series of studies with herring gull chicks designed to examine the relationship between dose, tissue level, and response to lead.^{99,100} These studies showed that lead affected neurobehavioral development at critical periods. Seventy-two 1-day-old herring gull chicks were randomly assigned to six treatment groups to receive a lead nitrate concentration of 100 µg/g at age 2 days or at age 6 days, a similar cumulative dose evenly divided on days 2, 4, and 6, or matched-volume saline injections on the same days. Behavioral tests were performed (some at 2- and others at 5-day intervals) to examine locomotion, balance, righting response, thermoregulation, and visual cliff. Overall, the data showed that the lead-6 group was more affected by the dose than the other groups, suggesting that 6 days of age may be a more critical period than earlier ages for some behaviors.

The same researchers also examined the effects of chromium and manganese on early neurobehavioral development in herring gulls.¹⁰¹ Each of 36 two-day-old herring gull chicks was randomly assigned to one of three treatment groups to receive chromium nitrate (50 mg/kg), manganese acetate (50 mg/kg), or a control dose of sterile saline solution. Behavioral tests examined food begging, balance, locomotion, righting response, recognition, thermoregulation, and perception. There were significant differences in begging behavior by 5 days postinjection, and there were significant differences in weight gain throughout development until 50 days of age, when the experiment was terminated. Behavioral tests, administered from 18 to 48 days postinjection, indicated differences between control and the exposed groups for time to right themselves; thermoregulation behavior; and performance on a balance beam, inclined plane, actual cliff, and visual cliff. Of the 14 behavioral measures with significant differences, control birds performed best on 12.

4.6.4 Great Egrets

The effects of mercury were studied on captive great egret nestlings, which were either maintained as controls or were dosed from 8 days of age for 13 weeks with 0.5 or 5 mg methylmercury chloride/kg wet weight in fish.¹⁰² Low-dosed birds were given methylmercury at concentrations comparable to exposure of wild birds in the Florida Everglades. Subacute toxicity was indicated for birds dosed with 5 mg/kg after 9 weeks. Growing feather concentrations of mercury were closely correlated with cumulative mercury consumed per unit of body weight. After 8 weeks of exposure, appetite and weight index (weight/bill length) declined significantly in the high-dose group, with the same response noted a week later in the low-dose group.

Other effects indicative of mercury toxicity in low-dosed birds included lower packed cell volumes, dingy feathers, increased lymphocytic cuffing in a skin test, increased bone marrow cellularity, decreased bursal wall thickness, decreased thymic lobule size, fewer lymphoid aggregates in lung, increased perivascular edema in lung, and decreased phagocytized carbon in lung.¹⁰³ High-dosed birds became severely ataxic and had severe hematologic, neurologic, and histologic changes. The most severe lesions were in immune- and nervous-system tissues. Manifestations of oxidative stress and elevated plasma enzyme activities were also apparent.¹⁰⁴ Comparison of responses in captive and wild birds indicated that sublethal effects of mercury occurred at lower levels in captive than in wild birds. This may be due to the reduced sources of variation characteristic of the highly controlled laboratory study. Conversely, thresholds for more severe changes (death, disease) occurred at lower concentrations in wild birds than in captive birds, possibly because wild birds were exposed to multiple stressors. Thus, caution should be used in applying lowest observed effect levels between captive and wild studies.

As an integral part of the above study, behavioral effects, including activity levels, maintenance behavior, and hunting behavior, were measured.¹⁰⁵ Mercury affected activity and maintenance behavior. Birds dosed with 5 mg/kg in fish (as above) became severely ataxic (lost muscle coordination) and were euthanized by 12 weeks of age. The low-dosed birds exhibited less tendency to hunt fish. Therefore, even at 0.5 mg/kg mercury concentration in the food there were significant effects of methylmercury on activity, tendency to seek shade, and motivation to hunt prey.

4.7 AVIAN TERRESTRIAL FIELD STUDIES

In the United States the EPA no longer requires terrestrial field studies for pesticide registration except under extremely compelling circumstances; however, protocols are available for limited testing or if the requirements are reinstated (Table 4.1). In place of the field study the U.S. EPA's ecological risk-assessment process uses laboratory toxicity data in quotient indices to characterize risks to wildlife. However, these data sometimes fall short of predicting actual field effects.^{106,107} For example, laboratory and field results of the toxicity of azinphos-methyl were compared with northern bobwhite.¹⁰⁶ Chick survival, brain cholinesterase activity, and growth in the field exposure study were significantly different from equivalent exposures in the laboratory, and temporal patterns of effects differed between field and laboratory. It was concluded that the effects observed in the field differed from that predicted by risk quotients because the quotient method did not consider alternate routes of exposure, behavioral responses, influence of spatial and temporal environmental variability, or indirect effects.

Avian die-offs due to anticholinesterase insecticide exposure include incidents varying from small-scale poisonings of only a few birds in a barnyard or on a golf course to massive die-offs with at least several hundred colonial breeding birds or migrants.¹⁵ The dimension of this problem is indicated by a review of raptor mortality in the United States, the United Kingdom, and Canada for the period 1985 to 1995; of 520 incidents evaluated, the largest number of poisonings were attributed to anticholinesterase pesticides.¹⁸ Anticholinesterase poisonings have also involved many other species, ranging in size and diversity from American robins and warblers (*Vermivora* spp.) to Canada geese and great blue herons (*Ardea herodias*).²⁹ Most of these were highly visible situations, and undoubtedly there are a multitude of undetected incidents for every one discovered. In a recent review on factors influencing estimation of pesticide-related wildlife mortality, it was concluded that most effects on wildlife are not observed, much of observed mortality is not reported, and the actual number of affected animals per mortality event typically exceeds the number recovered.¹⁰⁷ Therefore, larger-than-expected net losses could occur because of such cumulative events, but the real impact on bird populations is not known. Secondary poisoning of predatory birds and other carnivorous animals consuming prey poisoned by anticholinesterase pesticides is also an important contributing factor to wildlife mortality that had been generally disregarded prior to 1980.^{45,108-110}

4.7.1 Prerequisites for Testing

In assessing the need for required terrestrial field studies under FIFRA, the U.S. EPA considers the following prerequisites: (1) environmental concentration of the substance, which must exceed the lowest-effect level eliciting a biological response; (2) chemical properties of the pesticide (e.g., persistence, toxic metabolites and degradates, retention on food); (3) intended use pattern (areas and species likely to be exposed, treatment intervals); (4) margin between lowest-effects level and estimated environmental concentration; and (5) dose-response slopes in laboratory studies.^{34,111} Field studies are designed to evaluate survival and reproductive success of nontarget wildlife species under actual conditions of use of the pesticide. Potential outcomes of pesticides in field tests can include (1) direct poisoning by ingestion, dermal, or inhalation exposure; (2) sublethal effects indirectly causing death by reducing resistance to natural environmental stresses such as disease, weather, or predators; (3) altered behavior such as abandonment of nests or young and change in parental care; (4) habitat alteration that results in reduced food resources or greater vulnerability to predators; and (5) reduced productivity.

4.7.2 Types of Field Studies

Field studies consist of two types: (1) *screening field studies* to evaluate whether impacts are occurring and (2) *definitive field studies* to estimate the magnitude of the impact.¹¹¹ Generally,

species representative of areas where pesticide applications occur are utilized. In most instances screening studies monitor for overt signs of toxicity such as mortality or aberrant behavior and changes in biochemical and histological indicators of toxicity. Carcass searches, radiotelemetry, depression of cholinesterase in the event of anticholinesterase pesticide exposure, residue analysis, behavioral observations, and population parameters may all be components of screening field studies.

With definitive field studies, mark-recapture techniques and radiotelemetry are often used to monitor survival and behavior. Extensive monitoring of reproduction and survival of dependent young is often required. Active nests are periodically monitored at the study site for number of eggs laid, hatched, young fledged, and nest abandonment. Sometimes artificial nest structures are provided to increase nest sites. Incubation behavior and parental care are sometimes monitored. A further indicator of reproductive effects may include comparison of young-adult ratios between treated and untreated plots. A number of pesticide-related field studies using different resident avian species are summarized below.

4.7.2.1 Sage Grouse (*Centrocercus urophasianus*)

Avian studies have focused on a series of die-offs of sage grouse associated with increased agricultural applications of organophosphorus insecticides to irrigated meadows and cropland.¹¹² Sage grouse in Idaho were radio-tagged, and their brain cholinesterase activity was monitored over several seasons; nearly 20% of the birds died or were seriously affected by organophosphorus insecticides. Mortality was higher among juvenile grouse than adults. Since these studies deal with a species that is both vulnerable and nonmigratory (which provides ease of tracking), there is high probability that such studies will further elucidate the impact of pesticide usage on population dynamics. At present, sage grouse in several parts of the western United States are being considered for listing under the endangered Species Act.

4.7.2.2 Prairie Pothole Waterfowl Studies

The prairie potholes region of the northern plains of the United States and Canada provides breeding habitat for more than 50% of North American waterfowl production. Drainage of prairie wetlands for agricultural purposes has been intense; only 35% of the original wetland area remains.¹¹³ The potential for agricultural chemicals to enter the remaining wetlands and impact wildlife is substantial. Many of the most widely used organophosphorus and carbamate insecticides within the region have been found to be highly toxic to aquatic animals. Both direct (mortality and toxicity) and indirect (loss of invertebrate food items) effects were greater than expected when parathion or methyl parathion was applied by aircraft according to label instructions and county agent recommendations.¹¹³⁻¹¹⁵ The use of tank mixture combinations of insecticides and of herbicides during spraying further contributes to the toxicity. Of 16 widely used insecticides in North Dakota, nine were implicated in wildlife mortality. In addition, 13 of these were either highly toxic to aquatic invertebrates or vertebrates. Reduced availability of aquatic invertebrates as food for ducklings and egg-laying females affected waterfowl productivity.

4.7.2.3 Passerine Studies

Aerial spraying for western budworms (*Choristoneura occidentalis*) with relatively low volume trichlorfon and carbaryl in Montana forests did not alter the success of nests with eggs or young birds of various species.¹¹⁶ However, application rates for these two insecticides were lower than normal. In another study the effects of pesticides on mourning doves (*Zenaidura macroura*) nesting in orchards in southern Illinois were evaluated.¹¹⁷ The pesticides usually consisted of a combination of an insecticide and a fungicide and were sprayed at intervals of approximately 10 days from March through September. Most adult doves incubating eggs left during the actual spraying appli-

cation but all returned within 30 min. Nearly 90% of the nests that contained eggs during spraying were unsuccessful, with most failures occurring four or more days postspray, suggesting direct embryotoxicity from contact and penetration of pesticides on eggs.

Reproductive effects were assessed for multiple and varied organophosphorus and carbamate operational exposures on avian productivity.¹¹⁸ Nest, egg, and nestling daily survival rates (DSRs) were determined for northern mockingbirds (*Mimus polyglottos*), brown thrashers (*Toxostoma rufum*), and northern cardinals (*Cardinalis cardinalis*) nesting along edges of pecan orchards and row crops in southern Georgia (United States). Egg and nestling DSRs for all species combined were negatively correlated with exposure. Nestling growth was reduced with increasing exposure. Brain cholinesterase activities were age-dependent and substantiated adult, but not nestling, exposure. The authors concluded that increasing exposure to operational pesticide use may reduce songbird productivity.

Insecticide hazard to breeding birds in Christmas tree plantations in Quebec were assessed by examining potential deleterious effects of three insecticides (i.e., dimethoate, diazinon, and insecticidal soap) on American robins and song sparrows (*Melospiza melodia*).¹¹⁹ Cases of complete or partial mortality were recorded in nests. Abandonment of nests and egg infertility were ruled out as possible causes of mortality. No mortality was recorded for broods exposed to the insecticidal soap. The cases of total mortality observed in broods of both species exposed to dimethoate were similar to those recorded for control nests (18 and 25% vs. 14 and 21%, respectively). However, among robin and sparrow nestlings exposed to diazinon, about twice as many cases of total mortality (31 and 38%) were recorded than for the control nests. The authors concluded that American robin eggs are sensitive to diazinon and dimethoate, particularly when spraying is carried out early in the incubation stage. However, for song sparrows, it is mainly the nestlings that succumb after diazinon is sprayed on them or when dimethoate applications are made during incubation.

Organophosphorus insecticides were studied through examination of cholinesterase activity in tree swallows (*Tachycineta bicolor*) and eastern bluebirds (*Sialia sialis*) in apple orchards in Ontario, Canada treated with azinphos-methyl, diazinon, phosalone, or phosmet.¹²⁰ In nestlings, brain cholinesterase activities obtained postspray often fell below predicted activities calculated from control siblings. This trend was especially apparent in the younger nestlings, less than 6 days old. However, for bluebirds, the rate of increase of brain cholinesterase with age in nestlings from treated sites was lower than in nestlings from control sites. Results of depressed cholinesterase levels in tree swallows and eastern bluebirds inhabiting apple orchards were consistent with those in avian species in other orchard monitoring studies. However, there was no indication that organophosphorus exposure due to agricultural spraying in apple orchards adversely affected the survival of the birds monitored. Reproduction of tree swallows and eastern bluebirds was further assessed in pesticide-sprayed apple orchards in southern Ontario to evaluate egg fertility, clutch size, egg and chick survival, and pesticide exposure.¹²¹ In this study of cavity-nesting birds reproduction was compared for nest boxes in sprayed and nonsprayed apple orchards from 1988 through 1994. There was a significant increase in unhatched eggs in bluebirds, as organochlorine levels increased in eggs. There were significant associations between toxicity scores of current-use pesticides and at least one avian reproductive parameter in every year of the study, but the reduction in reproductive rates associated with pesticides did not exceed 14%, for either species, in any year. Reduced reproduction occurred in six years for tree swallows, but for bluebirds this occurred in only four years.

Increased spray drift was suspected to be a factor of potential concern experienced by nestling and adult great tits (*Parus major*).¹²² Nest boxes were placed in hedgerows bordering fields sprayed with pesticides (pirimicarb or dimethoate). One hedge was sprayed directly with pirimicarb to simulate maximum drift effect. Two hedges were left untreated to serve as control areas. Significant inhibition of blood plasma cholinesterase activity was detected within 24 h in adult birds exposed to drift of dimethoate and in adult birds from the hedge sprayed directly with pirimicarb. Inhibition of nestling plasma cholinesterase activity was found in all treated hedges after 24 h. A tendency toward reductions in weight gain, though not significant, was found in nestlings both between 0

to 24 h and 24 to 48 h after treatment in all the treated hedges compared to nestlings from the control hedge.

Studies with European starlings have provided a valuable avian model for field testing because starlings readily occupy artificial nest boxes installed in test spray fields.^{95,123} Nest boxes provide a large synchronous breeding population of a passerine species at treatment sites. Starlings consume soil invertebrates, which come in direct contact with pesticides in the soil. Using this technique, the effects of application of methyl parathion at 1.4 kg active ingredient (a.i.)/ha. to a cultivated field were examined, and it was determined that there was depression of brain cholinesterase in adults and nestlings, and the number of nestlings fledging from treated fields was reduced compared with the control field.¹²⁴ In a similar study with the same insecticide control birds had over 50% successful nests, whereas those in a field treated with 2.5 kg a.i./ha. of methylparathion had only a 20% success rate; fledglings were found to be more susceptible to postfledgling mortality when nestlings from each field were radio-collared and followed for 2 weeks after leaving the nest.⁹⁶

4.8 AVIAN BEHAVIORAL TOXICITY TESTING

Behavioral aberrations in wildlife can be manifested at one or two orders of magnitude below lethal levels and therefore can be regarded as sensitive toxic-response indicators.²⁹ In the laboratory subtle alterations in behavior have been associated with exposure to toxic substances. Peakall¹²⁵ reviewed behavioral responses of birds to pesticides and other contaminants and concluded that certain operant tests are relatively simple and reproducible, but that other more complex tests, such as breeding behavior and prey capture, are probably more relevant to survival in the wild. In field studies the presence of interacting environmental factors, such as ambient temperature and weather conditions, complicate establishing a cause-and-effect relationship. The best-documented field cases of behavioral aberrations in wildlife include exposure of birds to anticholinesterase insecticides and of fish-eating birds in the lower Great Lakes to organochlorines. Both of these classes of chemicals have affected reproduction by causing decreased nest attentiveness.¹²⁶⁻¹²⁸

Laboratory and pen studies have documented changes in mallard hen and brood behaviors in response to anticholinesterase pesticides. Methyl parathion caused broods to mostly preen and loaf on land, while control broods primarily fed and swam in open water.¹²⁹ Methyl parathion also affected incubation behavior, causing nest abandonment and decreased nest attentiveness.⁷⁰ Several other studies have demonstrated increased vulnerability of birds, including sharp-tailed grouse (*Tympanuchus phasianellus*), northern bobwhite, and European starlings, to predation following organophosphorus insecticide exposure and field release^{130,131} or increased susceptibility to experimental predation by a domestic cat.¹³² Evidence has also been developed indicating that migratory orientation may be affected in captured migratory white-throated sparrows (*Zonotrichia albicollis*) exposed to dietary acephate for 14 days.¹³³ Adult sparrows did not establish a preferred orientation, but juveniles displayed a seasonally correct southward migratory orientation. It was hypothesized that acephate produced aberrant migratory behavior by affecting the memory of the migratory route and wintering ground.

Two laboratory tests of natural behavior that may be performed on the same subject consist of response of newly hatched precocial birds to the maternal call (measured time a chick takes to approach a recorded call) and avoidance of a fright stimulus. Both tests are conducted in partitioned runways, permitting several chicks to be tested simultaneously with recorded responses. These tests showed that mallard ducklings from parents fed as little as 0.5 ppm methylmercury were less responsive to maternal calls and more responsive to a fright stimulus than were controls.¹³⁴ In another study opposite responses were observed for ducklings whose parents were fed 3 ppm DDE.¹³⁵ In a test of a carbamate insecticide, decreased duckling approach-response behavior was decreased following exposure to carbofuran-sprayed vegetation.¹³⁶

Tests of learning ability based on operant conditioning appear to be sensitive indicators of toxicant-induced effects in birds. Recent hatchlings are fed low dietary concentrations of toxicant for several months and are then trained via hunger motivation to peck a lighted key in the conditioning box for a food reward. After the correct pattern is learned, the pattern is reversed or changed, and the ability to adjust is measured. This technique has been applied to test responses at dietary concentrations of less than 1.0 ppm endrin, 10 ppm toxaphene, and up to 100 ppm paraquat in northern bobwhite.^{137,138} Learning impairment was caused by endrin and toxaphene, but not by paraquat.

4.8.1 Time-Activity Budgets

Time-activity budgets are important aspects of behavioral ecology that aid in understanding habitat utilization and energy consumption. Such measurements were used effectively in evaluation of the hazards to mallard ducklings of toxic drainwater components and lead-contaminated sediments. In one study environmentally reasonable concentrations of either boron or arsenic in the diet affected the activity schedules of developing ducklings, including increased time at rest and selection of supplementary warmth, with less time in alert behavior and in the water compared to controls.¹³⁹ In another study the incidence and duration of ten behaviors (resting, standing, moving, drinking, dabbling, feeding, pecking, preening, bathing, and swimming) were recorded. Consumption of diets containing 12 or 24% lead-contaminated sediment (3449 ug/g lead) affected the proportion of time spent swimming but did not affect any of the other recorded behaviors.¹⁴⁰ However, there were signs of impaired balance and mobility and effects on the brain due to lead accumulation (e.g., oxidative stress, altered metabolites, and decreased brain weights).¹⁴¹

The behavior of captive great egret nestlings was evaluated in a study of methylmercury.¹⁰⁵ Birds were randomly divided into a control group and groups that received 0.5 or 5 mg methylmercury chloride per kg of food between 12 and 105 days of age. Activity levels, maintenance behavior, and foraging efficiency were studied. During the postfledging period there were no differences between low-dosed and control birds in time required to capture live fish in pools or in efficiency of capture. However, the methylmercury affected their activity, tendency to seek shade, and motivation to hunt prey. Alterations in the allocation of energy in developing ducklings and egret chicks as seen above would have obvious drawbacks in the natural environment including avoidance of predators and foraging strategies. Birds dosed with 5 mg/kg became severely ataxic and were euthanized by 12 weeks of age.

4.8.2 Critical Periods of Development

The temporal effects of lead were evaluated on developing herring gull chicks.^{99,100} In these studies, 1-day-old gull chicks were placed into treatment groups to receive a lead acetate dose on day 2 (50 or 100 µg/g), on day 6 (100 µg/g), or on day 12 (50 or 100 µg/g); controls received saline injections on the same days. Behavioral tests were performed at 2- to 5-day intervals to examine locomotion, balance, righting response, thermoregulation, and visual cliff. Flight behavior was examined at fledging. Righting response and balance were disrupted immediately after exposure, regardless of the timing of exposure. Thermoregulatory, visual cliff, and individual recognition behavior were more affected by exposure at 2 to 6 days, and there was little effect with exposure at 12 days. Overall, the data showed that treatment at 6 days of age may be a more critical period than earlier ages for some behaviors. However, chicks treated with single doses of lead acetate solution (100 mg/kg) at day 2 experienced disrupted sibling recognition through fledging at 26 days of age. In nature lead-impaired chicks might be unable to use siblings as a cue to find their nests and could experience higher mortality from territorial adults and chicks as well as from cannibalistic adults. Feathers of some roseate terns (*Sterna dougallii*), herring gulls, and black

skimmers (*Rynchops niger*) contain lead in concentrations that have been experimentally correlated with behavioral impairment and growth retardation.

4.8.3 Food Discrimination and Feeding Behavior

Behavior studies have demonstrated the effects of contaminants on food discrimination.¹⁴²⁻¹⁴⁶ Procedures for evaluating the potential ability of birds to avoid chemically contaminated food have been published.¹⁴⁴⁻¹⁴⁶ The discrimination threshold is defined as the dietary concentration above which test animals will decrease the proportion of treated food they consume if alternative untreated foods are available. The field conditions under which wildlife species could utilize the ability to detect and avoid toxic foods are largely unknown. However, when alternative food choices exist, vulnerability to poisoning in northern bobwhite chicks by organophosphorus and carbamate insecticides can be reduced by the number and relative abundance of choices as well as by the bird's ability to detect the chemical.¹⁴⁶

Low-grade exposure to organophosphorus insecticides may produce long-term changes in bird feeding behavior.¹⁴⁷ This was demonstrated through tests for conditioned taste aversion in a series of field experiments in which independent replicates were large numbers of breeding territories of red-winged blackbirds. Birds freely consumed untreated insect prey offered to them in control territories, but those in treated territories consumed up to three meals of prey tainted with parathion and then avoided offered prey in the treated territories long after parathion tainted prey were no longer present. This long-term change in feeding behavior was produced by organophosphorus in amounts insufficient to induce signs of toxicity or to depress brain cholinesterase activity. The effect was long-term because, unlike noxious repellency, conditioned taste aversion induced by trivial amounts of parathion denied birds the opportunity to discriminate between tainted and untainted prey. Although birds may be spared repeated exposure to the toxic substance, continued avoidance of untainted prey disrupts foraging, endangers breeding efficiency, and reduces predation upon pest insects.

Other behavioral studies have been conducted for assessing and reducing avian risk from granular pesticides. The extant information regarding bird response to grit and granule characteristics (i.e., granule carrier type, color, size, shape, and surface texture) and pesticide load per granule has been summarized.⁵² When the efficacy of eight taste repellents for deterring the consumption of granular insecticides in northern bobwhite was evaluated, the most effective were d-pulegone and quinine hydrochloride.⁵³ The authors concluded that treating pesticide granules with a potent taste repellent, such as d-pulegone, is a promising approach to reduce the risk of their ingestion by birds.

4.9 MAMMALIAN WILDLIFE TOXICITY TESTING

Fewer laboratory studies have been conducted with mammalian than avian wildlife, most likely due to the fact that the human health effects literature and agricultural nutrition literature is abundant with studies conducted with laboratory rodents as well as other species of domestic mammals that are viewed by some as surrogate species for mammalian wildlife.

Toxicity testing with mammalian wildlife for regulatory purposes has been limited in scope and requirement compared to avian wildlife toxicity testing (Table 4.1). Much of the U.S. EPA's FIFRA mammalian toxicity data is derived from routine studies with the laboratory rat (*Rattus norvegicus*) for pesticide registration. However, if the margin of safety appears small, or if the likelihood is high that specific mammals of concern will be exposed, then additional and more ecologically relevant tests may be required. This next level of testing requires a dietary LC₅₀ study or acute oral LD₅₀ study with a nonendangered and representative species that is likely to be exposed (e.g., microtine rodent). Occasionally, other reproductive and secondary toxicity tests are mandated.

The U.S. EPA has been encouraged to expand its required mammalian studies to include a wild herbivore test species (a microtine rodent such as the meadow vole, *Microtus pennsylvanicus*), an omnivore (the deer mouse, *Peromyscus maniculatus*), and a carnivore (the mink, *Mustela vison*, or european ferret, *Mustela putorius furo*), as recommended by Ringer.¹⁴⁸ The mink may be a preferred carnivore because it (1) is indigenous to North America, (2) can be reared in the laboratory, (3) has a large biological database, and (4) is among, if not is, the mammalian species most sensitive to PCBs, PBBs, hexachlorobenzene, TCDD, and aflatoxins.^{149–155} However, it has been argued that the mink is no more sensitive than laboratory rodents to many other chemicals including DDT, dieldrin, and *o*-cresol.^{148,155–157} The use of wild mammals has also been proposed for setting water quality criteria for those species that consume aquatic life including the mink as a piscivorous species, the northern short-tailed shrew (*Blarina brevicauda*) as an insectivorous consumer of aquatic invertebrates, and the deer mouse as an omnivorous species.¹⁵⁸

Three published protocols describe guidelines for testing mink and European ferrets for conducting dietary LC₅₀ and reproductive toxicity tests and for assessing the primary vs. secondary toxicity of test substances.¹⁵⁶ For the LC₅₀ test, the dietary exposure period is 28 days, over which signs of toxicity and mortality are recorded. The reproductive protocol is designed to evaluate dietary exposure prior to and during the breeding period and through gestation and lactation. The main endpoints include adult survival, oogenesis and spermatogenesis, reproductive indices, embryo and fetal development, and offspring growth and survival. The third protocol compares the dietary toxicity and lethality for the parent compound of a test substance (primary toxicity test) with the same substance fed at identical concentrations but contained in animal tissue (prey) contaminated by previous exposure (secondary toxicity test). Secondary toxicity testing of Aroclor 1254 revealed enhanced toxicity of the metabolized form in mink.¹⁵⁹ PCB levels in wild mink on Lake Ontario are similar to those reported to cause reproductive problems in controlled-feeding studies, and correlations between organochlorine levels in fish and levels in mink and otter (*Lutra canadensis*) are apparent.^{149–160}

In a comparative toxicity study of potential mammalian models, LD₅₀ and 5-day LC₅₀ tests were conducted in the same laboratory. The laboratory mouse (*Mus musculus*), the meadow vole, and the white-footed mouse (*Peromyscus leucopus*) were equally sensitive to the organophosphorus insecticide acephate.¹⁶¹ A database of tests conducted at a single laboratory has been developed for acute oral toxicities of 933 chemicals to deer mice and house mice.¹⁶² These were first-line screening tests for discovery of potential economic poisons for use in invertebrate pest control; the authors did not test for, nor offer any opinion on, which species was the best model for regulatory purposes. In one effort to reconcile the need for wild mammal testing the U.S. EPA sponsored a study comparing oral LD₅₀ and 30-day dietary LC₅₀ tests with four members of the genus *Microtus*.¹⁶³ The results were compared with published values for standard tests of laboratory rats and mice. Though the comparison was limited to ten widely different pesticides, the authors concluded that laboratory rodents were generally more sensitive than voles to the compounds tested.¹⁶³

Factors such as food and habitat preference may affect routes and degree of exposure in the field, thereby rendering some species of wild rodents ecologically more vulnerable to certain contaminants. In studies with microtine rodents aversion to carbofuran-treated feed was associated with delays in the time to first breeding, whereas a female-biased sex ratio in offspring of breeding pairs receiving paraquat in the diet was apparent.¹⁶⁴ White-footed mice exposed to PCBs in the diet at 10 ppm through the second generation exhibited poor reproductive success in comparison with second generation controls and the parental generation. PCB-treated young were significantly smaller at 4, 8, and 12 weeks of age.¹⁶⁵ Other studies have suggested inhibition of reproduction and changes in liver, spleen, adrenal, and testis function at a PCB-contaminated field site for this species.¹⁶⁶ Experimental feeding studies with lead have revealed mortality and impaired postnatal growth in young bank voles (*Clethrionomys glareolus*) when their mothers received lead-contaminated food after giving birth.¹⁶⁷ Though wild mammals have not been used extensively in laboratory studies with environmental contaminants, they have been used as monitors of environmental contaminants in nature, especially in studies of metals, organics, or radionuclides.^{168–170}

In other situations studies have been conducted with unique species of wild mammals with varied sensitivities to certain classes of contaminants.¹⁷¹ A review of the recent book *Ecotoxicology of Wild Mammals* by Shore and Rattner¹⁷¹ clearly indicates the need for more controlled comparative laboratory studies with unique wild mammals. For example, much of the ecotoxicological research of contaminant effects on insectivorous mammals has focused on terrestrial shrews, but little is known about contaminant effects on water shrews, moles, or hedgehogs.¹⁷² Fish-eating marine mammals, including seals, occupy high trophic levels in the aquatic food chain and accumulate high levels of contaminants including polychlorinated biphenyls, polychlorinated dibenzo-p-dioxins, and polychlorinated dibenzofurans. Such chemicals have been found to be immunotoxic at low doses in studies with laboratory mammals and mink. Recent associations have been established between such contaminants and effects on the immune system, e.g., increased incidence of disease was noted for certain free-ranging seal population; laboratory studies with captive harbor seals have confirmed these findings.¹⁷³ On the basis of these and other studies it was concluded that complex mixtures of environmental contaminants may represent a real immunotoxic risk to free-ranging marine mammals in many areas of Europe and North America.¹⁷³

4.10 AMPHIBIAN AND REPTILE TOXICITY TESTING

Over the past decade widespread population declines of amphibians have been documented in North America, Europe, Australia, and Central and South America. Population declines in eastern Europe, Asia, and Africa have also been suggested but are not as well documented.¹⁷⁴⁻¹⁷⁷ Contaminants may be involved with amphibian population declines including their possible interaction with other factors, as discussed in Chapter 40 of this book and in a thorough review of the literature as provided in the recent book, *Ecotoxicology of Amphibians and Reptiles*, by Sparling, Linder, and Bishop.¹⁷⁷ In the past it was presumed that tests conducted on fish, birds, and mammals would be sufficiently conservative to protect amphibians and reptiles. This concept can no longer be supported. Comparative toxicities of organic compounds and metals between amphibians and fish have been summarized for a standard embryo larval test (exposure from fertilization through 4 days posthatching).¹⁷⁸

Fish species commonly used in toxicity tests, such as the rainbow trout (*Oncorhynchus mykiss*), fathead minnow (*Pimephales promelas*), and largemouth bass (*Micropterus salmoides*), were used for comparisons that were standardized as much as possible including comparable life stages, water chemistry, and durations. These tests included 28 species of native amphibians from the families of Ambystomatidae, Microhylidae, Hylidae, Ranidae, and Bufonidae and the African clawed frog (*Xenopus laevis*). Median lethal toxicity values for metals in amphibians varied by 100-fold. In all, 50 metals and inorganics as well as 13 organic compounds were tested, for a total of 694 comparisons of amphibians and fish. In summary, amphibians had lower LC₅₀ values than fish in: (1) 64% of all the tests, (2) 74% of the comparisons among the 15 most sensitive amphibian species and fishes, (3) 80% of the comparisons involving amphibians and warm-water fishes, (4) 66% of the 13 most metal-sensitive amphibians and rainbow trout, and (5) 74% of all amphibian species vs. the fathead minnow. The overall conclusions were that there was great variation among amphibian species in their sensitivity to metal and organic contaminants, that amphibians generally were more sensitive than fish, and that water quality criteria established for fish may not be protective of amphibians.

The U.S. EPA drafted a guideline (draft revised FIFRA Guidelines Document-Subdivision E, March 1988) with several acceptable protocols for preregistration testing of chemicals for acute lethal toxicity to amphibians and reptiles.^{179,180} The provisional species of choice are frog tadpoles (*Rana spp.*) and adult green anole lizards (*Anolis carolinensis*). There is also a U.S. EPA testing guideline for a "tadpole/sediment subchronic toxicity test" under aquatic testing guidelines of the series "850-Ecological Effects Test Guidelines." This guideline is used to develop data on the subchronic toxicity of chemical substances and mixtures of chemicals sorbed to natural sediments to bullfrog tadpoles. Here, test chambers are filled with appropriate volumes of dilution water (control) or

appropriate amounts of contaminated natural sediments and dilution water. If a flow-through test is performed, the flow of dilution water through each chamber is adjusted to the rate desired. This toxicity test may be performed by either of two methods: (1) dosing the tadpoles orally with a sediment/test substance slurry and maintaining tadpoles in test chambers with only clean dilution water for 30 days or (2) maintaining tadpoles in test chambers containing contaminated sediments and allowing tadpoles to ingest the contaminated sediments. Concentration-response curves and LC₅₀, EC₅₀, LOEC, and NOEC values for the test substance are developed from survival and growth responses. Any abnormal behavior (e.g., erratic swimming, loss of reflex, increased excitability, lethargy) and any changes in appearance or physiology such as discoloration (e.g., reddened leg, excessive mucus production, opaque eyes, curved spine, or hemorrhaging) are also evaluated.

As mentioned in Section 4.1 of this chapter, the U.S. EPA is implementing an Endocrine Disruptor Screening Program that includes several amphibian-based ecotoxicological screens and tests for identifying and characterizing endocrine effects of pesticides, industrial chemicals, and environmental contaminants. These include a “frog metamorphosis assay” and an “amphibian life cycle reproductive toxicity study with endocrine endpoints.”

A strategy for protection of herpetofauna has been developed.¹⁸¹ Rather inclusive recommendations include: (1) research should examine the relative sensitivity of major groups of amphibians and reptiles to major classes of environmental contaminants to detect possible inherent (taxonomic) variability in response; (2) chemicals with selective toxicity should be examined first, permitting comparison of data from aquatic and terrestrial tests; (3) a variety of *in vitro* procedures, such as effects in embryos or larvae, may reduce cost and time; and (4) laboratory investigation should provide a guide, but should not obviate the need, for well-designed field tests and postregistration vigilance by field biologists.

A summary of acute toxicity to amphibians of more than 200 different contaminants and field studies of over 50 contaminants indicated that neither test species nor protocols were standardized.¹⁸² A searchable database — RATL (Reptile and Amphibian Toxicology Literature, http://www.cws-scf.ec.gc.ca/nwrc/ratl/index_e.htm) — for published ecotoxicological data from studies with amphibians and reptiles has been created by the Canadian Wildlife Service. Currently, there are approximately 2000 references in this database for approximately 6200 contaminant-related studies, divided almost equally between reptiles and amphibians. Approximately 650 different species are included in the database.

Deformities in tadpoles have been studied as a possible sensitive indicator of environmental contaminants; multiple causes and types of deformities in amphibians have been reviewed.¹⁸³ Caged tadpoles in water receiving runoff or spray drift from agricultural fields has been used to identify potential hazard.¹⁸⁴ A standard test (FETAX, Frog Embryo Teratogenesis Assay: *Xenopus*) has been developed with embryos of the clawed frog (*Xenopus laevis*) as an assay for teratogenicity of chemicals and mixtures of contaminants.¹⁸⁵ Under the auspices of the ASTM, a comprehensive guideline for FETAX was published in 1991 and updated in 1998 [“Standard Guide for Conducting the Frog Embryo Teratogenesis Assay-*Xenopus* (FETAX),” Annual Book of ASTM Standards, Designation E143998]. The similarity of response to dieldrin between *Xenopus laevis* and two ranid species in a study conducted by the U.S. EPA supports the utility of this species.¹⁸⁶ Results with nine combinations of developmental toxicants have indicated that FETAX is useful for hazard assessment of mixture toxicity and of sediment extracts.¹⁸⁷

Short-term toxicity tests with *Xenopus laevis* and *Rana pipiens* were conducted with a 96-hour modified FETAX to assess paraquat toxicity.¹⁸⁸ The commercial formulation was three times as acutely toxic as the technical-grade chemical, and the 96-hour LC₅₀ of either form at least sixfold lower for *Rana pipiens* than *Xenopus laevis*. In another comparative study the embryotoxicity of the nonionic surfactant nonylphenol ethoxylate was determined in *Xenopus laevis* and the Australian frogs *Litoria adelaidensis* and *Crinia insignifera* using the FETAX protocol.¹⁸⁹ Growth inhibition as assessed by embryo length was the most sensitive indicator of effect in all three species. *Xenopus laevis* was the most sensitive of the three species and the only species that displayed indisputable

terata. Integrated field and laboratory studies have been used for evaluating amphibian responses in wetlands impacted by mining activities in the western United States, where FETAX was conducted in the lab and *in situ* in the field using the bullfrog.¹⁹⁰

For reptiles, a considerable portion of the published toxicological research has focused on turtles, especially snapping turtles (*Chelydra serpentina*) and sea turtles.¹⁹¹ Focus on these groups may be justified in part because snapping turtles are large, long-lived omnivores that live intimately with aquatic sediments and thus are considered excellent bioindicators of wetland conditions, whereas many species of sea turtles are rare or endangered. Snapping turtles have been used as monitors of environmental contaminants including use in tidal wetlands, freshwater ponds, rivers, and lakes.^{192–194} Contaminant-related DNA damage was detected in snapping turtles and in sliders (*Pseudemys scripta*).^{192,194} Higher rates of deformities and unhatched eggs were related to PCB exposure of snapping turtle in highly contaminated areas of the Great Lakes.^{193,195} Reptiles in general, and snakes and lizards in particular, are important although often neglected components of terrestrial and aquatic ecosystems and should be included in studies of environmental contamination.¹⁹⁶

Accumulation and effects of environmental contaminants on snakes and lizards have been comprehensively reviewed.^{197, 198} Since all snakes are secondary, tertiary, and top predators, they are especially subject to the bioaccumulation of environmental contaminants. Their unique life histories make their roles in food webs diverse and important, and they are crucial to the proper functioning of many ecological processes. Lizards may also be excellent bioindicators of contamination.¹⁹⁸ Lizards are a significant part of many ecosystems as well as an important link in many food chains. There are large gaps in data for many environmental contaminants on lizards. Ecotoxicological studies on a wide variety of lizard species are needed; both laboratory and field studies would provide useful information. Because the majority of lizards are insectivores, studies of the effects and accumulation of pesticides are essential. Furthermore, many species are listed as threatened or endangered in the United States.

Reptiles, including turtles and alligators, have been studied for evidence of contaminant-related endocrine disruption, as discussed in Chapter 39 of this book and elsewhere.^{195,199}

4.11 SUMMARY

Wildlife toxicology is the study of potentially harmful effects of toxic agents on wild animals. Wildlife toxicology endeavors to predict the effects of toxic agents on nontarget wildlife species and, ultimately, populations in natural environments. Avian toxicity testing protocols were first utilized by the U.S. Fish and Wildlife Service as a consequence of wildlife losses in the 1950s due to the increased use of DDT and other pesticides. The first testing protocols focused on single-dose acute oral toxicities with lethality as the major endpoint. Further protocol development resulted in subacute 5-day dietary tests. These, along with the single acute oral dose tests, are currently required by the U.S. Environmental Protection Agency in support of pesticide registration. The avian subchronic dietary toxicity test was developed as an extension of the subacute test as a precursor to full-scale reproductive studies, but it is not routinely required for regulatory purposes. Subchronic testing has been applied to compare the sublethal effects of different forms of mercury, to study hepatotoxicity of organic selenium, to comparatively study contaminated sediment ingestion, and to study delayed neurotoxicity of certain organophosphorus insecticides. Avian chronic toxicity tests are designed with reproduction as the primary endpoint and are required for both waterfowl and upland gamebirds during chemical registration. Persistent chemicals, such as chlorinated hydrocarbons, require relatively long-term exposures (at least 10 weeks) in advance of breeding, whereas shorter-term exposures may be utilized for less persistent chemicals such as organophosphorus insecticides. The U.S. EPA is presently implementing an Endocrine Disruptor Screening Program (EDSP), which includes an avian two-generation test with Japanese quail with endocrine-specific endpoints in addition to conventional reproduction endpoints.

Single-dose avian embryotoxicity and teratogenicity tests were developed in part to assess the potential contaminant hazard of external exposure of bird eggs; tests with multiple species and chemicals have revealed differential toxicities of a spectrum of chemicals and sensitivities among species. Recent focus has included hazard evaluations of aquatic weed control, mosquito control, and wildfire control agents. Developmental toxicity testing has also focused on the vulnerability of “neonatal” nestling birds, including kestrels, starlings, red-winged blackbirds, great egrets, and gulls, to oral ingestion of environmental contaminants.

Avian terrestrial field studies are basically of two types: (1) screening studies to ascertain whether impacts are occurring, and (2) definitive studies to estimate the magnitude. These studies often require extensive monitoring of reproductive success and survival of young wherein active nests are periodically examined and mark-recapture techniques as well as radiotelemetry are used. Sometimes, artificial nest structures are provided in the vicinity of test-spray fields to increase nest density, and hence experimental sample size, for species such as American kestrels and European starlings. Avian terrestrial field studies have been successfully undertaken using diverse species, including northern bobwhite, sage grouse, waterfowl, and at least five different passerine species, during and following applications of agricultural pesticides.

Behavioral aberrations in wildlife can be manifested at one or two orders of magnitude below lethal levels of environmental contaminants. In birds, changes in nest attentiveness, brood behavior, and increased vulnerability to predation have been documented in field and pen studies. Response time to maternal call, avoidance of fright stimulus, and tests of operant learning ability as well as time-activity budgets, effects at critical periods of development, and altered food discrimination and feeding behavior have been successfully applied to laboratory studies.

Laboratory studies with environmental contaminants and mammalian wildlife have been limited compared to avian studies. This may be due to the fact that the human health effects and agricultural nutrition literature is abundant with studies conducted with laboratory rodents as well as other species of domestic mammals that are viewed as surrogate species for mammalian wildlife. Mammalian toxicity data of the U.S. EPA FIFRA has consisted largely of laboratory rat data for pesticide registration, whereas wildlife testing requires a dietary LC_{50} or acute oral LD_{50} study with a nonendangered representative species likely to be exposed, quite often a microtine rodent. Previous recommendations have included use of an omnivore, such as the deer mouse, and a carnivore, the mink, for which there is a large biological database for both laboratory and field studies. The use of wild mammals has also been proposed for setting water quality criteria for those species that consume aquatic life, including the mink as a piscivorous species, the northern short-tailed shrew as an insectivorous consumer of aquatic invertebrates, and the deer mouse as an omnivorous species. There are many unique species of wild mammals with varied sensitivities to certain classes of contaminants; controlled comparative laboratory studies are needed for many of these species.

Worldwide concern over declining populations of amphibians and reptiles has revealed that numerous taxa of amphibians and reptiles are endangered or threatened. Comparative toxicities of organic compounds and metals indicate a wide variation in sensitivity among amphibian species. Amphibians are generally more sensitive than fish, suggesting that water quality criteria established for fish may not be protective of amphibians. The U.S. EPA is developing guidelines for preregistration testing under FIFRA for acute lethal toxicity to amphibians and reptiles. Also, the U.S. EPA is implementing an Endocrine Disruptor Screening Program (EDSP), which includes several amphibian-based ecotoxicological screens and tests for identifying and characterizing endocrine effects of pesticides, industrial chemicals, and environmental contaminants. These include a “frog metamorphosis assay” and an “amphibian life cycle reproductive toxicity study with endocrine endpoints.”

Reptiles, which are critical components of many food chains, are often neglected in studies of terrestrial and aquatic contamination. A considerable portion of the toxicological research on reptiles has focused on turtles, especially snapping turtles and sea turtles. Snapping turtles live intimately with aquatic sediments and are considered excellent bioindicators of wetland conditions. Turtles and alligators are being studied for evidence of contaminant-related endocrine disruption. All snakes

are secondary, tertiary, and top predators and are susceptible to the bioaccumulation of environmental contaminants. Lizards provide important links in many food chains and are perhaps more influenced by contamination than previously believed.

5.1 WHY TEST SEDIMENTS?

5.1.1 The Source and Sink

The significant role that sediments play in aquatic ecosystems is well known.¹ They serve as both a sink and a source of organic and inorganic materials, where critical cycling processes for organic matter and the critical elements (e.g., C, N, P, and S). The majority of decomposition of allochthonous and autochthonous inputs occur in the sediment. Since most chemicals of anthropogenic origin (e.g., pesticides, polycyclic aromatic hydrocarbons (PAHs), and chlorinated hydrocarbons) tend to sorb to sediments and organic materials, they also end up concentrating in the sediment. Sediment contamination can have many detrimental effects on an ecosystem, some of which are evident and others more discrete or unknown. For example, benthic invertebrate communities can be totally lost or converted from sensitive to pollution-tolerant species. These tolerant species process a variety of materials, and their metabolic products may also be different. These differences mean that ecosystem functions, such as energy flow, productivity, and decomposition processes, may be significantly altered.²

Loss of any biological community in the ecosystem can indirectly affect other components of the system. For example, if the benthic community is significantly changed, nitrogen cycling may be altered such that forms of nitrogen necessary for key phytoplankton species are lost and the phytoplankton are replaced with blue-green algae (cyanobacteria) capable of nitrogen fixation. The production of neuro- and hepatotoxins by the blue-green algae may then affect herbivorous fish and consumers of the water such as cattle and humans.³ Other effects from sediment contamination are direct, as observed in the Great Lakes, where top predator fish have become highly contaminated from consuming bottom-feeding fish and benthic invertebrates that are laden with sediment-associated pollutants such as PAHs, PCB, mercury, and pesticides. Effects on ecosystem processes have been very dramatic in areas affected by both acid precipitation and acid mine drainage. However, in most areas receiving pollutant loadings the effects are difficult to observe and require use of a variety of assessment tools such as benthic macroinvertebrate community analyses, chemical testing, quantification of habitat characteristics, and toxicity testing (Figure 5.1).⁴

5.1.2 Regulatory Concerns

In 1998 the U.S. Environmental Protection Agency (EPA) released its Contaminated Sediment Management Strategy. This strategy shows how the EPA has authority under a variety of statutes to manage contaminated sediments (e.g., Comprehensive Environmental Response, Compensation and Liability Act, CERCLA; Clean Water Act, CWA; and Resource Conservation and Recovery Act, RCRA). Currently, the various EPA programs are defining the methods and policies they will utilize to manage this pervasive problem. One of the goals of the Strategy is to “develop scientifically sound sediment management tools for use in pollution prevention, source control, remediation, and dredged material management.”⁵

In support of this goal the EPA has developed standardized methods for collecting sediments as well as methods for conducting sediment toxicity tests for freshwater and marine/estuarine sediments. In 1994 the EPA released guidelines on evaluating acute sediment toxicity utilizing the marine and estuarine amphipods *Ampelisca abdita*, *Leptocheirus plumulosus*, *Rhepoxynius abronius*, and *Eohaustorius estuarius*.⁶ Also in 1994 the EPA released guidelines on evaluating acute

Figure 5.1 Relationship between need to integrate assessment components and degree of ecosystem contamination. (From Burton, G.A. et al., in *Hazard Assessment of Chemicals — Current Developments*, Taylor & Francis, London, 1993, 171. With permission.)

sediment toxicity utilizing the freshwater amphipod *Hyalella azteca* and the freshwater midge *Chironomus tentans*.⁷ In 2000 the EPA released guidelines on evaluating chronic sublethal sediment toxicity utilizing the freshwater amphipod *H. azteca* and the freshwater midge *C. tentans*.⁸ Both the EPA 1994 and 2000 freshwater sediment toxicity test methods manuals outline methods for measuring bioaccumulation in freshwater invertebrates using the oligochaete *Lumbriculus variegatus*. The EPA has recently released guidelines on evaluating chronic sublethal sediment toxicity utilizing the marine amphipod *L. plumulosus*.⁹

A variety of theoretical and empirical approaches have been used to create sediment quality guidelines in aquatic ecosystems.¹⁰ The empirical approach derives a sediment concentration of contaminants associated with toxic responses measured in laboratory exposures or in field assessments (i.e., Apparent Effects Threshold (AET), Effects Range Low and Medium (ERL/ERM), and Threshold and Probable Effects Levels (TEL/PEL). The EPA has used an equilibrium partitioning (EqP) approach (theoretical) to develop draft equilibrium partitioning sediment guidelines (ESGs). This approach focuses on predicting the chemical interaction among sediments, interstitial water, and the contaminants. EqP theory holds that a nonionic chemical in sediment partitions between sediment organic carbon, interstitial (pore) water, and benthic organisms.¹¹ At equilibrium, if the concentration in any one phase is known, then the concentration in the others can be predicted. Because the water quality criterion (WQC) is the concentration of a chemical in water that is protective of the presence of aquatic life and that is appropriate for benthic organisms, the product of the final (or secondary) chronic value (FCV or SCV) from the WQC and the organic carbon partition coefficient (K_{OC}) represents the concentration of a nonionic chemical in sediments that, on an organic carbon basis, is protective of benthic organisms.

EqP theory can also be used for a mixture of cationic metals.^{12,13} For mixtures of cadmium, copper, lead, nickel, silver, and zinc, if the sum of the molar concentrations of simultaneously extracted metals (SEM, the metal extracted in the AVS extraction procedure) is less than the molar

concentration of AVS, the sediments are predicted to be not toxic because of these metals. The use of $(SEM-AVS)/f_{OC}$ reduces variability associated with prediction of when sediments will be toxic.¹³ These draft guidelines do not account for interactive (synergistic, antagonistic) effects of all chemicals in sediment, aside from the chemical mixtures addressed by specific draft guidelines (e.g., cationic metals and PAHs). These draft guidelines do not account for bioaccumulation or food chain effects.

5.2 ASSESSMENT ISSUES AND CONCERNS

5.2.1 Physical, Chemical, and Biological Interactions: Maintaining Sediment Integrity

Sediments are a semisolid medium comprised of minerals, organic material, interstitial water, and a myriad of physicochemical and biological components, all structured into micro- to macro-environments, many of which are interlinked. At the microenvironment level are approximately one billion bacteria per gram of sediment that, over the space of millimeters, occupy critical niches for metabolizing—cycling specific organic compounds, organic acids, nitrogen, sulfur, methane, and hydrogen. These populations lie at different depths in the sediment — from the narrow oxidized layer at the surface where the redox potential is high to several milli- to centimeters in depth where redox potential is strongly negative. The metabolic by-products from one zone are energy sources for the adjacent microbiological zones. Two common by-products produced in sediments containing adequate concentrations of organic matter are ammonia and hydrogen sulfide, both highly toxic and produced by numerous aquatic microorganisms. Many freshwater sediments in areas where urban and industrial inputs or organic materials have occurred contain elevated levels of ammonia. The unionized form of ammonia, which predominates in slightly alkaline conditions, has been shown to be the most toxic form for coldwater fish; however, *H. azteca* is affected equally by total ammonia.¹⁴

Chemical partitioning to sediment and colloidal particles via adsorption and absorption is controlled to some extent by sediment temperature, interstitial spacing and contact between particles, and dissolved organic and inorganic compounds present in the interstitial water. The surface layers of sediments are normally oxidized over a depth of 1 to several mm. This oxidized layer serves as a barrier to the transport of dissolved and reduced inorganic complexes such as ferrous iron, where reduced species become oxidized and complex with other anions and cations.

Benthic macroinvertebrates, which are infaunal, burrow into the sediment's anoxic zones (down to several centimeters) and create oxidized conditions within their burrows (tubes). This process can alter their exposure to ionic species of contaminants and result in transport of contaminants to and from contaminated sediments (by bioturbation). Most of the sediment environment is anaerobic, where the most toxic and problematic reduced chemical species exist. Though benthic macrofauna are in close proximity to these reduced sediments, they require oxygen and circulate overlying dissolved oxygen into their microenvironment. Some species of chironomids (midges) and oligochaetes (aquatic worms) are very tolerant of low dissolved oxygen levels or short periods of anoxia.

Many northern temperate freshwater lake sediment environments remain at low temperatures throughout the year. This means that the microbiological community is basically a psychrophilic one, which metabolizes best at cold temperatures. Therefore, when sediment samples are stored at 4°C, as is recommended for toxicological testing,¹⁵ sediment metabolism does not stop but continues on at a rate reflective of the nutrient supply and the microenvironmental conditions.

In 2001 the EPA Office of Water released a guidance document on the collection, storage, and manipulation of sediments for toxicity and chemical testing.^{15a} The guidance builds on recent guidance from ASTM and Environment Canada.^{15,16} The guidance rarely dictates methods that *must* be followed, but rather makes recommendations as to those that *should* be followed. The lack of

definitive guidance is because the optimal method to follow often is a function of both the sediment's characteristics and the study objectives. In addition, the lack of comparative studies of various methods dictates that "best professional judgments" have been made to arrive at consensus on optimal methods. Some of the more common and contentious issues of sediment handling are discussed below.

5.2.2 Sample Alteration

5.2.2.1 Collection, Transport, and Storage

Sediment samples cannot be collected in the field, transported to the laboratory, stored, and then tested for toxicity without altering their original structure/characteristics due to disruption of their fragile integrity. Some methods of sample collection and testing are more disruptive than others. For example, dredge (grab) samplers (e.g., Ponar, Ekman, Van Veen, Shipek, or Peterson) are more disruptive than core samplers. A standard core sampler is more disruptive than a box core sampler, and box core samplers are more disruptive than *in situ* sampling, which requires no sediment extraction.¹⁷

When the sediment is collected, the sampler tends to disrupt and lose the surficial fine particle layer, which is the most biologically active component and may contain the highest concentration of contaminants. Dredge samplers have a greater tendency to lose surficial fines than core samplers. The Ekman is perhaps the least disruptive of the dredge samplers, but it cannot be used in deeper waters and consolidated sediments. The sides of the dredge or core sampler also destroy the stratified gradients that exist vertically in the sediment. In addition, the underlying anoxic layers are exposed to oxygen in the collection processes most commonly used. This exposure results in the conversion of reduced species to oxidized complexes within hours; these complexes are less available for biological uptake/effects.

Sediment transport and storage are often performed under an aerobic atmosphere, which intensifies oxidation at the "new" sediment surfaces in the sampling container. This is readily observed in sediment sample bottles with the reddish-brown coloration of oxidized iron on the bottle sides and sample surface. The underlying sediments will return to the anoxic state. There have been reports that contaminated sediment samples did not show significant changes in chemistry or toxicity after several months of storage at 4°C,¹⁸ while others have shown significant changes within days to weeks.^{19,20} It is likely that sediments primarily contaminated with nonpolar, nonvolatile organics will change little during storage, due to their relatively high resistance to biodegradation and sorption to solids. Metals and metalloids, however, are more likely to be affected by changing redox or oxidation reduction and microbial metabolism (such as with arsenic, selenium, mercury, lead, and tin, all of which are methylated by a number of bacteria and fungi). Metal-contaminated sediments should be tested relatively soon after collection with as little manipulation as possible.

5.2.2.2 Manipulation

When sediments are removed from sample containers for toxicity testing, they are typically either stirred first in the bottle or placed in another container for mixing. Some methods commonly follow the mixing with sieving to remove large debris and indigenous organisms that may interfere with the toxicity assay and to better homogenize the sediment sample. All of these processes result in the introduction of oxygen to anaerobic environments, complete disruption of redox and microbiological gradients/microenvironments, alteration of equilibrium conditions for chemicals associated with the interstitial water and sediment particles, and the introduction of new compounds (such as nitrogen species, oxyhydroxy-metal compounds) into the sample via desorption and oxidation processes.¹⁹ The microenvironments of microorganisms are usually quickly depleted of available nutrients due to the rapid sorption and metabolism of compounds by bacteria (occurring within

minutes to hours). The microbial community is an excellent early warning indicator of environmental conditions because of the ability to respond so quickly to the immediate environment. For instance, regulatory testing of fecal coliforms recommends that sample analysis begin within 6 h of collection because of the quickly changing microbial population. The varying levels of sediment disruption described above will result in the introduction of new microenvironments with new sources of nutrients, thereby increasing metabolism and production of by-products (e.g., ammonia). In addition, contaminants may become either more available (from desorption or chelation) or less available for biological uptake/effects (due to sorption, complexation, biodegradation, hydrolysis, or oxidation/reduction).

There are a number of reasons why testing the sediment's interstitial (pore) water is useful. This is perceived as being the primary route of exposure for many infaunal benthic invertebrates in contaminated sediments, although such may not be the case for those species that ingest sediments. The EPA EqP approach^{10,21} utilizes the interstitial water as the medium where sediment quality guidelines are applied and threshold effects equated to overlying water quality criteria. This fraction is simpler to test in many toxicity assays since test organism effects are easier to see and recover. It can also be used for assays that cannot be readily tested in solid-phase exposures, such as the algal growth assay with *S. capricornutum*.

There are a number of methods one may utilize to extract interstitial water¹⁵ including filtration, suction, centrifugation, and *in situ* sampling with "peepers" consisting of membrane bags or chambers.^{22,23} Of the laboratory methods used, the most commonly recommended is centrifugation (EPA in press).¹⁶ All of the laboratory methods alter interstitial water chemistry, but centrifugation has been shown to alter it the least.²⁴ With centrifugation, the force used is important, as small-sized clays and colloids that bind toxicants may not be removed easily. This makes it difficult to make interlaboratory comparisons if extraction methods are not similar. The pH of centrifuged interstitial water has been shown to increase slightly, which increases the fraction of unionized ammonia. Some laboratories have successfully used sediment presses whereby the interstitial water is forced out via a Teflon filter.

The most desired method is to extract the pore water *in situ*, since less sample manipulation occurs (EPA in press).²⁵ However, this is often difficult to accomplish and produces small quantities of water that may be inadequate for toxicity testing. In this approach, dialysis membrane bags of chambers with membrane walls are embedded in the sediment and allowed to equilibrate before the pore water is extracted either by bag or chamber removal or by suction of water through access ports on the chamber. Others have embedded air stones in the sediment attached to tubing and then withdrawn pore water with a suction syringe. The reader should refer to other reviews on interstitial water sampling for additional information (EPA, in press).^{15,17,22}

Testing of the elutriate (water-extractable) fraction of the sediment is a commonly used technique. It has the advantages noted for interstitial water, as the test method is similar to water-column testing and is easy to perform. Typically, sediments are mixed for 30 min in a 1:4 sediment:water ratio. They are allowed to settle for 1 h, and then the supernatant is withdrawn for testing (with or without subsequent filtration). This protocol was developed by the U.S. Army Corps of Engineers²⁶ to simulate dredging conditions and evaluate water quality effects during dredging operations. It is most appropriately used in dredged material evaluations. The elutriate fraction produces biological effects that are procedurally defined; if the method was modified, the responses would be different. It is obvious that the conditions used in the extraction process and assay are never identical to field conditions, so results must be extrapolated to the field with caution. Elutriate responses tend to be slightly less sensitive than exposures to solid-phase or interstitial water fractions.^{14,27} The strengths and weaknesses of elutriate, pore water, and solid-phase testing have been discussed previously.^{15,19}

Another manipulation of sediments occasionally employed is sediment dilution to obtain effect levels such as LC₅₀ or no observable effect concentrations (NOECs). There is no standard protocol, and methods have varied widely,^{15,19} including diluting the sediment with water, diluting sediment

with sand or reference sediment of a similar quality, or extracting the interstitial water or elutriate fraction and diluting it. Results have been inconclusive, and the optimal method is likely sediment specific. A key issue in sediment dilutions is the alteration of contaminant partitioning from the natural conditions and allowing equilibration to return. Introduction of new binding sites that may or may not be similar to site characteristics will influence bioavailability to varying degrees depending on the toxicant type and sediment characteristics. It would appear that dilutions with a nearby reference sediment with similar characteristics would be optimal. However, in this circumstance one must still allow an appropriate amount of time to pass after dilution for equilibration to occur between the contaminants and the reference sediment. These unknowns place sediment dilutions into the category of research. When used for regulatory purposes sediment dilution results should be used with caution.

A useful manipulation for identifying single chemical effect response patterns is spiking (dosing) of sediments with pure compounds. Here again there are no standard methods and few studies that have evaluated spiking methods.^{20,24} There are different approaches used for spiking metals and organics.¹⁵ Metals are usually dissolved in water and added to the sediment, which is mixed by rolling or shaking for minutes to hours. After an equilibration time (which varies widely), testing is initiated and samples are removed for toxicity testing and chemical analyses. With organics, the nonpolar compounds must be dissolved in a carrier (such as acetone) and inoculated into the sediment directly, or added to an empty container and allowed to dry to the wall of the container, with the carrier evaporating. Sediments are then added, followed by mixing. As discussed with sediment dilutions, equilibration time is an important issue for which no standard guidance exists. This may have a profound impact on the results of the toxicity test, as it will determine bioavailability and affect the accuracy of laboratory-to-field extrapolations. It is recommended that spiking studies include routine analysis of the spiked chemical in the overlying water, interstitial water, and bulk sediment to ascertain the degree of partitioning. In bioaccumulation studies tissue residues should be monitored at several points in time to determine when uptake plateaus.

5.2.2.3 Summary of Manipulation Effects

Unfortunately, when we collect and test sediments we know little more than the fact that changes are occurring in the sediment.²⁸ We have precious few data that quantify any of the multitudinous alterations occurring due to sample collection, handling, and manipulation. Therefore, one cannot predict if the effects will be of significant consequence to the study objectives. It may be that the alterations that occur do not significantly affect measurable toxicity. Given that the contaminants of concern and the influencing sediment characteristics are not always known *a priori*, it is recommended that toxicity testing commence soon after collection, not to exceed 2 weeks' storage at 4°C.¹⁵

5.2.2.4 Laboratory-to-Field Extrapolations of Toxicity Data

When toxicity assays are conducted in the laboratory one typically exposes organisms in a static, static-renewal, or flow-through system for 48 h to 10 days. The effect of the exposure system design on toxicity can be substantial, with dramatically differing results from the same contaminated sample. In solid-phase sediment assays flow-through tests that replace overlying water quickly may show fewer effects than systems in which overlying water is slowly replaced. "Static" toxicity assays, where waters are not renewed, are often considered a "worst-case" exposure, producing the most detrimental effects possible from the sample. However, this is not true in all situations. For example, if the sediments are calcareous, they will leach carbonates into the overlying water, thereby increasing hardness.²⁹ If the sediment contaminants are metals, metal toxicity may be reduced by the carbonates in the water column.

Given the above discussions on manipulation effects, it is obvious that laboratory results may not reflect *in situ* conditions, so there should always be some degree of field validation. Studies in the past decade have provided more information on the ecological relevancy of sediment toxicity testing. Ecological relevance can be evaluated in terms of the linkage between response endpoints and the ecological resources to be protected. Survival of amphipods exposed to field-collected sediments in 10- to 28-day toxicity tests has been correlated with abundance of amphipods, species richness, and other measures of community structure in the field. Also, growth of the amphipod *H. azteca* or the midge *C. tentans* has been correlated to measures of community structure.^{30–34} Burton et al.³⁴ compared results from laboratory sediment toxicity tests to colonization of artificial substrates exposed *in situ* to contaminated Great Lakes sediment. Survival and growth of *H. azteca* and *C. tentans* in laboratory exposures were negatively correlated to percent chironomids and percent taxa colonizing artificial substrates in the field. Schlekat et al.³⁵ also reported general good agreement between sediment toxicity tests with *H. azteca* and benthic community responses in the Anacostia River in Washington, D.C.

There may be concern over the use of surrogate species as indicators of indigenous species effects at the same or differing levels of biological organization. The EPA conducted several field validation studies of the toxicity assay approach in their Complex Effluent Testing Program during the 1980s.³⁶ The results supported those of many other investigators — that sensitive species and assays (such as the *C. dubia* 7-day survival-reproduction and the *P. promelas* 7-day early-life-stage assays) did show responses indicative of effects in resident fish and macroinvertebrate populations. The EPA³⁷ provides a comprehensive review of the reliability of single-species toxicity test results for predicting aquatic ecosystem impacts (e.g., ecological relevance of laboratory single-species toxicity tests). Others have shown the utility of toxicity assays as predictors of receiving water quality.³⁸ There have been other studies,³⁹ however, that have shown the opposite and point to the need for multiple assays and assessment of resident communities.

Grab samples provide a “snapshot” of *in situ* conditions. Contaminant concentrations, modifying ecosystem factors, and resident communities vary over space and time in aquatic ecosystems. Fortunately, the grab sample approach of monitoring has been effective in detecting contamination, though it is uncertain how frequently false negatives may have been produced in these monitoring studies. The “gray” zones of contamination (where significant effects are more difficult to discern) will require more intensive sampling than has often been utilized in routine assessment studies. Stemmer et al.⁴⁰ showed that sediment toxicity could vary from 0 to 100% mortality in samples collected centimeters apart, while particle size and water content of the samples were equal. One approach to dealing with spatial sediment variation is composite sampling. While this is better than collecting one grab, it serves to moderate high levels of contamination and may produce false negatives.

5.2.2.5 The Integrated Approach

For most sites containing contaminated sediments there is a zone of *significant* contamination and a zone of *insignificant* contamination (pollution). Determining the location of the boundary area (also known as the gray zone) requires the use of multiple assessment tools. Contaminant concentrations typically are highest in one localized area and decrease laterally in all directions. This zone can range in size from 1 m to several kilometers and vertically from centimeters in sediment depth to several meters.

Chapman and others^{41–44} have promoted the use of an integrated assessment approach that utilizes measures of chemical concentrations, physical habitat, *in situ* biological communities, and sediment toxicity. No one component can delineate significant levels of contamination in the gray zone that exists at every site. Each component provides unique information about the system but results in uncertainty if used in isolation from the other components. Increased use of a variety of assessment components provides a clearer ecosystem description. The chemical approach quantifies

levels of specific contaminants and can be related to water quality criteria. However, it provides no information on chemical interactive effects with other chemicals (such as additivity, antagonism, or synergism) and does not provide information either on the quantity of the chemical that is bioavailable or its effect.

The biological-community approach (discussed in other chapters) is a direct measure of *in situ* conditions and has been used effectively for decades in regulatory monitoring and assessment programs. It provides information on both community structure and function and human health risk from consumption of contaminated fish. In areas of questionable contamination the data may be inconclusive, as (1) biological communities are affected by natural disturbances (e.g., high-flow events or drought), habitat alteration (e.g., siltation from erosion or channelization), and natural spatial/temporal variation; (2) the populations being monitored may be relatively resistant to contamination (e.g., some chironomids and oligochaetes); and (3) the populations may not be responsive to short-term pollution events. Toxicity testing shows the integrative effects of multiple contaminants, providing data that are easy to interpret. The assays are relatively simple to perform and inexpensive. However, they may not provide a sensitive measure of long-term exposure to some contaminants, such as PCBs, which have carcinogenic and other chronic effects and which are tightly bound to the sediment. Another shortcoming is the need to extrapolate laboratory data to field conditions and extrapolate surrogate organism responses to indigenous species at various levels of biological organization.

The uncertainty produced by laboratory extrapolations is reduced by exposing test organisms *in situ*.²⁷ This approach has been used extensively in marine bioaccumulation studies using mussels. It is now being used effectively in sediment and stormwater contamination studies using cladocerans, fish, and amphipods.^{23,27,45-48} Uncertainties still exist, however, in the extrapolation of the effect levels of one indicator species to effects in the test ecosystem. In addition, *in situ* exposures reduce the effects of potential stressors such as predation, stream power, and suspended solids.

The integrated approach may be most efficient when conducted in a tiered manner,^{41,49} whereby toxicity testing is first conducted to guide sampling and analyses of more expensive chemical tests. If an accurate assessment is not conducted, the spatial extent of the problem may go undetected and "remedial" activities will be ineffective. Or, remedial activities may waste thousands to millions of dollars cleaning up areas that are not causing significant damage to the natural resources. This can be the more likely scenario when contamination is defined using only chemical data, as sediments can accumulate relatively high concentrations of contaminants that may or may not be biologically available.

It is evident that each approach for assessing sediment contamination has its own unique advantages and disadvantages. The magnitude or importance of these strengths and weaknesses will, to a large degree, be site- and study-objective-specific. No one rigid assessment protocol can be recommended for all situations. The sediment environment is extremely complex, and when combined with natural biological and physicochemical variability determining or predicting toxicant effects becomes an involved process requiring multidisciplinary expertise. While this may frustrate the regulator or environmental manager, it is a reality that can be and has been effectively dealt with using tiered integrative assessment strategies.^{41-43,49}

A cost-effective approach is to utilize historical data to target critical areas and collect numerous samples for testing with inexpensive tests (e.g., total organic carbon, ammonia, Microtox). Fewer samples from each site can be tested with a minimum of two toxicity assays such as the 10-day solid-phase *H. azteca* survival and *C. dubia* survival-reproduction tests. These assays have been shown in many studies to be relatively sensitive and discriminatory of sediment contamination.^{4,30,34} This second tier of testing should also include chronic sediment toxicity testing (e.g., the 28-day solid-phase *H. azteca* assay) and would target sites where toxicity was detected or questionable, using benthic community and habitat analyses. Once sites of significant impact were identified, chemical analyses could be better focused to help establish the impact zone, pollutant sources, and appropriate clean-up criteria.

Supplemental toxicity testing with other species will also help delineate zones of contamination and reduce the uncertainty of the “gray” zone. It has been shown at many sites^{4,19} that the need to integrate these various assessment components and to use additional measures within each assessment component (such as several toxicity measures or several benthic indices) is a direct function of the degree of contamination (Figure 5.1).¹⁰ As contamination increases, it becomes more apparent and can be detected with fewer methods.

5.3 TOXICITY TESTING

5.3.1 Recommended Assays and Test Conditions

Sediment toxicity tests have been performed with a wide variety of freshwater and marine organisms. These tests have been applied to both “water column” and benthic species with measured endpoints including survival, growth, reproduction, larval development, and luminescence. The choice of the appropriate endpoint (response) to measure is an important step in the assessment process. All toxicants do not affect the same metabolic processes and result in the same effects since they have differing modes of action and target receptors. Some toxicants may interfere with a process essential to reproduction or growth. They may also stimulate a process due to interruption of a feedback mechanism or, conversely, be essential nutrients at low concentrations. Stimulation at low concentrations of toxicant exposure has been commonly reported in the literature and is often called *hormesis*. Some responses are much more sensitive than others (e.g., enzyme inhibition vs. lethality) and should not be considered equally in evaluating the significance of ecosystem impact. For assessing the extent of contamination the most sensitive assay response may be the most useful for Tier I assessments.^{42,49} Some techniques were developed specifically for testing benthic organisms (e.g., amphipods) with whole sediments. Other tests were developed by modifying methods developed for effluent toxicity testing and applying them to whole sediments, elutriates, pore water, or extracts. Test methods for some of the more commonly used organisms are described in the following pages.

5.3.2 General Requirements for Test Organism Care

Test organisms may be obtained from laboratory cultures, commercial suppliers, or by field collection of wild organisms. Laboratory cultures of such organisms as algae, cladocerans, fish, insects, and some amphipods can provide organisms that have a known history, age, size, and quality and that are similar at all times of the year. Adult bivalves, echinoderms, and some amphipod species are usually collected from wild populations. Test species obtained directly from wild populations should be collected only in areas documented to be free of contamination. Permits for collection, transportation, and importation of these organisms may be required by local or state agencies. These requirements, which may also specify organism disposal procedures, should be confirmed with the appropriate authorities before planning any collections.

All organisms used in a test must be from the same source or batch and must be of acceptable quality.⁵⁰⁻⁵² Damaged, dead, abnormal, and diseased organisms should be disposed of as appropriate. A group of organisms should not be used for a test if the individuals appear to be diseased or otherwise stressed or if more than 5% die during the 48-hour period immediately preceding the test. If a group of organisms fails to meet these criteria, all individuals should be discarded. The procedures for organism collection and holding should be reviewed prior to obtaining a new supply to try to identify the source of the problem. An alternate source of test organisms should always be available. In general, it is preferable to replace unhealthy organisms, since treatment may alter their sensitivity and impose additional handling stress.

The conditions for holding test organisms will vary with each species; holding conditions may be static, static-renewal, or flow-through and may be with or without substrate material. The holding tanks and any areas used for maintaining live organisms should be located in a room or space separate from that in which toxicity tests are conducted, stock solutions or test materials are prepared, or equipment is cleaned. Organisms should be cared for and handled in such a manner that they are not unnecessarily stressed. Any organisms that are accidentally dropped or handled directly must be discarded. Test organisms should not be crowded or subjected to rapid changes in temperature or water quality. Dissolved oxygen concentrations must be provided. Monitoring of ammonia levels is recommended if organisms are held under static conditions. An appropriate photoperiod should also be maintained. Holding containers may need to be covered to minimize disturbance of the organisms.

Whenever aquatic animals are brought into a laboratory, they should be kept separate from other organisms, including those of the same species. In addition to maintaining any necessary quarantine requirements, this ensures that only organisms from a particular batch are used for a given test. Dip nets and other handling equipment should be disinfected before and after each use.

Organisms must be fully acclimated to laboratory test conditions before testing begins. If a different water supply is to be used, then the water in the acclimation tank should be gradually changed from 100% holding water to 100% dilution water over a period of 1 or more days. Similarly, the water temperature should be changed over a period of several hours until the test temperature is reached. They should not be tested at temperatures outside the recommended range. With organisms that can tolerate a range of salinities, acclimation should not usually exceed 3 to 5 ppt every 2 days.⁵⁰ All organisms, with the exception of embryonic or larval stages, should be maintained in dilution water at the test temperature for at least the last 48 h before they are placed in test chambers.

5.3.3 Freshwater Test Organisms

Examples of test species and their associated methods are presented in the following sections, encompassing trophic levels ranging from decomposers and producers to predators and representing multiple levels of biological organization. The freshwater species that have been used successfully in assessments of sediment toxicity include both water column and benthic species: *Selenastrum capricornutum*, *Daphnia magna*, *Ceriodaphnia dubia*, *Pimephales promelas*, *Hyalella azteca*, *Chironomus tentans* and *Chironomus riparius*, and *Hexagenia limbata*. A few “standard” methods exist for freshwater sediment toxicity tests.⁸ The EPA’s Office of Science and Technology and Office of Research and Development have developed methods for *H. azteca* and *C. tentans* 10-day whole sediment exposures and a 28-day bioaccumulation test with the oligochaete *L. variegatus*. Standard guides for whole-sediment toxicity testing have been published by the American Society for Testing and Materials for invertebrates, including *H. azteca*, *C. tentans*, *C. riparius*, the cladocerans *Daphnia magna* and *C. dubia*, the mayfly *Hexagenia*, the Great Lakes amphipod *Diporeia*, and the oligochaete *Tubifex tubifex*.⁵¹ Dredged material evaluations in the United States should follow protocols published by the EPA and U.S. Army Corps of Engineers — in 1991 for dredged material proposed for ocean disposal, and protocols published in 1998 for dredged material proposed for disposal in “inland” waters of the United States.^{26,53} Canada’s Ontario Ministry of the Environment has also published solid-phase test methods.⁵⁴

5.3.3.1 Algae

The standard freshwater algal toxicity test has been the 96-hour growth test with the unicellular green alga *Selenastrum capricornutum*. Methods for culture and testing are described by the EPA.⁵⁵ This method was originally developed for use with effluents, receiving waters, and pure compounds, but it is also suitable for testing sediment elutriates and pore water. Inasmuch as the cells must be

kept in suspension during the exposure period, this procedure is not suitable for use with whole sediments. In fact, it is seldom used in sediment quality assessments for this reason and the tendency for stimulated responses in the presence of nutrients. The test can be used to measure changes in cell density, biomass, chlorophyll content, or absorbance.

Starter cultures of the algae can be obtained from biological supply houses or certain university culture collections (e.g., University of Texas or University of Toronto) and then maintained in continuous culture in the laboratory. Instructions for the preparation of glassware and nutrient stock solutions are detailed by the EPA.⁵⁵ The use of appropriate aseptic techniques is critical to prevent contamination. Cultures are normally grown in a nutrient medium that includes EDTA and then tested in a medium without EDTA. The cultures can be grown in any size flask, ranging from 125 mL to 4 L; 250-mL glass Erlenmeyer flasks containing 100 mL culture medium are typical. New cultures should be started each week. The flasks are sealed with foam plugs to prevent contamination and placed in an incubation chamber at $25 \pm 1^\circ\text{C}$ under continuous illumination. The flasks should be placed on a shaker table or manually shaken twice daily. Subsamples should be examined regularly for contamination and growth assessment. To initiate a toxicity test the stock culture should have a cell density of 1×10^2 cells/mL and be entering a log-phase growth stage. Healthy cultures are characterized by rapid growth and a bright green color; older cultures tend to be yellowish-green in color.

The test may be conducted as a screen (100% concentration) or by using a series of dilutions to determine the no-observed effect concentration (NOEC). It may be necessary to filter elutriate or pore water through a 0.45- μm filter to remove particulate material (filtration may also reduce toxicity). The sample is warmed to test temperature, and water quality values are measured. If the dissolved oxygen (DO) level is outside the range of 40 to 100% saturation, a few minutes of aeration may be required to bring the DO to an acceptable level. Nutrients (without EDTA) are added to ensure that reduction in growth is not due to nutrient limitation. The test is generally conducted in 250-mL Erlenmeyer flasks, with a test volume of 100 mL and three replicates per treatment. Methods are also being developed to make use of microplate testing techniques. The negative (clean) control consists of three replicates of culture medium, prepared without EDTA. The inoculum density is adjusted to 1×10^6 cells/mL and each flask is inoculated with 1 mL stock culture. Each flask is sealed with a foam plug and placed randomly in an incubation chamber at $25 \pm 1^\circ\text{C}$ with a continuous photoperiod. The flasks are swirled twice daily by hand, if a shaker table is not available, and randomly repositioned in the incubation chamber.

If direct cell counts are being made to measure changes in cell density, duplicate subsamples can be removed from each well-mixed replicate container. The samples can be counted immediately or preserved (e.g., 10% Lugol's solution). Cell counts are made of duplicate samples using a haemocytometer or a particle size counter (e.g., Coulter), and the average count (cells/mL) is calculated for each treatment. Percent inhibition and stimulation of growth relative to the control are also determined. The mean cell counts are used to calculate the no-observed effect level (NOEL) value. Water quality measures should include alkalinity, hardness, pH, and temperature at test initiation and termination.

5.3.3.2 *Daphnia magna*

Daphnia magna has been used extensively to determine the toxicity of effluents and water samples and has been demonstrated to be sensitive to many environmental contaminants. Methods for conducting acute and sublethal (partial life cycle) tests with liquid samples have been well established^{51,55,56} and may be readily adapted for testing elutriates and pore water. Extensive research has also been performed to evaluate the effects of different culture and testing regimes (e.g., diet, temperature, or culture medium). *D. magna* has largely been replaced in the United States by *Ceriodaphnia dubia*, but it is still often used in other countries. Standardized techniques involving whole sediment exposures, with acute or sublethal endpoints, have been developed.⁵¹

Daphnids are very sensitive organisms, and their health is easily affected by the diet and culture medium used. Cultures are prone to periodic “crashes.” Once suitable culture conditions have been refined for a particular laboratory, maintenance of the cultures is relatively straightforward. Generally, *Daphnia magna* are cultured at 20 to 25°C, under a photoperiod of 16:8 h light:darkness and a light intensity of 10 to 20 $\mu\text{E}/\text{m}^2/\text{s}$ (50 to 100 ft-c). A number of water sources may be suitable for culturing *D. magna*, including the use of natural spring water. One acceptable culture medium is deionized water, reconstituted to a hardness of 160 to 180 mg/L as CaCO_2 . Mass cultures of *D. magna* can be raised in 2-L glass beakers at a maximum density of 20 to 25 daphnids per liter. The culture water is replaced three times per week, and cultures are thinned at that time. Daphnids used in toxicity tests are usually neonates (<24 h old), although slightly older organisms (5 days old) are used for short-term chronic whole sediment toxicity tests. Brood adults should be 2 to 4 weeks old, and young from the first and second broods should be discarded. Neonates used for a particular test must all be from the same brood. To obtain test organisms brood adults are transferred to fresh culture media the day before the test is initiated. On the following day neonates (<24 h old) may be collected and used in toxicity tests. Neonates collected for a 7-day partial life cycle test can be held in 2-L glass beakers for 5 days and treated as above until the test is initiated. Daphnids can be fed a YCT (yeast-Cerophyl-trout chow) diet, supplemented with algae, on a daily basis. Healthy cultures are characterized by a golden color, absence of males, no ephippia present, and a high ratio of young to adults. Daphnids are very fragile organisms that must be handled carefully; a large-bore glass pipette should be used to transfer daphnids between containers, and they should always be released below the water surface.

A static 48-hour acute test, with an elutriate or pore water sample, may be conducted as a screen (100% concentration) or by using a series of dilutions to determine the 48-hour LC_{50} value. A sufficient number of neonates of acceptable age (<24 h old) and health should be collected from a laboratory culture. The test is conducted in 250-mL glass beakers, with a test volume of 200 mL and two to four replicates per treatment. The negative (clean) control consists of an equal number of replicate containers containing dilution medium. Dissolved oxygen and temperature should be measured daily, while pH, ammonia, conductivity, alkalinity, and hardness should be determined at test initiation and termination. Each beaker is randomly seeded with five neonates, taking care to gently release the organisms below the water surface. The daphnids should be checked after about 2 h to ensure none are floating on the water surface. Water chemistry is measured daily, and each beaker is checked daily for mortalities. Daphnids that become trapped at the air-water interface are gently resubmerged. After 48 h, survival data from replicate beakers are pooled to determine the LC_{50} value.

The procedure for performing static 48-hour toxicity tests using whole sediments is similar to that described above, except that there are no dilutions of sediment. Each test container is a 250-mL glass beaker, and there are normally three to five replicates per treatment. Approximately 50 g sediment (wet weight) is placed in each beaker, and then 200 mL culture water is added, taking care not to disturb the sediments. Smaller test containers can be used, as long as the 1:4 ratio of sediment to water is maintained.⁵¹ After a brief settling period (reported times vary from 1 h to 4 days), ten neonates are added to each container, and care is taken to release them below the water surface. Monitoring of water quality is performed as described above. After 48 h, survival data are pooled and treatments are compared to the negative control.

A 7-day partial life cycle test may be conducted with 5-day-old daphnids and whole sediments. Daphnids of this age are almost ready to produce their first brood of offspring. The test is conducted in 300-mL glass beakers, with 10 replicates for each treatment. Each beaker contains 5 g sediment and 20 mL overlying water, and each is seeded with one daphnid. The overlying water is normally the same as that used for culture, but the experimental design may also require that reconstituted or receiving water be used. During the 7-day exposure the sediments are left undisturbed, but the overlying water is renewed daily or three times per week. This renewal is necessary because of the need to count and remove offspring and to prevent a buildup of food in the test containers. Each

day, the adult is carefully transferred to a beaker of culture water, and any offspring are counted and removed. A total of 15 mL overlying water is removed and replaced, and care is taken not to disturb the sediments. At that time food is added to each container. The adult daphnid is then returned to its test container, and the exposure is allowed to continue. The endpoints are survival and reproduction. For toxicity tests with *Daphnia* to be considered valid, mean control survival must be at least 80%. The test is terminated when at least 60% of the control or reference sample have produced their third brood, which should occur by day 7 when tested at 25°C.

5.3.3.3 *Ceriodaphnia dubia*

Methods for culturing *Ceriodaphnia dubia* and for performing 7-day partial life cycle tests with liquid samples are described by the EPA.⁵⁵ As described above for *D. magna*, they have been used for whole sediment testing as well as elutriate and pore water testing and are very sensitive to the presence of sediment contaminants.^{30,34,51} They are much smaller than *D. magna* and therefore more difficult to see in turbid samples. However, their faster reproduction rate and slightly greater sensitivity than *D. magna* make them a desirable test organism. Test organisms should be obtained from an in-house laboratory culture. *C. dubia* are cultured at $25 \pm 1^\circ\text{C}$, under a photoperiod of 16:8 h light:darkness. The culture medium may be either dilute mineral water (deionized water plus 10% mineral water), or moderately hard reconstituted water, with a hardness of 80 to 100 mg/L as CaCO_3 .

Mass cultures of *C. dubia* can be reared in 0.6 to 2-L glass beakers at a density of approximately 50 daphnids per liter. The culture water is changed three times per week, and the cultures are thinned at that time. Organisms used in toxicity tests must be neonates (<24 h old). To obtain test organisms daphnids that have not yet produced their first brood are placed in individual 30-mL glass beakers containing 15 to 25 mL culture water and reared until they are 14 days old. The water is changed three times per week, and offspring are removed and counted daily. Neonates from the first and second broods should be discarded. Neonates for testing should only be collected from females that produce a minimum of 15 offspring and at least 5 neonates in their third brood. *C. dubia* may be fed YCT diet, supplemented with green algae or a *S. capricornutum*-Cerophyl mixture, on a daily basis. Healthy cultures are characterized by a golden color, absence of males, and a high ratio of young to adults. Daphnids are very fragile organisms that must be handled carefully; a large-bore glass pipette should be used to transfer daphnids between containers, and they should always be released below the water surface.

The techniques used for performing 48-hour acute and 7-day partial life cycle tests and the water quality measurements with *C. dubia* are the same as those described above for *D. magna*. The tests should be performed with neonates that are less than 24 h old. The endpoint for the acute test is survival, while the endpoints for the 7-day tests are survival and reproduction. As with the *D. magna*, short-term chronic toxicity test is terminated when at least 60% of the controls or reference sample have produced their third brood.

5.3.3.4 *Fathead Minnow*

Toxicity tests with fathead minnow, *Pimephales promelas*, may be performed with the juvenile stage (1 to 14 days old) or with <24-hour-old larvae. Juvenile fish are typically used for acute exposures, while the larval fish are used for 7-day sublethal tests that have endpoints of survival and growth. Methods for testing fathead minnow with liquid samples are well established.^{55,56} These test procedures can be applied when using elutriates, pore water, or whole sediment.³⁴

Juvenile fathead minnows can be obtained from a laboratory culture or commercial supplier. Moderately hard reconstituted water should be used for culture and testing. Reagent-grade chemicals are added to Milli-Q deionized water to achieve a hardness of 80 to 100 mg/l as CaCO_3 . The EPA⁵⁵ specifies the use of 1- to 14-day-old fish. The minimum size of test container that is recommended

for an acute test is a 250-mL glass beaker, with a 200-mL test-solution volume. Elutriates or pore water may be tested at a single concentration (usually 100%) or by using a series of concentrations to determine the LC₅₀ value. Acute tests may also be performed with whole sediment, although without dilutions.

When testing whole sediments, a 1:4 ratio of sediment to water should be maintained in the test containers, and the water should be added carefully to reduce sediment disturbances. Culture water is usually used for the negative (clean) control. For each treatment, there should be a minimum of three replicates, with 10 fish in each. The test solutions or sediments should be distributed into their respective beakers, and each beaker carefully seeded with 10 fish. Test duration may be 24, 48, or 96 h. If the test is longer than 48 h, test solutions or overlying water should be renewed and the larvae fed daily. The tests are conducted at 20 or 25°C with a photoperiod of 16:8 h light:darkness. Water quality measurements are as described above for *D. magna*. The test endpoint is survival; observations are made daily to determine responses in the test containers. At the end of the exposure survival is recorded in each test container, and replicate data are then pooled for each treatment.

The 7-day larval fathead minnow growth and survival test can be conducted as described by the EPA,⁵⁵ using either elutriates, pore water, or whole sediments.^{34,57} Pore water testing is seldom conducted due to the volume of pore water required. Test conditions and experimental designs are the same as those used for the acute tests with juvenile fish, except that the tests are normally performed at 25°C. Fathead minnow eggs can be obtained from a laboratory culture or commercial supplier. The eggs are laid on ceramic tiles (or PVC-halved pipe) that are placed in plastic basins filled with culture water and supplied with vigorous aeration. Larvae that hatch within 24 h are used for each test. Ten randomly selected larvae are placed in each test container, and test containers should be randomized with respect to position. Each replicate should be fed 0.1 mL (700 to 1000) newly hatched *Artemia nauplii* two to three times daily on days 1 through 6. Replicates are not fed on day 7. Water quality is measured each day. Dissolved oxygen and pH are measured at the start and end of each 24-h period in one test container from each treatment.

For elutriate tests, test chambers are cleaned and test solutions are renewed every 24 h. For whole sediment tests, a portion of the overlying water should be replaced each day and dead brine shrimp should be carefully siphoned from the sediment surface in each container. Daily observations should be made and the number of live larvae recorded each day. Dead larvae should be discarded. At the conclusion of the test, final counts of surviving larvae should be made and live larvae collected and killed by immersion in cold deionized water. The larvae should be rinsed with deionized water, placed in preweighed aluminum pans, and oven dried at 100°C for 2 h to obtain final dry weights. Mean survival and growth (measured as dry weight) of larvae exposed to test samples can then be compared to mean survival and growth of larvae exposed to controls and reference samples.

5.3.3.5 *Hyalella azteca*

Hyalella azteca is a small freshwater amphipod that has been shown to be a sensitive indicator of the presence of contaminants in freshwater sediments. *H. azteca* is an epibenthic detritivore and herbivore and will burrow in the surface sediments in search of food. Its short life cycle, widespread and abundant distribution, ease of culture, and wide tolerance of sediment grain size and salinity make it a very suitable test species. Methods for culture and testing are summarized in the ASTM and EPA.^{51,7,8} They have been used extensively for whole sediment toxicity testing in North America. In Europe *Gammarus* is the amphipod of preference.

H. azteca can be obtained from a commercial supplier or laboratory culture. The amphipods can be held in 80-L glass aquaria filled with about 50 L moderately hard reconstituted water (80 to 100 mg/L as CaCO₃).²⁹ A flaked food (e.g., Tetrafin[®]) is added to each culture chamber, receiving daily water renewals to provide about 20 g dry solids/50 L of water twice weekly in an 80-L culture chamber.⁸ Each culture chamber has a substrate of maple leaves and artificial substrates (six 20-

cm diameter sections per 80-L aquaria of nylon “coiled-web material”; 3-M, St. Paul, MN). Before use, leaves are soaked in 30% salt water for about 30 days to reduce the occurrence of planaria, snails, or other organisms on the substrate. The leaves are then flushed to remove the salt water and residuals of naturally occurring tannic acid before placement in the cultures.⁸

Cultures should be maintained at 23°C under a 16:8-hour photoperiod at an illuminance of about 100 to 1000 lux. Gentle aeration is provided. Water in culture chambers is changed weekly. Survival of adults and juveniles and production of young should be measured at this time. Mixed-age amphipods may be separated by sieving the amphipods through 250- μm , 425- μm , and 600- μm sieves. Sieves should be held under water to isolate the amphipods. Artificial substrates or leaves are placed in the 600- μm sieve. Culture water is rinsed through the sieves, and small amphipods stopped by the 250- μm sieve are washed into a collecting pan. Larger amphipods in the other two sieves are returned to the culture chamber. The smaller amphipods are then placed in 1-L beakers containing culture water and food (about 200 amphipods per beaker) with gentle aeration. Newborn amphipods should be held for 6 to 13 days to provide 7- to 14-day-old organisms to start a 10-day test or should be held for 7 days to provide 7- to 8-day-old organisms to start a long-term test.⁸

Assessment of whole sediment toxicity involves a 10- to 4 two-dimensional exposure of juvenile amphipods to sediments, using procedures described by the EPA and ASTM.^{8,51} Both the short-term (10-day) and long-term (42-day) sediment toxicity tests are conducted in 300-mL high-form lipless beakers. The sediment volume for both tests is 100 mL with 175 mL of overlying water. The recommended number of replicate chambers for routine testing for the 10-day sediment test is 8, and the recommended number of replicate chambers for the 42-day sediment test is 12.⁸ Sediments are prepared the day before test initiation and allowed to equilibrate overnight. The following day (day 0), test organisms are added (10 organisms per chamber for both the short- and long-term sediment tests), and the experiment begins. Prior to distribution to the test containers, the overlying water is renewed, with two volume replacements per day, continuous or intermittent (e.g., 1 volume addition every 12 h), thereafter.⁸ Other successful test methods have consisted of a 1:4 sediment:water ratio in 30 (1 organism per beaker, 10 replicates) to 250-mL beakers (10 organisms per beaker, 3 replicates), with daily water renewal; however, these methods do not follow the EPA methods.⁵⁷ A negative (clean) control, consisting of fine silica sand (culture material) or mesh, is tested concurrently. Juvenile amphipods (as outlined above) are sieved or picked from their holding containers, and 10 amphipods are randomly distributed to each test container. Sieved organisms should be held for 1 to 3 days prior to testing to check for sieve-related mortality.

The short-term sediment test is allowed to proceed for 10 days, and the long-term sediment test is allowed to proceed for 42 days. Both tests are conducted at $23 \pm 1^\circ\text{C}$ under a 16:8-hour light:dark photoperiod. Gentle aeration is provided if needed to keep the DO greater than 2.5 mg/L throughout the test. Hardness, alkalinity, conductivity, and ammonia are monitored at the beginning and the end of both sediment tests. For the 10-day sediment test, pH is also monitored at the beginning and end of the test. Also for the 10-day sediment test with *H. azteca*, temperature and DO are monitored daily. For the 42-day sediment test, temperature is monitored daily, conductivity weekly, and DO and pH are three times per week. Amphipods are fed 1.0 mL of YCT daily to each test chamber. At test termination of the 10-day sediment test the sediments are sieved and the number of live, dead, and missing amphipods in each test container recorded. The test endpoints from the short-term sediment test with *H. azteca* are survival and growth measured on day 10.

For the long-term sediment test, the amphipods are isolated on day 28 from the sediment and placed in water-only chambers where reproduction is measured on days 35 and 42. Endpoints measured in the long-term amphipod test include survival (days 28, 35, and 42), growth (days 28 and 42), and reproduction (number of young per female from day 28 to 42). For best recovery of the live organisms, the test beakers should be gently swirled several times to resuspend the upper layer of sediment and then quickly poured into the sieve. Since the *H. azteca* do not burrow into the deeper layers, this method allows recovery with minimal sieving. Test acceptability for the 10-

day sediment test is a minimum mean control survival of 80% and measurable growth of test organism in the control sediment. For the 42-day sediment test, acceptability is defined as a minimum mean control survival of 80% on day 28. For both tests, additional performance-based criteria specifications are outlined in EPA.⁸

5.3.3.6 *Chironomus tentans* and *Chironomus riparius*

This test provides information on the bioavailability and adverse effects of contaminants associated with whole sediment using the freshwater midges. *C. tentans* and *C. riparius* have been used successfully in freshwater toxicity tests because these species are fairly large midges with a short generation time, are easily cluttered, and the larvae are in direct contact with the sediment. They have been shown to be sensitive to many contaminants associated with sediments. Methods for culture and testing are summarized in ASTM for both *C. tentans* and *C. riparius*, and in EPA for *C. tentans*.^{8,51} *C. tentans* has been used extensively for whole sediment testing in the United States, and *C. riparius* has been used often in Canada and western Europe.

Assessment of whole sediment toxicity involves a 10–day to about 60-day exposure of juvenile *C. tentans* to sediments. Both the short-term (10-day) and long-term (about 60-day) sediment toxicity tests are conducted in 300-mL high-form lipless beakers. The sediment volume for both tests is 100 mL with 175 mL of overlying water. The recommended number of replicate chambers for routine testing for the 10-day sediment test is 8, and the recommended number of replicate chambers for the 60-day sediment test is 16. Sediments are prepared the day before test initiation and allowed to equilibrate overnight. The following day (day 0) test organisms are added (10 organisms per chamber for the short-term sediment test, and 12 organisms per chamber for the long-term sediment test), and the experiment begins. Prior to distribution to the test containers the overlying water is renewed, with two volume replacements per day, continuous or intermittent (e.g., 1 volume addition every 12 h), thereafter.⁸

Second- to third-instar larvae (approximately 10 to 12 days postdeposition; all organisms must be third instar or younger with at least 50% of the organisms at third instar) are used in the short-term sediment test. Less than 24-hour-old larvae are used to initiate the long-term *C. tentans* sediment test. *C. tentans* can be cultured in soft water in glass aquaria. A water volume of about 6 to 8 L in these flow-through chambers can be maintained by drilling an overflow hole in one end 11 cm from the bottom. The top of the aquarium is covered with a mesh material to trap emergent adults. Panty hose with the elasticized waist are positioned around the chamber top, and the legs are cut off. About 200 to 300 mL of 40-mesh silica sand is placed in each chamber. The stocking density of the number of *C. tentans* eggs should be about 600 eggs per 6 to 8 L of water. Fish food flakes (i.e., Tetrafin®) are added to each culture chamber to provide a final food concentration of about 0.4 mg dry solids/mL of culture water.⁸

The short-term sediment test is allowed to proceed for 10 days, and the long-term sediment test is allowed to proceed for about 60 days. Both tests are conducted at $23 \pm 1^\circ\text{C}$ under a 16:8 h light:dark photoperiod. Gentle aeration is provided if needed to keep the DO greater than 2.5 mg/L throughout the test. For the short-term sediment test, hardness, alkalinity, conductivity, pH, and ammonia are monitored at the beginning and end of the test. Temperature and DO are monitored daily. For the long-term sediment test, hardness, alkalinity, conductivity, and ammonia are monitored at the beginning, on day 20, and at the end of the test. Temperature is monitored daily, DO and pH three times per week, and conductivity weekly. For the short-term test, each test chamber is fed 1.5 mL of Tetrafin® (1.5 mL contains 6.0 mg of dry solids) daily. For the long-term sediment test with *C. tentans*, each chamber is fed 1.5 mL of Tetrafin® (1.0 mL contains 4.0 mg of dry solids) daily starting the day prior to when the organisms are added to the test chambers. The test endpoints for the short-term sediment test is survival, and growth is measured on day 10.

The test endpoints measured in the long-term sediment exposures with *C. tentans* include survival and growth measured on day 20, with emergence and reproduction being measured daily

starting on day 23 to the end of the test (approximately 60 days). The number of eggs per female is determined for each egg mass, which is incubated for 6 days to determine hatching success. Test acceptability for the short-term test is a minimum control survival of 70%, with a minimum mean weight/surviving control organism of 0.48 mg ash-free dry weight (AFDW). For the long-term test, test acceptability is defined as the average size of *C. tentans* in the control sediment at 20 days that must be at least 0.6 mg/surviving organism as dry weight or 0.48 mg/surviving organism as AFDW. Emergence should be greater than or equal to 50%. For both tests, additional performance-based criteria specifications are outlined in EPA.⁸

5.3.3.7 *Hexagenia limbata*

Hexagenia are large-bodied mayflies belonging to the order Ephemeroptera. The most common test species include *H. limbata* (Serville), *H. rigida* (McDunnough), *H. bilineata* (Say), and *H. munda* (Eaton), and they are common to the United States and Canada.⁵⁸ Mayfly nymphs live in U-shaped tubes that are formed in freshwater aquatic sediments and are continuously exposed to sediment, pore water, and overlying water.^{65,66} Mayfly nymphs have been used in whole sediment toxicity tests⁵⁸⁻⁶³ and pore water exposures^{65,67} as well as for examining the bioaccumulation dynamics of sediment-associated contaminants.⁶⁸ Their life history consists of four stages: eggs, nymphs, subimagos, and adults or imagoes; their life cycle is 1 to 2 years, depending on temperature. The emergence of adults occurs over a short period of time, culminating in massive swarms during the summer months. Each female adult can produce an average of 4000 eggs. Edmunds et al.⁶⁹ report body length of the nymph between 12 and 32 mm and adult wing length between 10 and 25 mm. They are tolerant of a wide range of grain size and organic content, but growth has been reported to be limited in sediments with a high sand fraction and low total organic carbon. An annex to ASTM,⁵¹ which provides guidance for conducting *Hexagenia* tests, has recently been developed.

Organisms can be obtained from the wild, another laboratory, or a commercial source either in the form of nymphs⁶¹ or eggs.⁷⁰ All individuals in a test should be obtained from the same sources and collected from a clean site. Mayfly nymphs used for testing are reared in the laboratory and not continuously cultured due to the length of the mayfly's cycle and the conditions necessary to mature successfully. Therefore, nymphs or eggs are collected as necessary.⁵¹ Mayfly nymphs are found in lakes, rivers, and ponds with soft mud and fine silt/clay bottoms and are found infrequently in areas containing gravel, sand, or peat.⁷¹ The method of collection will vary (e.g., dipnet, grab sampler) depending on water depth, current, and substrate characteristics. Once collected, they are collected from their native sediments and then transported to the laboratory in cool, aerated water. *Hexagenia* spp. nymphs brought back into the laboratory should be acclimated (at a rate not to exceed 2°C within 24 h) to the culture water by gradually changing the water in the holding chamber from the water in which they were transported to 100% culture water. Adult mayflies can be collected during the summer to obtain fertilized eggs.⁴⁸ The eggs can be stored at 8°C within polypropylene bags or petri dishes holding clean water and containing an air space. These eggs can be held at 20°C for 6.5 days and gradually cooled to 8°C in 4°C increments every 4 days. Eggs can be stored for 41 weeks, and for successful hatching the eggs may be transferred from 8°C directly to 20°C (room temperature) or warmed in 4°C increments every 7 days (12°C for 7 days, 16°C for 7 days). Hatching begins in 6 to 8 days at 20°C using either approach.⁵¹ Newly hatched nymphs have been held in static, aerated aquaria ranging from 1 to 40 L in size. The photoperiod can be maintained on a 16l:8D or the natural photoperiod of the region (196, 277, 281). Dechlorinated water has been used for rearing *Hexagenia* spp., with a pH of 7.1 to 8.2 and total hardness of 100 to 144 mg/L as CaCO₃ (277). Nymph density will vary with organism size.

Fine silt/clay sediment can be obtained from a native area known to support mayfly populations^{59,62,70} or can be made by mixing reconstituted potting soil and clay⁶³ with the addition

of silica sand.⁷² The field-collected sediment is prepared by initially autoclaving the sediment,^{59,70} which may be followed by an exposure to air for 48 h.⁶² The sediment is placed into aquaria to a uniform depth (1 to 2 cm^{62,70}), overlain with water, and allowed to settle.⁷⁰ Newly hatched nymphs are interstitial sediment dwellers and do not require feeding for the first 7 days since the sediment can provide sufficient nourishment for establishment. Young organisms may be fed an algal suspension for the first month of development (that is, 10% *S. capricornutum* and 10% *Chlorella fusca*⁶²). The feeding solutions are prepared by blending the appropriate amount of material in water until a fine slurry is achieved.⁵¹

As stated earlier, toxicity tests can be performed using whole sediments or aqueous fractions, such as pore water or elutriates. If the mayflies are tested without sediment, artificial burrows (e.g., small glass tubes) must be provided as a burrowing substrate to reduce stress.⁶⁷ Nymphs used in toxicity tests are usually approximately 3 to 5 months old. Nebeker et al.⁵⁹ described 10-day, static, whole sediment toxicity tests using 10 young mayfly nymphs (<10 mm long) placed into 1-L beakers or 10 older nymphs (>10 mm long) placed into 4-L glass beakers. The 1-L jars contained 200 mL of sediment and 800 mL of overlying water, and the 4-L jars contained 800 mL of sediment and 3200 mL of overlying water, both achieving a 4:1 (v:v) water:sediment ratio. Organisms are not fed in either the static or recirculating short-term tests.^{59,63,73}

In addition to the standard 10-day exposure, Bedard et al.⁷⁴ have also developed a 21-day sediment test that has growth and survival as endpoints. This 21-day, static, whole sediment toxicity tests uses ten early instar mayfly nymphs (<8 mm long, about 5-mg wet weight) placed into 1.8-L (11.5 × 11.5 × 14.5-cm) wide-mouthed glass jars with a minimum of three replicates. The 1.8-L jars held 325 mL of sediment and 1300 mL of water, providing a 4:1 (v:v) water:sediment ratio. Air was bubbled through Pasteur pipettes positioned just below the water surface to maintain a dissolved oxygen concentration of 7 to 10 mg/L in the overlying water. A flowmeter was used to regulate the air supply to every six test chambers. The test chambers were covered with loosely fitting plastic lids.

Organisms might not need to be fed during the 21-day tests depending on the natural food content of the sediment. Previous studies indicated that diet did not influence early instar nymph growth or survival over a 21-day test exposure for a number of sediment types.⁷⁴ The endpoint for short-term tests is mortality.^{59,61,63} The endpoints for long-term tests are survival and growth. Burrowing behavior⁶³ and molting frequency^{63,73} can also be monitored throughout the test depending on the turbidity of the overlying water. For any toxicity tests performed with *Hexagenia*, mean control survival must be at least 80% for the tests to be considered valid. Additional performance-based criteria specifications are outlined in the ASTM annex.⁵¹

5.3.3.8 Estuarine and Marine Test Species

The following section presents examples of toxicity tests for marine and estuarine species; these range from fish to bacterial levels of biological organization. The marine and estuarine species frequently and successfully used in studies of sediment contamination include the fish *Cyprinodon variegatus* and *Menidia beryllina*, and amphipods *Rhepoxynius abronius*, *Ampelisca abdita*, *Eohaustorius estuarius*, *Grandidierella japonica* and *Leptocheirus plumulosus*, the bivalves *Haliotis rufescens*, *Crassostrea gigas*, and *Mytilus* sp., the echinoderms *Strongylocentrotus purpuratus*, *Dendraster excentricus*, and *Arbacia punctulata*, the polychaetes *Dinophilus gyrociliatus* and *Neanthea arenaceodentata*, the mysid *Americamysis bahia* (formerly *Mysidopsis bahia*), the algal *Champia parvula*, and the bacterial assay Microtox using *Vibrio fischeri*. As with freshwater tests, several “standard” methods for marine and estuarine organisms exist. The EPA has standardized protocols for toxicity testing with the amphipods *Rhepoxynius*, *Ampelisca*, *Eohaustorius*, and *Leptocheirus* using a 10-day survival assay, a chronic 28-day survival, growth reproduction assay with *Leptocheirus*, and 28-day bioaccumulation assays with *Macoma* and *Nereis*.^{6,9} The European OECD (Organization of Economic Cooperation and Development) is discussing the possibility of

developing standardized sediment tests. Environment Canada has developed methods for sediments, elutriates, and leachate samples using *Vibrio fischeri* luminescence, sea urchins and sand dollars (echinoids), and seven amphipod species. Methods were recently published by the Chesapeake Bay Program for benthic testing using *Lepocheirus plumulosus*, *Ampelisca abdita*, *Lepidactylus dytiscus*, and *Monoculodes edwardsi*. Dredged materials in the United States should be tested using EPA and U.S. Army Corps of Engineers protocols.^{26,53} The American Society for Testing and Materials has standard procedures for amphipods, fish, mysids, echinoderm and oyster early life stages, polychaetes, and algae.⁷⁵⁻⁷⁸

5.3.3.8.1 Larval Fish

Sediment toxicity tests with estuarine and marine samples can be performed using the juvenile or larval stages of the sheepshead minnow, *Cyprinodum variegatus*, or the inland silverside, *Menidia beryllina*. Juvenile fish are typically used for acute exposures, while the larval fish are used for 7-day sublethal tests that have endpoints of survival and growth.^{55,77} These test procedures may also be applied when testing elutriates, pore water, or whole sediment; however, as with the algae tests, volume requirements (200 mL/rep) prohibit the use of porewaters except under the most unusual conditions.

Juvenile fish (1 to 14 days old for sheepshead minnow, 9 to 14 days old for inland silverside) can be obtained from a laboratory culture or commercial supplier. Methods for culturing and testing sheepshead minnow and silverside with liquid samples are well established.^{55,56,77} Both species are tolerant of a wide range of salinities 0 to 32 ppt if they are acclimated following hatching, making them suitable for testing estuarine and marine samples. Water used for culture and testing should be either natural seawater from an uncontaminated source or artificial seawater (prepared from hypersaline brine or aquarium salt mix), adjusted to the salinity required for a particular test. The minimum recommended test container size for an acute test is a 250-mL glass beaker, with a 200-mL test solution volume. Elutriates and pore waters may be tested at a single concentration (usually 100%) or using a series of concentrations to determine the LC₅₀ value. Acute tests may also be performed with whole sediment.⁷⁹ When testing whole sediments a 1:4 ratio of sediment to water should be maintained in the test containers, and the water should be added carefully to reduce sediment disturbance. Culture water is usually used for the negative (clean) control. For each treatment there should be a minimum of three replicates, with 10 fish in each. The test solutions or sediments should be distributed into their respective beakers and each beaker carefully seeded with 10 fish. If the test is longer than 48 h, test solutions or overlying water should be renewed and the larvae fed. The tests are conducted at 20 or 25°C with a photoperiod of 16:8 h light:darkness. Temperature, dissolved oxygen, salinity, and pH should be measured in each treatment every 24 h. The test endpoint is survival; observations are made daily to determine responses in the test containers. At the end of the exposure survival is recorded in each test container, and then replicate data are pooled for each treatment.

The 7-day larval growth and survival test can be conducted with either species for effluents, using pore water, elutriates, or whole sediments.^{56,77,79} Test conditions and experimental designs are the same as those used for the acute tests with juvenile fish, except that the tests are normally performed at 25°C. Larval fish (<24-hour-old sheepshead minnow or 7- to 11-day-old inland silversides) can be obtained from a laboratory culture or commercial supplier. Larvae that hatch within 24 h of each other are used for each test. Ten randomly selected larvae are placed in each test container, which should be randomized with respect to position. Each replicate should be fed 0.1 to 0.15 mL newly hatched *Artemia nauplii* suspension daily on days 1 through 6. Replicates are not fed on day 7. Water quality is measured each day. Dissolved oxygen and pH are measured at the start and end of each 24-hour period in one test container from each treatment. For elutriate or pore water tests, chambers are cleaned and test solutions are renewed every 24 h.

For whole sediment tests, a portion of the overlying water should be replaced each day and dead brine shrimp carefully siphoned from the sediment surface in each container. Daily observations should be made and the number of live larvae recorded each day. Dead larvae should be discarded. At the conclusion of the test final counts of surviving larvae should be made and live larvae collected and killed by immersion in cold deionized water. The larvae should be rinsed with deionized water, placed in preweighed aluminum pans, and oven-dried to constant weight to obtain final dry weights. Mean survival and growth (measured as dry weight) of larvae exposed to test samples can then be compared to mean survival and growth of larvae exposed to controls. An acceptable test should have 80% survival in the controls.

5.3.3.8.2 Amphipods

Static or flow-through acute 10-day toxicity tests can be used to determine the relative toxicity of marine and estuarine sediments using the amphipods *Eohaustorius estuarius*, *Ampelisca abdita*, and *Leptocheirus plumulosus*. *Rhepoxynius abronius* and *Grandidierella japonica* can be used to test marine sediments with salinities >25 ppt. These tests can be conducted according to procedures described in several publications.^{6,9,75,80-88} Both the EPA and ASTM provide guidance for conducting tests with these species that summarizes ecological and testing conditions for each.^{6,75} On the west coast of the United States, *R. abronius* has been widely used in sediment toxicity assessments and has been recommended as a benchmark test species for comparing different data sets and assessing the sensitivity of newly developed test methods.^{75,81,82,89} It is suitable for marine sediments having interstitial salinities of at least 25 ppt. These tests are conducted using filtered seawater at a salinity of 28 ± 2 ppt. *Grandidierella japonica* has also been used in studies along the southern west coast of the United States; its ability to survive in varying sediment types makes it useful for a variety of research and regulatory applications. *A. abdita* has been tested in marine sediments at interstitial water salinities of 0 to 35 ppt when overlying water salinity is >28 ppt. The estuarine amphipods *E. estuarius* and *Leptocheirus plumulosus* are suitable for testing sediments for interstitial salinities ranging from approximately 1 to 33 ppt.

Rhepoxynius abronius is found on the west coast of the United States, from Puget Sound, Washington to California. It is a free-burrowing amphipod, typically found in the low intertidal-subtidal areas in the upper 2 cm of clean fine sands.⁸¹ This organism may exhibit mortality when held in sediments composed largely of silt and clay.⁸² Test organisms are obtained from field collections at uncontaminated sites, rather than from laboratory cultures. The amphipods can be collected with an epibenthic dredge, using short hauls (20 m) to prevent damaging the animals. Amphipods are sieved from the sediment for enumeration and then placed in holding containers with clean seawater and about 10 cm sieved sediment; up to 1000 amphipods can be held in a 20-L plastic bucket. The buckets should be kept cool and transported to the laboratory as soon as possible. About 5-L sieved collection site sediment should also be retained for use as the negative control. In the laboratory amphipods are held at $15 \pm 1^\circ\text{C}$ under continuous light with gentle aeration provided. Swartz et al.⁸¹ recommended sorting the amphipods, transferring them into small containers (20 in each) with clean sediment, and holding them in flowing seawater until used for testing. The amphipods can be held under static conditions if the overlying seawater is replaced every 1 to 2 days. The cultures are not fed, but the seawater (28 ± 2 ppt) is replaced every 1 to 2 days. The amphipods should be used within 2 to 10 days of collection.

Ampelisca abdita is found on the east coast, from Maine to northern Florida, and in the eastern Gulf of Mexico; there is also an introduced population in San Francisco Bay.⁸⁴ Unlike burrowing *Rhepoxynius abronius* and *Eohaustorius estuarius*, this species is a tube dweller, building soft 2- to 3-cm-long tubes in fine silty surface sediments. There is some evidence that sediments containing >95% sand may elicit mortality (John Scott, SAIC Narragansett, RI, personal communication). *A. abdita* has a shorter life cycle (6 weeks at 20°C) than other amphipods, which makes it a candidate

for tests using reproduction as an endpoint.⁸⁴ Test organisms can be purchased or obtained from field collections. For field collections, *A. abdita* are collected using a small dredge or grab or by skimming surficial sediments with a hand-held long-handled net. The amphipod tubes are then gently sieved in the field to separate them from surrounding sediments and the amphipods and tubes are immediately transported back to the laboratory in clean buckets with overlying seawater and maintained at temperatures either at or below collection temperature.

In the laboratory the amphipods and tubes are placed on a sieve series consisting of 2.0-, 1.0-, and 0.5-mm sieves. Collection temperature seawater is sprayed over the tubes to separate the amphipods from the tubes. The amphipods fall through the sieve series and are sorted according to size. In the laboratory *A. abdita* are held in clean sediment under flow-through conditions at collection. If need be, they are acclimated at 2 to 3°C/day until they reach test conditions (20°C). During holding and acclimation they are fed a diatom algae (*Phaeodactylum tricorutum* or *Skeletonema*) daily.⁶ Organisms should be used within 2 to 10 days of collection.

Eohaustorius estuarius is distributed from British Columbia to central California⁸³ and is found in clean, fine sediments in the intertidal region. Amphipods can be collected near the shore using a shovel and handled and maintained using the same methods as for *R. abronius*, except that the holding containers are placed in aquaria filled with water at the same salinity as the collection site (3 to 10 ppt). *E. estuarius* has been successfully tested in salinity ranges from 0 to 34 ppt and in sediments with a wide range of grain-size characteristics.⁹¹ Tests are generally performed at the salinity of the test sediments, so it may be necessary to acclimate the amphipods to increased salinities. *E. estuarius* can acclimate to changes from 5 to 25 ppt within a matter of hours, but such a short acclimation period should probably be avoided.

Grandidierella japonica has been used for environmental studies in southern California and is found throughout California bays and estuaries. Its ability to survive well in a variety of different sediment types makes it useful as a test species. It can be collected from intertidal and subtidal sediments, by collecting the top 2 to 4 cm of sediment in a bucket, stirring the sediment gently, and pouring the supernatant fluid through a 1.0-mm sieve. The material collected on the sieve should then be transported to the laboratory for sorting. Females with embryos in their marsupium should not be used. Tests should be conducted between 15 and 19°C with overlying water of 30 to 35 ppt.⁷⁵

Leptocheirus plumulosus has been reported in the literature as a useful species for testing the toxicity of estuarine sediments.^{86,87} It is found along the east coast of the United States from Massachusetts to northern Florida. It inhabits both oligohaline and mesohaline areas in subtidal sediments ranging from fine sand to clay. Organisms may be either field collected or cultured.⁶ Field-collected organisms are obtained using a small dredge or grab and should be held no longer than 4 days prior to testing. Organisms should be 2 to 4 mm in length or retained on a 0.5-mm sieve after passing through a 0.71-mm sieve. *L. plumulosus* may be tested in an acute or chronic test.⁹ The chronic test method is similar to the acute test method described below, with the following exceptions. The test organisms should not vary more than 2 to 3 mm in size, and 10 organisms per replicate are used. In a 28-day exposure organisms are fed approximately three times per week — 20 mg finely ground TetraMin during days 0 to 13 and 40 mg finely ground TetraMin during days 14 to 28. One third of the water in each jar is replaced two times per week. At test termination survival, young production, and growth (length) are the response measures. A 28-day exposure assay is acceptable with 80% survival in the controls.

Test containers for 10-day whole sediment toxicity tests are 1-L glass jars or beakers, each containing a 2-cm layer of sediment and 800 mL filtered seawater (adjusted to the appropriate salinity as necessary). Test containers for *A. abdita* are 1-L glass jars with a screened hole drilled near the top to allow water overflow in a flow-through arrangement. Negative controls consist of sediment from the amphipod collection site or “clean” sediments proven to be nontoxic and filtered seawater. The sediments are prepared the day before test initiation and allowed to equilibrate overnight, and the amphipods are added the following day (day 0).

Replication of treatments is dependent upon the objectives of the experiment; however, a minimum of five replicates is recommended for each treatment. Each replicate should contain 20 amphipods. Daily monitoring of water quality parameters (temperature, pH, dissolved oxygen, and salinity) should be conducted and may be done in one of the replicates or an additional separate monitoring replicate. The test is conducted at $15 \pm 1^\circ\text{C}$ ($20 \pm 1^\circ\text{C}$ for *A. abdita*, $25 \pm 2^\circ\text{C}$ for *L. plumulosus*), under continuous illumination for 10 days, with gentle aeration provided. Water quality and emergence (*R. abronius* and *E. estuarius* only) are measured daily. Organisms are not fed during the test. After 10 days the sediments are sieved, and the number of living, dead, and missing amphipods is determined for each replicate.

The level of effort required to recover surviving amphipods varies with the species. *R. abronius* are the easiest to recover because they are more easily distinguished by their pink color and because they tend to float during sieving. *A. abdita* are the most difficult to recover from their tubes. Response criteria include mortality, emergence from sediment, and ability to rebury in clean sediment after a 10-day exposure. Test acceptability in all the amphipod 10-day exposures is 90% survival.

5.3.3.8.3 Bivalves

Methods for performing toxicity tests with aqueous samples using four species of bivalve embryos are described in the EPA⁸⁸ and ASTM⁵⁰ and the red abalone larval development in the EPA.⁸⁸ Application of the oyster larvae test method to sediment toxicity assessment was developed by Chapman.⁸⁹ Species of bivalves are commonly used to conduct 48-hour larval development toxicity tests: the Pacific oyster, *Crassostrea gigas*, and the mussel, *Mytilus* sp. (*M. edulis*, *M. californianus*, *M. galloprovincialis*, or *M. trossulus*). Since the different mussel species have been difficult to distinguish, on the west coast bay mussels are referred to at the genus level for toxicity testing. Although the larvae do remain in the water column during the exposure period, tests can be conducted in the presence of pore water⁹⁰⁻⁹³ or by using elutriates.²⁶

Adult oysters may be obtained from wild populations, oyster farms, or commercial hatcheries, depending on the season. The natural spawning season for oysters in the Pacific Northwest is June to September, but this can be extended with some success by artificial conditioning and by obtaining gravid oysters from California. Upon arrival, the oysters should be cleaned of fouling organisms and held in either a flow-through or static-renewal seawater system at $20 \pm 1^\circ\text{C}$, 30 ± 2 ppt salinity, and a photoperiod of 16:8 h light:darkness. The oysters should be kept in small shallow trays (5 to 10 oysters per tray) to minimize losses due to mass spawnings. Care must be taken with the animals as rough handling may cause spontaneous spawning of very mature oysters. Oysters being brought into spawning condition should be held initially at the collection site temperature and acclimated to the conditioning temperature at intervals of 2°C every 2 days. During the summer oysters may require little or no conditioning, but in the winter the process may take 6 weeks or more and may be unsuccessful. The condition of the gonads should be checked regularly by sacrificing a few oysters and examining them by dissection. Healthy, mature oysters are characterized by plump, milky gonads, with females having many round or teardrop-shaped granular eggs and males having active, motile sperm. Conditioned oysters should not be held for more than 6 to 8 weeks, as gamete condition will begin to deteriorate. The oysters should be fed daily, using an algal suspension prepared from a marine diatom paste. Fecal material should be siphoned from the tanks daily when any mortalities are removed and recorded.

Adult mussels can be obtained from wild populations collected from uncontaminated areas or from commercial suppliers. The natural spawning season for local mussels on the U.S. west coast can be extended all year by locating different mussel species up and down the coast. Much of the information provided for oysters also applies to mussels. The mussels are kept in small shallow trays (10 to 20 per tray) to prevent mass spawnings, at 15 to 1°C . Development rates may depend on the species, local population characteristics, or other factors. Healthy, mature mussels are characterized by plump, orange gonads along the insides of the shells.

Toxicity tests are used to provide information about the effects of marine sediments (solid-phase or elutriate) on the embryos and larvae of Pacific oysters and mussels.⁹⁴ Mature adult bivalves are stimulated to spawn when they are placed in individual spawning dishes in a warm-water bath (30°C for oysters and 20°C for mussels) and adding a small amount of sperm suspension obtained from a sacrificed male bivalve. Once spawning begins the bivalves are removed from the water bath and allowed to spawn for approximately 30 min. The eggs and sperm should be examined under a microscope to assess their viability, and then all the eggs from at least one female and an aliquot (20 to 50 mL) of sperm suspension from a male should be combined in a stock beaker. While spawning and fertilization are in progress, the treatments can be prepared.

For tests conducted in the presence of sediment, the methods described by the EPA⁸⁸ or the ASTM⁵⁰ can be used. The test containers are clean 1-L containers. For each treatment, five replicates are prepared: 20 g of material are weighed into each test jar and covered with 1 L of filtered seawater. The sediments are shaken for 10 s and then allowed to settle for 4 h before inoculation with newly fertilized embryos. Sediment elutriates can be prepared according to the EPA/COE.²⁶ The elutriates are prepared by combining sediment and clean seawater together in a 1:4 ratio, stirring for 30 min, and then allowing the mixture to settle for 60 min. The supernatant is then decanted and used for testing. Test containers are clean 250-mL beakers, with a 200-mL test solution volume. Each elutriate is tested at three concentrations (10, 50, and 100%), with five replicates per treatment. Negative (clean) controls for both tests consist of filtered seawater.

Within 1.6 to 2 h of fertilization the embryo density in the stock beaker is measured by making duplicate counts of a 1:99 dilution of embryo suspension. Each test container is inoculated with a sufficient number of embryos to provide a density of 20 to 30 embryos per milliliter. Additional “zero-time” controls are also prepared. These are used to collect subsamples after inoculation to confirm the embryo density and to monitor the progress of the test without disturbing the test organisms. Counts from the “zero-time” controls are used in subsequent larval mortality calculations. The test containers are allowed to incubate at test temperature ($20 \pm 1^\circ\text{C}$ for oysters and 15 or $18 \pm 1^\circ\text{C}$ for mussels) for 48 ± 4 h. After 48 h, the water in each test container is carefully decanted (if sediment was present) and then mixed to resuspend the larvae. Multiple 10-mL aliquots of test solution are removed by pipette, transferred to screw-cap glass vials, and preserved with 5% buffered formalin. The larvae are examined under a compound microscope at 100 \times to enumerate normal and abnormal larvae. Larvae that fail to transform to the fully shelled, D-shaped prodissoconch I stage are considered abnormal. The test endpoints are larval abnormality and mortality. Control survival must be = 70% for oyster embryos or = 50% for mussel embryos and = 90% normal shell development in surviving controls.

The red abalone (*Haliotis rufescens*) is a 48-hour embryo-larval development test⁸⁸ that has been utilized with pore water samples.⁹⁰ Adult male and female abalone are induced to spawn by exposure to hydrogen peroxide solution in seawater for approximately 2.5 h. Fertilized eggs are distributed to test chambers within 1 h of fertilization. The test is conducted at $15 \pm 1^\circ\text{C}$, 34 ± 2 ppt salinity, and a photoperiod of 16:8 h light:darkness. At the end of the 48-hour period, larvae are preserved and counted to determine the number of normal and abnormal larvae. Control normal larval development must be = 80%.

5.3.3.8.4 Echinoderms

Several echinoderm species can be used to conduct echinoderm sperm cell fertilization or echinoderm larval development toxicity tests. On the west coast the purple sea urchin, *Strongylocentrotus purpuratus*, and the sand dollar, *Dendraster excentricus*, are commonly used for both test endpoints.⁸⁸ A method for performing a sperm cell fertilization test with the east coast, sea urchin, *Arbacia punctulata*, has been published.⁹⁵ The sperm cell fertilization test has a very short duration and requires very little sample; echinoderm sperm are exposed to test solutions for 60 min for *Arbacia* and 20 min for the west coast species. After sperm exposure, echinoderm eggs are added

for a 20-min fertilization period; then the eggs are preserved for later enumeration. The endpoint is fertilization success, demonstrated by the formation of the fertilization membrane. This test was developed for testing aqueous samples; because the eggs settle after preservation and particles may interfere with fertilization this test is appropriate for pore water and elutriates, but not for whole sediments. In addition, the interstitial water and elutriates need to be relatively clear and particle-free to allow the researcher to view the presence (or absence) of the fertilization membrane and to prevent the sperm from attempting to fertilize sediment particles.

Most recently, the sediment-water interface approach has been adapted for a sea urchin larval development test described by Anderson et al.⁹⁶ The test utilizes an intact sediment core with a screen tube inserted to the top of the core with clean overlying seawater. The embryos are inoculated into the screen tube, and the negatively-buoyant embryos settle to the bottom and develop on the screen at the sediment interface. An advantage of this approach is that it more closely represents *in situ* exposure conditions and utilizes intact sediment samples. The larvae remain in the water column during the 48-hour exposure, and the test endpoints are normal development to the echinopluteus stage.

Adult sea urchins can be obtained from wild populations at uncontaminated locations. The natural spawning season for the purple sea urchin, *S. purpuratus*, is approximately September to April, but this may be extended either by conditioning animals in the laboratory through manipulation of temperature and photoperiod⁹⁷ or by purchasing animals from California. Some facilities have been able to maintain supplies of gravid sea urchins on a year-round basis⁹⁸ and reuse spawned animals after recovery and reconditioning. Locally collected animals should be transported in buckets of seawater with aeration, with care taken not to damage the animals' spines. Purple urchins can be held either in a static aquarium filled with seawater ($15 \pm 1^\circ\text{C}$ and 34 ± 2 ppt salinity) and equipped with an under-gravel filtration system or preferably in flowing seawater at 15°C . Purple sea urchins should be kept in darkness. A sediment substrate (other than the gravel filtration system) is not required. Urchins can be fed either fresh *Macrocystis pyrifera*, or fresh or dried kelp, *Laminaria* sp., gathered from uncontaminated zones. Animals should be sacrificed periodically, or used in trial spawnings, to assess the condition of the animals.

Adult sand dollars can be obtained from wild populations from uncontaminated locations. The natural spawning season for the sand dollar, *Dendraster excentricus*, is approximately May to October on the west coast, but this may vary from year to year depending on the weather. Animals can be collected at low tide and transported in buckets of sediment and seawater with aeration, with care taken not to damage the animals' exoskeleton. Sand dollars can be held in shallow trays containing a 3- to 5-cm layer of clean sediment with flowing seawater at 15 to 1°C . Sand dollars feed on suspended or benthic materials such as phytoplankton or benthic diatoms. Animals should be sacrificed periodically, or used in trial spawnings, to assess the condition of the animals.

The sperm cell fertilization test can be conducted according to procedures described by the EPA or Environment Canada.^{55,88,99} The test species are sand dollars (*Dendraster excentricus*) or sea urchins (*Strongylocentrotus purpuratus*) depending on seasonal availability. High-quality natural seawater, which has been filtered through a 1- μm filter, should be used for the dilution, control water, making hypersaline brine, or all three. The test may be conducted using a single concentration (e.g., 100%) or a series of dilutions, if a definitive dose-response is desired. Spawning is induced by injection of 0.5 M KCl into the coelomic cavity. Female organisms can be wet-spawned into 250-mL beakers filled with seawater, but males should be dry-spawned. Males can be spawned into petri dishes containing a little seawater; the sperm can be collected by pipette before they become activated, transferred to a small vial, and stored on ice. The tests are conducted in small glass test tubes at 15°C for west coast species or 20°C for *Arbacia* with a 20-min sperm exposure for west coast species or 60-min sperm exposure period for *Arbacia* and a 20-min egg fertilization period. Prior to conducting a definitive test, a pretrial fertilization may be performed to determine the sperm:egg ratio that yields the desired control fertilization. Toxicity of the test solutions to echinoderm sperm is based on fertilization success of the eggs. Percentage fertilization is determined

by examining subsamples of 100 eggs from each replicate for the presence or absence of a normal fertilization membrane. Control fertilization must be between 70 and 90% for *Arbacia* and = 70% for the west coast species.

Sediment-water interface toxicity tests with the purple urchin echinoderm larvae can be conducted according to methods described by the EPA,⁸⁸ as modified from ASTM procedures.¹⁰⁰ Spawning is induced by injection of 0.5 M KCl into the coelomic cavity. It may be necessary to spawn many animals to obtain a sufficient number of eggs to inoculate a large number of test containers. The eggs and sperm are examined under a microscope to assess their viability and then combined at a density of 500 sperm per egg. At least 95% egg fertilization should be achieved. Sediment samples are placed into the test chambers, as described in Anderson et al.⁹⁶ and filled with uncontaminated overlying seawater and equilibrate for 24 h prior to addition of embryos. The test containers are allowed to incubate at $15 \pm 1^\circ\text{C}$. The test duration is between 72 and 96 h to reach the echinopluteus stage. At the end of the test the water in each test container is carefully washed to remove embryos into a funnel, with buffered 5% formalin, capped, and evaluated later. The larvae are examined under a compound microscope at $100\times$ to enumerate normal and abnormal larvae. Larvae that fail to transform to the echinopluteus stage are considered abnormal. The test endpoints are larval normal shell development, with an acceptable test having 80% normal larval development. This test procedure has been utilized in California by Hunt et al.¹⁰¹ and Phillips et al.⁹⁸

5.3.3.8.5 Polychaetes

Two species of polychaetes used successfully in sediment toxicity tests include *Dinophilus gyrociliatus* and *Neanthes arenaceodentata*. *D. gyrociliatus* is tested for survival and growth in 4-day pore water exposures.^{102,103} Many species of polychaetes have been used in toxicity tests (see Reish for a review).¹⁰⁴ Two types of relatively short-term sediment toxicity tests using *N. arenaceodentata* include a 10-day static, acute test or a 20- to 28-day static-renewal, sublethal growth test, according to Dillon et al.,¹⁰⁵ Standard Methods,¹⁰⁶ or the ASTM.¹⁰⁷ A comparison study was conducted between the amphipod *Rhepoxynius abronius* and the polychaete *N. arenaceodentata*, with 341 samples collected in California.¹⁰⁸ Anderson et al.¹⁰⁸ found that the amphipod was a greater indicator of toxicity; however, the polychaete protocol could be improved by minimizing replicate variability and thereby increasing test sensitivity. Long-term studies (10 weeks) examining the effects of sediment exposure on survival, growth, and reproduction have also been performed with *Neanthes*.^{109,110} Juvenile polychaete worms, *Neanthes arenaceodentata*, can be obtained from Dr. Don Reish at California State University, Long Beach, California, or cultured in-house and require very little time to maintain.¹¹⁰ Laboratory cultures can also be readily maintained.

Worms used in the tests should be 2 to 3 weeks postemergence and of uniform size. If worms are purchased, they are transported in Whirlpak bags (20 each) with seawater and a little *Enteromorpha* algae and shipped by overnight courier. Upon arrival at the laboratory the Whirlpaks should be placed in a small aquarium filled with 20°C seawater. Once the temperature has equilibrated, the bags should be carefully opened and the worms teased out with a fine paintbrush. At this age the worms are small (10 to 15 mm in length) and delicate and must be handled very carefully. A small amount of *Enteromorpha*, presoaked in seawater if available, should be added to the aquarium for the worms to use in tube formation. The worms can be fed *Enteromorpha* or finely ground up TetraMarin as needed. Be careful not to overfeed, especially with TetraMarin since it may foul the water. The worms are held under static conditions at $20 \pm 1^\circ\text{C}$, at 28 to 35 ppt, with gentle aeration provided. The worms should be held for less than 1 week, or they may mature sexually before the 20-day growth test is complete.

The test containers are 1-L glass jars, each containing a 2-cm layer of sediment and 800-mL filtered seawater. The sediments are prepared the day before test initiation and allowed to settle overnight, and then the worms are added the following day (day 0). The negative control consists

of sediment from an uncontaminated location and filtered seawater. There are five replicates per treatment.

In the 10-day acute test, each container is seeded with ten worms. There are no water changes, and the worms are not fed. Water quality parameters are measured daily for 10 days. After 10 days the worms are sieved from the sediments, and the number of live, dead, and missing worms is recorded. Replicate data are pooled and compared to responses in the negative control and the reference sediment.

For the 20-day sublethal test, each container is seeded with five worms. Approximately one third of the water volume in each test container is replaced every third day; water quality parameters are measured at that time. The worms are fed ground TetraMarin flakes (8 mg per worm) every second day. On day 0 at least three subsamples of five worms should be set aside, rinsed with distilled water, and dried at 50°C for 24 h to provide an initial estimate of dry weight. At day 20 the worms are carefully removed from the sediments, and the surviving worms are rinsed, dried, and weighed. The average dry weights obtained for each treatment are compared to the initial dry weights to determine the percent change in biomass. Acceptable tests have a minimum of 90% control survival.

Carr et al.^{102,103} have described a 4- to 10-day liquid-phase exposure using the archiannelid *Dinophilus gyrociliatus*. The 96-h assay measures survival with the 7- to 10-day assay measure survival and reproductive impairment, that is, egg production, eggs per egg capsule, time until laying and hatching, and juveniles per female. The organisms can be cultured and have been collected from North American coasts as well as Japanese and European waters.¹⁰²

Tests are conducted in 20-mL Stender dishes with a 10-mL test solution. At least four organisms are used per replicate (five per treatment). Tests use 1- to 2-day postemergence females. At time zero 50 µl of 0.5% spinach food suspension is added to each dish. Dishes are examined at days 1, 4, and 7 using a dissecting microscope. At test termination mortality and sublethal reproductive effects are recorded.

5.3.3.8.6 Mysids

Methods for conducting 96-hour static, acute tests⁵⁶ and 7-day static-renewal, sublethal tests⁵⁵ with the mysid, *Americamysis bahia* (formerly *Mysidopsis bahia*), are described by the EPA and ASTM. These methods were developed to test aqueous samples such as effluents and receiving waters. *A. bahia* is also listed in the EPA/COE as a possible species for testing elutriates and sediments.²⁶ Although mysids are usually associated with the water column, they can be used for testing whole sediments or aqueous fractions. Juvenile mysids have been observed to remain in close contact with the aquarium gravel in their culture containers and are generally in contact with sediments in a laboratory experiment. Pore water and elutriates can be tested using standard protocols for effluent tests; whole sediments can be tested using the same type of procedure described for fathead minnow or amphipods.

Juvenile mysids for acute toxicity tests should be 1 to 5 days old within a 24-hour range. Mass cultures of adults can be transmitted in 70-L aquaria filled with seawater and equipped with under-gravel filtration systems. If seawater is artificial, it should be aged for several weeks prior to use. New culture tanks should be prepared 1 week before needed and inoculated with a small amount of *Artemia*. A few mysids can be added and observed before making mass transfers. The mysids should be maintained at $25 \pm 1^\circ\text{C}$, 8.0 ± 0.2 pH, and a salinity of 20 to 30 ± 2 ppt. The mysids are fed newly hatched live *Artemia* twice daily. To obtain test organisms gravid females should be removed from the culture tank and placed in a separate tank in an incubation basket fitted with a mesh bottom. After 48 h the incubation basket containing the adults is removed. The juveniles remaining in the tank can be used until they are 5 days old.

Acute toxicity tests can be conducted in 2-L glass beakers equipped with Nitex mesh baskets to hold the mysids. Use of the Nitex baskets facilitates daily mortality observations in turbid treatments,

without unduly stressing the organisms. A test volume of 1 L can be used, with at least two replicates per treatment, each containing 10 juvenile mysids. The test is conducted at either 20 (acute) or 25 (chronic) $\pm 1^\circ\text{C}$ under a 16:8-hour light:dark photoperiod with gentle aeration. The test duration of 96 h and the mysids are fed newly hatched *Artemia* each day. The negative control consists of an equal number of replicate containers containing natural seawater (20 to 30 ± 2 ppt salinity). Successful assays have at least 90% survival in acute exposures and 80% in 7-day exposures.

5.3.3.8.7 *Algae*

Methods for conducting toxicity using the red alga, *Champia parvula*, are described by the EPA and ASTM.^{55,78} The procedure was designed to measure the effects of toxic materials in effluents and receiving waters on sexual reproduction of this marine alga. This test is not suitable for testing whole sediments because test containers are shaken during the exposure, and this would result in disturbance of the sediments. In addition, the large sample volume necessary for this toxicity test (100 mL/replicate) makes this organism unacceptable for interstitial water testing except under the most unusual conditions. The only sediment fraction that this test may be used for are elutriates; however, particulates in elutriates must not interfere with light transmission that may affect test results.

The *Champia* toxicity test involves a two-dimensional exposure of sexually mature male and female plants to test solutions, followed by a 6- to 7-day recovery period in culture medium to allow maturation of cystocarps. Fertilization occurs during the two-dimensional exposure period. Cultures of male and female plants may be obtained from the University of Texas Culture Collection (<http://www.bio.utexas.edu/research/utex/>). Once established, new cultures can be propagated asexually from the algal branches, making it possible to maintain the same clone continuously. Male and female plants are reared separately in 800 mL aerated culture medium in 1-L glass Erlenmeyer flasks at 23 $\pm 1^\circ\text{C}$, using a 16:8-hour light:dark photoperiod and a light intensity of 100 $\mu\text{E}/\text{m}^2/\text{s}$ (500 ft-c). Details for preparation of nutrient stock solutions and culture and testing media are provided by the EPA.⁵⁵ One limitation to using this test is that natural seawater is the preferred water source for culture and testing, and suitable supplies may not always be available.

Plants should be checked for maturity prior to initiating a test. Female plants are characterized by the presence of trichogynes (reproductive hairs) at the apex of the branches, while males should have mature spermatial sori (clusters of reproductive bodies that protrude from the edge of the thallus surface). If a female plant is placed in water from a male culture for a few seconds, spermatia should be visible on the trichogynes. Toxicity tests are conducted in 250-mL Erlenmeyer flasks, with a 100-mL test solution (elutriate or interstitial water) volume and a minimum of three replicates per treatment. Test media are prepared without addition of metals or EDTA. One male plant cutting and five female plant cuttings are added to each test container.

Test containers are incubated under the same conditions used for culture and are either swirled by hand twice daily or placed on a rotary shaker at 100 rpm. After 48 h the female plants are transferred to a new set of containers with culture medium, provided with gentle aeration, and incubated for an additional 5 to 7 days. Following this recovery period the plants are examined under a microscope and the number of cystocarps per female enumerated. Cystocarps are characterized by an apical opening for spore release and the presence of dark spores. If cystocarps are not fully developed, the test can be extended a short period (24 to 72 h); no new cystocarps will form without the presence of male plants. Toxic effects are expressed as a reduction in cystocarp formation relative to the negative control. For a test to be considered valid, average control mortality must be = 20%, and the average number of cystocarps must be at least 10.

5.3.3.8.8 *Microtox*

The Microtox test uses the photoluminescent marine bacterium *Vibrio fischeri* and may be used in freshwater, estuarine, or marine studies.^{30,110,112} Changes in bioluminescence in response to

exposure to test solutions are detected using a Microtox analyzer. Methods for preparing saline and organic extracts from whole sediments are described by the EPA.¹¹⁰ In addition, a solid-phase test protocol was recently developed. Initial testing of this method shows it to be at least as sensitive as the conventional elutriate fraction assay.¹¹³ In addition, interlaboratory comparison tests performed with the solid-phase test indicates test variability to be within normal biological testing parameters.¹¹⁴ The solid-phase protocol is similar to the liquid phase; however, there is a sediment exposure/filtration step added.

Freeze-dried bacteria are rehydrated with 1-mL reconstitution solution and stored in the Microtox analyzer at 4°C. Serial dilutions of 0, 12.5, 25, 50, and 100% are prepared with the elutriate or pore and Microtox diluent (2% NaCl in sterile water). The 0% dilution is a control blank containing only diluent. Each of 10 cuvettes receives 10 µl of the bacterial suspension and 350 µl of diluent. These are allowed to incubate at 15°C for 5 or 15 min; then, an initial light reading is taken. Aliquots of 500 µl are added to two of the cuvettes from each extract dilution (two replicates per dilution). At 5 or 15 min after addition of the extract a final light reading is taken.

Measured values are relative to standard light levels set at the beginning of the test. The light given off by the bacteria diminishes naturally over time. Light loss in the blank controls is used as a ratio to normalize results from the cuvettes containing sample supernatant. The blank response is the ratio of light levels read at time zero and after 15 min. Light-level results of the test chambers are normalized against the blank response to yield gamma values. The gamma value is a percent decrease (represented as a positive value) in light that has been adjusted to take into account the natural loss in luminescence over time of the bacteria. Negative gamma values represent an increase in light output in the system. The 15-min EC₅₀ (effective concentration yielding a 50% response in the test system) values for each sample can be calculated.

With some samples it is necessary to alter the method to optimize sensitivity. Some samples have turbidity or color associated with them that can be determined and removed from the effect determination. For samples containing ionic compounds, such as ammonia, the response can be optimized by replacing the NaCl osmotic adjusting solution with 20.4% sucrose.¹¹⁵ Because turbidity, grain size, and color play a large role in the interpretation of the solid-phase test, factoring in these effects should be considered in the assessment of toxicity.¹¹⁶

5.4 QUALITY ASSURANCE AND QUALITY CONTROL (QA/QC)

Quality assurance (QA) is a total integrated program organized and designed to provide accurate and precise results to assure data reliability. Included in this program are selection of proper technical methods or laboratory procedures, sample collection and handling, data quality objectives, evaluation of data, quality control, and qualifications and training of personnel. Quality control (QC) includes specific actions for obtaining prescribed standards of performance as part of a quality assurance program. Included are standardizations, calibration, replicates, and control and reference samples suitable for providing statistical estimates of data confidence. The following general QA/QC guidelines^{8,9,55,56,77,110} apply to all toxicity tests.

5.4.1 Negative Controls

All toxicity assays must be conducted using well-established negative (clean) controls. For every test series with a particular organism or biological system, one test chamber (or series of chambers) must contain diluent water (or clean sediment plus diluent water) only. If solvent carriers are used to introduce organic compounds (e.g., pesticides), then the concentration of the solvent used in the highest treatment must be added to clean dilution water and used as an additional set of controls. In the case of tests involving chemical extraction procedures, solvent controls and solvent extracts of clean, inert sediment comprise the negative controls. The complete test series

must be repeated if more than 10 to 20% (depending on the test method's test acceptability criteria) of the control organisms die or show evidence of sublethal effects.

Sediments should be tested as soon as possible after collection. It is recommended that the storage time not exceed 2 weeks.¹⁵ If storage is to exceed a 6-week period, then an initial chemical or toxicity analysis (e.g., ammonia, Microtox) should be conducted when the samples are brought into the laboratory and immediately prior to toxicity testing to verify stability.

5.4.2 Positive Controls (Reference Toxicants)

All toxicity assays should include positive (toxic) controls, conducted with well-established standard reference toxicants. For sediment tests, these are conducted in the absence of sediment. Reference toxicants (e.g., KCl, Cu, Cd, Zn) are used to provide insight into mortalities or changes in organism sensitivity that may occur as a result of acclimation, disease, loading density, or handling stress. Concurrent tests using a reference toxicant should be implemented at regular intervals (e.g., monthly for cultures maintained in-house) and for each new batch of test organisms obtained. Control charts as described by the EPA^{55,56,88} are constructed for each species, and reference toxicant is used. The cumulative mean value (recalculated with successive data points until the results are stable) and upper and lower control limits (mean \pm 2 S.D.) are plotted on each chart. These charts should be available in the laboratory so that the results of each reference toxicant test can be compared to the mean.

Reference toxicant testing can be conducted using either water-only exposures of 48 to 96 h or spiked sediments of 7- to 10-day exposures. The water-only exposure is preferred as there are fewer variables involved; thus, results can be more consistent than when spiking sediments. Standard spiking protocols currently do not exist, and the toxicity of the sample will be influenced by procedural differences and sediment characteristics. For reference toxicant testing in water-only exposures using benthic species, it is advantageous to provide a substrate to reduce organism stress. For *H. azteca*, *C. tentans*, and *H. limbata*, this involves use of a plastic mesh, sand monolayer, and glass tube, respectively. Organisms may be fed at time zero and at 48 h. There has been limited testing of spiked sediments.^{15,19,20,24} Environment Canada has developed a standard guidance for reference toxicant testing with spike sediments.¹¹⁷ At present, however, there has been little research into this area, and issues such as proper spiking methods, equilibration times of spiked sediments, and recipes for formulated sediments have not been adequately resolved.

5.4.3 Reference Sediments

Reference sediments are most commonly required for sediment tests but may also be appropriate for water-column tests. Physical and chemical characteristics of control sediments may be very different from test sediments. Reference sediments are collected from an area documented to be free of chemical contamination and should represent the range of important physical and chemical variables found in the test sediments. The ASTM defines a reference sediment as a whole sediment near an area of concern used to assess sediment conditions, exclusive of materials of interest. A control sediment is defined as a sediment essentially free of contaminants and is used routinely to assess the acceptability of a test. Data derived from such samples can be used to partition toxicant effects from unrelated effects such as sediment grain size.

5.4.4 Test Organisms

Only healthy organisms of similar size, age, and life history stage are used for toxicity assays. Taxonomic identification should be confirmed by a qualified taxonomist. Records of collection, shipping, and holding should be maintained for species obtained outside the laboratory. Records

of culture history, culture conditions, food, and water quality should be maintained for laboratory cultures.

5.4.5 Blind Testing

All treatment and test containers should be randomized, and testing should be conducted without laboratory personnel knowing the identities of the samples. Replicates of each treatment should be assigned a sample code during testing and randomized in the test sequence.

5.4.6 Replication

The number of replicates required varies from one protocol to another but should be sufficient to account for variability in test-organism response. Some tests may require two to five replicates. Sediment bioassays typically require five replicates per treatment. Unless otherwise specified in the experimental design, each treatment in a test series must begin with the same number of replicates. Statistical significance of toxicity test results has been evaluated for certain marine sediment tests by determining the ninetieth-percentile minimum significant difference.¹¹⁸ The examination of detectable difference is important for assessing whether an individual test result had either low sample variance (e.g., able to discern differences) or high sample variance (e.g., differences cannot be found).

5.4.7 Water Quality Measurement/Maintenance

Toxicity assays involving exposure of organisms in aqueous media require that the media be uncontaminated and that proper water quality conditions be maintained to ensure the survival of the organisms and to ensure that undue stress is not exerted on the organisms, irrespective of the test materials. Appropriate water quality parameters must be measured at least at the start and end of a test, and preferably every 24 h. Typically, alkalinity, hardness, pH, ammonia, and conductivity are measured at test initiation and termination. Dissolved oxygen, pH, salinity, and temperature are measured as specified in each test protocol.

5.4.8 Standard Laboratory Procedures

Standard laboratory procedures must be followed in all testing. These include proper documentation, proper cleaning, avoidance of contamination, and maintenance of appropriate test conditions. All unusual observations or deviations from established procedures must be recorded and reported. Records should be recorded and signed in ink.

5.5 SUMMARY

Sediment toxicity testing has only been a recent activity in ecological assessments. The first testing was spawned by concerns over dredged material contamination and its suitability for open-water disposal by the U.S. Army Corps of Engineers in the late 1960s and early 1970s. There was relatively little testing until the 1980s, with a dramatic increase in recent years.¹⁹ The science has been able to progress at a relatively rapid rate because of the similarities to, and state of, the more traditional water-column and effluent toxicity testing. As discussed in a preceding section, the EPA has initiated new efforts in managing contaminated sediments and method standardization that will undoubtedly result in an even greater degree of sediment toxicity testing, regulation, and research in the near future.^{5,53}

Table 5.1 Desirable Traits of Sediment Toxicity Assays

Sensitivity (responsiveness and protective capacity)
Discriminatory (discerns degrees of contamination)
Relevance (to ecosystem or study objectives)
Validity (field verification, lack of false positives or negatives)
Comprehensiveness (surrogate for wide range of species)
Reliability (consistent cultures and successfully completed test assays)
Reasonable resource requirements (expertise, time, cost, availability of organisms)
Standardization (accepted methods, large database, QA/QC criteria)
Uniqueness (produces nonredundant ecosystem information)
Confirmatory (opposite of uniqueness, provides weight-of-evidence)
Significance (critical ecosystem link or species)

The process of selecting the optimal tests for use in an ecosystem assessment is not as simple and straightforward as many would like. The optimal assay can only be selected when the study's objectives and associated data quality objectives have been defined and there is a reasonable understanding of the physical, chemical, and biological characteristics of the study site. This information must be combined with an understanding of the strengths and weaknesses of the various sediment toxicity assays available. Once standardized methods are recognized by the EPA, the process will be dictated for many studies. These methods provide information on successfully used procedures with advice on which conditions are the most critical; however, they are not definitive test methods and allow some investigator flexibility, which may be inappropriate for use by the inexperienced or for regulatory programs.

No one assay is superior to all others. A number of useful tests have been evaluated in freshwater and marine studies.^{4,19,119–124} The better tests have been described in the previous sections. To reduce both uncertainty and the likelihood of obtaining false positive or false negative results it is important to test more than one species. The importance of testing multiple species increases with the importance of protecting the ecosystem and the need to define “significant” contamination in the “gray” zone. The methods described below are for assays that represent critical levels of biological organization, have been shown to be sensitive to a wide variety of contaminants, are relatively discriminatory of differing levels of contamination, use relevant species for many desirable ecosystems, and have been successfully used in sediment contamination studies.⁵ The tests include optimal characteristics in that they are relatively standardized, the species can be obtained and cultured in a number of locations throughout North America, have a high degree of reliability (successful completion), are relatively inexpensive and short-term in nature, and have associated performance criteria to evaluate testing quality assurance and quality control (Table 5.1).

For most applications, a test battery consisting of two to three species can be recommended. These recommendations are for waters in temperate regions of North America, but they may be useful elsewhere and are based on the above characteristics and on comparison studies where multiple species have been used simultaneously in sediment contamination investigations.^{4,19,30,34,41,119–124} For both freshwater and marine systems, Microtox is recommended as a screening tool; it is useful in assessing a large number of samples and directing more intensive sampling. The bioluminescence response has been shown to be relatively sensitive to many contaminants and often correlated significantly with responses of other test species. It should never be used as the sole toxicity test method. The resource efficiency of the method; its degree of standardization and simplicity; and its ability to test water, pore water, elutriates, and a new solid-phase procedure make it versatile and relevant.

Both freshwater and marine studies should also use a water column and benthic species in solid-phase exposures. For freshwater studies in North America, the useful water-column tests are the early life stage *P. promelas* assays (larval growth or embryo-larval growth and deformities) or the 3-brood, survival, and reproduction assays with *C. dubia* or *D. magna*. Both of these cladoceran assays recently became ASTM methods.⁵¹ The freshwater benthic assays that have been most

Table 5.2 Toxicity Test Batteries: Recommended Assays for the EPA Assessment and Remediation of Contamination Sediments (ARCS) Program

Minimal size recommended: two test species and four measurement endpoints from at least three groupings.

Group A: *Chironomus riparius* 14-day survival; *Chironomus tentans* 10-day length; *Hyalella azteca* 28-day survival, length, sexual maturation, and antennae length; *H. azteca* 14-day survival; *Daphnia magna* 7-day reproduction; *Lemna minor* 4-day frond growth; and *Ceriodaphnia dubia* 7-day reproduction.

Group S: *C. dubia* 7-day survival; *C. riparius* 14-day length; *H. azteca* 14-day sexual maturation; and *Pimephales promelas* 7-day larval weight.

Group C: *Hydrilla verticillata* 10-day root growth; *Diporeia* 5-day avoidance/preference; and *H. azteca* 14-day survival.

Group D: *Hexagenia bilineata* 10-day survival and molting frequency.

Minimal Groupings with the Recommended Size Limits:^a

Option 1: a. *H. azteca* (14 days)
 b. *C. dubia*, *C. riparius*, *D. magna*, *P. promelas*, *Diporeia* or *H. bilineata*

Option 2: a. *C. dubia* or *C. riparius*
 b. *Diporeia* or *H. bilineata*

Option 3: a. *D. magna*
 b. *P. promelas*
 c. *Diporeia* or *H. bilineata*

^a All endpoints associated with each of the assays should be measured. Microtox should be used in reconnaissance surveys due to its high degree of correlation with the above assay response^{30,34} patterns. A predominant amphipod in the Great Lakes, *Diporeia* sp. (formerly *Pontoporeia hoyi*), survival and avoidance assay (5 days) showed behavior to be the most sensitive measurement endpoint in a U.S. EPA study that compared 25 toxicity assays comprised of over 50 endpoints.³⁰ For marine studies in North America, the choices are more varied with some geographic specificity. For water column species, the sea urchin *A. punctulata* and the red macroalga *C. parvula* are useful indicators of sediment toxicity. For benthic species testing, 10-day static sediment survival tests are used, with the Pacific coast amphipod species including *R. abronius* and *E. estuarius*, and on the Atlantic coast *A. abdita* and *L. plumulosus*.

successful are the 7- to 10-day survival test with *H. azteca*, the 10-day survival and growth assays in *C. tentans* or *C. riparius*, or the 10-day survival and molting frequency assay with *Hexagenia* sp. In addition, Ingersoll et al.²⁹ observed *H. azteca* growth, including length, antenna length, and sexual maturation, to be very sensitive indicators in 14- and 28-day exposures.

Also, with the recent publication by U.S. EPA and ASTM long-term sublethal sediment toxicity tests using *H. azteca* and *C. tentans*, various investigators are reporting sublethal endpoints (e.g., amphipod growth) that correlate with benthic response in the field.³⁰⁻³⁴ Burton and Ingersoll³⁰ have recommended three test battery options based on studies of "Areas of Concern" in the Great Lakes basin (Table 5.2). These recommendations were based on assay comparisons of toxicity sensitivity, ability to discriminate differing degrees of sample toxicity, response relationships (correlations) to other endpoint response patterns, and factor analysis that showed four unique response patterns. These test batteries will monitor at least two species, four measurement endpoints, and represent three response patterns.

These test methods have proven useful for assessing sediment toxicity in North America on a routine basis and can be conducted at a reasonable cost and with a reasonable level of training. The assays reported here are only those that have become "relatively" standardized or used extensively in assessments of sediment contamination. There are a number of other assays that show promise and may be standardized in the future. The recent and near future standardization of the methods reported in this chapter allows them to be incorporated into regulatory programs to provide more comprehensive assessments of protection of our aquatic ecosystems.

6.1 INTRODUCTION

Most wild and domestic animals ingest some soil or sediment, and some species may routinely, or under special circumstances, ingest considerable amounts. Ingested soil supplies nutrients, exposes animals to parasites and pathogens, and may play a role in developing immune systems.¹ Soil ingestion is also sometimes the principal route of exposure to various environmental contaminants.²⁻⁷ Ingestion of soil and earthy material is defined as geophagy and may be either intentional or unintentional, occurring as an animal eats or grooms.

The importance of soil ingestion for estimating exposure to environmental contaminants has been best documented in assessments of pesticides or wastes applied to land supporting farm animals. Soil ingestion tends to be most important for those environmental contaminants that are found at concentrations in soil that are high relative to concentrations in a soil-free diet. Lead is an excellent example. Reviews of soil ingestion by domestic animals that emphasize effects on mineral nutrition and the intake of chemical pollutants have been prepared by Healy,⁸ Fries and Paustenbach,⁹ and Fries.¹⁰ Evaluation of the soil-animal-product pathway is now a part of all risk

assessments that involve the presence or potential introduction of pollutants into agricultural environments.^{11,12}

The next section of this review examines the methods for determining soil ingestion and identifies the limitations and uncertainties associated with these methods. Intentional geophagy, discussed in the third section, has in general not been considered in risk assessments, although it is potentially an important route of exposure. The fourth and fifth sections present general conclusions from studies of soil ingestion by domestic and wild animals and include extensive tables summarizing rates of ingestion. The sixth section presents laboratory and field studies demonstrating injury through ingestion of contaminated soils or sediments. The seventh section addresses the texture of ingested soil, which is relevant to estimating exposure since environmental contaminants tend to be associated with particular soil fractions. The eighth section considers the bioavailability of environmental contaminants in soil. This topic is widely recognized as important, although risk assessors generally lack reliable measures of bioavailability that can be incorporated into risk assessments. The final section discusses default values in regulatory guidance documents of the U.S. Environmental Protection Agency (EPA).

6.2 METHODS FOR DETERMINING SOIL INTAKE

Studies of soil ingestion by domestic animals have employed a marker that was present in soil, taken up poorly by plants, and absorbed poorly by animals. The concentration of the marker in feces is thus a measure of the concentration of soil in feces, which with appropriate assumptions provides a means to estimate soil intake. Acid-insoluble ash and titanium oxide were the usual markers used in studies of soil ingestion by farm animals. At times, other markers were used for measuring soil ingestion by humans because titanium oxide is present in some consumer products.^{13,14} No one marker has been found to be consistently superior to the others. Acid-insoluble ash provides the advantage of ease of analysis, whereas analyses of titanium oxide, a single chemical entity, should be more precise and reproducible. The concentrations of a marker in the soil and fecal dry matter are the only analytical measurements required for estimation of soil ingestion. Soil calculated as a fraction of the feces is

$$F_{\text{soil}} = C_{\text{feces}}/C_{\text{soil}} \quad (6.1)$$

where C_{feces} is the concentration of marker in feces and C_{soil} is the concentration of marker in the soil. The amount of soil ingested is estimated by the equation

$$I_{\text{soil}} = I_{\text{DM}} * (1-D) * F_{\text{soil}}/(1-D * F_{\text{soil}}) \quad (6.2)$$

and soil as a fraction of dry matter intake is

$$I_{\text{soil}}/I_{\text{DM}} = (1-D) * F_{\text{soil}}/(1-D * F_{\text{soil}}) \quad (6.3)$$

where I_{soil} is the amount of soil ingested (kg/day), I_{DM} is the dry matter consumed (kg/day), D is the fraction of dry matter that disappears in the digestive tract, and F_{soil} is the fraction of soil in feces.¹⁵ The soil content of feces is measured, but values for digestibility and feed intake are estimated from the literature because these parameters are difficult to measure directly in grazing animals.

Several types of errors and uncertainties are associated with the estimation of soil ingestion. The least serious of these are the analytical errors in the determination of acid-insoluble ash or titanium oxide. Certain plants may accumulate silicates, and with some exceptions like McGrath et al.,³⁹ this potential contribution to the intake of acid-insoluble ash is not always corrected for in

published studies. Also, the soil samples collected for determining marker concentrations may differ from the soil ingested by the animals studied.

By far, the greatest sources of uncertainty are associated with (1) the necessity to use estimated values for the amount of dry matter consumed by domestic animals and (2) digestibility, which is the fraction of the dry matter that disappears in the gastrointestinal tract. Typically, digestibility decreases as plants mature. If a single value for digestibility is used for the entire grazing season, soil ingestion will be underestimated early in the season when digestibility is high and overestimated later in the season as digestibility decreases. Feed intake in most studies was assumed to be constant throughout the grazing season. However, dry matter intake will decline if the amount of forage available per animal is low.¹⁶ If dry matter intake is reduced, the same amount of ingested soil would yield a higher concentration in the feces than would occur with normal intake. Thus, when calculating intake, soil as a fraction of intake will be overestimated. It has been shown that estimates of soil ingestion can vary as much as twofold, depending on the assumed values for feed intake and digestibility.¹⁷

Methods for estimating soil and sediment ingestion by wildlife are slightly different from those used for domestic animals.⁶ Because the amounts of food eaten by wild animals are not well documented, soil and sediment ingestion is generally expressed as a fraction of the diet, rather than as an amount per day. Also, it may be difficult to estimate the concentration of a soil marker, since that concentration may vary over the feeding range of the animal. The use of acid-insoluble ash may be a more reliable marker when little is known about the particular soil that was ingested. However, acid-insoluble ash is not as accurate as some other markers for estimating very low rates of soil or sediment ingestion because the diet contains some acid-insoluble ash.

Analyzing prey or plant material for soil provides an alternative approach to estimating ingestion rates, although this approach may sometimes be misleading. For example, consider the hypothetical food chain from soil to earthworms to predators, which is frequently used in risk assessments of wildlife on contaminated soils. The soil content of earthworms is variable but is typically 20 to 30% of the dry weight of the whole body. In general, when an animal eats an earthworm, it ingests all of the soil inside the earthworm and additional soil on the outside of the earthworm. Predators of earthworms would be expected to ingest 20 or 30% soil in their diets. In some instances, however, predators are exposed to less soil than would be predicted. Moles, for example, are known to squeeze out some of the soil from an earthworm as it is swallowed. Gorman and Stone¹⁸ describe moles as eating with finesse, squeezing out soil like toothpaste from a tube, possibly to reduce tooth wear associated with ingesting soil. Estimating soil ingestion associated with plant material may also be inexact because the way in which a biologist collects plant material and prepares it for analysis may be different from the ways in which animals ingest plant material. Grazers might crop off vegetation above the soil surface, ingesting little soil, or they might pull up vegetation by its roots, ingesting much soil. Analyzing dietary items of waterfowl for sediment may also be misleading, since some waterfowl clean dietary items by shaking them and by filtering them in their mouths.¹⁹

6.3 INTENTIONAL GEOPHAGY IN ANIMALS

Most studies on intentional geophagy have emphasized nutritional implications, although at contaminated sites intentional geophagy may also lead to exposure to environmental contaminants. In reviewing the literature, Setz et al.²⁰ suggested that animals ingest soil for supplemental minerals, to reduce gastric disturbances, to reduce acidity in the gut, to adsorb toxic chemicals, and for the tactile sensations created in the mouth. At least fifty species of animals, particularly ruminants, are known to ingest soil purposely at licks, possibly for sodium.²¹⁻²⁴ Rhesus macaques (*Macaca mulatta*) and mountain gorillas (*Gorilla gorilla*) mine and ingest tropical soil, possibly to reduce intestinal ailments.^{25,26} African elephants (*Loxodonta africana*) excavate termite mounds and eat the associated

soil, which tends to have elevated concentrations of bases, pH, and clay content.²⁷ Diamond et al.²⁸ suggested that the geophagy they observed in about ten species of frugivorous birds in New Guinea was a means to reduce the toxicity or bitterness of ingested seeds and fruits. Setz et al.²⁰ examined several explanations of ingestion of soil from arboreal termite nests by golden-faced saki monkeys (*Pithecia pithecia*) but failed to find any of them convincing. Lizards, crocodilians, tortoises,²⁹ and box turtles³⁰ also intentionally ingest soil. Many species of birds that eat seeds ingest grit, which is coarse material used to grind food in the gizzard.³¹ Some grit supplies calcium and other minerals,³² whereas grit composed of sand and gravel from quartz have little nutritional value beyond the grinding of the diet. The search for grit may endanger birds when they mistakenly ingest pesticide granules or lead shot.³²

6.4 SOIL INGESTION BY DOMESTIC ANIMALS

Soil ingestion has been measured in most domestic animal species and in production classes that are important in carrying out exposure and risk assessments involving persistent environmental pollutants. The original impetus for research on soil ingestion was to evaluate the nutritional significance of soil ingestion as a source of trace elements.³³ A second impetus was the discovery of an association of soil ingestion with excessive wear of teeth of sheep grazing on poor pastures.³⁴ It was soon recognized that soil ingestion could be an important pathway of animal exposure to persistent organic pollutants, like DDT, when present in soil.³⁵

Studies on sheep provide the most comprehensive database on the effects of management and climatic conditions on soil ingestion.^{33,34,36-39} Dairy and beef cattle have been studied less extensively, but data are available for temperate pastures, semiarid rangeland, and unpaved confinement lots.^{3,15,40} Data on swine are limited to a single study.⁴¹

Results of representative studies with sheep, cattle, and swine are summarized in Table 6.1. The extensive data on sheep were reasonably consistent, and several broad conclusions may be drawn. When pasture was the sole animal feed source, soil ingestion generally was related inversely to the availability of forage. The lowest soil ingestion values occurred during spring, when grass growth was the greatest (Table 6.1). The lowest soil-ingestion rates of sheep were as little as 1 or 2% of dry matter intake. When forage was sparse, during fall or winter, intake of soil was estimated to be as great as 18% of the diet. The high values of soil ingested when forage is sparse can be attributed mainly to the need of the animals to graze close to the ground. The calculated yearly average soil intake was about 4.5% of dry matter intake for sheep when animals in New Zealand grazed 365 days a year and pasture was the only feed source.³⁴ This average is equivalent to intake of 45 g/day soil by a 50-kg sheep consuming 1 kg/day dry matter.

Two management factors had a significant effect on the amount of soil consumed by sheep. Soil ingestion was reduced about 50% when sheep were offered supplemental feed during the winter months.^{37,38} This reduction would be expected because the sheep would depend less on pasture for adequate feed intake. It can be inferred from the increased soil ingestion during periods of spare forage availability that increasing the number of animals per unit area would increase soil intake because less forage would be available per animal. The best example of the effect of stocking rate is given by McGrath et al.,³⁹ in which an increase in stocking rate from 11 to 15 animals/hectare resulted in a sixfold increase in soil ingestion.

Studies with cattle are less numerous than with sheep, but the qualitative findings are similar. The three cattle studies involving pasture have similar high and low soil intake values related to the availability of forage. The average intake for the English study in Table 6.1 was somewhat lower because the average values included dairy herds, which under English practice would have received supplemental feed. The soil ingested by a 500-kg dairy cow in the New Zealand study was estimated to average 900 g/day when it was assumed that dry matter intake was 15 kg/day, that cows grazed 365 days per year, and that no supplemental feed was offered.

¹ Dairy cattle.

² Stated to be both dairy and beef cattle. Authors did not separate the results by production class.

³ Beef cattle grazing semiarid range.

⁴ Dairy cattle on unpaved confinement lots.

There are several situations other than grazing in which soil ingestion can be the source of animal exposure and residues in products. Cattle confined in unpaved lots ingest a small amount of soil that may amount to 1 to 2% dry matter intake.¹⁵ Although most commercial swine and poultry production is conducted in confined operations, soil ingestion can be quite significant when these species have access to soil. Pigs may ingest as much as 8% of their dry matter intake as soil because of their rooting habits.⁴¹ Intuitively, it might be expected that free-range poultry would have high rates of soil consumption, but no data could be found in the literature.

6.5 SOIL AND SEDIMENT INGESTION BY WILDLIFE

Table 6.2 provides estimates of soil and sediment ingestion rates for various wildlife species. It should be emphasized that some of the sample sizes are small and that a mean from a single collection does not adequately represent variation throughout the year or in different habitats. In general, animals that browse (deer, elk, moose) ingest scant soil with their diet. Browsers also tend to be the species commonly associated with deliberate ingestion of soil at salt licks. Mice, voles, woodchuck, and other herbivores also tend to ingest only small amounts of soil. Bison ingest somewhat more soil. The inverse relation between forage availability and soil ingestion rates observed in domestic grazers presumably holds for wild grazers.

Soil ingestion rates of herbivores tend to be high in dry climates, possibly because soil is pulled up with roots of sparsely available forbs and grasses. Jackrabbits and pronghorn in sagebrush and black-tailed prairie dogs in a short-grass prairie⁴ ingest more soil than do most other herbivores. Arthur and Gates⁴ suggested that some of the soil ingestion by jackrabbits and pronghorn is related

¹ Calculated assuming a digestibility of 50%.

to the animals' needs to ingest adequate sodium relative to potassium. Armadillos and opossums, which prey on soil organisms, tend to ingest more soil than do herbivores. Among waterfowl, dabblers tend to ingest little sediment, generally less than 2%,^{6,46} although occasionally individuals are found that have ingested large amounts of sediment. Sediment ingestion by dabblers may increase in winter. Canada geese and tundra swans, which feed closer to the bottom than do dabblers, ingested about 9% sediment in their diets. Mute swans were observed to ingest sediment at a lower rate (3%) than tundra swans (9%). We are uncertain whether the difference is related to the feeding habits of the two species or to a difference in the collection times. Samples of digesta from the mute swans were collected when submerged aquatic vegetation was plentiful, rather than at a time when the swans would have been feeding on plant material in the sediment. As a group, shorebirds tend to ingest the most sediment, although willets, feeding on mollusks, ingested only 3% sediment in one study.

At least some species of animals can tolerate surprisingly large amounts of ingested soil if it is not contaminated. For example, mallards were able to maintain their weights for two weeks when fed diets containing 50, 60, or 70% sediment in a mash diet (G. Heinz, personal communication, Patuxent Wildlife Research Center).

6.6 TOXICITY OF ENVIRONMENTAL CONTAMINANTS IN SOIL OR SEDIMENT TO ANIMALS

Laboratory studies have demonstrated both the bioavailability and the toxicity of environmental contaminants in soil and sediment ingested by wildlife. When Connor et al.⁴⁵ fed to bobwhite a diet containing contaminated sediment from the Coeur d'Alene River Basin, their blood lead increased to concentrations that the authors considered clinically significant. When mute swans were fed a high concentration (24%) of sediment from the Anacostia River in their diet for six weeks,⁵⁰ the dietary lead concentration (85 mg/kg) was high enough to reduce the activity of red blood cell ALAD (amino-levulinic acid dehydratase) activity. The presence of polynuclear aromatic hydrocarbons in this sediment was the probable cause of an observed increase in hepatic microsomal monooxygenase activity in the livers of these swans.

A series of laboratory studies was conducted on the toxicity to waterfowl of ingested sediments from the Coeur d'Alene River Basin, known to be severely contaminated with lead and other metals. A survey of scat from tundra swans from the site had found that swans on average were ingesting about 9% sediment in their diets and that 10% of the swans ingested 22% or more sediment in their diets.⁴⁴ In a controlled study, Heinz et al.⁵¹ demonstrated a linear dose response in mallards between ingestion (0, 3, 6, 12, and 24% of diet) of that sediment and blood lead. One of the mallards fed the 24% sediment diet died, and the others in that group showed signs of lead poisoning. Hoffman et al.^{52,53} demonstrated the toxicity of this sediment to goslings of Canada geese and to mallard ducklings, and Day⁵⁴ demonstrated its toxicity to mute swans.

The poisoning of wild animals from the ingestion of contaminated soils or sediments has been documented at a few sites. Hundreds of waterfowl feeding in the severely polluted Coeur d'Alene River Basin have been diagnosed as lead-poisoned.⁵⁵⁻⁵⁷ These waterfowl rarely contained the lead shot or sinkers usually associated with lead poisoning. Although some of the lead ingested by these waterfowl was associated with their diets, the great majority was associated with ingested sediment, as shown by analyses of the feces.⁴⁴ Similar waterfowl mortality from lead poisoning has been recorded previously at other mining sites.^{58,59} Ingestion of white phosphorus in sediment has killed waterfowl in Alaska.⁶⁰ Soil ingestion was suggested as an important route of exposure of small mammals to lead in a skeet range contaminated with lead shot.⁶¹ Pain et al.⁶² suggested that the contamination of the Coto Doñana avian overwintering site in Spain with mining wastes presents hazards to European birds.

6.7 RELATION OF PARTICLE SIZE OF INGESTED SOIL TO EXPOSURE TO CONTAMINANTS

Ingested soil or sediment may have a different texture from the soil or sediment in an animal's habitat as a whole. When birds seek grit, for example, they selectively ingest coarse particles. Geophagous birds, in contrast, commonly select clay or silt.²⁸ Sheppard⁷ concluded that the soil associated with plant surfaces is especially fine. Whereas clay may become incorporated into the wax on leaf surfaces, coarse particles are removed when soil on plants is disturbed or washed by rainfall. Soil found adhering to human fingers has been found to be greatly enriched in clay, increasing lead concentrations up to twentyfold.⁷ McGrath et al.³⁹ found that soil ingested by sheep was enriched in silt and clay. Enrichment of the fine particles is important because metals tend to be associated with the fines and because the fines are the most chemically reactive portion of the mineral soil.

Digesta of mute swans feeding on aquatic vegetation in Chesapeake Bay contained finer sediment than that present in the habitat as a whole.⁴⁷ These swans were ingesting about 3% sediment in their diet. Presumably the particles that settled onto vegetation eaten were representative of the fine particles suspended in the water column rather than the coarser material found on the bottom. The lead content observed in the digesta of these swans was two or three times that expected from the

lead content of the sampled sediment and from the acid-insoluble ash content of the digesta, a measure of total sediment ingested. Lead concentrations in their digesta were closely correlated with concentrations of aluminum, which is associated with clay. In contrast, lead concentrations of waterfowl digesta samples collected from the Coeur d'Alene River Basin were precisely those expected if the waterfowl had been ingesting unsorted sediment from the bottom.⁴⁴ The difference between the studies is probably related to the rates of sediment ingestion. When only small amounts of soil or sediment are ingested, the material may be sorted by texture, but when waterfowl ingest an average of 9% sediment in their diet, they are presumably eating sediment from the bottom rather than just a thin film of clay on vegetation. When sorting by particle size has occurred, uncorrected bulk soil or sediment samples may provide inaccurate estimates of exposure.

6.8 BIOAVAILABILITY OF ORGANIC CONTAMINANTS IN SOIL

Hazards to animals from contaminants ingested with soil or sediment depend on the bioavailability of the contaminants as well as on the exposure and the toxicity of the contaminants. Risk assessors recognize the importance of including a measure of bioavailability in their analyses.⁶³

The term *bioavailability* refers to the fraction of the compound that is absorbed, which is then stored, metabolized, or excreted from the animal. True bioavailability can be evaluated only in mass balance experiments, which rarely have been conducted with environmental contaminants. But relationships between dietary intakes and concentrations in tissues or products like milk are established for many compounds. Measurement of the residue concentrations produced by feeding a soil-borne contaminant will provide a measure of the bioavailability from soil relative to the bioavailability from the normal diet.

An environmental contaminant associated with soil may have lower bioavailability than the same contaminant incorporated into other matrices. The effect of matrices on uptake of lipophilic compounds can be illustrated with 2,3,7,8-tetrachloro-*p*-dioxin (TCDD), which has been studied in a variety of matrices. Net absorption of TCDD by rats was 75 to 80% when administered to rats in corn oil⁶⁴ but only 50 to 55% when TCDD was contained in normal rat and cow diets.^{65,66} Reviews of the available literature indicated uptake of TCDD from soils is typically about 40% and is less than 20% from soils at some industrial sites.⁶⁷⁻⁶⁹ Stephens et al.⁷⁰ found that about 70 to 80% of a dose of tetrachlorinated dioxin congeners in soil was absorbed by chickens, which suggests that soil had very little effect on the bioavailability of dioxin to chickens. When TCDD was administered with activated carbon, a strong adsorbent, uptake by rats was negligible.⁷¹ Data are not available for such comprehensive comparisons for other lipophilic compounds, but comparable results can be anticipated. Although the uptake from soil is consistently lower than from normal diets, the reduction may not be great enough to merit inclusion in risk assessments.

Lipophilic compounds in soil tend to be adsorbed to the organic matter fraction.⁷² Organic matter content varies greatly among soils and can be altered by manure, sludge, and other amendments. Differences in bioavailability due to organic matter content might be expected, but the uptake of PCBs by rats was unaffected by the organic matter content of the soil to which the soil had been added.⁷³ Similarly, animal uptake of PBBs from soil was not affected significantly by amending soil with activated carbon.⁵ The failure to detect differences due to organic matter content and amendments suggests that conditions of the gastrointestinal tract favor dissociation from soil organic matter to dietary lipids.

Kadry et al.⁷⁴ found that when rats were exposed to phenanthrene, the residues in the plasma accounted for about 60% of the dose. There was little difference whether the phenanthrene was administered in the pure form or adsorbed to soil, which suggests that soil does not significantly reduce its bioavailability.

The absorption of polar compounds to soil involves an electrostatic attraction to negatively charged clay and mineral particles and may differ by orders of magnitude depending on the

properties of the soils and the compounds.⁷⁵ The acidic conditions of parts of the gastrointestinal tract may lead to the dissociation of chemicals that are adsorbed at the pH range of normal soils, thereby making the compounds available for absorption. However, because polar compounds are readily metabolized and excreted in urine by mammals, they tend not to be an important concern when conducting human risk assessments.

6.9 BIOAVAILABILITY OF INORGANIC CONTAMINANTS IN SOIL

The ingestion of soil can have both beneficial and deleterious effects on the mineral status of the animal. Ingested soil may provide a number of necessary trace elements to an animal that might otherwise be deficient.^{8,76} On the other hand, excessive soil intake can inhibit the absorption of some minerals. The production of iodine deficiency is a prominent example.⁷⁷ Concerns have been raised about the uptake of heavy metals by domestic animals from such activities as deposition of emissions from smelting activities and addition of sewage sludge to land, although Thornton and Abrahams³ and Hogue et al.⁷⁸ failed to find adverse effects in their studies. Although soil ingestion can be a significant source of heavy metal intake by grazing animals, the heavy metals are generally not taken in at toxic concentrations by human consumers if these metals are stored in animal tissues, such as bone, that are not used for food.

Rates of intestinal absorption depend on the species and experimental conditions. Ingested soil generally reduces absorption of metals from digestive tracts. Based on the cadmium concentration in the blood of rats fed cadmium chloride in soil compared to the cadmium concentration in the blood of rats fed cadmium chloride at the same dose in a saline solution, Schilderman et al.⁷⁹ concluded that incorporation into soil reduced the bioavailability of cadmium to 43% of its reference value. Diamond et al.²⁸ and Mahaney et al.²⁵ suggested that animals deliberately ingest soil to bind to toxic substances in their diet. Soil was deliberately added to the diets of domestic animals to reduce their uptake of cesium released during the Chernobyl accident.⁷

Chaney and Ryan⁸⁰ concluded that as a laboratory mammal is fed greater amounts of soil contaminated with lead, lead absorption by the animal does not increase linearly with dose but reaches a plateau. The authors' model predicted that the concentrations of free lead ions in solution would level off as additional soil in the gut adsorbed additional lead. These studies were designed to be relevant to a child ingesting soil on an empty stomach. In contrast, when Canada geese, mute swans, and mallards were fed increasing amounts of lead-contaminated sediment, up to 48% of the diet, blood lead concentrations increased linearly with dose.⁸¹ We presume that the difference in absorption curves between the laboratory mammals and the waterfowl results from the experimental conditions; the laboratory mammals were fed doses of soil without food, whereas the waterfowl were chronically fed large amounts of sediment incorporated into a diet for waterfowl. The presence of food in an animal's digestive system, as well as soil, affects the bioavailability. Maddaloni et al.⁸² estimated that human volunteers who had fasted absorbed 26% of a dose of lead in soil from a mining site, but that volunteers who had eaten absorbed about 2.5% of that same dose.

It is widely accepted that the chemical form of an ingested metal affects its absorption and potential toxicity. When the National Research Council⁸³ established "maximum tolerable levels of dietary minerals for domestic animals," it noted that the elements used in the supporting studies were generally soluble salts and that the recommended values might not apply to elements naturally found in diets. When data are available, a "relative absorption factor" may be incorporated into risk assessments to adjust for the differences in chemical form.⁸⁴ Absorption of lead from soil has been widely studied because soil ingestion is the most important route of exposure of lead to children. Mosby⁸⁵ measured the uptake of lead by juvenile swine fed lead-contaminated soils from a mining site in Missouri. (Juvenile swine are considered appropriate models for children in their absorption of lead.) Compared to a control diet containing lead acetate, untreated mine soils had relative bioavailabilities of 0.67 and 0.63. Amending the contaminated soils with phosphoric acid

reduced bioavailability by 27% to 38% (compared to the untreated contaminated soil). In a similar study on juvenile swine, Casteel et al.⁸⁶ concluded that lead in two severely contaminated soils from a mining site in Colorado had bioavailabilities of 58% and 60% compared to lead acetate in a diet fed without soil. Summarizing the relative absorption factors reported for soil lead primarily from mining wastes, Ruby et al.⁸⁴ found that relative absorption values were generally between 0.2 and 0.6, but were as low as 0.01. Values for arsenic were generally between 0.2 and 0.4, but were as low as 0.03. Because the experiments used to derive the relative absorption factors are expensive, Ruby et al.⁸⁴ have developed a quick *in vitro* procedure, designed to measure solubility of metals under conditions that mimic those in a human gut.

Hoffman et al.⁵³ measured the bioavailability of lead from Coeur d'Alene River Basin sediments in a feeding study on mallards based on blood lead concentrations. Blood lead concentrations were about half as high in ducks fed the sediment as in ducks fed lead acetate at a comparable rate of exposure in the diet. Sheppard et al.⁸⁷ concluded that adding soil to a diet fed to mice reduced bioavailability of isotopes of four cations by a factor of 1.1 for lead, 2.1 for cadmium, 2.3 for mercury, and 4.6 for cesium.

Some elements may be sparingly bioavailable in soil and are rarely, if ever, toxic threats to terrestrial animals. Examples include aluminum, barium, and iron, which are ingested by many animals primarily with soil, sometimes at high concentrations. Earthworms from confined disposal facilities for dredged materials were found to contain medians of 3400 mg/kg of aluminum, 31 mg/kg of barium, and 8000 mg/kg of iron, mainly associated with ingested soil in the earthworms.⁸⁸ All three of these concentrations are well above the tolerances of these minerals established for domestic animals (200 to 1000 ppm aluminum, 20 ppm barium, 500 to 3000 ppm iron) by the National Research Council.⁸³ Even higher concentrations of these three metals have been found in tadpoles,⁸⁹ probably associated with sediment in the tadpole gut. From a risk assessment based on feeding studies of soluble salts of the metals an assessor might conclude that these metals are toxic to predators of earthworms or tadpoles. However, it seems unlikely that these metals would be toxic under normal circumstances, and the examples illustrate the potential error introduced when the form of a metal in a feeding study does not match the form of that metal in an environmental sample being evaluated.

A science panel convened by the Agency for Toxic Substances and Disease Registry concluded that assuming 100% bioavailability of mercury in contaminated soils is excessively conservative; however, the panel was unable at that time to suggest default assumptions or to develop guidelines for determining relative bioavailability in soils.⁹⁰ Many risk assessors recognize that ignoring the bioavailability of elements in soil and sediments may lead to erroneous conclusions about hazards from ingestion. However, they lack adequate studies for most elements to account for bioavailability in risk assessments.

6.10 APPLICATIONS TO RISK ASSESSMENTS

The soil-animal-product pathway to humans is important in many risk assessments of persistent organic pollutants in agriculture. It may be the most important pathway when the pollutant is introduced directly to the soil, as in the application of sewage sludge to agricultural land. For a given measured or projected concentration of a contaminant in soil, the two most important factors that determine the amount of contaminant transported to human foods are the amount of soil consumed and the bioavailability of the contaminant. Very conservative (i.e., protective) default values are generally suggested in risk assessments.^{11,12} We will identify areas of uncertainty and conservatism, and site-specific circumstances that would allow the use of less conservative parameters will be identified.

Although the extensive data available for sheep are useful for establishing general principles, agricultural risk assessments are generally based on beef and dairy cattle. The cattle studies

(Table 6.1) provided the basis for deriving the default values for cattle soil ingestion included in regulatory agency guidance documents.^{11,12} In general, the default values will overestimate the amount of soil consumed in most circumstances.

The expression of soil ingestion as a quantity rather than a fraction of intake has been the normal practice in regulatory guidance. Estimation of the quantity of soil ingested requires assumed values for digestibility and dry matter intake (Equation 6.2), whereas estimation of soil as a fraction of intake requires only an assumption for digestibility (Equation 6.3). Generally, digestibility can be estimated reasonably well, but the assumption of single values for dry matter intake may be erroneous in periods of low forage availability. Thus, the average values for the amounts of soil ingested that are listed in Table 6.1 may be too high. The fraction of soil in the diet does not require assumptions about dry matter intake. The use of the bioconcentration factor approach (concentration in product/concentration in diet) has been adopted for dioxins and related compounds in some guidance documents.^{11,12} This approach does not require assumptions concerning the amount of soil and dry matter consumed, which should reduce uncertainty.

The recommended default intake of 0.4 kg/day for dairy cattle¹¹ is somewhat less than the yearly mean for New Zealand cattle offered no supplemental feed (Table 6.1). This recommendation recognizes that standard dairy feeding practices in the United States include supplemental feeds in the form of concentrates (grain, etc.) and hay or silage in periods of sparse pasture. The default value is equal to approximately 2% of dry matter intake if the cow is consuming 20 kg of dry matter per day. This fairly conservative value is reasonable for the subsistence farmer scenarios commonly included in risk assessments. However, the value greatly overestimates soil intake under commercial dairy conditions because use of pasture for lactating dairy cows is not a common practice in the United States.

The suggested value for beef cattle, 0.5 kg/day,¹¹ is greater than the average intake for beef cattle in Table 6.1 because it includes consideration of the dairy cattle results. The value is probably a reasonable representation of beef cattle being maintained for breeding purposes on pasture only. The value, however, was derived assuming a dry matter intake typical of mature cattle, and the value would overestimate soil intake by the younger animals that had not attained their mature weight. This younger class of animals would represent the largest portion of the meat supply, and use of the high default value would overestimate exposures to large populations. On the other hand, it would probably provide a reasonable worst case for the subsistence farmer scenario.

Most commercial swine and poultry do not have access to soil, but soil consumption can be quite high when these species do have access. The suggested default intake for swine in guidance documents was 0.37 kg/day,¹¹ which is approximately the same as the highest measured value in the only published study on swine (Table 6.1). There have been no direct measurements of soil ingestion by free-range chickens. Soil ingestion by free-range chickens has been inferred in several cases,^{70,90} and a default value of 10% of dry matter intake has been suggested.¹¹ This value seems reasonable because it agrees with the 9% intake measured in wild turkeys, which are birds with similar eating habits.⁶

Ingestion rates of soil and sediment are not as well documented for wildlife as for farm animals, and less guidance for conducting risk assessments is available. Wildlife risk assessors may benefit from generalizations about soil ingestion by farm animals but must consider the range of wildlife species present at a site and may prefer not using a mean for a species when diets may vary greatly with seasons and habitats. At this time there are no default values recommended for use with wildlife as there are for farm animals. Although the importance of estimating bioavailability of soil contaminants is widely accepted, risk assessors are likely to have difficulty in incorporating a measure of bioavailability without conducting feeding experiments.

Inclusion of estimates of soil and sediment ingestion may change the emphasis of risk assessments. Whereas wildlife risk assessments have often emphasized bioaccumulation of persistent contaminants in top predators, the soil and sediment ingestion route of exposure is most important to those species lower in the food chain. Raptors, for example, might be poisoned by organochlorines

or through ingestion of lead shot, but they have low exposure to lead through the soil-ingestion route. Predators of earthworms and other soil organisms, shorebirds, and waterfowl feeding in sediments may be key species in risk assessments where the contaminant is found in the soil and sediment. Soil and sediment ingestion is most important for contaminants that are poorly absorbed and do not biomagnify. Risk assessors should also bear in mind that soil and sediment are not just vehicles for contaminants, but they supply nutrients and modify the bioavailability of contaminants. Research on contaminants to date has considered only the unintentional ingestion of soil and sediment, but it is possible that wildlife will be found sometimes to intentionally ingest contaminated soil because of its taste.

7.1 INTRODUCTION

As a process, ecological risk assessment (ERA) may benefit efforts to remediate soils contaminated with chemicals intentionally or unintentionally released to the environment. The ERA process has gained increased application across a wide range of environmental issues because it attempts to integrate and synthesize available technical information that may contribute to environmental decisions and to help forge environmental policy developed by environmental decision-makers. By applying the process and technical tools available in ERA to a wide range of land-use and water-use issues, fish and wildlife scientists and resource managers can

- Identify resources that are “at risk” from a variety of environmental stressors (chemical, physical, and biological) that may be characteristic of habitats variously impacted by a range of anthropogenic activities,
- Prioritize data collection, including the design of field investigations for assessment and monitoring when the current status of “at-risk” resources is adequately characterized, and
- Link human activities — both causal and remedial in character — or naturally occurring hazards with their potential ecological effects during the restoration or rehabilitation of habitats of concern.

This chapter will focus on applications of the ERA process beyond an evaluation of risks associated with chemical release. Here, we will briefly summarize (1) ERA tools used to characterize a lower bound on the concentration of residual chemicals remaining in soil following remediation (that is, contribute to establishing preliminary remedial goals, or PRGs, for habitat restoration), (2) the role of bioavailability in critically evaluating these lower-bound PRGs and establishing residual chemical concentrations that reflect field conditions, and (3) remediation measures that are intended to address field conditions and modify soil in order to decrease a chemical’s immediate bioavailability, while increasing the likelihood of recovery to habitats suitable to future use by fish and wildlife.

7.2 TERMINOLOGY AND APPLICATION

Because words often acquire meaning through their regulatory context, the terms restoration, remediation, reclamation, and rehabilitation will be defined as used in this chapter, so their definitions will not confound the discussion that follows. Conceptually, ecological restoration is “the process of assisting the recovery and management of ecological integrity, where ecological integrity is specified by a critical range in the variability of biological diversity, ecological processes and structures, regional and historical contexts, and sustainable cultural practices.”¹ Given the scope of that definition, however, a relatively simple dictionary definition seems more appropriate to our present discussion. Here, restoration will be considered as the act or process involved with bringing habitats back to a former condition, given a past perturbation that has yielded an “impacted,” “disturbed,” or “adversely affected” condition. Adverse effects may be associated with chemical releases (e.g., oil spill or other chemical release), physical perturbations (e.g., habitat alteration resulting from vegetation removal consequent to construction or remedial activities), or release of biological agents (e.g., nonnative species). A common observation finds chemical and physical stressors occurring in tandem when a habitat is degraded or altered from its initial preimpact condition.

Restoration and remediation are closely related, since the latter act or process reflects the implementation of a remedy for a past action that has yielded an impacted system. For our purposes,

restoration may be one possible goal of remediation focused on an impacted habitat; that is, the remedial activity is intended to return a habitat to its preimpact condition. The goal of “return to preimpact condition” may be difficult, if not impossible, to achieve depending on both qualitative attributes of the release — “what was released” — and the magnitude of the release — “how much was released.” Like restoration in a dictionary definition, rehabilitation may also be defined as the act or process of returning an affected area to a former condition or capacity, which appears largely synonymous with restoration. However, from a practical perspective, shades of difference between restoration and rehabilitation are often reflected by differences in likelihood of success in attaining preimpact or initial condition. For a restoration project, a return to preimpact condition is generally more likely to be achieved, while rehabilitation entails the reestablishment of a specified target condition that, from necessity, is not truly a return to preimpact condition. Differences between restoration and rehabilitation, then, reflect the degree of success in recovery of a habitat’s preimpact or initial condition.

In contrast to restoration or rehabilitation, reclamation is generally considered the act or process of recovering a given habitat from some “undesirable” condition. Reclamation generally reflects the intentional recovery of lands for subsequent human use, whether that initial condition for reclamation is an unwanted natural state (e.g., wetland conversion to farmland or to urban development through drain-and-fill programs) or an impacted managed landscape (e.g., brownfield developments targeted for continued human use or otherwise intensively managed condition).

Application of the tools and process of ERA under the auspices of restoration or rehabilitation provides a foundation for comparing different management options and potentially helps policy-makers and the public to make better-informed decisions about the management of natural resources that have variously been impacted by anthropogenic activities. These natural-resource-management decisions, however, must occur against a backdrop of naturally occurring hazards, ranging from relatively short-term (but potentially high-consequence) events such as floods, volcanic activity, earthquakes, and extreme atmospheric events, such as hurricanes, or relatively long-term events such as cumulative impacts associated with human use of a particular geographic area.²

7.2.1 Tools Available for Evaluating Habitat Remediation

Fish and wildlife scientists and resource managers must recognize that many of the ecosystems in which they are interested have been variously impacted by anthropogenic activities, ranging from those systems having relatively limited impacts to those highly disturbed systems having marked physical and chemical perturbations from some initial condition.³⁻⁶ Chemicals released into the environment are only one source of environmental perturbation likely to drive the restoration or rehabilitation of habitats within a landscape. From an ecotoxicological perspective the evaluation of adverse effects associated with chemicals released into terrestrial and wetland habitats may directly support efforts beyond retrospective risk assessment focused on current conditions at recovering contaminated terrestrial and wetland habitats. A retrospective risk assessment for a terrestrial or wetland location often considers remediation of soils as one of the outcomes of the ERA process. Although this brief overview of the ERA process applied to restoration and rehabilitation is focused on chemically degraded terrestrial and wetland habitats, from an ecological perspective the interrelationship of habitats (especially for wetlands) clearly suggests that remediation of soils in these habitats could also impact sediments, surface water, and groundwater.^{7,8}

In borrowing tools from ERA, the techniques and methods applicable to restoration and rehabilitation efforts include diagnostic methods focused on biochemical and molecular-, cellular-, tissue-, and organ-level measures as well as physiological measures of adverse effects associated with exposure (e.g., biomarkers).⁸⁻¹³ Other tools may be focused on population and community measures that potentially reflect adverse changes in higher levels of biological organization associated with stressors in the environment.^{10,11} Across these levels of biological organization, these tools may be applied to the (1) evaluation of current conditions, (2) characterization of reference

condition, or (3) monitoring of recovery during the restoration or rehabilitation process. Regardless of their application, current practice largely depends on species-specific tools (e.g., individuals as surrogates for guilds), with subsequent extrapolation to potential ecological effects associated with these measures of exposure and effects. Population- and community-level analysis may be used to confirm whether these extrapolations are on target or whether the calibration of the lower-level analysis is required. Ideally, population- or community-level metrics are included in monitoring plans instituted to evaluate recovery in restored or rehabilitated habitats.¹¹

7.2.2 Setting Targets for Soil Preliminary Remediation Goals (PRGs) Focused on Habitat Remediation

From an ecotoxicity and bioaccumulation perspective the development of target preliminary remediation goals (PRGs) for contaminated upland and wetland soils can be considered through a process that answers a simple question: “How much residual material can be left *in situ* yet not be associated with risks or injury related to long-term exposures to chemicals that occur at low levels in the environment?” Such a simple question assumes that low-level exposures would not be characterized by acute toxicity since risk assessments reliant on available guidance should have clearly identified those levels as part of the risk-assessment process.

For example, while benchmark values for soils are presently limited (few, if any) or under development (e.g., Ecological Soil Screening Levels, or EcoSSLs¹²), biological assessments conducted using standard test methods may directly evaluate the short-term effects of soil exposures, for example, to plants and soil invertebrates.¹³ Similarly, guidance values for sediments, such as probable effect concentrations (PECs) and threshold effect concentrations (TECs) as characterized by McDonald et al.¹⁴ for freshwater sediments, or effects range-medians (ERMs) and effects range-lows (ERLs) for marine and estuarine sediments,^{15,16} may provide preliminary benchmarks for hydric soils indicative of wetland habitats. These latter tools from sediment risk assessment may have been considered within a risk context to characterize concentrations that directly relate to toxicity of wetland soils (e.g., emergent zone habitats or tidal mudflats), and their extension to restoration or rehabilitation activities may be pertinent to restoration or rehabilitation issues.

However, for remedial application, the concern associated with low-level chemical exposure should primarily be focused on chronic effects (e.g., altered reproductive capacity, altered immune function) and bioaccumulation.^{13,17} These endpoints may be incompletely captured by available risk-based guidance values, and additional efforts may be required to assure restoration or rehabilitation success. For example, with a focus on chemicals having bioaccumulative potential, trophic transfers resulting from food-web interactions among exposed biota and their likely “predators” (that is, any consumer dependent upon exposed organisms as a food source) must figure prominently in the analysis and derivation of soil PRGs. Existing management practices (e.g., land and water use, especially as they relate to potential habitat interactions) and environmental fate issues (e.g., related to sediment transport subsequent to soil erosion) should also be sufficiently characterized to assure that pathways potentially linking sources with receptors account for future events such as soil erosion and increased sedimentation of surface waters adjacent to remediated habitats.¹⁷

Even with a technical analysis sufficient to the issues related to trophic transfer of *in situ* chemicals, this focus on biological interactions related to food-chain contamination may not be directly associated with ecological effects linked to residual chemicals remaining *in situ* at low levels. The available information regarding bioaccumulation and adverse ecological effects (e.g., change in populations and community structure) is very poorly developed, and depending on the chemicals of ecological concern, an analysis of bioaccumulation potential may not be the only aspect of exposure critical to management decisions regarding cleanup.¹⁸ For example, an evaluation of bioaccumulation potential is not particularly pertinent to chemicals that are metabolized or otherwise not accumulated in the tissues of receptors of concern, yet long-term exposures to

residual chemicals or their degradation products in remediated soils must be considered in the restoration or rehabilitation process. The following discussion reflects a primary focus on bioaccumulative chemicals of concern (BCCs) and the analysis of *in situ* BCCs that may remain following a remedial action.

7.2.2.1 Bioaccumulative Chemicals of Concern: Developing Soil PRGs Focused on Habitat Remediation

For evaluating risks of residual chemicals remaining in soil following remediation, chemicals with bioaccumulation potential may be a primary concern, and a two-step analysis of residual risks may be followed: (1) to estimate the exposed dose of BCCs that organisms encounter in chemical transfers from soil-to-soil biota and (2) to estimate exposed dose of BCCs to higher trophic levels exposed to chemicals in soil either directly through coincidental ingestion of soil or indirectly through ingestion of soil-exposed food sources.¹⁹ For remediation purposes, developing soil PRGs should initially be focused on chemical risks and adverse biological effects associated with long-term exposure to low-level chemicals, with their derivation being based in part on management practices applicable to a given remedial activity.^{2,17}

Technically, three general approaches to the evaluation of bioaccumulation are applicable to the restoration and rehabilitation process. These tools may be used singly or in combination in the development of soil PRGs:

- A laboratory approach exposing organisms to soil under controlled conditions
- A field approach collecting species from a study area
- Models to estimate bioaccumulation, including the assessment of food-web transfer (generally through food-chain analysis as the primary tool to evaluate exposure)

Laboratory approach: Individuals of a single species are exposed under controlled laboratory conditions to soils collected from the study area being assessed. After a defined exposure period, tissues of test organisms are analyzed for the chemicals of concern. Bioaccumulation is generally considered to have occurred if the final concentration in tissues exceeds concentrations that were present in tissues before the exposure was started (i.e., tissue residues characteristic of organism's baseline condition at test initiation).^{13,18,19}

Field approach: Tissue concentrations of contaminants are determined by collecting one or more species exposed to soils at the study area being assessed. These concentrations are compared to some reference condition (e.g., local or population of reference areas) for interpretation.^{20,21} Two methods have been used to determine bioaccumulation in the field: (1) organisms resident at the area are collected *in situ* for analysis or (2) organisms are transplanted from another location (presumably with a history of little contaminant exposure) to the area of concern and then re-collected, and tissues are analyzed after an established period of exposure.

Models for evaluation of bioaccumulation and food-chain transfer: Although not validated, models that describe bioaccumulation are widely applied to ERA and, by extension, to evaluations focused on residual chemicals present in remediated soils.^{12,13,20–22} For example, site-specific models may be developed to estimate bioaccumulation on the basis of laboratory-derived methods (using standard test species or, alternatively, more habitat-specific species)¹³ and field-determined chemical measurements at the area of concern. Field studies should also be considered to characterize bioaccumulation potentials of chemicals *in situ*, although exposure may confound linkages directly with soils, given the multiple chemical inputs captured in most field exposures.^{13,23} Models that link (1) bioaccumulation of chemicals from soil to (2) transfer of chemical from soil biota to “predators” through a food-chain analysis have been technically developed but have not been validated with respect to their predictive capabilities for estimating field-measured tissue residues in consumers (primary or secondary).^{12,20,21}

Regardless of the tools used, variability is a common problem in bioaccumulation studies and can lead to imprecise estimates of exposure. For example, laboratory bioaccumulation tests of soils (upland or wetland) potentially yield precise estimates of bioaccumulation; however, their precision is directly dependent upon controlling biological factors through test standardization, e.g., specification of appropriate test organisms or use of organisms of similar size, age, and life-history stage.^{13,24} Under field conditions bioaccumulation may be highly variable, since organisms variously alter exposure through, for example, avoidance, or multiple stressors and life-stage differences apparent in the exposed population serve to confound the answer to a relatively simple couplet interrogative focused on bioaccumulation (“Does bioaccumulation occur and, if so, to what extent?”). Also, under field conditions individuals may respond differently to residual chemicals in soil, and if bioaccumulation is sufficient to alter biological response, the kinetics of bioaccumulation may be affected.²⁵ Depending on exposure in the field, organisms exposed to lower doses in remediated soils may accumulate greater tissue residues than estimated.

Bioaccumulation models are generally imprecise because of the knowledge gaps that characterize model parameters, such as ingestion rates and body-size-related functions, that influence exposure.¹⁸ Key parameter values, such as bioaccumulation factors (BAFs), may differ by orders of magnitude among studies. Hence, predictions differ and imprecision of model outputs must be considered when values for soil PRGs are evaluated within the context of habitat restoration.

Whether framed about soil-to-soil biota transfers or on food chains dependent on soil-dwelling invertebrates, a limitation to food-chain evaluations applied to the restoration of soil is the poorly characterized relationships among model outputs (e.g., a soil concentration term), ecological effects, and unacceptable change^{7,18,22} potentially linked to that soil PRG. Bioaccumulation does not necessarily mean an adverse biological or ecological effect is occurring.¹³ Correlations between bioaccumulated contaminants and effects of contaminants are frequently not well established, and the relevance of bioaccumulation stems mainly from its value in characterizing exposure, which in turn reinforces the need to characterize dose. Understanding dose is essential to understanding effects, whether the dose is from the chemical itself or from its metabolites.²⁵ The concentration of contaminants assimilated into tissues may be one of the most sensitive measures of the dose an organism can realize, given the uncertainties in defining bioavailability from chemical measures alone.^{12,13}

Exposures under field conditions are complex, and the temporal and spatial complexities of exposures are likely reasons why effects of contaminants may be difficult to demonstrate or to interpret from field data alone.²⁶ Collection of organisms exposed in the field, food web bioaccumulation estimates, and both empirical and site-specific models provide direct measures of contaminant concentrations in wildlife foods, which may suggest alternatives applicable to the characterization of soil PRGs.^{20,21,27} For example, some soil PRGs might be developed given available regulatory values that are triggered by bioaccumulation concerns (e.g., FDA action levels), while others would necessarily reflect case-specific studies (or equally accepted modeling efforts) that would follow a stepwise process similar to that detailed for evaluating ecological risks.

Rather than rely solely on a single tool for their derivation, soil PRGs could be technically developed as a stepwise process based on laboratory-derived or field-derived estimates of bioaccumulation potential.^{12,13} Such information should be in hand for soils targeted for remediation, as should estimates of reference conditions as baseline or reference areas. These empirical values should reflect some specified “co-location” of soil and tissue samples so the spatial context of exposure can be identified.^{20,21,22} Ideally, a conceptual site model or linked conceptual site models for soil remediation are consistent with those from the ERA,^{7,22} where critical receptors (most often mammalian or avian wildlife) are specified such that derivation of soil PRGs associated with soil concentrations or trigger values for tissue residues can be estimated using available empirical data collected during ERA activities. Regardless of the tools used to derive soil PRGs, the role of post-remediation monitoring should not be ignored, especially given the relatively large uncertainties associated with even the “best” practice available for developing soil PRGs and implementing restoration or rehabilitation plans.³⁻⁶

7.2.2.2 Derivation and Calculation of Soil PRGs

Lower bound targets for soil PRGs may be derived from a “back calculation” of a species-specific exposed dose calculation routinely used in evaluation of chemical risks to vertebrate wildlife (birds and mammals).^{12,13,18} Here, our starting point is the basic exposure model derived from food-chain analysis,

$$\frac{(Cs \times IRs) + (Cp \times IRp)}{BW} = \text{Edose} \quad (7.1)$$

where:

Cp = concentration of chemical x in prey, mg X /kg prey tissue;
 IRp = ingestion rate of prey, kg prey tissue/day;
 Cs = concentration of chemical X in soil, mg X /kg soil;
 IRs = ingestion rate of soil, kg soil/day;
 BW = body weight of receptor of concern, kg; and
 $Edose$ = exposed dose, mg/kg/day.

For an analysis focused on soil, inhalation routes of exposure, dermal uptake, and water consumption are considered negligible and are not considered a significant contribution to exposed dose (Ed). Additionally, with the role that BAF (bioaccumulation factor) plays in the derivation of soil PRGs (especially in the absence of empirical bioaccumulation data),

$$(Cs \times BAF) = Cp \quad (7.2)$$

may be substituted for Cp , the concentration of chemical in prey tissue (in mg X /kg prey tissue where X is a chemical of concern) with

BAF = bioaccumulation factor, [(mg X /kg tissue)/(mg X /kg soil)]

Upon substitution, this yields the basic equation for evaluating a dietary exposure to a chemical as:

$$\frac{(Cs \times IRs) + (Cs \times BAF \times IRp)}{BW} = \text{Edose} \quad (7.3)$$

The equation can then be rearranged to solve for Cs , the concentration of chemical in soil (in mg X /kg soil where X is a chemical of concern).

Then, setting hazard quotient (HQ) to unity^{12,13,18}

$$HQ = \frac{\text{Edose}}{\text{TRV}} \equiv \text{TRV} \times HQ = \text{Edose} \quad (7.4)$$

where:

TRV = toxicity reference value, mg X /kg tissue/day

subsequently yields

$$\frac{(Cs \times IRs) + (Cs \times BAF \times IRp)}{BW} = \text{TRV} \quad (7.5)$$

on substitution. Rearrangement then yields,

$$C_s(IR_s + [BAF \times IR_p]) = TRV \times BW \quad (7.6)$$

$$C_s = \frac{TRV \times BW}{IR_s + [BAF \times IR_p]} \quad (7.7)$$

The simplest, screening-level derivation of C_s views BAF as a simple ratio estimator, ideally developed from study-specific data (either literature-derived or site-specific).^{12,13,18} Regression analysis of empirical data capturing a range of exposure concentrations and associated tissue residue values, however, will likely improve estimates of C_p , which would subsequently improve derived values of C_s , which could be considered a lower bound estimate of a soil PRG for a particular chemical of concern.^{28,29}

7.2.3 Bioavailability: Its Evaluation and Role in Designing and Implementing Remediation Plans Focused on Wildlife

The derivation of soil PRGs may yield target values that are not attainable given the remedial technology available for cleanup.²⁷ For some chemicals of concern, target estimates for soil PRGs are frequently less than reference condition values. Risk-management tools must be applied when targeted values for soil PRGs cannot be attained owing to the limitations of remedial technology (e.g., institution controls such as capping are likely insufficient for remediation goals) or to a poor characterization of a chemical's bioavailability in the particular soils. When values for soil PRGs are at odds with background values or impractical to achieve given the available cleanup technology, the bioavailability of a chemical of concern must be considered in a critical evaluation of the target soil PRG.¹³

Bioavailability refers to a measure of actual entry of chemicals into receptors and is specific to the receptor, route of entry, time of exposure, type of chemical (e.g., metal, polycyclic aromatic hydrocarbon, etc.), chemical concentration, and the matrix containing the chemical.^{12,13,18} As such, bioavailability is not necessarily measured as an adverse effect but is simply measured as uptake of chemical by an organism. As a biological process common to life on earth, bioaccumulation was critical to biological systems long before its association with ecotoxicology (for example, in the accumulation of nutrients from the environment). As with numerous terms in environmental science, the definition of bioavailability may vary from user to user, which in part reflects the context supporting the term's use. For terrestrial vertebrates, bioavailability of a chemical in soil is generally considered the fraction of exposed dose that enters into the blood stream.¹² Here, the classical method for quantifying bioavailability commonly relies on the toxicological concept of "area under the time-vs.-blood concentration curve" (AUC) where the toxicologist follows the time-course change in concentration of chemical in circulation following an intravenous injection against that time-course described by AUC following oral ingestion of an equivalent dose of the same chemical.²⁵

In contrast, bioavailability for terrestrial and wetland plants, soil invertebrates, and soil microorganisms is that fraction of chemical in soil that is available for uptake.^{31,32} Terms from soil science have been adopted to characterize bioavailability for soil biota, since the vast majority often lack physiological systems amenable to the approach applied to birds and mammals. Here, we are concerned with other descriptors that may estimate the bioavailable fraction of chemical. For example, exchangeable ions occur at the interface of soil-soil interstitial water surrounding soil particles. Exchangeable ions may be removed from the soil by solutions of neutral salts and may be referred to as the fraction of total chemical concentration adsorbed on soil particle surfaces, excluding irreversibly adsorbed and precipitated fractions. Similarly, adsorbed exchangeable ions are generally assumed to occur in dynamic equilibrium with that fraction that can be exchanged

back to interstitial water. Overall, exchangeability of any chemical refers to the capacity of a soil to exchange adsorbed ions with those occurring in the soil interstitial water. Cation exchange capacity (CEC) and related measures of a soil's exchangeability are frequent measures of a chemical constituent's bioavailability. Generally, chemicals occurring in soil interstitial water are more directly available to soil biota, while exchangeable forms are potentially bioavailable.^{31,32}

For our purposes, absolute bioavailability (also referred to as realized bioavailability) refers to the fraction of a chemical (as elemental or compound) that is ingested and actually absorbed and reaches the systemic circulation (e.g., of a vertebrate receptor) or the internal milieu of the soil organisms (e.g., uptake by plant root or soil bacteria).^{12,13} On the other hand, relative bioavailability refers to a comparison of the absolute bioavailability of two or more forms of a specific chemical (e.g., elemental lead vs. oxides of lead), different vehicles (e.g., lead in food, soil, or water), or different doses (e.g., lead at 1 µg/kg vs. lead at 100 µg/kg).^{12,13} Most often, relative bioavailability is expressed as the ratio of contrasts, e.g., the realized dose or absorbed fraction achieved from exposure to soil relative to the absorbed fraction from the exposure medium used in a toxicity study used to characterize a benchmark value such as a TRV. Then, given this simple ratio estimator, simple arithmetic calculations may be used to calibrate the models specified in Equations 7.1 through 7.7, and target soil PRGs derived from such simple models may be revised toward achievable soil PRGs that incorporate bioavailability in the derivation process.

Similarly, in an effort to bring physiological processes to food-chain analysis and the derivation of soil PRGs, the incorporation of a "relative absorption fraction" (RAF) or "gut absorption factor" (GAF) has frequently been incorporated into the basic exposure equation.³³ Early implementations of food-chain analysis developed "absorption-transfer factors" (ATFs) as macrorate coefficients or factors that accounted for various transfers of chemical from one compartment to another in a food web.^{20,21} Regardless of the nomenclature, in each of these instances the fraction of exposed dose that is actually incorporated into tissues is estimated by empirically characterizing the relationships between exposed dose and the fraction of that dose bioaccumulated in tissues. Food-chain multipliers have also been applied to the evaluation of BCCs that are highly lipophilic and likely to be biomagnified.¹⁸ Such modifying factors may be developed largely from a modeling effort, or they may be empirically developed depending on the case-specific data required in the evaluation process. Either a modeling or empirical characterization of these factors may benefit the estimation of bioaccumulation as a refinement beyond a simple calculation of exposed dose, since these relatively simple fractional estimators of bioavailability reflect biological and ecological processes (e.g., biotic and abiotic factors) that determine a chemical's bioaccumulation in terrestrial wildlife.

7.3 WORKING WITH SOIL PRGs AND DIFFERENTIAL BIOAVAILABILITY: REMEDICATION OF TERRESTRIAL AND WETLAND HABITATS

Whether focused on relatively small parcels of land characteristic of brownfield developments or more widely disturbed landscapes characteristic of mining districts in the western United States,^{34,35} successful restoration or rehabilitation projects all require the design and implementation of soil remediation and revegetation plans in order to achieve habitat restoration or rehabilitation.³⁶ For the most part, the design and remediation of chemically contaminated and physically disturbed soils depend on management plans supporting future land-use goals identified for the habitats of concern. The development and application of technical methods required to achieve these goals are highly interdependent. While land-use decisions and management practices are critical to landscape restoration and must be clearly developed to assure technical success,³⁶ our focus for the balance of this chapter is on soils and plant interactions that influence the success of a revegetation effort.

Whether robust with respect to reestablishing habitats suited to all vertebrate wildlife or just a limited population, the ultimate goal of many restoration and rehabilitation plans frequently centers on birds and mammals; however, here we will center our discussions on soil characteristics —

abiotic and biotic — that must be considered to ensure successful revegetation. Without habitat, successful restoration or rehabilitation focused on wildlife resources would be frustrated because soils and their interrelationships with vegetation are a core requirement in establishing a sustainable system supporting the desired wildlife species.³⁻⁶ We will also focus on potential remedies that alter the bioavailability of residual chemicals, while attending to problems associated with diminished soil tilth and its impact on achieving long-term revegetation success.

7.3.1 Soils: Abiotic and Biotic Factors Influencing Revegetation Success

Two highly interrelated components of the revegetation process should gain the primary focus in restoration or rehabilitation activities focused on wildlife, especially when remedial activities have resulted in a highly disturbed soil bearing residual chemicals. First, abiotic factors critical to successful restoration or rehabilitation will be identified and reviewed within the context of developing and implementing a revegetation plan.^{26,31,32} These soil characteristics must be evaluated and are the most likely to limit the success of revegetation, especially those associated with physico-chemical characteristics of the soil matrix. Second, we will review biotic factors characteristic of soils that are critical to the success of revegetation projects. Here, a brief summary of the soil processes that are critical to revegetation success will be reviewed.

7.3.1.1 Soil Classification and Evaluation of Soil Matrix and Site for Metal Impacts

In disturbed habitats identified for restoration or rehabilitation the existing physical, chemical, and biological properties of the soil will determine the soil's productivity and influence the success of any revegetation project.^{3-6,26,36} Here, we will briefly discuss methods for evaluating the effects of disturbance and metals on the soil's productivity as well as soil tilth in general. Most habitats disturbed by human activities result in altered soil physical and chemical properties that may also influence — directly or indirectly — biological properties of the soil.^{26,37-39} These existing, or ambient, soil properties will predispose a site to a certain productivity level; therefore, it is necessary to evaluate basic soil properties to assess this ambient condition and any deviation attributable to residual chemicals in the soils. In addition, a quantitative knowledge of certain soil properties is often necessary for calculations involving the design of the restoration or rehabilitation project. For example, some designs may specify the addition of soil amendments that require the conversion of residual chemical concentrations to loading rates on a spatial basis. These calculations require knowledge of the bulk density and depth of the soil horizon bearing the residual chemicals of concern.²⁶

Adequate description of soil properties involves both field observations and laboratory measurements. Field observations include variables that are commonly recognized as site characteristics, while laboratory measurements are those commonly associated with traditional soil testing. Both are important in defining soil productivity. This discussion of soil properties is separated into a field and a laboratory section and is summarized in Table 7.1.⁴⁰⁻⁴³

7.3.1.1.1 Field Observations

Field observations can be subdivided into those that describe general site conditions and those that specifically describe the soil or soils that are found at a given site. General site parameters are type of overstory and understory vegetation, aspect, slope, and slope position. Aspect and slope characteristics are important parameters related to the water relations of a site. Vegetation type and distribution are often indicators of spatial variability of soils or metal distribution in soils.

Specific soil parameters are those integral to a complete description of the soil profile.^{44,45} This profile description should be conducted to a depth sufficient to adequately represent the rooting volume of the soil and for all major soil types at a site. The description should delineate the depth

Table 7.1 Summary of Applicable Methods for Measurement of Soil Properties in the Field and Laboratory

Soil Property	Determination in Field or Laboratory	Electrical Conductivity	References
Texture	Laboratory	Percent by weight in various size classes (i.e., % sand, silt, clay)	40
Organic matter (carbon) content	Laboratory	Percent of dry weight (% C or % OM)	43
pH	Laboratory or field	pH units	43
Cation exchange capacity (CEC)	Laboratory	cmol(+)/kg meq/100 g	43
Base saturation	Laboratory	Percent of CEC	43
Extractable acidity	Laboratory	cmol/kg mEq/100 g	43
Extractable nutrients (Bases: Ca, Mg, K, Na)	Laboratory	cmol/kg meq/100 g	40, 43
Nitrogen (Various forms)	Laboratory	Percent of dry weight or mg/kg	43
Phosphorous	Laboratory	mg/kg	43
Electrical conductivity	Laboratory	mmhos/cm	43
Water retention (available water capacity)	Laboratory	Volume percent (cm/cm)	40
Bulk density	Field and laboratory	g/cm ³ mg/m ³	40
Infiltration capacity	Field	cm/hour	40
Hydraulic conductivity	Field or laboratory	cm/day or cm/hour	40

and thickness of the horizons present in the profile including the litter *O* horizon, if present. For each horizon, the following information should be collected: color, structure, rock content, bulk density, and root distribution. Homogeneous samples should be collected from each horizon for laboratory testing. In addition, it may be desirable to measure infiltration capacities of water to the soil surface and hydraulic conductivities of water within the profile. These would be important if metals in the soil are susceptible to being carried by water as it moves over or through the soil profile. These soil parameters are briefly summarized in Table 7.1.

Horizon description. Delineating the types and sequences of horizons present accomplishes two major tasks. When compared to undisturbed sites, a complete description documents the absence (removal), enrichment (augmentation or deposition), and mixing of soil horizons and thus indicates the degree of disturbance. Second, the description forms the basis for field observation and sampling for laboratory analyses. In this context the depth of various horizons can be used to calculate volumetric quantities of various elements, including metals or other chemical constituents.

Color. A Munsell color chart (book) is used to evaluate soil color. Color is used primarily to indicate organic matter status of a soil horizon or the water relations in a particular horizon or profile. Dark colors indicate high content of organic matter, while light colors generally point to lower content. Bright colors (generally reds and yellows) indicate soils that have greater internal aeration; that is, they are better drained. Gleyed soils (blue-gray colors) indicate anaerobic conditions (poor internal drainage) in which a soil is commonly saturated for a major portion of the year. Variable coloring with interspersed gley and bright colors (mottles) indicates a horizon or profile that is subject to a fluctuating water table and therefore experiences alternating aerobic and anaerobic conditions. The internal oxygen/water relationship is important because it determines the reduction-oxidation potential of a soil and hence influences chemical forms and some chemical reactions that can occur in the soil matrix.

Structure. Structure refers to the way and degree to which individual soil particles bind together in larger units. The type of structure in a soil influences the paths of water movement (in reality,

is partially dependent on water movement) and paths of root penetration and expansion. Lack of structure can be an indication of intense physical disturbance.

Bulk density. Bulk density refers to the weight per unit volume of solid particles in a soil. It is a measurement that must be taken in the field; it cannot be successfully reconstructed from laboratory data. Bulk density indicates the degree of natural or induced compaction in a given horizon. It is inversely related to porosity, or the amount of air space in a soil. Compacted (bulk densities with greater values) horizons are barriers to both root growth and vertical (downward) water movement and may induce lateral pathways of water flow. Bulk density is also a parameter that is necessary in order to convert concentrations of a chemical constituent, such as a metal (usually reported on a weight basis), to an area or volume basis. It is used in conjunction with horizon thickness to calculate the content of a constituent (element) in that horizon.

Rock content. The rock or stone content of a soil horizon can be an important consideration because of its influence on water relations, the volume of finer soil particles important in soil chemical reactions, and the soil volume available for root growth. With respect to water relations, greater stone content reduces the soil volume active in storing soil water for subsequent plant use (lowers soil water-holding capacity). In addition, the paths of water movement within a soil are determined by the amount and arrangement of any rock that is present. In general, the greater the rock content the greater the volume of water interacting with the fine-earth portion of a soil horizon and the greater the potential for chemical alteration or leaching.

Root distribution. Root growth and the patterns of root distribution found in a soil profile provide an integration of most of the soil properties discussed above as well as the soil's chemical properties. Lack of roots (or reduced rooting) in a particular horizon or soil serve as an indication that a chemical, physical, or biological barrier is inhibiting root growth. However, it is necessary to recognize there is a "natural" root distribution characterized by decreasing root distribution with depth. This natural distribution is a function of vegetation type and regional climate and can be characterized to provide a standard for comparison of subject sites.

Infiltration capacity and hydraulic conductivity. Infiltration capacity is a measurement of the ability of the soil surface to absorb water. The greater the value the greater the rate at which water is taken into a soil and the lesser the chance of surface runoff and, hence, erosion. Infiltration capacity is strongly related to texture and organic matter content of surface horizons. Hydraulic conductivity refers to the rates of movement within a soil profile. It is also referred to as permeability. It is important because it characterizes the "residence time" of water within a soil profile and hence its chances of interacting with soil chemical constituents. Hydraulic conductivity is directly related to infiltration capacities. The slower the hydraulic conductivity the lesser the infiltration capacity.

7.3.1.1.2 Laboratory Analysis

Various laboratory analyses are typically conducted on samples obtained from field sites. These analyses are important for understanding the chemical, physical, and biological reactions that might take place in the soil. They are also important for assessing the mobility and potential pathways of movement of a contaminant, especially with regard to water movement and water-mediated biological decomposition. However, the results of these analyses only represent the properties of the sample itself. Adequate interpretation must consider the entire site setting and the horizon the sample came from in the soil profile. As such, the thoroughness of field observations is especially critical.

Laboratory analyses suggested for routine characterization and interpretation of soils include those for texture, organic matter, pH, cation exchange capacity, base saturation, extractable acidity, electrical conductivity, water retention, and concentrations of the elements nitrogen, phosphorus, potassium, calcium, magnesium, and sodium. The importance of these soil properties is discussed below.

Texture. Texture refers to the proportion of particles of different size classes (sand, silt, clay) that make up a sample. Knowledge of texture is important for assessing water relations, erodibility, and retention of cations, anions, and toxicants.

Organic matter content. The organic matter content of a soil is an indicator of its fertility, ability to support microbial populations, retention of elements, and water relations. In general, the greater the organic matter content the better the soil serves as a medium for plant growth.

pH. The pH of a soil sample is a measure of its hydrogen ion concentration (or, more accurately, its activity) and thus its acidity or alkalinity. This is an important property because it influences (or regulates) many chemical and biological processes occurring in a soil including the availability of soil nutrients and metals.

Cation exchange capacity. Cation exchange capacity (CEC) is a measure of a soil's ability to retain positively charged ions. The greater the CEC the greater the capacity of a soil to retain cations, and the greater its "storage" or "buffering" capacity. CEC is especially important for assessment of the mobility of positively charged metallic elements.

Base saturation and extractable acidity. These two measurements characterize opposite ends of the spectrum relative to the composition of cations occupying the cation exchange complex of a soil. They are strongly related to the pH of a soil. Base saturation represents the proportion of the CEC electrically satisfied by base cations such as calcium, magnesium, potassium, and sodium, whereas extractable acidity measures the proportion satisfied by the acidity cations — hydrogen and aluminum.

Electrical conductivity. Electrical conductivity is an indirect measurement of the ionic content of a soil sample. The greater the conductivity the greater the ion content of a soil. It is an especially important measurement in soils that have "free" salts, such as saline soils, and serves as an indicator of adverse conditions for growth of many plants in such soils.

Water retention. Water retention refers to the amount of water that can be retained by soil when it is subjected to different pressures. Characteristically a "water retention curve" is established for a soil sample by measuring its water content (on either a volumetric or weight basis) at 1/10-, 1/3-, 1-, 5-, and 15-bar pressures. The difference in water contents between the 1/3-bar (also termed field capacity) and 15-bar (wilting point) pressures is termed the available water content of a soil. It represents the amount of water storage the soil can provide against the force of gravity and the amount available for plant uptake.

Concentrations of various elements. Knowing the concentrations of the complete spectrum of nutrient elements in a soil allows interpretation of whether a specific nutrient deficiency is possible or whether there is an imbalance in the distribution of elements present in a soil or soil sample. Specifically, these analyses of extractable element concentrations provide a measure of their availability for plant or microbial uptake.

References such as the American Society of Agronomy (ASA) Monograph Series⁴⁰⁻⁴³ provide information valuable in the interpretation of analytical results and are the source of instructions for performing specific analyses given in Table 7.1.

7.3.2 Soil Factors Commonly Limiting Revegetation Success on Disturbed Soils

While each of the soil properties and characteristics briefly outlined above may contribute to problems encountered in revegetation efforts of disturbed soils, the combination and interaction of these factors (e.g., interactions of residual metals with soils or overburden at physically disturbed mining sites) frequently contributes to the relatively poor revegetation of some remediated soils bearing residual chemicals. In general, the factors that recur as prominent causes of failure of revegetation projects are associated with pH (or hydrogen ion concentration), salinity, sodicity (elevated sodium concentrations), cation exchange capacity, organic matter, soil texture and structure, and bulk density and porosity.⁴⁶ Each of these soil factors, their critical values for enhancing revegetation success, and soil manipulations that may promote remediation efforts when these critical values are not present are briefly summarized in Table 7.2 and in the following section. Although each restoration or rehabilitation activity will require independent analyses to determine a course to assure successful habitat recovery, Table 7.2 lists critical values for some of these soil

Table 7.2 Critical Values for Selected Soil Factors (Physical and Chemical) that May Yield Poor Revegetation

Soil Factor	Critical Value
Physical Characteristic	
pH	Less than pH 5.5 or greater than pH 8.5
Conductivity	4–6 mmhos/cm or greater
Sodium Absorption Ratio (SAR)	Greater than or equal to 12
Texture	40% clay, or loamy sand to sand
Chemical Characteristic ($\mu\text{g/g}$)	
Boron (B)	8 or greater
Cadmium (Cd)	0.1–1.0 or greater
Copper (Cu)	40 or greater
Lead (Pb)	10–15 (at pH less than 6.0) 15–20 (at pH greater than 6.0)
Manganese (Mn)	60 or greater
Selenium (Se)	2.0 or greater
Zinc (Zn)	40 or greater

Source: Modified from Munshower.⁴⁶

factors that should be viewed with caution when soils are being considered for revegetation, especially in soils of the western United States.

7.3.3 Evaluation and Reestablishment of a Soil Biota for Long-Term Revegetation Success

The development of a habitat-restoration or rehabilitation plan requires, in addition to the physicochemical evaluations outlined above, a characterization of the existing biological integrity of the soils.²⁶ Many revegetation efforts fail, or do not achieve long-term restoration goals, when soils are not critically evaluated during baseline activities of the revegetation phase of the project. The level of effort devoted to these biological characterizations will depend on the restoration goals identified in the management plans for future use as well as the time line developed for the activities to accomplish those goals.

7.3.3.1 Overview of Soil Biota and Its Role in Successful Revegetation

Nutrient limitations frequently diminish the success of long-term revegetation or restoration efforts. For example, of the major nitrogen transformations mediated by microorganisms, nitrogen cycling is one of the most important and directly related to plant productivity and successful revegetation.^{47–50} Nutrient cycling, however, cannot occur without soil organisms to perform the majority of the processes critical to the soil-rhizosphere interactions required for nutrient uptake. While abiotic factors like those physicochemical properties described previously may influence the presence and activity of soil nutrients, an understanding of the biological factors along with these physicochemical properties improves the site-specific characterization of processes like nitrification and respiration that will determine the overall success of any revegetation effort. Soil organisms, especially in concert with plant roots, are the filter through which all nutrients pass, and an understanding of their ability to cycle nutrients is critical to ensuring a successful revegetation or restoration project (Figure 7.1).

Soil organisms perform many processes, often with varying degrees of redundancy. This redundancy is important to resiliency of soil following disturbance. In healthy soil, there are usually (but

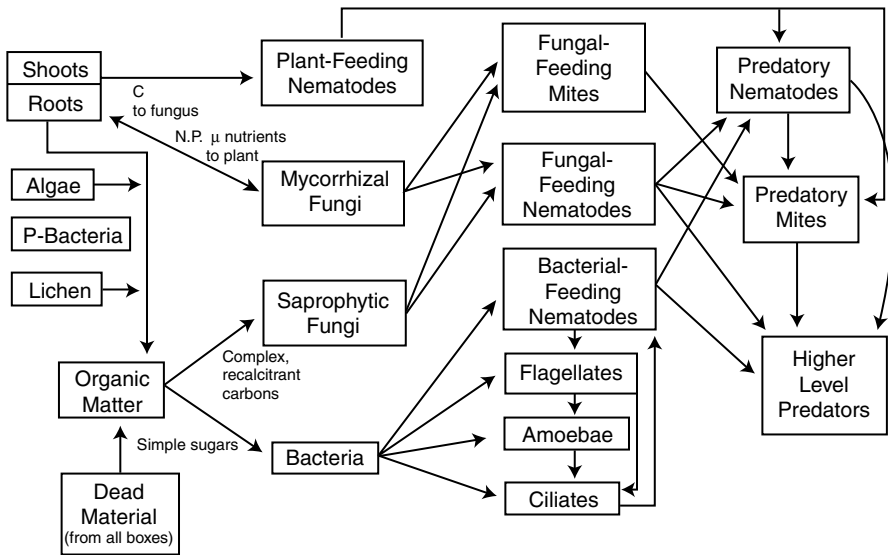

Figure 7.1 Generalized soil foodweb illustrating interrelationships of soil biota.

not always) several organism groups that perform any particular process, and in highly disturbed soils these organisms may be lacking or sufficiently impacted to dramatically limit the success of revegetation. For example, in soils of good tilth, some organisms function in colder conditions, some in warmer, wetter, or drier conditions, higher or lower organic matter, high or low pH, and so forth. Thus, nutrient cycling in soils of good tilth, as well as disturbed soils like those in the mining districts of the western United States, depend on soil microorganisms performing these functions. Regardless of the disturbance, functional redundancy can be diminished or destroyed in soils. For example, in many soils of the western United States, successful revegetation will depend on the presence of mycorrhizal fungi and on the functional soil organism-nutrient cycling system characteristic of undisturbed soils. At least some plants preferred for revegetation and restoration are obligately dependent on symbiotic organisms for establishment or survival.^{26,47}

In healthy soils, soil organisms are functionally interrelated via foodwebs. A foodweb consists of primary producers, primary consumers, secondary consumers, consumer generalists, and higher-level consumers.²⁶ One can consider the first “trophic” step as organic matter that drives the system, derived from leaf litter, roots, algae, moss, small mammal and bird fecal material, and secondary metabolites from microbial decomposition. These materials are used by the two primary decomposer groups, saprophytic fungi and bacteria, corresponding to the primary consumer trophic level. Nutrient and energy from living plant material also moves into nondecomposer, root-mutualist fungi and bacteria, such as mycorrhizae and nitrogen-fixing bacteria, and root-feeding organisms (parasites, pathogens) such as plant root-feeding nematodes. These organisms should be considered primary consumers as well.

The next trophic level is comprised of secondary consumers, which feed on both the decomposers and root-associates, i.e., bacterial-feeding (nematodes and protozoa) and fungal-feeding organisms (nematodes, certain amoebae, and a number of microarthropods). Secondary consumers are fed upon by higher-level predatory fauna such as mesostigmatid mites, predatory nematodes, insects, insect larvae, small mammals, and birds. There are a variety of generalist consumers within the soil such as enchytraeids, earthworms, rotifers, and microarthropods. Thus, a typical soil foodweb is complex, redundant, highly diverse, and quite stable. Disturbed soils, and especially soils that have been mined, generally have low diversity and, depending on the site, may be relatively depauperate and poorly colonized with indigenous microbial and fungal populations.

By characterizing soil foodwebs in part or in total, short-term and long-term revegetation success can be critically evaluated and remedial activities developed, if necessary. For example, reductions in foodweb organism numbers in disturbed mining soils as compared to undisturbed soils may indicate a negative impact on long-term revegetation success unless remedial options intervene. Significant decreases in soil organism populations may suggest a significant impact on revegetation success, and with time the ecological effect of reductions in numbers of organisms may be more clearly interpreted with respect to whether an impact improves or degrades soil fertility and ecosystem productivity. While the wildlife manager likely does not present sufficient knowledge to actively participate in the remediation of soil, if the biological components are critical to the long-term sustainability of habitat, their perspective on habitat requirements of vertebrate wildlife must be considered when the soil scientist's focus is drawn toward remedial measures channeled toward recovery of a soil's biological integrity (e.g., bacterial and fungal communities as well as soil protozoa and nematodes communities) and nominal processes (e.g., microbial nitrification and soil respiration).

7.3.4 Soil Tillth and Vegetation: Restoring Remediated Soils to Assure Long-Term Sustainability

While not all restoration or rehabilitation projects will require an exhaustive evaluation of the disturbed soil's baseline properties, when the soil physicochemical and biological characteristics outlined above are adequately characterized, the likelihood of successful revegetation will be enhanced. If soil conditions permit, successful revegetation will then depend on plant species selection and assurance that plant nutrients are adequate to support both initial and long-term success for the revegetation effort. Depending on the short-term as well as the long-term restoration or rehabilitation goals established for the project, various seed mixes, nursery material (bareroot or container-stock), and wilding transplants may be used to achieve site management goals.

While beyond the scope of the present overview, species lists should reflect a selection of plant materials consistent with the native flora of the region, especially at those locations identified as self-sustaining and likely to have little, if any, long-term landscape management. Indeed, within the site or landscape setting, an exhaustive list of grasses and grass-like species, forbs, shrubs, and trees may not necessarily satisfy the needs of site managers or revegetation specialists; rather, lists of plant species conducive to a variety of revegetation and restoration goals should be developed within the context of the ecoregion where the disturbance site is located. With such lists, plants species may be selected that are physiologically adapted to the soils and climatological setting of the site. Some locations, especially if they cover large areas of space or contain numerous microsites, may require numerous different lists of plant species or different seed mixes to assure long-term revegetation or restoration success in very heterogeneous sites or landscapes.

The success of any restoration effort depends on many interrelated technical factors including the characterization of the physicochemical and biological properties of soil and selection of plant species that have successfully been used in revegetation projects in the surrounding areas. While site-specific variation in soils may require that expert judgment and experience be used in the selection of methods to characterize the site-soils identified for revegetation, these soil properties should be considered early in the design and implementation of the site-management plan, especially if long-term restoration is driving the revegetation effort. When the evaluation of the existing physicochemical and biological properties of the disturbed soils suggests that no critical values (e.g., pH, salinity, plant nutrients) are deficient or in excess and that soil tillth should adequately support the plant species identified in the revegetation plan, the likelihood for a successful revegetation of the site will be increased. But if the baseline characterization of the disturbed soils is incomplete or indicates that soil tillth is insufficient to achieve revegetation or restoration goals, then soil remediation activities will have to be pursued prior to the revegetation effort.

Table 7.3 Trace Elements in Western Soils and Their Relationship to Plant Nutrition^{46,51,55,56}

Element ^a	Ranges		Extractable	
	Total	Extractable or Soluble	Low or Deficient	High or Toxic
Al	0.5%–10%	Varies with pH	NA ^b	1–5
B	20–70	< 1–8	0.5	8–10
Cd	0.1–2	0.01–0.05	NA	Not known (varies with soil type)
Cu	2–90	0.1–0.7	0.2	Not known (varies with soil type)
Fe	0.3%–6.8%	1.5–200	2.0	Not known under natural conditions
Mn	65–1300	1–40	1.0	Not known (varies with soil type)
Mo	0.5–20	0.05–0.3	Varies with Cu concentration	Varies with Cu concentration
Pb	3–25	0.1–3	NA	Not known (varies with soil type)
Se	2–20	0.01–10	Vegetation levels < 0.05	Vegetation levels > 0.05

^a Concentrations in µg/g unless otherwise noted.

^b NA = not applicable (element not required for plant growth).

Disturbed habitats frequently are characterized by poor soil tilth, where the relationship between the plant and the physical condition of the soil is poorly developed.^{51–53} While the soil analyses previously identified are critical in designing and implementing any revegetation project, they enable us to regard soil as only a single “snapshot” in time. The successful revegetation project must consider numerous snapshots collected throughout the project’s lifetime if long-term sustainability and revegetation success are to be achieved.⁵⁴ Soils, and especially disturbed soils, are continually changing, albeit at a relatively slow rate, throughout the restoration process. And depending on the initial conditions of the soils and the extent of intervention planned as part of the restoration effort, changes in soil will vary from being quite rapid to very slow. These changes, whether relatively slow with little intervention or rapid with much design and intervention, may improve soil tilth, or they may contribute to the continued degradation of the soil resource. Similarly, plant nutrients, such as nitrogen, phosphorus, potassium, calcium, magnesium, and sulfur (i.e., macronutrients), should be characterized throughout the restoration or rehabilitation project to assure their sufficiency, especially within the management context for the project as a whole (e.g., planned periodic fertilization programs).^{3–6,46}

Under baseline conditions trace elements and micronutrients (e.g., boron, copper, manganese, molybdenum, zinc) generally occur at highly variable concentrations in soils. For example, Table 7.3 briefly lists some frequently considered trace elements and plant micronutrients that recur as critical components in revegetation projects in the western United States.⁴⁶ The role of these micronutrients is frequently poorly characterized or varies from plant species to plant species, which reinforces the role that soil physicochemical characterization plays in the restoration or rehabilitation process, since some revegetation projects may have to consider their role in plant-soil interactions to assure long-term success.⁵³

7.3.4.1 Physical Manipulations

Successful revegetation of any disturbed soil, whether related to chemical releases or not, is only assured if sufficient planning has preceded the implementation of the project. Depending on the site and long-term land use plans associated with its restoration, some restoration strategies

may have to include short-term as well as long-term plans, for example, to assure an initial stabilization of the disturbed soils as a developmental step in the long-term restoration of the site with a highly diverse plant community. Such short-term practices may include liming amendments that, initially designed to alleviate soil pH problems, will be discontinued once soils have recovered their normal biogeochemical processes for nutrient cycling.⁴⁶

While various activities will be required in the restoration of vegetation to disturbed soils, the physical manipulations required to assure success will likely alter residual chemicals' bioavailability while improving soil tilth. Methods commonly available to the remediation process include recontouring and slope reconstruction, topsoiling, surface manipulation,⁴⁶ and the addition of various soil amendments, fertilizers, and mulches.^{46,56}

Recontouring and slope reconstruction. When water is a major factor limiting the success of revegetation efforts (for example, in the western United States), the control of erosion by wind and water runoff requires interrelated physical manipulations that are closely related to the maintenance of soil surfaces to enhance the capture of water when it occurs as rain and snow. Land recontouring should establish stable slopes and the reconstruction of the original topography to assure satisfactory surfaces for reestablishing plants and maintaining a drainage basin to capture water. Recontouring should reestablish linkages to the surrounding undisturbed landscape; ideally, long-term revegetation success will depend on the successful germination and establishment of native vegetation to obscure the boundary between the restored and undisturbed plant communities.³⁻⁶

Topsoiling. Throughout the United States topsoil is frequently preferred as a growth medium for plants being used in a revegetation project, primarily because spoil material (e.g., from mining or other excavation activity) stored for restoration purposes may be nutrient deplete and physically unsuited for establishing sustainable plant-soil relationships.^{46,55} As a general term, cover soil may be more appropriate. Nonetheless, topsoil often times refers to the plow layer, or that layer of surface soil that is a minimum depth removed through operation of an earth scraper, and still possesses good plant-growing characteristics. In disturbed arid lands like those of the western United States, there is little, if any, A horizon in topsoil. More frequently, topsoil at disturbed mine sites is a mixture of soil horizons.^{35,36,46}

Salvaged surface soils at disturbed sites are preferred for restoration because of its more favorable physical and chemical properties relative to other materials. Ideally, cover soil for revegetation projects should have sufficient organic matter, as well as an indigenous soil flora and fauna to enhance and promote plant growth. The long-term sustainability of any revegetation project will depend on the development of a soil community capable of cycling plant nutrients and maintaining a favorable microenvironment in the rhizosphere. Even a shallow layer of a few centimeters of surficial soil improves infiltration, and seed germination and early seedling survival are improved in topsoil materials.^{46,55}

Surface manipulation. The preparation of a seedbed is critical to the germination and establishment of seeds, and to a certain extent the successful propagation of transplanted plant materials also depends on adequate preparation of the cover soil's surface. These surface manipulations most generally include plowing, chiselling, disking, and harrowing and should be practiced on the contour. Special manipulations may be required on some sites to minimize the long-term, as well as short-term, problems associated with compaction and the development of slippage planes between subsoil and overburden and cover soil. Gouge depressions and "dozer" basins may also be used when water infiltration is considered a problem for a specific site. Often plants may be initially established in these surface depressions to promote growth in sheltered, well-watered areas; then, these "islands" of growth may fill in the bare ground between surface depressions in subsequent seasons, especially when rhizomatous species are used to establish the initial vegetation cover.⁴⁶

Soil-incorporated amendments, biosolids, and commercial fertilizers. Amendments are additions to surface soils and overburden that occur immediately prior to or following seeding operations; in general, these amendments are intended to provide a better medium for growth, especially with respect to the rooting medium. Overall, amendments should provide supplemental nutrients

and increase soil organic matter, adjust soil pH to enhance plant growth, and improve physical properties to enhance soil moisture. On a larger scale amendments may also be used to reduce erosion and modify temperature.^{46,56}

To achieve these objectives related to the promotion of plant growth several types of amendments are available to the restorationist, including commercial fertilizers (as sources of nitrogen, phosphorus, and potassium) and various sources of organic material (such as composted manures, wood chips, sludge, and straw). For acid soils characteristic of disturbed mining lands, lime amendments may be used to alter pH regimes in the rhizosphere, and salts may be added to soils to promote the leaching of growth-inhibiting anions and cations.^{31,46,55}

Mulches and surface-applied organic amendments. Closely related to soil amendments are mulches of various types, including surface-applied organic amendments. In general, mulches are organic materials applied to the soil surface after seeding or transplanting of root stock. Like soil-incorporated amendments, mulches are diverse in their character and include wood chips and other wood residues, straw, and native hay. While not strictly a mulch, composted manures and sludges may also be used as a surface-applied material after planting. Regardless of the type, mulches reduce erosion and evaporative water loss from soil, help prevent soil crusting, and reduce soil temperatures, which may be critical to seed germination and early seedling survival. Surface-applied mulches may be subsequently incorporated into the soil through crimping or rototilling (or any similar practice) and as such become an organic amendment that will affect soil physical structure and chemical characteristics.^{31,46,55}

7.3.5 Interactions between Remediated Soils and Surface Water Habitats

Soil erosion includes the processes of detachment of soil particles from the soil mass and the subsequent transport and deposition of those soil particles on land surfaces or as bed sediments in surface waters. Erosion is the source of 99% of sediment loads in surface waters in the United States.^{57,58} Soil erosion and sedimentation contribute to the degradation of streams, lakes, and reservoirs as well as disturbance to wildlife habitat. Additionally, financial costs (e.g., costs associated with dredging) are also directly related to soil erosion and sedimentation processes. For residual chemicals in soil, this cost could extend to issues associated with what may become “contaminated sediments” when erosion occurs, releasing soil-bound chemicals to surface waters.

Erosion of soil is an important process involved in the transport of soil-bound chemicals (e.g., agricultural chemicals, waste chemicals derived from mining operations, and chemicals associated with various land-use practices) from nonpoint source areas to waterways, where the resulting soils may create water- and sediment-quality problems.^{57,58,59} From a water-quality perspective, soil erosion is the source of 80% of the total phosphorus and 73% of the total Kjeldahl nitrogen in the waterways of the United States.^{58,59} In addition to providing a source of nutrient enrichment, unless adequate assurance is available the likelihood that residual chemicals in soil will be lost to surface waters through erosion will diminish the success of any soil-restoration or rehabilitation plan. A characterization of erosion potential can be achieved through various sources including the Revised Universal Soil Loss Equation (RUSLE),^{58,59} which may be beneficial to evaluating the overall restoration or rehabilitation plan, particularly if residual chemicals in soil present a potential risk if transported to the sediment environments of adjacent surface waters.

7.4 SUMMARY

Keys to successful remediation targeted at restoring terrestrial wildlife populations center on estimating remediation goals in terrestrial and wetland habitats, identifying functional goals for ecosystems to be remediated and the spatiotemporal scales for the remediation activity, identifying locations inappropriate for future wildlife use, and designing management plans to minimize adverse

effects associated with such areas. Currently, there is little or no federal, state, or other guidance to derive soil cleanup values or ecological-based remedial goal options, and derivation of “cleanup levels” is usually subject to negotiation among regulators and others having an interest in the habitat of concern.⁶⁰ The derivation process for soil PRGs focused on habitat remediation consists of:

- Developing target PRGs for soil that reflect lower bounds for residual chemicals likely to present risk (negligible or no risk) to wildlife exposed to low levels over long periods of time, and
- When target PRGs are not attainable, data on a chemical’s bioavailability are considered to modify these target PRGs to levels and characterize soil PRGs that can be achieved with the available technology and will be allowed to remain at the site without further remedial action.

Within a restoration and rehabilitation context, when a target value for a soil PRG cannot be reached, a chemical concentration should be characterized by its differential bioavailability in order to reach this attainable soil PRG.

As was detailed earlier in this chapter, bioavailability varies as a function of (1) the receptor, (2) the route of entry or mode of exposure, (3) time of exposure (i.e., biotic-abiotic frame of reference, largely spatiotemporal), (4) type of chemical and its concentration, and (5) the matrix containing the chemical. The biological components characteristic of disturbed habitats that should be considered when chemical releases and remedial activities are concerned include soil biota (soil-dwelling flora and fauna, including rhizosphere biota), soil surface-dwelling biota, including macro-invertebrates, plants, and associated fauna (e.g., plant-dwelling invertebrates and mycorrhizal fungi), invertebrate wildlife, and vertebrate wildlife. Ultimately, in view of our relatively limited set of truly predictive tools, the development of monitoring programs to evaluate remediation and restoration of terrestrial and wetland habitats is essential to any restoration or rehabilitation plan likely to be successful. The costs both monetary and aesthetic may be unacceptable if our best estimate of soil PRG proves to be associated with subsequent risk or injury.

8.1 INTRODUCTION

The evaluation of the phytotoxicity of a chemical is an essential component of the ecological risk assessment of that compound. Primary producers form an essential trophic level of any ecosystem. Further, since all chemicals introduced into the environment ultimately find their way into aquatic ecosystems, aquatic algal and plant toxicity evaluations are particularly critical. This

chapter presents the current state of phytotoxicity testing with particular attention to algal and vascular plant bioassays. The algal bioassay section focuses on test methods due to the relatively long history of algal toxicity testing. The vascular plant section focuses on the different plants used for bioassays and the various endpoints used in these bioassays.

8.2 ALGAE

8.2.1 Introduction

Phytoplankton, benthic and epiphytic microalgae, and macroalgae are energy sources critical to most aquatic ecosystems. Changes in their density and composition can affect the chemical and biological quality of the habitat. Therefore, the evaluation of the phytotoxicity of a contaminant is an essential component of any ecological risk assessment. Freshwater microalgae are used more frequently in phytotoxicity tests than any other type of freshwater or marine plant. However, algae are used less often than animal species. This is attributable to several factors. First, technical expertise is needed to conduct phytotoxicity tests. In addition, some consider plants to be less sensitive than animals to toxicants. However, algae have been found to be more sensitive than animal species to a variety of potential contaminants (Table 8.1). A review of the toxicity database for PMN submissions for the Toxic Substances Control Act (TSCA) indicated that algae were more sensitive than animal species in 50% of the submissions and less sensitive in 30%.¹ It is clear that the sensitivities of plants and animals to toxicants is unpredictable and that no assumptions of equivalency should be made. Therefore, the use of algae is necessary to estimate the environmental hazard of chemicals. This use is most frequent in the United States for commercial chemicals to comply with requirements for TSCA and the Federal Insecticide, Fungicide and Rodenticide Act (FIFRA). In contrast, the phytotoxic effects of most municipal and industrial effluents, contaminated sediments, and hazardous wastes are unknown.

Most of the information available to the scientific community concerning the phytotoxic effects of chemicals and other potential toxicants is based on the results for a few green algal species, such as *Selenastrum capricornutum*, and several *Scenedesmus* species. The use of *Selenastrum* in

various studies conducted during the 1960s and the 1970s has been reviewed by Leischman et al.² The majority of the standard test methods and culture techniques developed in the U.S. have been designed for its use. It is important to note that toxicity data for these and other algal species have been used as surrogates for marine algae, macrophytes, and even terrestrial plants. However, this type of data extrapolation is decreasing as methodologies for marine algae and vascular plants become more available.

8.2.2 Test Methodologies

Algicidal or acute toxicity tests are conducted less frequently than chronic tests with algae. Numerous chronic methods are available that can be used to evaluate the phytotoxicities of toxicants (Table 8.2). These chronic methods are based on the Algal Assay Procedure Bottle Test³ or a modification of it.⁴ Other test methods have been described that are either variations of those based on population growth, such as that by Payne and Hall,⁵ or others that are more different such as those using microplate methods,⁶ chemostat culture,^{7, 8} flow cytometry,⁹ and immobilized algae.¹⁰

The freshwater algal test methods currently used (Table 8.2) were developed during the past 20 years by a variety of organizations. These tests were designed to be conducted with an easily cultured alga, such as *Selenastrum capricornutum*, that rapidly grows and can be easily enumerated. The basic design of most methods is similar; the effect of a toxicant, usually five concentrations, is determined in the algal exponential-growth phase that occurs during the normal 3- to 4-day exposure period. This static exposure occurs in a nutrient-enriched medium that is diluted with well, reconstituted, dechlorinated tap, or river water under conditions of controlled pH, light, and temperature. See Figure 8.1 for an example of a typical 96-hour laboratory algal flask toxicity test conducted on an oscillation shaker. The effects of the toxicant are based on changes in biomass and growth rate that are monitored daily, in most cases by electronic or manual cell enumeration techniques. The response of the growing algae to the usual five test concentrations can be stimulatory, but more often it is inhibitory (Figure 8.2). Examples of the diversity of toxicants used in algal toxicity tests appear in Table 8.3.

The experimental conditions in the various types of algal toxicity tests available to the scientific community differ in some aspects (Table 8.4). The test results can be affected by several factors including the choice of test species, light intensity, temperature, and test duration. The effects of these and other variables on the test results have been reported on numerous occasions (Table 8.5) and have often exceeded several orders of magnitude. Another factor to consider is the use of a reference toxicant. There is no preferred compound, and cadmium chloride, sodium chloride, and sodium dodecyl sulfate have been used. Analytical verification of the test concentration is recommended in a few methods, but it is seldom performed. Nevertheless, this is an important issue that

should be considered since the toxicant solutions are not renewed in algal toxicity tests and the exposure concentration can be considerably different than nominal concentrations. A brief discussion of several important experimental factors in conducting algal toxicity tests follows. See the publications by Sirois¹¹ and Nyholm and Kallqvist¹² for additional details and evaluation.

8.2.2.1 Nutrient Medium

An important component of algal cultures and algal phytotoxicity tests is the nutrient medium. The concentrations of the micro- and macronutrients comprising the medium exceed those in natural waters, and therefore its use affects the environmental relevance of the results. Algal growth is rapid in the medium, and the population can double or triple within 24 h (Figure 8.2). A variety of suitable culture media have been reported^{13–15} in addition to those described in the published test methods. Test results can differ by as much as an order of magnitude depending on the type of medium.^{16–19} Media components of greater research interest have included the chelator, ethylenediamine tetracetic acid (EDTA), and nitrogen and phosphorus.^{7,20–22}

8.2.2.2 Test Species

The selection of the test species is an important consideration in phytotoxicity tests with algae, particularly if environmental realism is desired. The choice of a species has been usually dependent upon its availability, culture requirements, and case of use. Typically, only one species is used to determine the phytotoxicity of a commercial chemical, and usually a green alga has been the species of choice. Blue-green algae and diatoms are used infrequently because of their slow growth and difficulty in culture. However, there are exceptions, as shown for pesticides (Table 8.6).

Interspecific variation has been demonstrated for a variety of algae, including *S. capricornutum* and several compounds (Table 8.7). The difference in sensitivity can be less than ten or several orders of magnitude.^{23–26} In addition to interspecific variation, the sensitivities of different clones and geographical races of algae can differ,^{24,27,28} and the presence of other algae can affect the test results.^{29–31} The overall effect of the considerable interspecific response is the inability to predict the phytotoxic effects of chemicals from the results for only one or two algal test species, which

is the usual practice. Therefore, a species battery approach is needed where several taxonomically different species are used. This battery may include “nontraditional” species. Swanson et al.²⁶ reported that algal species of 35 genera have been used to evaluate the toxicity of atrazine.

8.2.2.3 Test Duration

The test duration is an important experimental consideration since it can influence the test result (Table 8.8). Most toxicity tests with algae are conducted for 3 to 4 days. Shorter durations have been recommended to reduce the possibility of a decrease in the test concentration due to sorption of the toxicant to the rapidly increasing algal biomass and test container walls as well as to pH changes in the test water. In contrast, tests of longer duration (5 to 21 days) allow for the determination of algistatic concentrations,⁵ the toxicities of intermediate biodegradation products, and stimulatory effects.³²

^a Data from Delistraty.⁴⁰

^b Data from Blaise et al.⁶

Algal toxicity tests can be 1 h or less if photosynthetic activity is the effect parameter. The effects of several herbicides,^{33–36} surfactants,³⁷ metals,³⁸ effluents,³⁹ and oil products^{40,41} have been determined based on the photosynthetic response of algae as measured by carbon uptake or oxygen evolution. These studies have been conducted with single cultured species of algae as well as with natural periphyton and phytoplankton communities. Although the short duration of these studies is desirable, short-term photosynthesis has been a less sensitive effect parameter than population growth monitored during the 3- to 4-day traditional studies.^{36,42}

There has been an effort recently to develop and validate tests of shorter duration that provide relatively rapid estimates of phytotoxicity; i.e., the microplate technique.²⁰ Microplate techniques are being used more frequently, and they have been shown in some cases to provide results comparable to those from flask bioassay procedures⁴³ such as shown in Figure 8.1. Examples of the experimental techniques used in the microplate method as well as in a short-term photosynthesis test appear in Table 8.9.

8.2.2.4 Light, Temperature, and pH

Light intensity, temperature, and pH may impact the results of phytotoxicity tests. This should not be unexpected since they affect the toxicities of chemicals to aquatic animals. Increases in light

intensity and temperature generally increase toxicity.⁴⁴ The effect of pH is less predictable; toxicity may decrease with increasing pH,⁴⁵ or it may be greatest at some intermediate level.⁴⁶

8.2.2.5 Response Parameters and Calculations

A variety of effects have been monitored in algal toxicity tests, including physiological and morphological changes. However, the inhibitory and, to a lesser extent, stimulatory effects of the toxicant on biomass are determined in most cases. Effects on biomass are directly or indirectly determined using measurements such as dry weight, cell counting, and chlorophyll *a*. Counting chambers (hemacytometer), spectrophotometers, and fluorometers are commonly used for this purpose.

The test results are usually reported as a change in standing crop, growth rate, or area under the growth curve. These measurements, as well as others, are described in the various published test methods reported by APHA et al.,⁴⁷ and ASTM.⁴⁸ Typically, an IC_{50} value and the no-observed effect concentration (NOEC) are calculated. However, these calculations are considered by some not to be as environmentally meaningful as algistatic and algicidal concentrations,^{5,49} which are seldom reported. Methodologies for determining algistatic and algicidal effects are provided by Payne and Hall⁵ and the U.S. EPA,⁵⁰ and they include the use of extended exposure and recovery periods as well as vital staining techniques.

Stimulation is not commonly reported in phytotoxicity tests, although it is occasionally observed. The calculation used most often to report stimulatory effects is the SC_{20} value, which was first described by Walsh et al.⁵¹ It represents the test concentration that results in a 20% increase in biomass relative to that for the control algal population. The importance of stimulation in the data interpretation and the definition of biologically relevant levels are issues that need to be resolved.

Appropriate statistical methods to analyze algal toxicity data have been summarized and discussed previously.^{47,52–56} Graphical interpolation is a simple and useful method to determine the EC_{50} and IC_{50} value,⁵⁷ and 95% confidence intervals can be provided using linear and nonlinear regression methods.⁵⁵ Parametric and nonparametric analyses have been used to determine the NOEC and the first-effect values, which is recommended in some methods. An inverse linear regression technique is used to calculate the algistatic concentration.⁵

8.2.3 Environmental Significance of Results

The environmental relevance of laboratory-derived phytotoxic concentrations for single species of microalgae is not known for most chemicals. The large difference in interspecific variation, the usual controlled experimental conditions, and the unknown impact of environmental modification such as biological adaptation⁵⁸ are several factors that reduce the relevance of these data as they are currently derived. Consequently, results from laboratory phytotoxicity tests are considered generally to be unrealistic estimates of concentrations expected to cause detrimental ecosystem effects.

Several experimental designs have been used to provide more realistic phytotoxicity estimates. These include adaptations to the traditional laboratory methods such as using river water for dilution,⁵⁹ the use of chemical mixtures,⁶⁰ and the simultaneous exposure of multiple algal species.⁶¹ In addition, more complex multispecies designs have been used in the laboratory and field, and these include microcosms, experimental ponds and streams, enclosures, and *in situ* dosing. The effects of various contaminants have been determined on natural phytoplankton and periphyton communities using these techniques (Table 8.10).

The results from the multispecies tests have been compared in several cases to those from the laboratory single-species tests conducted with the same effluents,³⁹ pesticides,^{35,62} metals, and surfactants.^{63–65} The outcomes of these data comparisons, which are relatively few, have been

Table 8.10 Methodologies Used to Determine the Effects of Contaminants on Aquatic Plant Species, Populations, and Communities

Adapted from Lewis.¹²⁷

species- and compound-specific. For example, cultured algae were less sensitive to anionic surfactants than a phytoplankton community but not to nonionic and cationic surfactants.³⁷ This inconsistent trend in sensitivity has been observed for different metals as well. Based on these and other reported results, the inability to generalize or predict ecosystem impacts from laboratory-derived toxicity results for microalgae and most chemicals is obvious.

8.2.4 Usefulness of Algal Phytotoxicity Tests

The importance of phytotoxicity tests in ecotoxicology and in the risk assessment process has not always been obvious. As stated earlier, these tests were once thought to be less worthwhile than those conducted with animals.⁶⁶ This opinion has contributed to the current minimal phytotoxicity database.⁶⁷ However, comparative toxicity evaluations have shown phytotoxicity tests to be more useful than some animal toxicity tests,⁶⁸ and they are conducted more frequently than animal chronic toxicity tests in support of the TSCA process.^{69, 70}

Current scientific knowledge concerning the phytotoxic effects of most chemicals is based primarily on the laboratory-derived results for freshwater green algal species. As stated earlier, these results are used, sometimes with little scientific justification, as surrogates for other types of freshwater algae, marine algae, vascular aquatic plants, and, in some cases, terrestrial plants.⁷¹ Furthermore, laboratory-derived results for single species of cultured microalgae are also used to predict ecosystem effects. The validity of this latter extrapolation has not been proven and should not be attempted unless supporting data are available.

In summary, laboratory-derived algal toxicity tests are worth the effort, despite current limitations. To improve their usefulness several taxonomically distinct test species need to be used, and the biological significance of the inhibitory and stimulatory effect levels need determination. The derivation of these data should be of high priority to the scientific, regulatory, and regulated communities since their availability will increase the relevance of the current risk assessment process for potential phytotoxic substances.

8.3 AQUATIC VASCULAR PLANTS

8.3.1 Introduction

Traditionally, algae have been the primary test organisms for aquatic phytotoxicity evaluations due, primarily, to the simplicity of algal culture systems. In fact, toxicity data for algae are often used as surrogates for vascular and terrestrial plants. Recently, this practice has been challenged since algae were less sensitive than vascular plants 20% of the time.⁷¹

Aquatic vascular plants, or macrophytes, are an extremely important component of the primary producers in many ecosystems. They include mosses, liverworts, ferns, and angiosperms and are usually classified as floating, submersed, or emergent. Taxonomical, ecological, and physiological characteristics of aquatic macrophytes are presented in detail elsewhere.^{128–130} Both freshwater and saltwater vascular plants serve as food sources for waterfowl, fish, and invertebrates; they capture solar energy, produce oxygen, participate in nutrient cycling, assimilate carbon, and provide habitat for a variety of aquatic life. For these reasons, this trophic level is critical to the stability of aquatic ecosystems, and pollutant burden on these organisms may have indirect repercussions on other trophic levels.

During the past 30 years the major focus of aquatic vascular plant research was directed toward controlling and eradicating troublesome vegetation. Literature is available on the control of the Haloragaceae (water-milfoil),¹³¹ Potamogetonaceae (Pondweeds),¹³² Najadaceae (Water nymphs),¹³³ Pontederiaceae (hyacinths),¹³⁴ Hydrocharitaceae (Frog's bit),¹³⁵ and several others.

In the last decade, however, the importance of aquatic vascular plants in the environmental risk assessment process has been recognized. These organisms are not only important as indicators of contaminant stress in the aquatic ecosystem but also as significant routes of chemical disposition, movement, and bioavailability.¹³⁶ Problems associated with the use of aquatic vascular plants in toxicity and fate studies include inadequate knowledge of typical growth conditions and the inability to obtain optimum and reproducible growth with the test species. In addition, these organisms do not lend themselves to nondestructive quantitative measurements of growth with time. Rooted species present an added difficulty if a complex rooting substrate is needed. Development of culture techniques, test methods, and sensitive endpoints for aquatic vascular plant bioassays has been limited. A few species of floating and submerged plants, however, have been used to successfully assess the toxicity and fate of aquatic contaminants.

8.3.2 Duckweeds

By far, the most commonly used vascular plants in toxicity tests are duckweeds, members of the Lemnaceae. Advantages of these floating macrophytes include their small size, their ability to be grown in axenic culture in a defined inorganic medium, the fact that they are not rooted in the hydrosol, and the fact that both their growth rate and final biomass yield can be determined visually and nondestructively. A review of the taxonomic literature has been presented by Hillman.¹³⁷ The use of duckweeds has been suggested or required by the Toxic Substances Control Act and the Federal Insecticide, Fungicide and Rodenticide Act.^{138,139} While there are four genera in the Lemnaceae family, *Lemna* are most often used in toxicity testing. The four species that are globally distributed are *Lemna minor*, *Lemna trisulca*, *Spirodela polyrhiza*, and *Spirodela oligorhiza*.¹³⁷ *L. minor* and *L. gibba* are the more commonly used bioassay species.

Duckweed toxicity bioassays can be static, static-renewal, or flow-through design.^{48,138–142} A variety of test lengths (4 to 10 days), light intensities (30 to 300 mE m⁻² sec⁻¹), and growth media (nutrient-enriched algal media⁵⁰ and Hoagland's media¹⁴³) have been used in these assays. Grant¹⁴⁴ optimized the growth of *L. minor* and *S. polyrhiza* in static toxicity bioassays. Experimental conditions that provided maximum growth rate included 33% Hutner's Medium¹⁴⁵ buffered to pH 6.5 with 0.015

M phosphate buffer, light intensity equal to $151 \text{ mE m}^{-2} \text{ sec}^{-1}$ with cool white fluorescent tubes and a temperature of 25°C . Hutner's reported sensitivity of *L. minor* to the anionic surfactant linear alkylbenzene sulfonate during a 10-day test was greater than that reported by Bishop and Perry.¹⁴⁶

Wang¹⁴⁷ reviewed the use of duckweed in toxicity tests and reported that the doubling time for *Lemna* species ranged from 0.35 to 2.8 days. In Grant's growth optimized system doubling times for *L. minor* and *S. polyrhiza* were 1.43 and 2.24 days, respectively.¹⁴⁴ To be a valid test the biomass of duckweed in the control needs to increase at least five-fold during one 7-day test.⁴⁸ The most commonly used calculations are the values that are based on a variety of effects such as the number of fronds and on biomass, root number, plant number, root length, and pigment content. Other calculations, such as the phytostatic, phytocidal, EC10, and EC90 values, have also been used.^{138,148}

Little information on the comparative sensitivities of various species of duckweed exists. Grant¹⁴⁴ reported that *L. minor* was more sensitive than *S. polyrhiza* to the herbicide Hydrothal-191 (Endothal) and to linear alkylbenzene sulfonate: the two were equally sensitive to ammonium carbamate. King and Coley¹⁴⁹ reported that *L. gibba* was less sensitive than *L. minor* and *L. perpusilla* to extracts of oils and coal distillates.

In some studies duckweed has been reported to be more sensitive to some chemicals than other macrophytes and algae.^{146,150} Wang¹⁴⁷ reported that duckweed was more sensitive than fish to Cd, Cr, Pb, Ni, and Se. Taraldsen and Norberg-King¹⁵¹ developed a test method for effluents and reported that duckweed was more sensitive than the fathead minnow or *Ceriodaphnia dubia* to two of three effluents tested. Other studies, however, have illustrated that duckweed is not as sensitive as some algae to chromium (VI), solid waste leachates, chlorinated phenolic compounds, and coal ash waste.¹⁵²⁻¹⁵⁵

There is great need for additional data concerning the relative sensitivity of duckweeds to a wide variety of toxic compounds. Only then will they be more widely incorporated into chemical registration and NPDES permit testing. In addition, the ecological significance of duckweed bioassay results and the utility of these organisms as surrogates for other aquatic vascular plants need to be examined more thoroughly.

8.3.3 Submersed and Emergent Vegetation

Submersed and emergent aquatic vegetation has been used even less in pollutant toxicity and fate bioassays than duckweeds. Most of these organisms are rooted, and culture and standard growth measurements are more difficult than with duckweeds. Issues as basic as suitable indicator species, method of contaminant exposure, duration of tests, and exposure-effect endpoints are yet to be resolved. One attribute that makes these organisms particularly desirable is that they are exposed to contaminants in both the sediment and the water column. While there exists an abundance of water-column bioassays, few organisms sample the sediment interstitial water like the roots of vascular plants. These organisms are naturally adapted to alter the physical and chemical parameters of the rhizosphere in order to make nutrients more bioavailable. Thus, sediment-incorporated contaminants may be more or less bioavailable in an active rhizosphere than in sediments without rooted macrophytes. Recent efforts by USEPA and others to establish sediment quality criteria may increase the use of these plants in sediment bioassays.

Numerous efforts to quantify the relationship between contaminant exposure and rooted aquatic vascular plant response have been reported. Test conditions vary widely, and as yet no attempt has been made to standardize experimental parameters or determine the most appropriate test species.

The majority of the research reported in the 1970s concerning inorganic contaminants centered on uptake, accumulation, and elimination of these elements.¹⁵⁶⁻¹⁶² Many of these studies demonstrated that heavy metals were accumulated by vascular plants to very high levels without serious reductions in the growth of the organisms. Some studies, however, have demonstrated a stress response by some rooted macrophytes to heavy metal burden.

Elodea canadensis has been used to assess copper toxicity.¹⁶³ A static bioassay was developed in which the growth of the organism was optimized with respect to illumination, temperature, and dissolved carbon dioxide. Relative toxicity was judged by reduction of photosynthetic oxygen evolution and visual evaluation of plant damage.

Another member of the Hydrocharitaceae family, *Hydrilla verticillata*, was used to assess copper toxicity under static conditions.¹⁶⁴ Whole plant and root exposures were conducted for 14 days in Hoagland's medium augmented with 200 mg/L Na_2HCO_3 .¹³⁵ Shoot growth, root growth, changes in chlorophyll *a*, and changes in whole plant dehydrogenase were determined. The most sensitive endpoint was root growth.

Both *Najas quadulepensis* (Southern Naiad) and *Myriophyllum spicatum* (Eurasian Watermilfoil) have also been used in static bioassays with heavy metals. In one study visual evidence of cadmium toxicity to *N. quadulepensis* was present at 0.007 mg/L.¹⁶⁵ In another study the toxicity of several heavy metals to *M. spicatum* was determined using reduction in dry weight as the endpoint.¹⁶⁶ Methylmercury was concentrated in the younger tissues of *Elodea densa*, while inorganic mercury was concentrated in the older tissues.^{167,168} Methylmercury was better absorbed and was more toxic than the inorganic form, which was released more readily from plants containing both forms.

Several different macrophytes have been used to assess the toxicity of surfactants, chlorine, and pesticides.^{166,169-173} These efforts have utilized not only different species and methods but also different endpoints.

One endpoint of interest is the peroxidase response reported by Byl and Klaine.¹⁷² They report a quantitative dose-response relationship with several different contaminants in the water column. Byl et al.¹⁷⁴ reported further on the peroxidase response to a range of chemicals including anthracene, the herbicide sulfometuron methyl, Cd^{2+} , Cr^{6+} , Cu^{2+} , Mn^{2+} and Se^{4+} . In many instances a statistically significant increase in peroxidase was observed at toxicant levels two or three orders of magnitude less than that required to decrease growth. They suggest that peroxidase may be a valuable measure of contaminant exposure but not necessarily stress.

Further studies indicated that peroxidase was also a good indicator of the bioavailability of sediment-incorporated metals.^{175,176} A strong relationship between plant metal content and peroxidase was demonstrated. Byl et al.¹⁷⁶ also demonstrated that rooted aquatic plants could oxidize sediment-incorporated cadmium-sulfide complexes. This made the cadmium more bioavailable and resulted in significant incorporation of cadmium into the plant material, even under anoxic sediment conditions.

Sutton¹⁷⁷ examined the peroxidase response of several aquatic and wetland plants to exposure to a variety of metals and pesticides. In general, the response of these organisms to contaminant stress was more variable and less sensitive than agronomic species typically used to evaluate phytotoxicity.

The development of biochemical endpoints of stress and exposure in aquatic vascular plants may result in increased sensitivities of these organisms to contaminant burden. Research is needed to determine when a change in a biochemical endpoint, such as peroxidase activity, represents stress or a decreased fitness of the organism in particular and the population in general.

Biochemical indices of stress have been used in terrestrial vascular plants to monitor air-pollution stress. Richardson et al.¹⁷⁸ demonstrated significant increases in the enzymes superoxide dismutase and peroxidase in loblolly pines (*Pinus taeda*) subjected to five ozone and two acid treatments. Concurrent with these increases was a decrease in net photosynthesis. They suggest that antioxidants may be useful as early-warning biomarkers of oxidative stress in trees.

It is important to note that two standardized rooted aquatic macrophyte bioassays have been developed. The American Society of Testing Methods (ASTM) issued two protocols. The first is a general protocol for the use of freshwater emergent macrophytes,¹⁷⁹ while the second is more specific to the use of an axenic culture of *Myriophyllum sibiricum* Komarov.¹⁸⁰ These procedures, while straight-forward, are much more complex than the duckweed bioassays.

8.4 TERRESTRIAL VASCULAR PLANTS

8.4.1 Introduction

Terrestrial plant bioassays have been used for several decades for determining herbicidal effectiveness in the agricultural and horticultural industries. Studies were used to identify agricultural crop and weed species sensitivity, resistance, and herbicidal mode of action/biochemical pathways.^{181–184} Several different types of bioassays (Table 8.11) exist such as soil or hydroponic, foliar, petri dish, and tissue culture assays;^{185,186} however, standardized phytotoxicity tests have centered mainly around algal and aquatic vascular plants. Fairchild et al.¹⁸⁷ performed comparative phytotoxicity tests with several algal and vascular plant species using atrazine, metribuzin, alachlor, and metolachlor. Two of the commonly tested species, the green alga (*Selenastrum capricornutum*) and duckweed (*Lemna minor*), were shown to have EC_{50} s over three times that of the macrophyte *Ceratophyllum demersum*. Jones and Winchell³³ exposed four macrophytes to atrazine and found a narrow range of EC_{50} s (77–104 $\mu\text{g/L}$); while Forney and Davis¹⁵⁰ exposed five macrophytes to atrazine and found a much greater range of EC_{50} s (80–1104 $\mu\text{g/L}$). Each of these studies measured a different endpoint including plant growth, chlorophyll fluorescence, and frond count. The results of these studies illustrate the large variation among existing toxicity tests. Lewis^{127,188} compared the sensitivities of plants and animals to several environmental contaminants and showed that sensitivity to chemicals is not only chemical-specific but also species-specific. Fletcher⁷¹ compared the alga *Chlorella* with several terrestrial plants using the PHYTOTOX database and came to similar conclusions. This suggests that a wide selection of both fauna and flora species should be examined for their sensitivity when characterizing the effects of a toxicant on nontarget species.

8.4.2 Test Methods

Recently, the Office of Prevention, Pesticides and Toxic Substances (OPPTS) of the U.S. Environmental Protection Agency (EPA) has developed a series of Ecological Effects Test Guidelines.^{189–203} These guidelines combine current standardized bioassays used under the Toxic Substances Control Act (TSCA) and the Federal, Insecticide, Fungicide, and Rodenticide Act (FIFRA). Group D of these guidelines is designed to estimate the effects of toxicants on nontarget plants and includes tests for terrestrial plant species (Table 8.12).

Several different types of bioassays exist including soil or hydroponics, foliar, petri dish, and tissue culture assays.^{185,186} Soil bioassays incorporate the toxicant into the soil, exposing the plant through the roots or as a seed.¹⁸⁶ In foliar bioassays the plant is exposed by application of the toxicant directly onto the leaves.^{204–206} Plants can be grown in either soil or hydroponic systems for foliar assays. Petri-dish bioassays are generally used for seed-germination studies, where seeds of the test species are directly exposed to a substrate (moist filter paper, sand, or glass beads) containing the toxicant.^{207,208} However, plant tissues may also be exposed in petri dishes.¹⁸⁵ Tissue culture assays use *in vitro* cultivation of plant cells or tissues for phytotoxicity, biochemical, and mode-of-action studies.¹⁸⁵

Table 8.12 Ecological Effects Test Guidelines, Group D — Nontarget Plants Test Guidelines, Developed by the Office of Prevention, Pesticides, and Toxic Substances (OPPTS)^{189–203}

OPPTS #	EPA #	Name
850.4000	712-C-96–151	Background — nontarget plant testing
850.4025	712-C-96–152	Target area phytotoxicity
850.4100	712-C-96–153	Terrestrial plant toxicity, Tier I (seedling emergence)
850.4150	712-C-96–163	Terrestrial plant toxicity, Tier I (vegetative vigor)
850.4200	712-C-96–154	Seed germination/root elongation toxicity test
850.4225	712-C-96–363	Seedling emergence, Tier II
850.4230	712-C-96–347	Early seedling growth toxicity test
850.4250	712-C-96–364	Vegetative vigor, Tier II
850.4300	712-C-96–155	Terrestrial plants field study, Tier III
850.4400	712-C-96–156	Aquatic plant toxicity test using <i>Lemna</i> spp., Tiers I & II
850.4450	712-C-96–157	Aquatic plants field study, Tier III
850.4600	712-C-96–158	Rhizobium-legume toxicity
850.4800	712-C-96–159	Plant uptake and translocation test

8.4.3 Plant Species

For phytotoxicity tests with terrestrial plants, agricultural crop species have generally been chosen. The OPPTS guidelines state that ten plant species must be used for each test. Soybean (*Glycine max* L. [Fabaceae]), corn (*Zea mays* L. [Poaceae]), and a root crop such as carrot (*Daucus carotta* L. [Umbelliferae]) or onion (*Allium cepa* L. [Amaryllidaceae]) must be used. The investigator can choose the other seven species. Although native species may be used, crops such as beet (*Beta vulgaris* L. [Chenopodiaceae]), tomato (*Lycopersicon esculentum* Mill. [Solanaceae]), cucumber (*Cucumis sativa* L. [Cucurbitaceae]), cabbage (*Brassica oleracea* L. [Brassicaceae]), lettuce (*Lactuca sativa* L. [Asteraceae]) or relevant weedy species are the most commonly used.^{185,192–197,209,210}

8.4.4 Support Media and Exposure

Various types of support media can be used depending on the growth characteristics or needs of the plant species and the experimental conditions. When mixing the toxicant into a soil substrate, common greenhouse potting soils may skew results of the assay due to a higher binding capacity than with field soils. Generally, a sterilized standard sandy, sandy loam, or clay loam soil with up to 3% organic matter is used. The toxicant is incorporated into the dry substrate by dissolving the toxicant in a solvent and mixing it thoroughly into the soil. The solvent must be allowed to completely evaporate overnight before use in phytotoxicity testing.^{186,192–197,209,211} Soil characteristics, such as pH, composition (sand/silt/clay content) organic content, and binding capacities, may affect the bioavailability of the toxicant and should be determined.¹⁸⁶

When plants are exposed via a foliar or nutrient solution, tests may be designed for hydroponics. The classic paper by Hoagland and Arnon^{143,212} describes a hydroponics system for growing terrestrial plants in nutrient solution. This system can be adapted to various phytotoxicity bioassays.^{213–215}

8.4.5 Measured Responses

Various plant responses (Table 8.13) can be measured in terrestrial phytotoxicity bioassays depending on the design of the experiment. Over all, effects of toxicants on the plants may be analyzed using seedling germination, seedling emergence, plant growth measured by fresh weight, shoot or root length change over the duration of the test, or physical observations such as chlorosis, yellowing of the leaves, cupping of the leaves, etc.^{186,192–197,209} Biochemical endpoints, such as

8.5 SUMMARY

Phytotoxicity assessment remains an important aspect of hazard assessment. In fact, the importance of phytotoxicity evaluations is better recognized today than anytime in the past. Currently, most pesticides are registered and regulated on the basis of toxicity bioassays using aquatic and terrestrial fauna, with relatively little contribution from data on flora. Pesticide regulators must rely on a restricted historical phytotoxicity database and a series of standardized phytotoxicity tests. Risk

assessments are routinely performed using laboratory toxicity tests to characterize ecological effects of contaminants. The endpoints of these tests are generally the mean lethal concentration or dose (LC₅₀ or LD₅₀) for long-term faunal studies (Lytle and Lytle²¹⁰). A limited macrophyte toxicity database results in the extrapolation of toxicity data from algae to macrophytes. For terrestrial plants, the situation is worse. The U.S. Environmental Protection Agency requires terrestrial phytotoxicity data for pesticide registration. This data set, however, is composed entirely of results from agronomic species, which may have little relationship with nontarget native plants. In fact, very little information is available to characterize the uncertainty in the extrapolation of these data to nontarget native plants. This is a huge research need in comparative phytotoxicity. Other research needs include the development and implementation of physiological, biochemical, and molecular endpoints to evaluate phytotoxicity and the characterization of factors controlling contaminant bioavailability in the soil environment.

9.1 INTRODUCTION

In recent years ecologists have increasingly tended toward studying natural processes not only at the individual, community, or ecosystem level, but over the entire landscape.¹⁻⁶ One of the primary reasons for this trend is the increasing recognition that most ecological studies are too small, both spatially and temporally, to detect many important natural processes. Landscape ecology focuses on (a) landscape structure, or the spatial arrangement of ecosystems within landscapes, (b) landscape function, or the interaction among these ecosystems through flow of energy, materials, and organisms, and (c) alterations of this structure and function.^{1,7} The growth of landscape ecology has resulted in increasing recognition that ecosystem processes occur within a hierarchy of different spatial and temporal scales.^{8,9} Ecological systems are constrained both by the range of potential behavior of lower scales and the environmental limits of higher scales.¹⁰ Measurements of ecological structure and function must be assessed at a scale appropriate to the process being observed.¹

Most ecotoxicologists have studied the effects of pollutants on single species, and only recently has a considerable amount of research been undertaken on the impacts of toxicants on entire ecosystems.^{3,11} However, for ecotoxicology to be a science that accurately assesses certain human impacts on natural processes, it must necessarily consider the effects of pollutants over the entire landscape since ecosystem boundaries are often not clearly defined, and movement of pollutants

between ecosystems is commonplace. Since the fate of pollutants is widespread, the impacts of these pollutants must be measured over more encompassing scales.

Cairns and Niederlehner³ define landscape ecotoxicology as examining “chemicals dispersed over a large spatial scale and their potential for adverse effects on biological systems, including humans.” The term *landscape* has been variably used to refer to areas ranging from a few square kilometers to entire continents.³ A landscape is usually composed of heterogeneous ecosystems; however, in certain regions a single type of ecosystem may dominate a sufficiently large area to cause the ecosystem/landscape distinction to be blurred. The examples cited in this chapter cover the range of definitions of *landscape* used in the literature.

9.2 THE NEED FOR A LANDSCAPE VIEW IN ECOTOXICOLOGY

Stated simply, pollutants impact natural systems over broad areas. Chemicals can cause ecological stress throughout large, complex landscapes in a variety of ways. First, many chemical stresses, such as air pollution and acid rain, are either emitted or spread soon after release over immense areas. For example, Hirao and Patterson¹² note that damage from car exhaust in coastal California cities is visible in the Sierra Nevada Mountains located in the eastern part of the state, and Freedman and Hutchinson¹³ found that the majority of sulfur dioxide, nickel, copper, and iron from a heavy-metal smelter was carried beyond the 60-km radius of their study area. In a number of cases, toxicants that appear to have adverse effects on a relatively small area may impact areas far from the release through chemical transformation and transport. Volatilization and atmospheric transport of hexachlorocyclohexanes, a common type of pesticide, have resulted in the contamination of surface water throughout the Pacific Ocean.¹⁴

Second, what appear to be small-scale environmental impacts can become a landscape stress when similar or interactive events occur over a large area.^{15,16} Odum¹⁷ describes this phenomenon of cumulative or interactive events, which are individually minor, becoming collectively significant as “the tyranny of small decisions.” Between 1973 and 1976, for example, 274,000 hectares of new farmland were brought into use in Georgia because of favorable crop prices.¹⁸ Each hectare of farmland caused runoff of an estimated 9.8 metric tons of sediment, 8.4 kg of nitrogen, and 1.5 kg of phosphorus. Although the impact of any given farm on local rivers is probably not significant, the sum over the entire state is staggering. The disastrous state of the Chesapeake Bay affords another example of the cumulative impacts of both urban and agricultural runoff.¹⁹

Third, although a toxicant may only directly affect one ecosystem, it may indirectly affect another, resulting in a landscape-scale effect. There are a number of possible ways in which such a process can occur.²⁰ Organisms that are capable of concentrating heavy metals may move from a contaminated to an uncontaminated ecosystem, thereby introducing the contaminant into the food web. Alternatively, decreased primary production in a stressed ecosystem could cause migration of mobile organisms to healthier systems, resulting in increased competition for resources.

Many chemical stresses impact natural systems over large areas, necessitating the evaluation of response to these stresses within the framework of the natural landscape. Natural landforms affect the spread of disturbance through the landscape.²¹ Slope, gradient, elevation, and aspect influence the movement of pollutants, materials, and energy across sites. Physical and climatic factors at a range of spatial scales affect the impact of pollutants. For example, in an extensive study of acidification of lakes in the eastern United States, certain regional trends were observed due to sources of pollution, climate, and soil type. However, a great deal of intra-region variation occurs due to hydrology, weathering rates, and nearby land uses.²²

In addition to considering broad spatial scales in landscape ecotoxicology, natural processes must also be observed over extended time periods to assess fully the impact of a chemical stress. The PCBs released into the Hudson River were previously believed to present a minimal environmental and health problem because they were trapped in the sediments; however, over time they

have slowly been remobilized and moved to other environmental compartments where they were “unexpected.”²³ Certain systems may show no-observable effects to a chemical stress initially, but if the same stress is repeated over a period of time, the system may lose its resistance.²⁴

Finally, the need for a larger scale view in ecotoxicology is becoming more acute since humans are altering the climate at a global scale, which will affect the large-scale transport of toxicants. Anthropogenic increases in carbon dioxide and other greenhouse gases will likely result in a 1.5 to 5°C increase in global air temperatures near the earth’s surface by 2050. This warming will, in turn, alter weather patterns, result in sea-level rise from the melting of the polar ice caps, affect microbial processes, and alter plant and animal species composition,^{25,26} all of which will affect the mobility of chemicals on a large scale.

Moreover, temperature and moisture stress will affect the susceptibility of organisms to chemical stress. Changes in precipitation associated with global change are likely to affect mobility of chemicals across the landscape. For example, Steding et al.²⁷ found that lead from gasoline emissions and hydraulic mining in the 1980s and earlier in California was mobilized during periods of high rainfall in the 1990s. Changes in weather patterns may affect movement of air pollutants. Reid et al.²⁸ suggest a number of mechanisms by which increased ocean temperatures will influence the effect of chemicals on fish; these include direct effects of temperature on chemical concentrations such as NH₃, changes in rates of fish metabolic processes such as heavy metal sequestration, and increased susceptibility to chemical stress because of simultaneous exposure to temperature stress. It is impossible to predict specific effects of climate change on toxicants, but it is certain that their large-scale transport will be altered, necessitating regional and global monitoring.

9.3 OBSTACLES TO LANDSCAPE ECOTOXICOLOGY

If the fate of pollutants is so widespread, the question arises as to why the effects of these pollutants at the landscape level have only recently been considered and why the vast majority of the toxicological literature remains focused on laboratory testing of single species. The reasons for this lack of information have been discussed previously and are only briefly reviewed here.^{29,30}

First, until recently there has been a paucity of large-scale data. In the field of toxicity testing, the move from the single-species level, an area that is still in need of further research, to the measurement of effects of chemicals on communities and whole ecosystems is still fairly recent.¹¹ At the next organizational level, the landscape, few precedents are available for indicators of toxicity. Fortunately, recent technological developments, such as Geographic Information Systems (GIS) and remote sensing (discussed later), necessary to measure landscape variables, have emerged at a rapid rate. Unfortunately, other obstacles to landscape ecotoxicology are not as easily overcome.

Second, the effects of pollutants can be detected at different organizational scales.^{11,31} It is difficult to distinguish the level or levels at which the chemical stress is acting or how the effects at different levels may be interacting, as effects at one level will be propagated to lower and higher levels.³² For example, the decline in a certain species could be caused by (a) a substance reaching levels toxic to that species, (b) the decline of a prey species affected by the toxicant, (c) the invasion of a predator species from another ecosystem where the prey population has declined due to a toxicant, (d) a combination of the above, or (e) any number of other reasons. As one tries to determine the effect of a chemical stress on increasing levels of biological organization, a concomitant decrease occurs in the precision of data that is possible^{11,15} if the attributes selected are inappropriate for that level of organization.³¹

Third, the majority of ecosystems on the planet are sufficiently disturbed that it is difficult to determine which specific toxicant or interaction of toxicants is causing a given ecosystem response and the source of that toxicant.^{30,33} An analogy is the common cold that could be caused by a number of viruses transmitted from any number of sources. As scales of organization become increasingly complex, the different chemical stresses acting and interacting on a given system

increase rapidly. A study in central Illinois found that increased phosphorus levels in aquatic systems resulted not from nonpoint source agricultural runoff, as commonly assumed, but rather resulted from urban runoff.³⁴ It appears that extensive areas of chlorotic dwarf eastern white pine (*Pinus strobus*) were caused by an interaction between ozone and sulfur dioxide stress.³⁵ One reason for difficulty in identifying the source of a landscape stress is that the spatial and temporal boundaries of a chemical stress are rarely clear.³⁶

A fourth obstacle to landscape ecotoxicology is that it becomes increasingly difficult on larger scales to determine direct reactions to toxicants as opposed to natural environmental stochasticity.^{15,30} In other words, the question of what to use as a reference system, which is always difficult in ecotoxicology, is an enormous challenge when working on large scales. To some extent, this problem cannot be combatted; the increasing availability of long-term data sets over large areas will help to provide a comparison for natural environmental variation. Standardization of data-collection procedures is essential to make such comparisons.

Finally, traditional research techniques are difficult to use on the landscape scale. Microcosm and mesocosm models have limited application in extrapolating to ecosystems^{11,37} and become nearly useless at the landscape level. Large-scale manipulations are possible at the ecosystem level and have been extremely informative,³⁸⁻⁴⁰ but they are minimally used because of cost, ethics, and problems with replication. Comparisons between disturbed and undisturbed systems are always approximations because of lack of control systems; undisturbed reference systems simply do not exist.¹⁵

9.4 LANDSCAPE INDICATORS IN ECOTOXICOLOGY

As stated previously, only recently has it been possible to assess the effects of pollutants at large scales. Therefore, there is only a small, though growing, number of studies of landscape indicators in ecotoxicology. One of the main focuses of the Environmental Monitoring Assessment Program of the U.S. Environmental Protection Agency is to develop landscape indicators, and research in this area is increasing worldwide. Here we discuss the accuracy and utility of various landscape indicators of ecotoxicology within the following framework: (a) the landscape itself with its component ecosystems and their spatial relationships, (b) structural changes such as species spread or decline over entire landscapes, and (c) functional changes such as pollutant flows between systems and recovery from disturbance. We primarily focus on indicators appropriate to the larger scales and measures of the relationships between different ecosystems.

Some stress indicators used at the ecosystem level, such as primary production and species diversity or richness,⁴¹ can be measured over the entire landscape; however, these indicators can become problematic when aggregated over large scales. For example, agricultural runoff could be decreasing production in agricultural lands while increasing production in lakes, thereby masking any landscape-level change. Therefore, such measurements must be compared to baselines appropriate to each ecosystem type. This requires using standardized monitoring procedures to allow comparisons over large spatial and temporal scales in order to be able to separate out natural environmental variation.^{6,42,43} Odjso et al.⁴⁴ used samples of guillemot (*Uria algae*) eggs collected annually at specified locations in the Baltic Sea and stored at the Environmental Specimen Bank at the Swedish Museum of Natural History to ascertain changes in PCB concentrations over three decades. This collection was only possible because of systematic sampling and careful cataloging of specimens.

9.5 TECHNOLOGICAL ADVANCEMENTS FACILITATING LARGE-SCALE ECOTOXICOLOGY

The ability to assess landscape-scale measurements and to scale up more localized structural and functional measurements relies heavily on increasingly sophisticated technologies. As men-

tioned in the previous section, rapid technological improvements present many new opportunities to assess effects of chemicals on large scales. The number of large-scale data sets available has increased exponentially in the past decade due to improvements in remotely sensed databases and the increasing availability of data on the World Wide Web (www). Enhanced computer capacities allow for the storage and analysis of such data. Moreover, GISs are becoming commonly used to link large-scale, spatially referenced data with computer simulation models to predict the effects of toxicants on ecosystems and prioritize management decisions. These technologies are critical to the development of the full suite of possible landscape ecotoxicology indicators.

An enormous amount of data that once would have been stored in paper form in one location is becoming easily accessible via the www or by request on CD-ROM. Increasing efforts are being made to provide clearinghouses for such data and to coordinate data-collection protocols across large areas.^{6,42,45} The U.S. National Science Foundation has made one of its highest priorities to "increase training in the use of large-scale research and monitoring databases, and increase access to those databases."⁴⁶

With the declassification of military satellites, improving sensors, and improved computing capacities, remotely sensed data are being increasingly used to measure environmental stress on large scales. These technologies are the subject of entire books,⁴⁷⁻⁴⁹ and we only briefly review them here. Remote sensors can measure radiation in the visible, near-infrared, thermal-infrared, microwave, or radiowave part of the electromagnetic spectrum. They can be mounted on satellites or aircraft, which greatly affects the area measured and level of precision. For example, the two types of satellite imagery most widely used are Landsat Thematic Mapper (resolution of 30 m) and Advanced Very High Resolution Radiometer (AVHRR; resolution of 1 km), both of which cover most of the earth's surface, with five to seven spectral bands in the visible near-infrared, and thermal-infrared parts of the spectrum.⁶ Hyperspectral imaging, which has become more common in the past few years, is currently usually done from aircraft and may collect up to 200 or more spectra.⁴⁹ Remotely sensed data have numerous applications in landscape ecotoxicology, ranging from measuring weather patterns to soil erosion, spread of oil pollution, and vegetation productivity.⁴⁷⁻⁴⁹ Herut et al.⁵⁰ used airborne hyperspectral imagery to remotely sense chlorophyll-*a* (an indicator of high nutrient levels from sewage) and suspended particulate matter (which was highly correlated with some heavy metals) in Haifa Bay, Israel. The AVHRR data were used to map the ash cloud trajectory from the 1983 eruption of Mt. Etna pollution.⁴⁷

Remotely sensed data have an enormous potential to provide detailed information on stress due to toxicants at temporal and spatial scales not possible for field-based sampling, but they cannot replace field measurements. Ground truthing of measurements is critical. And the type of remote sensing must be carefully applied to the particular question. For example, Allum and Dreisinger⁵¹ used Landsat data to assess vegetation recovery in areas disturbed by nickel and copper mining near Sudbury, Ontario, Canada but did not find spectral signatures that could be used to distinguish nine vegetation types distinguished in the field. They could only distinguish whether an area was totally, partially, or not vegetated and then calculate drastic changes in vegetation over time. Remote sensing can distinguish areas for field surveying, but field surveys are needed to detect subtle changes in chemical concentrations or species composition.⁵¹⁻⁵³

GISs are becoming ubiquitous tools for managing complex, spatially referenced databases. GISs can be used to overlay various environmental stresses on climatic, geographic, or biological variables in order to locate points of high risk⁵⁴ or to provide hypotheses for the cause of ecosystem deterioration. GISs can be used to better quantify the cumulative amount of nonpoint source pollution.^{55,56} Another benefit of GISs is their ability to display spatial arrangements of various ecosystems, thereby allowing for the inclusion of the flow of materials or organisms between systems in large-scale models.⁵⁷ The possible uses in landscape ecotoxicology are endless. In the highly polluted "Black Triangle" area of Poland, Germany, and the Czech Republic, a GIS was used to overlay critical load maps, land-use maps, and population data in order to prioritize strategies for reducing SO₂ emissions.⁵⁸ Zhang et al.⁵⁹ used a GIS model to identify factors that caused

pesticide leaching in an agricultural county in California to identify areas susceptible to leaching that might be removed from production. Clearly, GISs themselves do not solve the problem of identifying landscape indicators of ecotoxicology, but they are an invaluable tool in the process and are necessary for the evaluation of a number of the landscape indicators discussed.

Computer models can be used in combinations with GISs to predict effects of toxicants over large scales. Schindler et al.⁶⁰ and Minn et al.⁶¹ combined chemical and biotic models to predict the effects of regional acidification on the aquatic ecosystems of the eastern United States and eastern Canada, respectively. Feijtel et al.⁶² used a GIS and flow-path models to predict areas of high concentrations of chemicals in various European countries and then used this information to focus sampling and decide where to site treatment plants. The limitations of these models have been discussed extensively. Models should rely on reliable databases that often do not exist,³⁰ parameters are often simplified in order to achieve linear solutions,³⁰ the scale at which ecological processes occur in models is fixed,⁵⁷ and large-scale computer models can seldom be verified.¹⁵ Despite these weaknesses, the use of models is a necessity as it is impossible to take measurements in all ecosystems across an entire landscape or to perform large-scale manipulative experiments to test the effects of all chemical stresses.⁶¹ Although models, no matter how complex, rarely predict surprises,³³ all these tools should be applied carefully and assumptions and data quality evaluated. They are all critical to measuring any of the indicators discussed below.

9.6 THE LANDSCAPE COVER AND HETEROGENEITY INDICES

Changes in the amount and spatial distribution of various ecosystems within the landscape may be indicators of landscape stress or increased landscape susceptibility to stress. In the late 1980s a number of mathematical measures to quantify landscape pattern were proposed.^{1,63} However, translating these measures of landscape pattern into indicators of alteration of ecosystem processes has proven to be difficult.^{54,64} Examples of such indicators include the dominance index, the contagion index, and fractal dimensions.⁶³ The dominance index indicates the extent to which the landscape is dominated by one type of ecosystem. The contagion index measures the probability of the same type of ecosystem neighboring one another, or in other words, the clumping of ecosystems. Fractal dimensions quantify the complexity of the shapes of the different landscape components. These measures of landscape pattern distinguish differences between types of landscape such as forest and agricultural,⁶³ but it is debatable whether these measures can be interpreted to indicate ecosystem stress or susceptibility to disturbance.

Increased chemical stress could lead to increased homogeneity or increased heterogeneity of the landscape. The effects of some large-scale natural and human-caused disturbances, such as the Yellowstone Fires of 1988⁶⁵ and acid precipitation,²² may have a mosaic of effects on the landscape as variations of geology and topography within the landscape influence the response to stress. Other disturbances, such as the eruption of Mount St. Helens⁶⁶ and heavy-metal smelters,⁶⁷ result in large homogenous landscapes. These examples illustrate that, at the present state of knowledge, change in landscape pattern with stress is unpredictable and depends on the ecosystem and stress type. Moreover, in many cases, intentional conversion of land cover types (e.g., clearing forest for agricultural or urbanization) is likely to override changes in land cover due to chemical stress. Therefore, measures of landscape pattern are difficult to interpret as indicators of ecotoxicological disturbances.

However, these measurements, in particular percentage cover of certain land cover types and change in percent cover, may be useful in predicting the susceptibility of ecosystems to chemical stress. Measurements must be defined and selected with specific goals in mind rather than as abstract indices. For example, measures of dominance by land uses that are chemical intensive, such as agriculture, and whether such land uses are adjacent to areas that are particularly sensitive may

help to assist with identifying areas of risk and prioritizing areas to take out of agricultural production. Increase or loss of cover of wetlands and riparian buffers may be an indication of the ability of a watershed to uptake nutrients before they enter aquatic ecosystems.^{68,69} Basnyat et al.⁷⁰ used remotely sensed land-use/land-form data to test the effect of land use (forest, agriculture, urban, orchards) on in-stream nitrate concentrations in Alabama. Their results showed that forest cover in the vicinity of sampling points strongly influenced nitrate concentrations, but the amount of forest in the entire watershed did not have a significant influence, suggesting an appropriate scale for management.

As discussed in the preceding section, improved remotely sensed data will facilitate calculating changes in land use cover over time. But with increasing human impacts, it will undoubtedly be difficult to distinguish between landscape change due to a variety of chemical stresses, landscape change caused by other human impacts, and landscape change resulting from natural disturbance and succession. In summary, landscape spatial structure and change will both be affected by pollutants and affect the spread of pollutants. However, the utility of various measures to quantify spatial structure and change is limited, and landscape indicators should be selected carefully because no general trends of changes in landscape pattern in response to stress are apparent.

9.7 STRUCTURAL INDICATORS AT THE LANDSCAPE LEVEL

Landscape-scale stresses caused by pollutants may not cause a change in landscape type but may affect individual components or functions within the system. Traditionally, ecosystem-level indicators of stress have been separated as structural (i.e., species diversity, presence of sensitive indicator species, proportion of r-strategists) or functional (i.e., community respiration, nutrient turnover rates, nutrient loss).⁴¹ Debate over the relative sensitivity and utility of the two types of indicators has been extensive,⁷¹ and clearly the best approach is to consider both types.

Certain ecosystem-level structural measurements, such as species diversity or length of food chains, have less utility at the landscape level because of differences between various landscape components. Comparing species diversity between a forest and a stream in a watershed is meaningless. It is more useful to look at the distribution of certain species in similar ecosystem types throughout the landscape. The decline or spread of certain species, when summed over large areas, can be indicative of large-scale ecotoxicological stress. Also, disturbance may favor certain life history traits.⁷²

Numerous criteria for selecting indicator species have been offered: (a) their life histories are well known, (b) they are easily surveyed and identified, (c) their populations fluctuate little in the absence of anthropogenic stress, and (d) they are sensitive to anthropogenic changes to the environment.⁷³⁻⁷⁵ However, few species fulfill all these requirements. At the landscape level, it is also useful if an indicator species utilizes more than one ecosystem type within the landscape. For example, the bald eagle has been suggested as an indicator of organochlorines throughout the Great Lakes Region.⁷⁶

Certain taxonomic groups have been suggested as regional indicators of environmental health because of their large-scale distribution and sensitivity to stress. For example, air-pollution-indicator systems for a number of regions have been developed using lichens,^{77,78} as lichens are quite sensitive to air pollution, particularly SO₂, that interferes with photosynthetic pigments. Birds are another taxa that have been used in regional monitoring systems⁷⁹ because of their widespread distribution; their sensitivity to various toxicants directly,^{80,81} through the food chain,⁸² or through habitat alteration;⁸³ and the large database of information that already exists. Karr and Chu⁴³ and Hall et al.⁸⁴ discuss a number of multimetric aquatic indicator systems using either fish or benthic macroinvertebrates to assess the health of large areas of aquatic ecosystems. These indicator systems measure not just the number of species present but also categorize species by habitat type used,

trophic level, and sensitivity to chemical stresses, which allows the integration of structural and functional measures. Determining the change in distribution of indicator species is greatly facilitated by the use of GISs to compile and map databases.

Ecotoxicological stress often results in a decline of sensitive species and a concomitant increase in the distribution of resistant species through the landscape. Walker and Everett⁸⁵ studied the effect of road dust on moss species along a 577-km stretch of highway in Alaska. *Sphagnum* sp. declined from 37 to 0% within 25 m of roads, while minerotrophic species, such as *Auracomnium turgidum*, increased. Stokes et al.⁸⁶ recorded a shift to heavy-metal-tolerant algal species in lakes near smelters in Ontario, Canada. Often, human disturbance favors the spread of nonnative species,^{87,88} a phenomenon that has been proposed as one of the EMAP indicators.⁵⁴ For example, *Agrostis perenaris* and *Arenaria patula*, two introduced grass species rarely seen in Pennsylvania, were common in areas with high soil zinc concentrations derived from nearby smelters.⁶⁷ Exotic trout species appear better adapted than native trout to the highly polluted Great Lakes; because of their shorter life spans, the exotic species do not accumulate toxicants to the levels of their native counterparts.⁸⁹

It is important that the spread or decline of species is studied at the landscape scale as, ultimately, species distribution at the larger scale regulates the presence or absence of populations within a given ecosystem. The loss of habitat for a species due to a single ecosystem being perturbed can become extirpation or even extinction of this species if the stress is repeated or spread over a large area. As more and more components within a landscape are disturbed, sources of recolonizing populations become increasingly rare and the ability of an ecosystem within a landscape to recover decreases.

Although certain structural components of the landscape are sensitive to and may be useful as indicators of large-scale ecotoxicological stress, the choice of suitable indicator species and interpretation of results can be difficult. Ideally, indicator species are those that, in addition to the previously discussed characteristics, are the most sensitive to all toxicants, are widespread throughout the landscape, and are important to ecosystem function. However, fulfilling all these requirements is nearly impossible for a number of reasons that have been discussed at length elsewhere.⁹⁰

First, a “most sensitive species” to all chemical stresses does not exist.⁹¹ Second, species may exist in ecosystem types that are widespread throughout a landscape, but only a few species are present throughout all ecosystems in a given landscape. This presents a particular problem at terrestrial/aquatic interfaces, as there is little overlap in the types of biota. Most of the examples of indicator species and species decline or spread mentioned previously referred to species that were present in one type of ecosystem common in a given landscape, such as mosses on tundra in Alaska or lake algal species.

Finally, determining the specific cause of a structural change in an ecosystem is difficult,⁹² even if one is able to select appropriate indicator species. The decline of a given species could be due to a single chemical stress acting either directly or indirectly on the organism, the interaction of a number of chemical stresses, the spread of a disease, habitat fragmentation, natural stochastic events, or the interaction of any or all of the above. It becomes even more complicated to determine the cause of decline or spread of a species that utilizes more than one type of ecosystem since either habitat could be degraded. Therefore, as with landscape indicators, specific guilds of species to be used as indicators should be chosen with a focused question in mind.

9.8 FUNCTIONAL LANDSCAPE INDICATORS

As mentioned previously, functional, in addition to structural, measurements are often used to evaluate stress at the ecosystem level. Ecosystem functions that are commonly measured include the ratio of production to total biomass, community respiration, and rate of nutrient cycling.⁴¹ These measures become obsolete when aggregated across the landscape because of the immense variation between different ecosystems within the landscape; however, some, such as primary productivity,

may be useful indicators if they can be compared to baseline values for specific systems.⁶ Stress from many chemicals causes decreased productivity, whereas increased nutrients may cause increased productivity and eutrophication in aquatic systems. Primary productivity is relatively easily measured using remotely sensed data.

Few precedents exist of landscape functions to measure. We suggest considering the effect of pollutants on the flow of nutrients between ecosystems within a landscape,⁶ the rate of spread of disturbance through the landscape, and the ability of the landscape to recover from disturbance as possible functional landscape indicators of stress. As discussed previously, most ecosystems can tolerate some structural changes before functional attributes are altered due to ecosystem redundancy. However, as stress levels increase, a point is eventually reached where nutrient regulatory mechanisms are disrupted.^{1,88,92} At the ecosystem level, chemical stress often results in an increased export of nutrients and primary production.⁴¹ On a landscape level, this sums to an increased flow of materials between ecosystems. Jackson and Watson⁹³ found that lead from a heavy-metal smelter disrupted microbial communities in a forest, thereby increasing leaching of nutrients from the soil into nearby aquatic systems. Acid rain generally has been observed as having a similar effect.^{94,95}

Another measure of landscape integrity is the ability to contain the spread of a chemical stress through the landscape. The spatial structure of the different ecosystems within a landscape affects the spread of toxic chemicals through the landscape,²⁹ as ecosystems retain and detoxify chemicals to differing degrees.⁹⁶ Often, different ecosystems within the landscape may serve as sources or sinks for pollutants. For example, forests within agricultural landscapes may serve as sinks for excess nutrients that act as pollutants in aquatic ecosystems,^{68,69} and wetlands often help control the spread of storm water pollution.⁹⁷ If the amount of forests or wetlands, in the previous examples, is decreased or the amount of pollutant increases, the ability of the ecosystem to resist the spread of these pollutants will be altered. A dominance index, discussed previously, could be useful in quantifying changes in the amount of different ecosystem types within a landscape.

In addition to spatial structure, the spread of a chemical stress through a landscape is dependent on the health of the ecosystem components. The emissions from an iron-sintering plant in Canada caused sufficient acidification of the precipitation and runoff to exhaust the buffering capacity of the lime deposits, which resulted in acidification of nearby lakes.⁹⁸ Acidification of peatlands due to acid rain resulted in the release of toxic metals from the peatlands into downstream waters.⁹⁹ A study by Giblin¹⁰⁰ found that increased oxidation in the sediments, caused by excess nutrient inputs, resulted in the leaching from wetlands of lead and iron, two metals normally retained in wetlands. In each of these cases, the spread of a chemical stress would have been prevented if the ecosystem were not unhealthy and unable to perform this function because of previous disturbances.

In addition to disrupting the ability of ecosystems within the landscape to resist the spread of disturbances, chemical stress may inhibit the ability of a landscape to recover from disturbance. For example, a study on forests near a zinc smelter showed that the forest was less able to recover from the natural disturbance of fire than similar forests not subjected to intensive air and soil pollution.⁶⁷

As with the other indicators previously discussed, examples of chemical stress disrupting functional attributes within a landscape are numerous, but methods of quantifying such disturbances are limited, though improving with the increased availability of data. Measurement of nutrient and pollutant flows throughout a landscape are difficult to measure,¹⁰¹ and it is nearly impossible to quantify ecosystem resistance or resilience until these attributes are completely exhausted. Once again, no clear way exists to determine the cause of a functional alteration.

9.9 CONCLUSIONS

We have discussed a number of different types of landscape indicators in ecotoxicology, while recognizing that this area of research is rapidly developing. Although chemical stress causes changes in spatial, structural, and functional components of landscapes, quantifying and interpreting these

changes is a formidable challenge. With increasing research devoted to investigating landscape-scale processes and rapidly improving technology to analyze large spatial databases, understanding of the structure, function, and natural changes of landscapes is increasing at an accelerating pace. This knowledge should facilitate more accurate selection and measurement of landscape-level indicators of stress. These technologies alone will not answer all the many questions, but they help to organize existing information and prioritize areas for future research. It is important to balance a need for developing standardized measurement procedures to allow for comparison across large scales with the need to fine-tune measurements to specific, localized questions.

As has been stated throughout, numerous obstacles to developing accurate indicators of ecotoxicological stress must be acknowledged. As increasingly large scales of biological organization are considered, processes occurring at different levels and between different components of the same level must be recognized. Just as the ecosystem is more than the sum of its parts,¹¹ the landscape is more than the sum of its ecosystems. The interaction of all these processes is mind-boggling and challenging to interpret.

Disturbance of the planet has progressed to the extent that separating the effects of the various landscape stresses, such as chemical pollutants, habitat fragmentation, introduction of exotics, and influence of processes occurring at larger scales, is difficult. Just as some landscape processes limit, and are limited by, intraecosystem processes and vice versa, global disturbances, such as global warming, ozone depletion, and land-use change, affect landscape processes. Furthermore, no control systems exist with which to compare these stresses. Despite formidable obstacles, efforts must be made toward better understanding landscape-scale processes. We must work on larger scales, not only because of the large scale of our alterations, but also because policies to regulate chemical emission and treatment are often made at regional or national scales.

10.1 INTRODUCTION

Natural resource management decisions are being made that cost the nation millions of dollars every year. These decisions should be supported by scientifically sound data. This chapter discusses why monitoring programs are needed and how to design a program that is based on a good scientific approach with specific objectives. The purpose of this chapter is to identify many of the large-scale monitoring programs in the United States, how to access the information from these programs, and how this information can be used to improve long-term management of natural resources. Biomonitoring data form the basis upon which most long-term stewardship decisions are made. Monitoring data that supports stewardship decisions provide the critical link between field personnel and decision makers.

10.2 IMPORTANCE OF MONITORING IN RESOURCES MANAGEMENT

Monitoring and stewardship share an interesting connection. Both take an active role in the understanding of the condition of a resource to improve long-term sustainability. Over the past decade much change has occurred in the field of monitoring and management of data sources. Some of the change is due to advances in technology that allow easy access to large datasets and

enhanced capabilities to evaluate, analyze, and visualize data. Developments in remote sensing, geographic information systems (GISs), the Internet, and personal computers and personal data recorders have provided scientists, managers, and the general public the ability to access and evaluate data. In the past paper maps and overlays were used to identify alternatives for resource management. Today, maps and charts can be generated on the spot and served over network connections, allowing the audience to evaluate options immediately.

Stewardship is a term that has become much more common in natural resource management. A three-volume set titled *Ecological Stewardship*¹ is a good reference for scientists and managers involved in or responsible for ensuring natural resources are maintained so that future generations have options for their management. These three volumes summarize hundreds of years of experience of scientists and managers representing the major land-management agencies in the United States. To be good stewards it is critical that we understand where we have come from, where we are, and what is the desired future condition.

The Federal Government alone spends over \$650 million per year on environmental monitoring² to support regulatory compliance, evaluate the presence of contaminants, and improve our understanding of environmental systems. As stewards of the environment, scientists, engineers, and managers have critical responsibilities to ensure that monitoring programs are established with logical objectives, are designed to collect monitoring data following a well-established process, and take advantage of existing data. A recent article in *Scientific American*³ responding to the book, *The Skeptical Environmentalist*,⁴ clearly points out that there are multiple views to the environmental issues facing the nation and the world. The responsibility of natural resource stewards is to have as complete an understanding of the resource they are managing, the monitoring process, and a thorough understanding of how to acquire and use data to make decisions. As an analogy, it would be bad money management to invest without doing a thorough evaluation of what data exists on the status and trends of various investment programs.

To be good stewards of our investments, it is important to monitor performance data on a regular basis and adjust our management strategy periodically to ensure our goals are being met. In a similar manner many of us are tasked to design biomonitoring programs for systems we have limited knowledge about. A further complication is that many who are responsible for management of natural resources change work locations frequently. Those who are working on existing monitoring programs or who are designing new ones can often gain great insight by consulting the literature and reviewing existing information on local and regional biomonitoring programs. This review process is an important step to help ensure the program is best designed to meet management objectives. The sources identified in this chapter provide insight to those faced with determining how to use biomonitoring data to support long-term stewardship of natural resources.

Resource management requires accurate information that can be used in the decision-making process. We must take advantage of existing data where available and access monitoring networks to identify what information can help us better interpret how humanity's activities are affecting the biological systems we are tasked to manage.

The National Research Council (NRC)⁵ recently published a book on the grand challenges facing the nation in the environmental sciences. The NRC, at the request of the National Science Foundation, identified eight grand challenges: (1) biogeochemical cycles, (2) biological diversity and ecosystem function, (3) climate variability, (4) hydrologic forecasting, (5) infectious disease and the environment, (6) institutional and resource use, (7) land use dynamics, and (8) reinventing the use of materials. In their recommendations section the authors state that for most of these challenges, there needs to be a comprehensive understanding of relationships that govern processes (e.g., the relationship between ecosystem structure and function and biological diversity) and forecasting information to improve our comprehension of consequences.

To address the challenges put forth by the NRC, we must delve into the literature and identify what information exists from previous monitoring programs and how this can be used to improve

our understanding. Many of us facing challenges in the biological sciences feel that we are pioneers in addressing stewardship of the resources we are tasked to manage. However, in reality humans have been stewards of natural resources for many years. One challenge we face is to state a meaningful question. Once the question is identified, we can set out to determine how and if existing information can be used to help establish baselines and identify critical data gaps and how these gaps can be filled with new data.

Monitoring data, both existing and new, can play an important role in the design and evaluation of ecotoxicological studies. Anthropogenic impacts provide numerous stresses to environmental systems. The advent of low-level chemical analysis and techniques to evaluate genetic effects from environmental stress provide scientists new tools to better understand how biological systems can be impacted from chemical stresses. However, it is important that scientists use existing information from the sources identified in this chapter as well as others to identify the degree and type of management action required and understand how this information should be used in context.

Volumes of data are available through environmental monitoring program offices of the various agencies identified in this chapter. Even though much of these data may be obtained over the Web or with a phone call, these resources are underutilized. When designing new biomonitoring programs or ecotoxicology studies, it is important to avoid the trap of developing hypotheses and setting out to prove them without consulting existing data and benefiting from past experience. The hesitancy to use existing data can be traced to a lack of familiarity with the types of monitoring data available and to uncertainty about data quality, compatibility, and the means by which different program designs may be integrated. To make biomonitoring cost-effective and justify its benefits, scientists need to develop clear goals and objectives that build upon existing datasets and learn from previous studies. It is often more cost effective to invest in early detection than pay later for remediation.

Evaluating existing data and information from monitoring programs and previous ecotoxicology studies has benefits analogous to conducting a market survey before releasing a new product to the public. Reviewing and evaluating existing data sources can be tedious; however, the effort allows the study or program to

- Enhance understanding of the mechanisms behind observed trends
- Fill critical data gaps
- Define ecosystem interactions
- Develop a conceptual model of how the ecosystem operates
- Identify the best time to monitor for parameters of interest and variability
- Identify quality assurance/quality control issues
- Avoid problems encountered by previous biomonitoring efforts

Data in this chapter are defined as the raw values collected in the field or laboratory analysis, while *information* is the interpreted data that provides conclusions for making decisions. The chapter focuses on long-term, large-scale monitoring programs in the United States that can help assess the condition of the nation's natural resources. The term *existing data* is used here to refer to data in the literature or in electronic form on both large-scale and site-specific efforts. A distinction between the two will be made in cases where limitations in the use of the data exist. Other data sources that focus on human health or international monitoring efforts are not addressed in this chapter. Some reference is made to existing ecotoxicology data; however, many other sources like those listed in other chapters of this book are also available.

Monitoring data are available on site-specific, local, regional, and national scales. Data from one scale may be used to support a study on another scale. For example, a scientist interested in studying the site-specific impact of mercury from incineration may use data from a regional biomonitoring program to help identify important ecological endpoints to monitor (e.g., fish, wetland aquatic plants). Evaluating water and air pathways on a large scale can provide significant information on how distant contaminant sources can impact a study or management area.

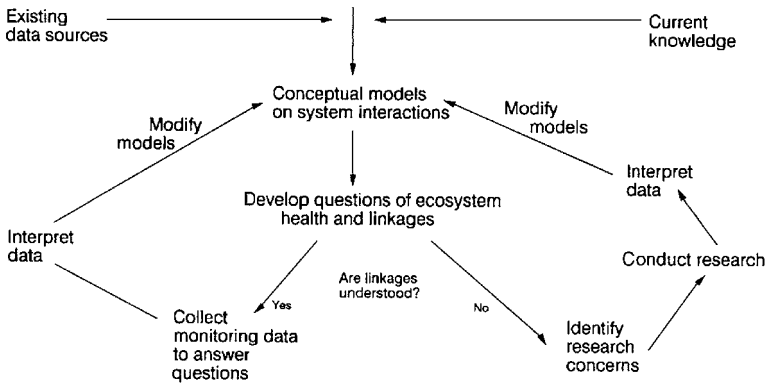

Figure 10.1 Relationship between existing data and its use developing monitoring questions and research options.

Research at the local scale can also help in the interpretation of results from a large-scale monitoring program. Local- or small-scale ecosystem studies may help address issues associated with sampling design, interactions within and between ecosystem processes (e.g., biogeochemical cycling, productivity, and population dynamics), and partitioning of chemicals in the ecosystem. Knowledge of how local- or small-scale studies can support or improve data interpretation for large-scale programs can be important to resource stewardship. Figure 10.1 presents this relationship and shows the importance of research to any monitoring program. Often questions that require new research to address are raised by a monitoring program.

10.3 REVIEW OF BIOMONITORING PROGRAMS

In 1990 scientists from the Idaho National Engineering and Environmental Laboratory and the U.S. Fish and Wildlife Service identified long-term, large-scale monitoring programs that could be useful for assessing the status of contaminants in U.S. fish and wildlife resources and their habitats.⁶ This material was published in the original edition of this handbook.⁷ Since then many of the data sources have been modified due to changes among agencies, access via the Internet, and addition of new datasets. The material in this chapter builds upon the original findings but focuses on web-accessible databases that provide contaminant information related to biota, sediment, and water. Other databases describing ecological and biological survey and monitoring results were also evaluated. A search was conducted for the existence of national (or large regional) monitoring programs and databases. These searches included the use of the Internet, literature, and phone contact with federal resource agencies, nongovernmental organizations, industrial organizations, and others.

The programs/databases identified were evaluated as to their status (e.g., ongoing, eliminated, modified), their content (e.g., type of data, frequency of collection, locations), and their accessibility. Long-term programs were of particular interest because of their spatial and temporal datasets for evaluating variability issues and their ability to somewhat transcend short-term political changes that occur with changes in administrations. Long-term was defined as 5 years or more; large-scale focused on regional or national scales, but some large site-specific programs were included. The effort identified a number of Federal agencies that are involved in 23 programs (Table 10.1) that provide potentially useful data for ecotoxicological assessments and in the stewardship of natural resources.

A review of existing data sources (Table 10.1) indicated that a number of different media were being monitored, but collectively they provide only a limited picture of toxic threats to ecological

Table 10.1 National and Regional Contaminant Monitoring and Assessment Programs

	Agency	Program Description	Extent	Contaminant Focus	Data/Databases
U.S. Environmental Protection Agency (www.epa.gov)

Agency	Program Description	Extent	Contaminant Focus	Data/Databases
17 The Interagency Monitoring of Protected Visual Environments (IMPROVE) Contact: Marc Pitchford Desert Research Institute 755 East Flamingo Road, Las Vegas, NV 89119	IMPROVE is designed to establish trends in visibility levels and identify sources of anthropogenic impairments to national parks and wilderness areas (Class I Areas). Agencies involved in this program include the National Park Service (lead agency), EPA, Fish and Wildlife Service, Bureau of Land Management, and the U.S. Forest Service. There are also several nongovernmental organizations that make up the program.	Nationwide in National Parks and wilderness areas	Measures aerosols, particulate matter, and optical data	Data are available at: http://vista.cira.colostate.edu/improve/Data/data.htm and at: http://improve.cnl.ucdavis.edu/
Interagency Programs				
18 Park Research and Intensive Monitoring Network (PRIMENet) Program Contact: NPS PrimeNet Coordinator: Kathy Tonnessen, NPS Air Resources Division (303) 969-2738 email: Kathy_Tonnessen@nps.gov	PRIMENet is an EPA-NPS program designed to assess the effects of environmental stressors on ecological systems nationwide. This network, formerly known as DISPro, consist of 14 monitoring and research sites in national parks which are representative of major ecosystem types and were chosen because of their status as Class 1 air quality parks. At these sites the NPS is sponsoring air quality monitoring, including ozone, wet and dry deposition, visibility, and meteorology. The EPA has added UV-B monitors at these parks to determine changes in irradiance that may be affecting human health and ecosystem processes.	National Parks located throughout the nation	Measures ozone, wet and dry deposition, visibility, UV-B, and meteorology	http://www2.nature.nps.gov/ard/gas/netdata1.htm
19 The National Atmospheric Deposition Program (NADP) Contact: Van C. Bowersox, Coordinator NADP Program Office Illinois State Water Survey 2204 Griffith Drive Champaign, IL 61820-7495 email: nadp@sws.uiuc.edu	The NADP monitors wet atmospheric deposition at over 220 National Trends Network sites throughout the United States. The network is a cooperative effort between many different groups including the State Agricultural Experiment Stations, U.S. Geological Survey, U.S. Department of Agriculture, and numerous other governmental and private entities. The NADP also administers two national networks. These are the Mercury Deposition Network (MDN), which measures weekly concentrations of total mercury in precipitation and the seasonal and annual flux of total mercury in wet deposition, and the Atmospheric Integrated Research Monitoring Network (AIRMoN), which monitors wet and dry deposition. This network is sponsored from the National Oceanic and Atmospheric Administration.	Nationwide network of sites	Precipitation chemistry with a focus on atmospheric deposition constituents (SO ₄ , NO ₃ -N, NH ₄ -N, Ca, Mg, Na, K, pH, specific conductance, and PO ₄) and mercury.	NADP Data at: http://nadp.sws.uiuc.edu/nadp/data/ AIRMon Data at: http://nadp.sws.uiuc.edu/airmon/GetAMdata.asp MDN Data at: http://nadp.sws.uiuc.edu/nadp/data/mdnsites.asp

20	The Clean Air Status and Trends Network (CASTNET) Contact: Gary Lear (202)564-9159 email: lear.gary@epa.gov	CASTNET provides atmospheric data on the dry deposition component of total acid deposition, ground-level ozone, and other forms of atmospheric pollution. CASTNET is considered the nation's primary source for atmospheric data for estimating dry acidic deposition and to provide data on rural ozone levels. CASTNET, established in 1987, is comprised of over 70 monitoring stations across the United States and is cooperatively funded and operated between the EPA and the National Park Service.	Nationwide	Acid deposition, ozone	CASTNET data are available at: http://www.epa.gov/castnet/data.html
21	State and Local Air Monitoring Stations/National Air Monitoring Stations (SLAMS/NAMS) (http://www.epa.gov/oar/oaqps/qa/monprog.html) Contact: David Lutz (919)541-5476 Fax: (919) 541-1903 email: lutz.david@epa.gov	NAMS and SLAMS are designed to measure air criteria pollutants, visibility, fine particulates, toxic chemicals, and ozone in urban areas throughout the United States. The network now includes over 4000 sampling stations. This network is part of the EPA National Air Ambient Monitoring Program and includes other federal and state agencies.	Nationwide	Air criteria pollutants, toxic chemicals, ozone, visibility	Data is accessible through the AIRData System http://www.epa.gov/air/data/
22	Photochemical Assessment Monitoring Stations (PAMS) (http://www.epa.gov/oar/oaqps/pams/) Contact: Rich Scheffe (Program Mgt.) email: scheffe.rich@epa.gov	PAMS includes measures of ozone and ozone precursors in areas known to have persistently high ozone levels (nonattainment areas). This network is part of the EPA National Air Ambient Monitoring Program and includes other federal and state agencies.	Nationwide	Ozone measurements (approximately 60 volatile hydrocarbon and carbonyl compounds) and nitrogen in non-attainment areas	Data from PAMS are currently in an interim database available through AIRData with plans for access to be through the AIRS system http://www.epa.gov/air/data/
23	The USDA UVB Radiation Monitoring Program Dr. James R. Slusser (Program Director) USDA UVB Radiation Monitoring Program Natural Resource Ecology Laboratory Colorado State University Fort Collins, CO 80523 Fax: (970) 491-3601 sluss@uvb.nrel.colostate.edu	The UVB Radiation monitoring Program is a program of the U.S. Department of Agriculture's Cooperative State Research, Education and Extension Service (CSREES). The program was initiated in 1992 (through a grant to Colorado State University) to provide information on the geographical distribution and temporal trends of UVB (ultraviolet -B) radiation in the U.S. Information from these efforts are used to evaluate the potential damage effects of UVB to agricultural crops and forests.	Nationwide	UVB radiation	Data is available at: http://uvb.nrel.colostate.edu/UVB/uvb_program_overview.html
State and/or Regional Monitoring Programs					
24	The Southern Oxidants Study Contact: Office of the Director 1509 Varsity Drive Raleigh, NC 27606 919-515-4260 or Fax 919-515-1700 sos@ncsu.edu	The SOS is an alliance of research scientists, engineers, and air quality managers from universities, federal and state governments, industry, and public interest groups working together to design and execute scientific research and modeling programs to increase the present understanding of ozone accumulation in the atmosphere.	Southern United States	Continuous monitoring of regional ozone concentrations, ozone precursor concentrations and other oxidants, and particulate matter	Data access for SOS is at http://vortex.atmos.uah.edu/essl/sos

	Agency	Program Description	Extent	Contaminant Focus	Data/Databases
25	Great Lakes National Program Contact: Great Lakes National Program 77 West Jackson Boulevard Chicago, Illinois 60604 phone: (312) 886-4040 fax: (312) 353-2018	The Great Lakes National Program is a collaboration of the EPA and Great Lakes states and private groups involved with monitoring and assessment activities related to the health of the Great Lakes.	Great Lakes ecosystem	Collects environmental data on a wide variety of constituents in water, biota, sediment, and air.	(http://www.epa.gov/glnpo/glenda/aboutglenda.html)
26	National Irrigation Water Quality Program (NIWQP) Contact: N. John Harb Manager, National Irrigation Water Quality Program Bureau of Reclamation P.O. Box 25007 (D-6200) Denver CO 80225-0007 Office: (303) 445-2789 Fax: (303) 445-6693 email: nharb@do.usbr.gov	The NIWQP is an inter-bureau program managed by the Department of the Interior. Participating bureaus within the Department include Bureau of Indian Affairs, Bureau of Reclamation, U.S. Fish and Wildlife Service, and U.S. Geological Survey. The scope of the program is to identify and address irrigation-induced water quality and contamination problems related to DOI water projects in the west. Reconnaissance investigations have been completed for 26 study areas.	Irrigation waters throughout the western United States	Measures contaminants in water, sediments, vegetation, invertebrates, fish and birds with an emphasis on arsenic, boron, copper, DDT, mercury, molybdenum, salinity, selenium, and zinc	Chemical data from water, bottom-material, inorganic and organic biological samples are available for 26 study areas
27	The Long-Term Resource Monitoring Program (LTRMP) (http://www.umesc.usgs.gov/ltrmp.html) Contact: Upper Midwest Environmental Sciences Center 2630 Fanta Reed Road La Crosse, WI 54602-0818 Phone: (608) 783-6451	The LTRMP is being implemented by the U.S. Geological Survey (USGS) in cooperation with the five Upper Mississippi River System states (Illinois, Iowa, Minnesota, Missouri, and Wisconsin), with guidance and overall program responsibility provided by the U.S. Army Corps of Engineers. The LTRMP monitors nutrients in water and sediments and environmental trends of invertebrates, birds, and fish.	Upper Mississippi River Basin	Water quality and nutrients in the Upper Mississippi River System	http://www.umesc.usgs.gov/data_library/sediment_nutrients/sediment_nutrient_page.html http://www.umesc.usgs.gov/data_library/sediment_contaminants/sediment_contaminant_page.html
28	The Chesapeake Bay Program Contact: Chesapeake Bay Program Office: 410 Severn Avenue, Suite 109, Annapolis, MD 21403/Tel: (800) YOUR-BAY/Fax: (410) 267-5777	Chesapeake Bay Program resulted from the Chesapeake Bay Agreement of 1983 which was designed to restore the Bay. Partners of this Program include the states of Maryland, Pennsylvania and Virginia; the District of Columbia; the Chesapeake Bay Commission (a tri-state legislative body); the US Environmental Protection Agency (EPA), which represents the federal government; and participating citizen advisory groups.	Chesapeake Bay	Monitoring efforts include measures of nutrients, metals, PAHs, PCBs, pesticides, etc. in water, sediment, and fish tissue	Databases from the CBP and other sources are available at: http://www.chesapeakebay.net/data/index.htm
29	The Chesapeake Bay River Monitoring (RIM) Program Contact: Doug Moyer (dlmoyer@usgs.gov) Mick Senus (mpsenus@usgs.gov)	The RIM Program was established to quantify loads and long-term trends in concentrations of nutrients and suspended material entering the tidal part of the Chesapeake Bay Basin from its nine major tributaries.	Chesapeake Bay and major tributaries	Nutrient concentrations and loads (nitrogen, phosphorus, ammonia), and suspended sediments	Concentrations, loads, and streamflow are available at: http://va.water.usgs.gov/chesbay/RIMP/dataretrieval.html

<p>30 Alaska Marine Mammal Tissue Archival Project (AMMTAP) Lyman K. Thorsteinson (Program Manager) USGS-BRD, Western Regional Biologist 909 First Avenue, Suite 800 Seattle, WA 98104 Telephone: (206) 220-4614 email: lyman_thorsteinson@usgs.gov</p>	<p>AMMTAP collects tissue samples from marine mammals for future retrospective analysis. The project is a joint effort by the U.S. Geological Survey Biological Resources Division (USGS\BRD), the National Oceanic and Atmospheric Administration's National Marine Fisheries Service (NOAA Fisheries), and the National Institute of Standards and Technology (NIST).</p>	<p>Alaska, arctic mammals</p>	<p>Collects baseline levels of chlorinated hydrocarbons and trace elements, including heavy metals, in arctic marine mammal species</p>	<p>Data is available through reports and requests (http://www.absc.usgs.gov/research/ammtap/index.htm)</p>
<p>31 The Seabird Tissue Archival and Monitoring Project (STAMP) Contact: Geoff York USGS, Alaska Science Center 1011. East Tudor Road Anchorage, AK 99503-6199 Telephone: (907) 786-3928 email: geoff_york@usgs.gov</p>	<p>The STAMP program mirrors the AMMTAP Program in purpose and procedure except the focus is on contaminants in eggs of arctic bird species. This project is a joint effort between USGS, NIST, and U.S. FWS.</p>	<p>Arctic United States</p>	<p>Collects levels of chlorinated hydrocarbons and trace elements, including heavy metals, in eggs of arctic bird species</p>	<p>Data are available through reports and requests (http://www.absc.usgs.gov/research/ammtap/index.htm)</p>
<p>32 The Mid-Atlantic Integrated Assessment (MAIA) Contact: Tom DeMoss, EPA/Region 3 Email: demoss.tom@epamail.epa.gov</p>	<p>MAIA is an <i>interagency</i>, multidisciplinary program research, monitoring, and assessment initiative. Its main goal is to develop high-quality scientific information on the condition of the natural resources of the Mid-Atlantic region of the eastern United States. Partners include numerous Federal agencies (headed by the US EPA), states, and public and private organizations.</p>	<p>Mid-Atlantic region of United States</p>	<p>Measurement of numerous contaminants in streams, sediments, groundwater, estuaries, and biota</p>	<p>Data are available at: http://www.epa.gov/emap/maia/html/data.html</p>
<p>33 The Gulf of Mexico Program Contact: James Giattina (Program Director) Email: giattina.jim@epa.gov Bldg. 1103, Room 202, Stennis Space Center, MS 39529-6000 Main Telephone: (228) 688-3726 Fax: (228) 688-2709/2306</p>	<p>The Gulf of Mexico Program was formed in 1988 to develop and implement voluntary, incentive-based management strategies to protect, restore, and maintain the health and productivity of the Gulf of Mexico ecosystem. Partners of the Gulf of Mexico Program include numerous Federal agencies (headed by the U.S. EPA), states, and public and private organizations.</p>	<p>Gulf of Mexico</p>	<p>Numerous contaminants and environmental health measurements in water and biota</p>	<p>Data is available at: http://pelican.gmpo.gov/datapage.html http://pelican.gmpo.gov/hgreport.pdf</p>

Agency	Program Description	Extent	Contaminant Focus	Data/Databases
34 The Gulf of Maine Contacts: Laura A. Marron Gulf of Maine Council Coordinator New Hampshire Department of Environmental Services P.O. Box 95 Concord, NH 03302-0095 Phone: 603-271-8866 Fax: 603-271-0656 email: info@gulfofmaine.org	The Gulf of Maine (GOM) is a collaborative effort by federal agencies of the United States and Canada, states, and public and private organizations. The goals of GOM are to: protect and restore coastal habitats, restore shellfish habitats, and protect human health and ecosystem integrity from toxic contaminants in marine habitats. Nested under these efforts is the Gulf Watch Program which uses mussels as a sentinel species for habitat exposure to organic and inorganic contaminants.	Gulf of Maine	Contaminant measures include mercury deposition, and organic and inorganic contaminants. Mussel tissue are analyzed for trace metals (Ag, Al, Cd, Cr, Cu, Fe, Hg, Ni, Pb, Zn), PAHs, PCB congeners, and chlorinated pesticides	Mussel data are available at: http://www.gulfofmaine.org/library/gulfwatch/#data http://ccmaserver.nos.noaa.gov/NSandT/NewNSandT.html
35 Arctic Monitoring and Assessment Program (http://www.amap.no) Contact: Arctic Monitoring and Assessment Programme Secretariat (AMAP) P.O. Box 8100 Dep N-0032 Oslo, Norway email: amap@amap.no	Efforts of AMAP include monitoring levels of, and assess the effects of, anthropogenic pollutants in the Arctic environment. This program is an effort by eight Arctic Rim countries (Canada, Denmark/Greenland, Iceland, Norway, Sweden, Soviet Union, and United States).	Arctic regions	Numerous contaminants (including persistent organic pollutants and heavy metals) in the arctic ecosystem and biota	http://www.amap.no/data-gis/data-gis.htm

resources in the United States. Numerous programs monitor the media that support fish and wildlife resources (e.g., water, soil, sediment, air), but data are limited to interactions of contaminants across media.

Existing data can help researchers seeking insight on the partitioning of contaminants in an ecosystem. Water-quality and sediment-monitoring data from a river can help identify areas where contaminants concentrate (usually fine sediments) or those areas that have elevated values because of human-induced contaminants or enriched natural-metal deposits. Information that can point to unique features of an area provides a new context for the study and can be used to evaluate the need for additional research.

Often large-scale programs select their monitoring stations randomly to avoid being biased by local contaminant sources. Theoretically, this should allow examination of trends in contaminants in different media to make associations. These types of associations are possible at the qualitative level, but quantitative statements are difficult because of inconsistencies in sample timing, collection, analytical methods, and level of quality control.

Presently, due to financial constraints many studies have to focus on only a part of an ecosystem (e.g., the aquatic or avian portion). There are often interactions between the aquatic and terrestrial portions that need to be considered. A study that considers the interaction between the terrestrial and aquatic systems at the species, population, community, or ecosystem level can benefit greatly from data collected in complementary studies and determine if they can be combined in a manner that conceptually describes associations between systems.

Scientists addressing contaminant impact issues need to consider several factors when evaluating the use of existing data: (a) Is the chemical of interest new or existing? (b) Is the projected impact local or regional? (c) Will the data be used to make a specific management decision (e.g., license a chemical) or as part of an ecological risk assessment? and (d) Is the potential impact associated with a common or limited natural resource?

Biomonitoring programs often provide data on selected chemicals. Table 10.1 lists the chemicals that most of the large-scale programs have focused on. If a monitoring program is to be manageable, it must focus on a select subset of chemicals or responses of a biological system and track these over time. Existing programs have limitations because they cannot track all chemicals but must select those that are representative of classes of chemicals.

Most biomonitoring programs do not collect data to determine toxicity values for a chemical, but this information is available from other sources. There are several good references available in supporting chapters of this book to provide data on toxicity values of existing chemicals.

Existing biomonitoring data can be used to provide long-term averages for evaluating site-specific data. For example, if there was concern about mercury causing toxicity problems in a specific area, water and fish samples could be collected and evaluated against regional values from large-scale programs, such as the USGS National Water Quality Assessment (NAWQA) (Table 10.1, item 9) program or National Contaminant Biomonitoring Program fish data collected from 1967 to 1987 (Table 10.1, item 15). Since mercury is often transported via the air pathway, scientists should consult the Mercury Deposition Network nested under the National Atmospheric Deposition Program (Table 10.1, item 20) to see if monitoring sites are close to their area. These data can also be compared with published toxicology data to assess threat to a resource or the need for corrective action.⁸ If, however, the chemical of concern is new, existing data may not be available.

The sciences of ecological risk assessment and ecotoxicology are developing quickly, but we are only starting to understand dose-response relationships at the species level. Toxicology needs to have a direct relationship with ecology if ecotoxicology is to emerge and face the challenge of assessing risk at community and population levels across complex natural ecosystems. The programs identified in Table 10.1 can help provide data needed to support risk assessment and toxicology studies. In conducting ecotoxicology studies conceptual models should be developed to link sources of contaminants to receptors. Van Horn⁹ provides a brief overview of risk assessment and toxicology

and explains in detail how contaminant sources, exposure pathways, and receptors are linked using conceptual models.

Some data are available to help scientists make habitat assessments of marine, upland, inland, and coastal areas. Better information is available for coastal areas than upland and inland areas, possibly because these coastal areas are higher in population and the resources are targeted for use, exploitation, and protection by the public and many different agencies and organizations. These coastal areas also serve as some of the major migratory routes for fish, waterfowl, and nongame birds.¹⁰ NOAA strives to make multimedia assessments in coastal areas, and interagency programs are being established to study larger U.S. estuaries. The U.S. Environmental Protection Agency's (EPA's) Environmental Monitoring and Assessment Program (EMAP) is a research program designed to develop the tools necessary to monitor and assess the status and trends of national ecological resources (see EMAP Research Strategy). EMAP's goal is to develop the scientific understanding for translating environmental monitoring data from multiple spatial and temporal scales into assessments of ecological condition and forecasts of the future risks to the sustainability of our natural resources. Data collected by EMAP are available at <http://www.epa.gov/emap/html/data/index.html>.

10.4 USE OF EXISTING DATABASES

Data from existing monitoring programs can be very useful in designing ecotoxicology studies and monitoring projects. However, existing data are only tools with both applications and limitations. The most difficult problem is determining how, when, and where to use them in designing a new project. This discussion focuses on some general issues regarding the use of existing data and how those data can be helpful in conducting natural resource damage assessments, ecological risk assessments, and designing environmental monitoring projects.

Datasets from various federal agencies have limitations and cannot be combined to produce meaningful assessments unless the data are comparable, applicable, and transferable. There are three types of constraints that scientists must check when attempting to integrate existing datasets into new-program design: data, program, and institutional. Data constraints are usually related to whether the data can be obtained in a cost-effective manner, the format in which they are available, whether they are compatible and at the appropriate scale, their geographic and temporal coverage, and the types of analytes. Program constraints include compatibility of objectives, differences in sampling periods, intensity, statistical design, resource of interest, and level of quality assurance and quality control. Institutional constraints are mainly an issue when crossing over between agencies and include different agency missions, requirements for upward reporting, and interagency reporting.

The development of geographic information systems (GISs) and global positioning systems (GPSs) and efforts by the Federal Geographic Data Committee (FGDC) to coordinate the development of the National Spatial Data Infrastructure (NSDI) to develop policies, standards, and procedures for organizations to cooperatively produce and share geographic data are improving the accessibility and utility of new and existing data. The FGDC is comprised of 17 federal agencies along with organizations from state, local, and tribal governments, the academic community, and the private sector. Part of this effort includes establishing regional and state data clearinghouses (see <http://www.fgdc.gov>) and developing a standard for metadata, (i.e., "data about data" that describe the content, quality, condition, and other characteristics of data). It is important that scientists check the type and amount of supporting documentation that exists to determine whether datasets can be integrated. Topics to evaluate include sampled media, sampling and analytical methods, statistical design, field collection methods, and data reporting.

Existing data that has a geographic component can now be converted, digitized, or formatted to be used with a GIS, allowing managers to assess data in ways that would have been impossible in the past. Application of spatial analysis and modeling techniques to existing data that have been

digitized can provide information on relationships of ecosystem components, long-term trends, regional- or landscape-level influences, location of contaminant sources, with the added possibility of adding new georeferenced data.

Existing data can be a valuable asset in the Natural Resource Damage Assessment process. For example, monitoring data collected for a river can be used as baseline data. Similarly, data from existing long-term, regional monitoring programs can help interpret data from a new program by providing insight on natural variability and trends for the region. The existing data provides a link to past conditions, thereby providing scientists and managers with the opportunity to assess trends or, if needed, to make informed decisions based on limited new data. This aspect is becoming more important given the global transport of many contaminants.

The variability of data is directly related to its quality. Scientists should consider this when investing in monitoring resources. Good quality monitoring data can form the basis by which scientists and managers assess the degree of change that has occurred over time.

If data quality is sufficient, the data may be allowable in legal defenses. There are several important factors that scientists need to consider when assessing the quality requirement of existing or new data. Items that should be checked if the data are likely to be used in a legal defense include, but are not limited to:

- Established and documented quality assurance/quality control plan that governs data collection, handling, and reporting
- Rigorous and defensible statistical study design and reporting requirements
- Chain-of-custody procedures for all environmental samples submitted for analysis
- Established shipping, holding time, and analytical procedures
- Appropriateness of methods for handling outlier and less than detectable values.

The following is an example of how existing ecotoxicology data can be (and are) used in legal defenses. At numerous hazardous waste sites across the country cleanup is occurring to reduce the hazard to humans and the environment to an acceptable level. It is often difficult to establish background levels for the soils, sediment, and water and determine what is the result of site history and regional or global contaminant input. Existing data can often be used to help determine background and guide remediation discussions. In a similar manner data on species diversity, productivity, and composition for an area located near a spill site are useful when establishing the worth of a resource in a natural resource damage assessment.

Data may also be used in the four main areas of an ecological risk assessment:^{11,12} (a) conceptual framework (stressor and environmental characterization, endpoint identification, and conceptual model formulation), (b) hazard assessment, (c) exposure assessment, and (d) risk assessment. These components address the fate, transport, and effect of chemicals in the ecosystem.¹³ During the early years of ecotoxicology studies it was acceptable to characterize the risk of using a chemical by evaluating the response of an individual organism to various doses. This approach was borrowed from the human health risk assessment approach that focuses on dose to an individual. However, our knowledge has improved, and we now understand that exposure to an organism from a chemical or contaminant only partially characterizes the risk to an ecosystem. Exposure information addresses the quantity of a contaminant present, how much it had degraded, and how long it was exposed, but it fails to address the hazard of the contaminant (how toxic it is to different species and whether the toxicity is acute or chronic) and the condition of the receptor (species threatened, their life stage, and part of their habitat affected). All this information needs to be compiled in a manner that evaluates the risk across different levels within an ecological system.¹⁴ Existing information from documented studies and ongoing monitoring programs can provide the data required to make these assessments.

Because ecological risk assessment requires an extensive amount of information to establish ecotoxicology relationships, scientists will be forced to rely more on existing or ancillary data to

conduct cost-effective studies. Classical toxicology work considers impacts of a chemical to molecules, cells, tissues, organs, and, in some cases, individuals. Most of the literature and data on ecotoxicology focuses on aquatic-related impacts to individuals and populations (e.g., benthic, fish, and birds).^{13,15,16} Limited studies have attempted to consider the true ecotoxicology effects on communities or to an ecosystem. Most are conducted on the local scale, which makes it difficult to extend results much past the community level. However, the results and data from these studies do help form the basis for conducting regional ecosystem and global biosphere studies. For example, several ecotoxicology modeling¹⁷ efforts conducted on heavy metals in aquatic and terrestrial systems lead to the conclusion that because mercury has a higher degree of complex biogeochemistry (in the way it reacts with organic matter and bioaccumulates) compared to cadmium in the same environment, different data are needed to assess their impact to an ecosystem. Data from existing literature¹⁸ and existing monitoring programs (e.g., USGS's NAWQA)¹⁹ can help identify relationships useful in establishing models.

Existing information from the literature and indicators used in monitoring programs are useful in characterizing the pathways and receptor components when conducting an ecological risk assessment. For example, if there is a proposal to construct a new hazardous waste incinerator in a rural area, an ecological risk assessment could be used to evaluate different sites. This approach could help select the site that would have the least likelihood of causing adverse ecological effects. These results can be overlaid (using a GIS) with the results from a human health risk assessment to select the best option with the lowest overall risk. Data from existing monitoring programs (Table 10.1) can help guide selection of important ecosystem parameters that should be included in the risk assessment. Programs like NAMS, SLAMS, IMPROVE, and NADP (see Table 10.1) identify critical or sensitive airsheds to avoid; the USGS's NAWQA program¹⁹ is a source for identifying important surface and ground water resources to avoid; and data from the FWS, BLM, USGS, and from NatureServe (<http://www.natureserve.org/>) can provide information on sensitive areas for plant and animals that should be avoided.

If scientists need to conduct both ecological and human health risk assessments for the incinerator example, they would benefit by looking at several of the existing data sources from the atmospheric monitoring programs listed in Table 10.1 (e.g., programs 11, 12, 16, 19, and 21). Depending on the location these data sources can provide status and trend data to help establish the following:

- Average annual wind patterns for the area
- Importance and extent of atmospheric pathway
- Critical aquatic and terrestrial receptors or indicators of ecological change for selected contaminants
- Data that would assist in developing a conceptual model depicting the interaction of the atmospheric pathway with ecological receptors like those detailed in Figure 10.2
- Information about sensitive species and habitats

Existing atmospheric data, in combination with other data sources from other media, are a powerful tool when conducting ecological risk assessments. However, some level of independent verification (i.e., collection of field data) must be done on any assessment that relies solely on existing data.

Collecting and analyzing samples and interpreting data to evaluate all components of an ecotoxicology study can be cost-prohibitive. But, depending on the scale of the study, there may be several data sources available to provide information about the resource or topic. For example, if the objective of the study is to assess ecological risk from a new pesticide on wildlife, existing data would be most useful in assessing information about pathways and critical receptors from an existing chemical with similar properties. Existing data can help provide baseline values and identify pathways for movement of contaminants in the ecosystem of concern — areas where contaminants

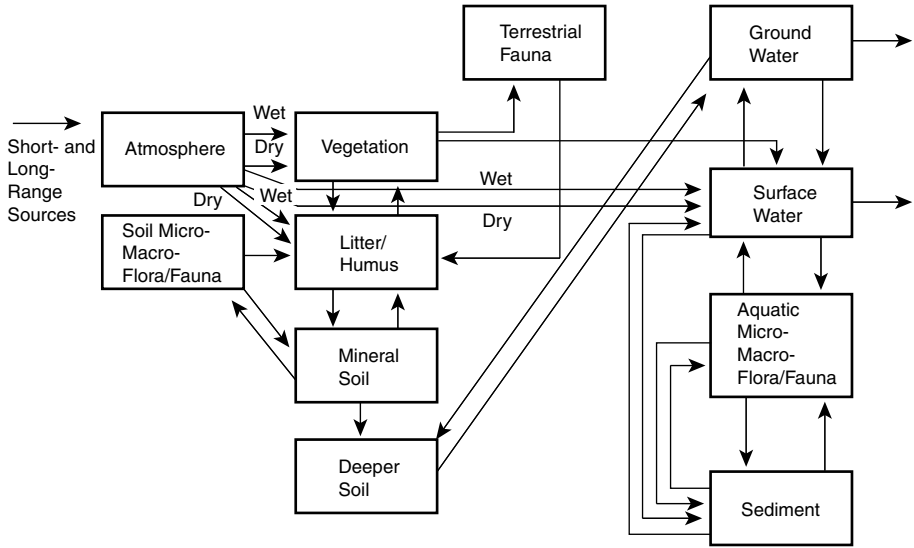

Figure 10.2 Existing data can be used to help identify ecosystem dynamics and formulate these into a conceptual model. This model was used to design a monitoring program to assess the impact of atmospheric deposition of contaminants on a high alpine ecosystem. (From Bruns, D. A. et al., *Environ. Monitor. Assess.*, 17, 3, 1991. With permission.)

partition — and important indicator species; however, specific parameters for the chemical in question will still need to be provided to meet regulatory requirements.

In the past monitoring systems often concentrated on a single medium for sampling (e.g., air, water). This is clearly demonstrated in the types of programs identified in Table 10.1 at an annual cost of billions of dollars.²⁰ This single-medium focus has been fostered by the way regulations have been promulgated. Because of regulations like the Clean Air Act and Clean Water Act and the organization of Federal agencies, the interactions within and among ecosystems have not been appreciated or studied. Ecotoxicology is pushing regulators to reconsider how and why the regulations were developed. If the purpose is to protect natural resources, then regulations will change to reflect the enhanced interest in protecting the complex nature of natural systems.

Existing data are very useful in the design and interpretation of results of new ecotoxicology and monitoring studies. Existing data can

1. Provide information on media to monitor, identify optimal collection time (index period), assess variability, guide statistical design, and develop conceptual models of system- and process-level interactions (e.g., EMAP, NAWQA) (see Figures 10.1 and 10.2).
2. Provide data on reaction rates or partitioning coefficients between components when designing integrated monitoring networks.^{17,21}
3. Identify problems and limitations of previous research.
4. Suggest reporting formats and appropriate distribution networks for various users (e.g., management, research scientist, and public).
5. Provide approximate estimates for scheduling time and costs.

Study design can be improved by using existing data sources in combination with current knowledge to develop a conceptual model of how the system of interest interacts. Figures 10.1 and 10.2 illustrate this concept of how models can be used to help identify questions and level of understanding about the interactions between various components in the ecosystem (e.g., influence of atmospheric deposition on biogeochemical cycling). An exercise evaluating existing data often reveals the most sensitive part of the system to monitor or identifies data gaps related to the

Figure 10.3 Key elements of designing and implementing a monitoring program. (From National Research Council, *Managing Troubled Waters: The Role of Marine Environmental Monitoring*, National Academy Press, Washington, D.C., 1990. With permission.)

interactions and linkages being studied. The feedback loops presented in Figure 10.1 help ensure that objectives are properly formulated and addressed. Once the generic linkages are established, they can be focused to meet the need of the individual study. Figure 10.2 provides an example of how this process was applied to establish the relationships important in addressing questions about the impacts of wet and dry deposition on a high alpine ecosystem.²²

The NRC published a seven-step conceptual approach to designing and implementing monitoring programs.²³ Developed by the Committee on a Systems Assessment of Marine Environmental Monitoring, the approach also has application to designing research projects and large-scale monitoring programs. Existing information plays an important role in providing answers to many of the steps. Existing data can be accessed at several steps in the process to make it a more powerful tool in designing useful research projects and monitoring programs. The general elements of the seven-step approach are presented in Figure 10.3. Each of the steps in the process is presented in Table 10.2 along with discussion and examples on how to include existing data and recognize data limitations.

Once the study objectives are selected, the next step should be to seek out existing information and data that can help address study objectives. A question often asked by management and Congress is, why do we need another monitoring program? To answer this question scientists need to spend time identifying which environmental media are being monitored, by whom, and how often. The result of this effort can provide the convincing argument as to what is the unique need for existing and new programs.

Table 10.2 Benefits and Limitations on Using Existing Data to Help Design and Implement Ecotoxicology Studies and Monitoring Programs

Steps for Implementing a Monitoring Program ^a	Benefits of Considering Existing Data and Information	Limitations with Existing Data
1 — Define expectations and goals for study	<p>Existing data identify compliance requirements for the area (e.g., water contaminants, NPDES permit, Class I airshed, etc.).</p> <p>Identify past and current stressors²⁴ and metals,²⁵ areas sensitive to acid deposition (NADP).</p> <p>Identify gaps in existing monitoring efforts (i.e., currently little known about numbers or contaminant effects on terrestrial or amphibian species).</p> <p>Identify data quality needs (e.g., previous data not legally defensible).</p>	<p>Access and time required to collect and evaluate data is time-intensive; data referral services are very useful.</p> <p>Quality of existing data may be too poor to be useful</p>
2 — Define study strategy	<p>Identify resources at risk from different stresses; large-scale effort can identify regional stresses (e.g., acid deposition, mercury deposition). Local stresses identified by regional, state, and private efforts.</p> <p>Help develop conceptual models of interaction occurring or expected in system. Data from literature important for establishing exchange rates (first order kinetics) between different part of system of interest.²¹</p> <p>Provide data to assess natural variability of system or components of interest, thus, allows investigator to assess signal to noise-ratio.</p> <p>Identify sources of contaminants coming into study area; can help establish rough mass balance of contaminant load (e.g., SO₂ or NO_x deposition rate).</p> <p>Identify baseline data for study area.</p>	<p>Possible to overlook unidentified stress</p> <p>Existing data helpful in establishing initial model, but data need to be verified with field or laboratory-specific data.</p> <p>Statistical value must be checked</p> <p>Quality of data and collection methods may not be comparable</p>
3 — Conduct exploratory studies	<p>Identify data-rich area useful to help plan study and improve data interpretation potential (e.g., with good existing data set could make trend assessment from 1 year of data).</p> <p>Identify previous problems with access, logistics, or regulatory issues (e.g., does National Environmental Policy Act (NEPA) apply?).</p>	<p>Quality of data and access need to be checked carefully</p>

Table 10.2 Benefits and Limitations on Using Existing Data to Help Design and Implement Ecotoxicology Studies and Monitoring Programs (Continued)

Steps for Implementing a Monitoring Program ^a	Benefits of Considering Existing Data and Information	Limitations with Existing Data
4 — Develop sampling design	<p>Quantify variability levels to establish data quality objective before starting work; data most useful for aquatic and near coastal resources.</p> <p>Identify what has been previously monitored in similar studies and success rates (e.g., Pb levels in blood of birds have been used for assessing metal smelter.²⁹ Metals in different species of fish can be compared, but not directly because many species have different accumulation factors.²⁸).</p> <p>Enhance statistical base for making comparisons or statements from short-term study.</p>	<p>Chemical-specific data are limited</p> <p>Limited data for assessing contaminants in terrestrial species or systems.⁴</p>
5 — Implement study	<p>Identify proven methods and assess usefulness</p> <p>Identify logistical problems (e.g., contact point for access, environmental and safety hazards).</p>	<p>Must be careful data and methods are comparable</p> <p>Existing data and information are always subject to change; thus, they must be verified, especially if regulations change</p>
6 — Produce information	<p>Provide good examples on how to conduct assessments, statistical tests, and format report.</p> <p>Provide basis for comparison of study results with previous studies.</p>	<p>Quality of data must be checked</p>
7 — Disseminate information	<p>Help identify different types of audiences and level of report needed or expected.</p> <p>Identify appropriate means and places to distribute information (e.g., journals that previously accepted similar results, use of different media for internal vs. external audiences).</p> <p>Identify limitations or requirements associated with dissemination of results (e.g., path clearance, peer review, and transmittal process).</p>	<p>Previous studies can set precedent for type and level of detail expected by management or peers</p>

^a Steps from NRC²³ (see Figure 10.3).

10.5 ACCESSING EXISTING DATABASES

Many of the Federal datasets have been organized and made available via the Internet or can be ordered on CD or to be downloaded (see Table 10.1). Also available are data compilation or reference services that sell or provide computer access to large datasets. Most of these services place advertisements in trade and scientific journals. This information can generally be accessed either by using standard personal computer systems with CD-ROM readers or via the Internet. The National Technical Information Service is also a good source of data that can be accessed through most technical libraries.

Because of the large quantity of and increasing interest in accessing existing databases, most agencies have established an office of information management. Many of these information management systems are accessible through computer and phone line access (see Table 10.1). For example, the EPA has developed an Environmental Information Management System (EIMS) (<http://www.epa.gov/eims/emshome.html>) that stores, manages, and delivers descriptive information (metadata) for datasets, databases, documents, models, multimedia, projects, and spatial information. Users including scientists, resources managers, and others searching for information sources of interest based on topic or criteria related to types of environmental resources, geographical extent, data, or content origin.

10.6 CONCLUSION

Capitalizing on the millions of dollars invested in monitoring of the United States' environmental systems requires an understanding of opportunities and limitations. Managers are becoming increasingly aware of the high cost of conducting ecotoxicology and monitoring studies. Existing information can play an important role in reducing costs of performing an ecological risk assessment or in the design of new ecotoxicology or monitoring studies. Scientists can use existing information to obtain support for a new program or hypothesis by identifying both gaps in existing information and a need for new programs.

In order for scientists to produce high-quality studies or projects in the most cost-effective manner one of the initial steps should be to seek out applicable information and assess its usefulness. Many scientists do not take full advantage of existing data because this can be a tedious effort. However, by developing a set of selection criteria tailored to the special interest of the new effort, the new project can often be given a boost during its initial stages by taking advantage of lessons learned from previous efforts, by identifying important components to monitor, and by improving interpretation of results even with only limited data.

Existing data are useful when they can be exchanged between users in a comparable manner. For this to occur, the existing data must have good documentation as to quality, purpose, place and time period of collection, and limitations. Use of GISs and spatial analysis and modeling techniques enhance the use of existing and new data, allowing scientists and managers to assess data in ways that were impossible in the past.

Environmental science is at an exciting stage in its development. With each year come new and better ways of conducting ecotoxicology and ecological risk assessment studies. Scientists have an obligation to consider future activities and efforts when designing their studies. The data and information collected from the program must be documented so they are useful to future investigators. This requires that the data be of known quality and that future users are able to identify why, when, where, and how they were collected. Teaching new scientists about the benefits and utility of existing data is the responsibility of all established scientists. Users must be aware of the limitations and biases of the existing data and use those data appropriately. The right fit of the data can enhance the development of a new study; the wrong application (because it does not identify

limitations) can cause serious design or interpretation problems. By establishing acceptance criteria tailored to their needs, scientists can identify and benefit from existing information.

11.1 INTRODUCTION

There are many different types of contaminants present in the environment, ranging from synthetic chemicals, which would not be present in the environment without human intervention, to trace metals that are required for life. Concerns range from possible harmful effects on flora and fauna to possible harm to humans from consuming contaminated organisms. The complete chemical analysis for all possible environmental contaminants in sediments, water, air, and every species and sample of interest would not only be excessively costly, but the facilities to handle so many samples do not exist. Furthermore, such chemical analysis would only establish the presence of contaminants, without revealing how available or active they were within the organism.

Bioindicators, sometimes called biomarkers, are responses of living organisms that may simply signify exposure to contaminants, may predict future harm due to the exposure, or may themselves be harmful effects. In this chapter *bioindicator* will be interpreted to mean the same as a biomarker (a biochemical physiological or morphological response), but not a population or ecosystem bioindicator such as a sentinel species, genetic variability, or species richness. Thus, a bioindicator (biomarker) may be studied in a particular species to assess the status of that species or in a sentinel species to assess habitat status. Individuals of the sentinel species might be those already residing at the site of interest or might be pristine organisms brought to the site and maintained in cages (fish) or released and recovered (birds). Although most bioindicators are measured in tissue samples taken from the study organisms, the exposure itself must have occurred in a living organism.

Systematically, the responses can range from minor biochemical or physiological responses (homeostatic responses) in individual organisms to major toxicity (in an individual, a species, a community, or an ecosystem).

At the least, a bioindicator response shows that a contaminant (or contaminants) is present in the environment, that it is available to the organism, and that it has reached the affected tissue or organ in sufficient amounts for a period of time long enough to cause the observed response. The relative value of such a response to indicate harm ranges from a simple homeostatic response to a progression of levels of response indicating possible damage. The progression includes responses that indicate that a process that may lead to harm has been initiated, that a process that definitely leads to harm has been initiated, that the indicator itself is a harmful effect, that this harmful effect will lead to death or decreased reproduction for the individual, or that this harmful effect will lead to significant population effects.

For a response to a contaminant to be a useful biomarker, there are a number of properties of the response that are desirable, some of them even necessary. There must be a known specificity of the response to a contaminant presence or exposure, some correlation of the presence or magnitude of the response to the amount of the contaminant present, and a known temporal relationship between exposure and effect. The biomarker response should precede harm, but ideally it would be a predictor of future harm. Samples should be readily obtainable in quantities needed for measurement. Ideally, the sampling would be nonlethal, which would greatly increase its applicability. The assay method must be accurate and reproducible. The overall costs should be reasonable in regard to equipment, supplies, and technician time when compared to the cost of nonbiomarker approaches.

Although the biomarkers are discussed individually in this chapter, their most effective application may be as a suite of biomarkers, unless information is needed only on a particular contaminant or class of contaminants for which there is a highly specific biomarker. Because in most cases a variety of contaminants may be present, and most biomarkers have limited specificity, a battery of biomarkers is required to assess multiple classes of contaminants. An added advantage of using a suite of biomarkers is that it might also distinguish types of contaminants that can affect more than one element in a suite of biomarkers. This chapter will present an overview of selected biomarkers that are presently in use or ready to use in the field and present suggestions for future directions in the area of bioindicators. Four books, *Biomarkers of Environmental Contamination*;¹ *Biomarkers:*

Biochemical, Physiological and Histological Markers of Anthropogenic Stress;² *Animal Biomarkers as Pollution Indicators*;³ and *Nondestructive Biomarkers in Vertebrates*⁴ contain details on a wide variety of biomarkers and provide more extensive information on the biomarkers covered in this review. More recently, there have been manuscripts and chapters devoted to the biomarker concept and biomarker descriptions.⁵⁻⁹

11.2 INDIVIDUAL BIOINDICATORS

11.2.1 Cholinesterase Inhibition

In most cases a bioindicator response to a particular contaminant is fortuitous because contaminants generally arise from anthropogenic processes independent of specific processes in fish and wildlife. However, the anticholinesterase pesticides, such as the carbamate and organophosphorus compounds, were designed to cause death by inhibition of cholinesterase activity. Even though designed as insecticides, they are well known as agents causing kills of wild vertebrates and as such present an unusual opportunity for assessing exposure of fish and wildlife. Thus, it is possible to monitor terrestrial and aquatic organisms for inhibition of a system that a contaminant was designed to affect. Although cholinesterase activity is present in many tissues, such inhibition in environmental samples is generally determined from samples of brain tissue or blood (serum or plasma). Brain contains mainly acetylcholinesterase activity, while blood generally contains both acetylcholinesterase and butyrylcholinesterase activities.

The use of cholinesterase inhibition in the determination of cause of death of an organism is more definitive than the use of such inhibition in a living organism. A finding of $\geq 50\%$ inhibition of brain cholinesterase activity, along with the residual presence of a carbamate or organophosphorus pesticide in the body (GI tract), is considered diagnostic for the cause of death in birds.¹⁰ Fish in general present a more variable relation between death and brain cholinesterase inhibition; lethal inhibitions reported range from 40 to 80%.¹¹⁻¹³

It has been demonstrated that normal cholinesterase activity varies between species¹⁴⁻¹⁶ and that age affects cholinesterase activity significantly in species such as altricial birds¹⁷ and mammals.¹⁶ There are several approaches for determining the control or normal levels to which to compare the possibly inhibited levels. The best approach is to collect concurrent reference samples of comparable individuals of the species of interest from an uncontaminated area. Other approaches are to use previously collected data on comparable uncontaminated individuals of the same species or to treat the sample so as to reverse or remove the inhibition (reactivation assay¹⁸) so that the sample can serve as its own control. Although 50% inhibition of cholinesterase activity may be found in some dead birds, other individuals may survive with even greater inhibition.

The effectiveness of using cholinesterase inhibition as a biomarker in living, field-collected animals depends on the quality of the control values and whether possibly inhibited samples can be demonstrated to be significantly different from control values. Johnson et al.¹⁹ have reported on the stability and correlation of tissue pesticide residues and cholinesterase activity in attributing death to such pesticides. Depressed brain cholinesterase activity is indicative of significant exposure to anticholinesterase pesticides, and the inhibition of activity may remain for several weeks following exposure and correlate well with effect. Depressed blood or plasma cholinesterase activity is indicative of exposure to anticholinesterase pesticides rather than harm, and the inhibition of activity is short-lived. Despite these limitations blood sampling has the advantages that animals do not have to be sacrificed for sampling, serial samples may be collected from the same animal, and continuing exposure can be detected. Although more definitive results are usually obtained with brain cholinesterase inhibition than with blood or plasma cholinesterase inhibition,²⁰ for biomonitoring the advantage of obtaining blood samples without sacrificing an animal may be the more important consideration.

The use of cholinesterase as a biomarker has been studied, including field validation, in many species¹⁴⁻¹⁶ and is widely accepted as a biomarker in avian, mammalian, and aquatic species. The number of species to which this technique has been applied continues to increase. The use of cholinesterase inhibition in additional species requires sufficient testing to ensure adequate baseline data for the analytical technique selected.

Pertinent reports include that of Hill on brain cholinesterase activity of apparently normal wild birds,¹⁶ two letters to the editor expanding upon this report,^{21,22} the book, *Cholinesterase-Inhibiting Insecticides: Their Impact on Wildlife and the Environment*,²³ a brief review of esterases as biomarkers, including cholinesterase inhibition,²⁴ and a Canadian Wildlife Service methods report.²⁵

11.2.2 Cytochromes P450

The cytochromes P450 are a class of hemoproteins present in all tissues but found in especially high concentrations in the liver. They are inducible, that is, increased amounts of specific cytochromes P450 are found after treatment of organisms with a variety of organic chemicals. Of greatest interest for biomonitoring is that several major classes of environmental contaminants induce cytochromes P450. The two major types of cytochromes P450 that are induced by contaminants are those classically described as the 3-methylcholanthrene-inducible and the phenobarbital-inducible types. Currently, these inducible cytochrome P450 classes are referred to as CYP1A and CYP2B, although in some species the phenobarbital-inducible cytochromes P450 have been designated differently within the CYP2 family.²⁶ Although in laboratory studies, administration of large quantities of an inducing agent can increase the amount of total cytochromes P450 several-fold, such magnitude of induction usually is not the case in environmental exposure. Environmental exposures to contaminants that are inducing agents usually occur at concentrations much below those for maximal induction, so the total mass of cytochromes P450 may not increase significantly. Thus, more sensitive methods must be used to discriminate between constitutive cytochromes P450 and induced cytochromes P450.

11.2.2.1 Monooxygenase Activity of Cytochromes P450 in Microsomes or S9 Fraction

Associated with the cytochromes P450 is a wide range of enzyme activities referred to as monooxygenase activities. In an organism these enzyme activities increase the polarity of lipophilic xenobiotics, thereby speeding detoxication and elimination, but they can also metabolize some xenobiotics to more toxic forms. A number of highly sensitive monooxygenase assays, mainly oxidases, hydroxylases, and dealkylases, have been developed for evaluating the amounts of induced cytochromes P450 present.²⁷⁻³⁰ Appropriate assay conditions and specificity of response (CYP1A- or CYP2B-linked) must be ascertained for each species. Ethoxyresorufin-*O*-dealkylase (EROD) is the monooxygenase assay usually used in biomonitoring because it is a highly sensitive fluorometric assay, and because in most species, it is CYP1A-linked rather than CYP2B-linked, and it is effective in species such as fish where CYP1A, but not CYP2B, is induced by contaminants.³¹

11.2.2.2 Immunological Assessment of Cytochromes P450

Cytochromes P450 are frequently evaluated by Western blot. Both monoclonal and polyclonal antibodies have been used successfully for avian, mammalian, and aquatic species.³²⁻³⁵ A major advantage of Western blot over monooxygenase assays is that the constitutive cytochromes P450 may possess some activity in a particular monooxygenase assay, but the antibody method is specific for an individual or a family of induced cytochromes P450. The Western blot technique might also permit assessing cytochromes P450 in samples that have not been stored adequately for assaying monooxygenase activity. The use of antibody to fish CYP1A has also been applied to a semiquantitative ELISA.^{36,37}

11.2.2.3 Cytochromes P450 mRNA

Increase in the hepatic mRNA for CYP1A has been demonstrated in a number of fish species following exposure to contaminants by exposure routes ranging from manual dosing to environmental exposure.^{38–40}

11.2.2.4 Nonlethal Methods of Assessing Cytochromes P450

The use of *in vivo* metabolism of xenobiotics and tissue biopsy samples for P450 quantitation in wildlife is still in development. Such nonlethal methods are important because they provide the opportunity (1) to use cytochromes P450 as a biomarker in species for which sacrificing individuals is not possible and (2) to monitor the same individuals over time. The sleeping-time method is an indirect method for evaluating the cytochrome P450 status of an individual by comparing sleep duration after administration of phenobarbital to animals with suspected contaminant exposure and control animals. If the contaminant caused increased metabolism of phenobarbital, then sleeping time for the contaminant-exposed group will be shorter than that of the control group. This has been observed in wild-trapped muskrats, *Ondatra zibethicus*.⁴¹ Also, the metabolism of an administered chemical like caffeine may be determined by several methods, including disappearance of the caffeine from the blood, appearance of metabolites in excreta, or appearance of tagged CO₂ from ¹³C- or ¹⁴C-labeled caffeine in exhaled air.^{42,43} It also is possible to apply monooxygenase assays or Western blot to tissue obtained by biopsy from species with sufficient size and hardiness to exhibit rapid and complete recovery after the removal of approximately 0.05 to 0.25 g of liver tissue. The observation of *in vivo* ethoxyresorufin dealkylation in killifish embryos has also been reported.⁴⁴

Cytochromes P450 have been studied in too many fish species to list them all in this brief review, and the number of wildlife species studied, including mammals, birds, reptiles, amphibians, and aquatic organisms is increasing rapidly. Numerous review articles have covered induction of cytochromes P450 as a biomarker for exposure to environmental contaminants.^{31,45–49}

11.2.3 Reproductive Problems

11.2.3.1 Eggshell Thinning

Severe eggshell thinning can result in breakage of an egg before hatching, effectively preventing reproduction. In such cases determination of the shell thickness of the broken eggs would be diagnostic. Less severe, but significant, eggshell thinning provides an indicator for possible reduced reproductive success. DDE, the metabolite of DDT, is the major, if not the only, cause of contaminant-induced shell thinning in many species of fish-eating birds.^{55–56} Eggshell thickness can be measured directly with a micrometer or the thickness index calculated as the weight of the shell (mg) divided by the product of shell length and breadth (mm²).⁵⁷ Recent studies show a better correlation for shell strength than for shell thickness to contaminant-associated abnormalities.^{58–60} Because the shell is partially used up by the developing embryo, these measurements must be done early in incubation. Because only one egg is taken early in incubation, for many species the use of this biomarker would have minimal effect on reproduction. Though one of the earliest biomarkers, it is still being used.⁶¹

11.2.3.2 Terata

Environmental contaminants can cause a variety of developmental abnormalities in aquatic and terrestrial organisms. In the environment, exposure of the embryo could occur via the mother (placental transfer or egg formation) and also (in cases such as birds and fish) via direct exposure of the eggs after they are released. Laboratory studies have utilized exposure by injection of

contaminants into the egg air sac or yolk. The embryotoxicity and teratogenicity of externally applied petroleum and related materials and pesticides to avian embryos have been summarized by Hoffman.⁶² Some of the most clearly established relations between terata and contaminants include the crossed bills caused by chlorinated hydrocarbons in water-birds in the Great Lakes and beak and other abnormalities caused by selenium in waterfowl and shorebirds using irrigation drainwater ponds. The most extensive study of bill malformations caused by chlorinated hydrocarbons included the examination of over 31,000 cormorant chicks from colonies in the Great Lakes and almost 21,000 chicks in reference areas.⁶³ Only two chicks in reference areas had bill deformities, while 70 of those in the Great Lakes had bill deformities. Selenium exposure of American coot (*Fulica americana*), mallard (*Anas platyrhynchos*), eared grebe (*Podiceps nigricollis*), and black-necked stilt (*Himantopus mexicanus*) resulted in embryo death⁶⁴ and terata in embryonic livers.⁶⁵ Embryo deaths were found in 17 to 60% of the nests of these species involving 2.5 to 31.7% of the eggs. Based on observations of at least two viable embryos per nest, abnormalities of eyes, brain, feet, or beak were found in 13 to 53.8% of nests and 8.6 to 16.4% of embryos.

11.2.3.3 Vitellogenin as a Biomarker for Estrogenic Activity in Males

Since the discovery of male alligators at Lake Apopka, Florida, with smaller than normal external genitalia, there has been concern about environmental chemicals that modify androgenic and estrogenic activity. In the mid-1990s blood level of vitellogenin was suggested as a biomarker for estrogenic activity in oviparous species.^{66,67} This is a very sensitive biomarker in male and immature organisms that should not have vitellogenin present and is less sensitive in mature females, where it is normally present. This biomarker utilizes antibodies to vitellogenin in Western blot or ELISA, and it quickly became established as a biomarker in fish.⁶⁸⁻⁷¹ Detailed directions for preparing the necessary reagents and performing the antibody-based vitellogenin assays were recently published.⁷² An assay for vitellogenin mRNA in largemouth bass has also been reported.⁷³ This and other hormone-related effects are covered in depth in Chapter 38.

11.2.4 Aberrations of Hemoglobin Synthesis

11.2.4.1 Red Blood Cell- δ Aminolevulinic Acid Dehydratase (ALAD)

Activity of ALAD, the enzyme responsible for condensing two molecules of aminolevulinic acid to form porphobilinogen in the synthesis of hemoglobin in red blood cells, is very sensitive to lead. Inhibition of red blood cell ALAD activity as a direct effect of lead has been clearly demonstrated in numerous human studies and in fish⁷⁴ and wildlife.⁷⁵ The negative correlation between red blood cell ALAD activity and blood lead concentration was studied in fish^{76,77} and birds.^{78,79} Examples of species in which the effects of environmental exposure to lead on ALAD activity have been monitored are canvasbacks (*Aythya valisineria*),^{80,81} European starlings (*Sturnus vulgaris*),⁸² suckers (catostomid fishes),⁸³ and snapping turtles (*Chelydra serpentina*).⁸⁴ The sensitivity of response must be determined in each species to be monitored. Two approaches are available for assessing the inhibition. Reference values or concurrent samples from relatively unexposed individuals may be used, or the inhibition can be reversed with zinc and the ratio of inhibited to restored activities can be used.⁸⁵ Among the advantages of this assay are that it does not require sacrifice of the animal to be monitored, the sample may be stored in an ultracold freezer for up to two months before assay, and only readily available laboratory equipment is required for the assay.

11.2.4.2 Porphyrin

A number of chlorinated organics affect hemoglobin synthesis at points closer to hemoglobin formation and result in the accumulation of highly carboxylated porphyrins that may be found in

liver, blood, urine, or feces.^{86–88} Although an early approach to such measurements gave a total porphyrin value, the use of high-performance liquid chromatography (HPLC) makes possible the determination of individual porphyrins, which gives greater sensitivity and specificity to this method.^{89,90} This effect was clearly shown in herring gulls (*Larus argentatus*) from the Great Lakes, which were contaminated with chlorinated aromatics, as compared with herring gulls from control locations⁸⁸ and in river otters (*Lontra canadensis*) following a petroleum spill.⁹¹ Lead has also been demonstrated to cause increased concentration of protoporphyrin in erythrocytes in mallard ducks^{92,93} and black ducks.^{94,95} As a biomarker, porphyria has the advantage that it is a negative effect on a necessary pathway, not merely a homeostatic response. Depending on the quantity of porphyrins found, this response may be representative of minor effects, probably without implications for survival, through a gradation of responses, to severe liver damage. Because of the requirement for HPLC, quantitation of porphyrins is not a method that is amenable to occasional use but is not overly complex if set up and run on a regular basis.

11.2.5 DNA Damage

After uptake by an organism, some chemicals or their metabolites or both are capable of interacting with DNA to modify or damage it. The common methods for evaluating such interactions are based on direct measurement of DNA structural damage, assessment of DNA repair, or determination of mutations present in genomes.

The activated forms of a variety of polycyclic aromatic hydrocarbons can become covalently bound to DNA. Tests for assessing the presence of such adducts may be general or specific. The ³²P-postlabeling technique⁹⁶ is a sensitive method for determining the quantity of DNA adducts present, regardless of the adduct, and has been applied to aquatic species from many contaminated areas.^{97–101} Researchers at the National Marine Fisheries Service laboratory in Seattle have described extensive studies on the presence of DNA adducts in liver, some of which relate their presence to PAH-contaminated sediments and the occurrence of tumors in several species of marine fish.^{97,102–104} The sensitivity is approximately one adduct per 10¹⁰ bases. It is also possible to hydrolyze the DNA and determine the specific adduct present by gas chromatography/mass spectrometry. This approach is much less sensitive, however. Attempts are being made to quantify such adducts via antibodies. Modification of DNA, such as by adduct formation, is the first step in contaminant effects on DNA and can lead to greater changes in the DNA, which can be detected or measured by other methods.

Strand breakage can be quantified by an alkaline unwinding assay in which the rate of unwinding, measured in an alkaline medium, is facilitated by strand breaks. This approach has been applied successfully to demonstrate increased strand breakage in freshwater fish exposed to benzo(a)pyrene^{105,106} and in turtles from contaminated, as compared with clean, sites.¹⁰⁷

Standard chromosome analysis and sister chromatid exchange are sensitive methods for detecting mutagenic damage. Flow cytometry, which has been used to detect genetic damage in small mammals¹⁰⁸ and birds,^{109,110} is a good approach to assess such damage because of its sensitivity, convenience, and low cost. Several reviews^{111,112} discuss DNA alterations and their role as a biomarker for contaminant exposure. See also Chapter 40.

11.2.6 Histopathological Effects

Many contaminants are capable of damaging specific cell types or organ systems. Unless severe and extensive, and therefore readily observable at necropsy, such damage may best be evaluated by histopathological techniques. Because of the variety of cell types and the many organs and organ systems present in any individual, there are an overwhelming number of histological approaches to detecting the effects of contaminants.¹¹³ The main limitations are field validation studies in the species in question, assessment of whether convenience and cost are better for this approach, and whether this would serve as part of a suite of biomarkers.

Tumors are probably the most widely occurring aberration studied by histological methods. Tumors have been observed in a variety of fish species from contaminated areas, with the most common occurrences in bottom-dwelling fish in areas of PAH contamination, flatfish (*pleuronectitums*) in the marine environment, and bullheads (*Amerinons* spp.) in freshwater.^{114–118} A notable exception is the finding of tumors in saugers (*Stizostedion canadense*) and walleyes (*S. vitreum*) in Torch Lake in Michigan.¹¹⁹ There have been good correlations between sediment PAH levels, DNA adduct formation, and presence of tumors in flatfish.^{117–119} A recent study with brown bullheads found tumor occurrences as high as 60% in liver and 37% in skin.¹²⁰

This approach is well established and may be applied whenever a species is known to produce tumors in response to the contaminants of interest, reference values are available, and the frequency of tumor formation is high enough for likely detection.

11.2.7 Metabolites of Contaminants in Bile

Some contaminants, such as polycyclic aromatic hydrocarbons (PAHs) and substituted phenols, are metabolized so rapidly that concentrations of parent contaminant in an organism might not be indicative of the extent of exposure. In such cases analysis for the metabolites produced by the organism would be an advantageous approach. Although a variety of tissues could be selected for this analysis, bile is a good choice because of the relatively high concentration of metabolites in this fluid^{121–123} and its relatively clean state (i.e., free of tissue lipids, etc.). Krahn and co-workers¹²⁴ developed a protocol for measurement of metabolites of PAHs in bile that involves separation of such metabolites into three fractions and quantification of these classes via fluorescence measurements at three wavelength pairs. Using this methodology they have demonstrated the presence of metabolites of a number of PAHs in bile from flatfish from areas thought to be contaminated.^{125,126} In subsequent studies other researchers at the same laboratory have related such measurements to induction of cytochrome P450, DNA adduct formation, and the presence of tumors in several species of marine bottom fish.^{102–104} Assessment of PAH metabolites in bile continues to be utilized in both freshwater and saltwater fish.^{39,127–129} Metabolites of chlorinated phenols and resin acids have been found in bile of fish collected downstream from pulp paper mills.¹³⁰ A review of metabolites as biomarkers of contaminant exposure has been published.¹³¹

11.2.8 Oxidative Damage

Contaminants such as polycyclic aromatic hydrocarbons, halogenated aromatic hydrocarbons, heavy metals, selenium, industrial solvents, and many of their metabolites are capable of causing oxidative damage within an organism. The role of free radicals in such oxidative stress has been reviewed by Kehrer et al.¹³² In response to oxidative stress, there may be adaptive responses of the protective (antioxidant) systems, modification of cellular macromolecules, and ultimately tissue damage. Changes in the antioxidant systems and modified macromolecules can serve as bioindicators for a variety of contaminant exposures.¹³³ The protective systems include reduced glutathione (GSH)/oxidized glutathione (GSSG)/glutathione reductase, catalase, superoxide dismutase, peroxidase, ascorbate, and alpha-tocopherol. Macromolecules that may be affected include lipids, proteins, and nucleic acids. Although most of the early studies in this area utilized typical laboratory research species, some recent studies have utilized wildlife species.

Excess dietary selenium caused increased glutathione peroxidase and glutathione reductase activities, GSSG/GSH ratios, and hepatic lipid peroxidation in mallard ducks.^{134–136} Livers of adult coots with high levels of selenium collected from the Kesterson National Wildlife Refuge had elevated glutathione peroxidase activity and decreased thiol concentrations.⁶⁴ Spot (*Leiostomus xanthurus*) from a polluted site had elevated superoxide dismutase as compared to a clean site,¹³⁷ bivalves from contaminated areas had antioxidant parameters that related to heavy-metal concentrations,¹³⁸ and scaup from a contaminated area had elevated hepatic lipid peroxidation that correlated with several heavy metals and with PCBs.¹¹⁰

The potential of both adaptive and damaging responses to oxidative stress to serve as biomarkers of contaminant exposure appears excellent. Because of the wide variety of contaminants that can cause oxidative stress, these biomarkers can serve as indicators for exposure for a wider range of contaminants than can most other biomarkers. This lack of specificity also requires that this be used as part of a suite of biomarkers or that follow-up work would be required to determine more precisely the types of contaminants causing the response. Field validation studies are needed, both for specific oxidative stress-related responses and for concurrent exposures to multiple classes of contaminants.

11.2.9 Immune Competence

A variety of contaminants are known to affect the immune system. Phylogenetically, the presence of an immune system is widespread, and effects of contaminants on immune systems have been reported from earthworms (*Lumbricus terrestris*) to mammals.^{139,140} Because compromise of the immune system by contaminants may lead to serious effects in aquatic and terrestrial organisms, these responses are not only indicators of exposure but also of potential or actual harm.¹⁴¹⁻¹⁴² Numerous assays for immune function are available because of the complexity of this function and the need to assess its many parts.

An early study with a wildlife species examined the effects of organochlorine residues on susceptibility to infection in mallard ducks.^{143,144} More recently, there have been demonstrations of impaired immune response in free-ranging wildlife. Macrophages isolated from kidneys of spot and hogchoker (*Trinectes maculatus*) from the Elizabeth River were less than those isolated from those species from a control location.¹⁴⁵ In dolphins immune response correlated inversely with blood PCBs and DDT.¹⁴⁶ In nestlings of Great Lakes terns and gulls T-lymphocyte function, as assessed by the phytohemagglutinin skin test, was inversely correlated with egg organochlorine contamination.¹⁴⁷ In a more controlled study, seals fed fish from a contaminated site had reduced immune function as compared to those fed fish from a cleaner site.¹⁴⁸

The impact of toxic metals on immune function in earthworms has been evaluated in a number of studies.¹⁴⁹⁻¹⁵⁴ Effects of contaminants on immune function have been demonstrated in controlled exposure studies of polychaetes,¹⁵⁵ bivalves,^{156,157} starling,¹⁵⁸ and white-footed mouse.¹⁵⁹ Many of these assays are suitable for environmental application, needing only background information on responses in particular species and field validation.

11.2.10 Metallothionein

Metallothioneins are a class of small proteins, rich in cysteine, capable of binding metal ions and inducible by cadmium, copper, mercury, zinc, cobalt, bismuth, nickel, and silver ions¹⁶⁰ and by a variety of nonmetal factors.^{161,162} Because they are induced by the metal ions enumerated above, they have been viewed as possible biomarkers for exposure to those metal ions. The methods currently used evaluate individual metallothioneins via the use of antibodies specific to those metallothioneins¹⁶³⁻¹⁶⁷ or quantify the mRNAs for metallothioneins by the use of cDNAs specific to those mRNAs.¹⁶⁸⁻¹⁷⁰ Evaluating metallothionein is slower and more expensive than analysis for the causative metals themselves. It must be determined on an individual basis whether the additional information on the route and time of exposure that are provided by this approach warrants the increased costs.

11.2.11 Heat Stress Proteins

Heat stress proteins (HSPs) are one group of a larger class of proteins referred to as stress proteins.¹⁷¹ Previously referred to as heat shock proteins because of their rapid appearance following heat stress, they have since been found to increase in response to a variety of chemical and

nonchemical stressors.¹⁷²⁻¹⁷⁵ Initially, this broad responsiveness suggested that HSPs lacked adequate specificity to be of value as a biomarker. Subsequent studies demonstrated that there are many stress proteins, falling into major groupings by weight. These include HSP90 (80 to 100 kda), HSP70 (65 to 75 kda), HSP60 (chaperonin, approximately 60 kda), low molecular weight (20 to 50 kda), and ubiquitin (8 kda).¹⁷⁶⁻¹⁷⁸

Although all of these heat stress proteins deal with the structural integrity of other proteins, they differ in their functions in stressed and nonstressed individuals, baseline levels in nonstressed individuals, and magnitudes of increases following stress.¹⁷⁹ Although HSPs are referred to as constitutive and inducible, constitutive HSPs are also inducible. The tissues in which induction of heat stress proteins occurs and the patterns of individual heat stress proteins induced appear to be specific to species and to different types of stressors.

With the development of antibodies to some heat stress proteins,¹⁸⁰⁻¹⁸⁴ Western blotting is the best of the already developed analytical methods for evaluating heat stress proteins.

In general, heat stress protein responses have been studied in laboratory experiments.¹⁸⁵⁻¹⁸⁷ Although there have been some field studies,¹⁸⁸⁻¹⁹⁰ investigations in additional species, including more field studies, are required before this biomarker can be widely applied to environmental samples. Much more information is needed on the response of particular stress proteins to particular contaminant and noncontaminant stressors. It also must be determined whether the information obtained by heat stress protein analysis is equal to or more valuable than results of chemical analysis for contaminants or other biochemical or physiological responses, whether heat stress proteins serve better as integrative or specific biomarkers, and whether such approaches are cost effective.

11.2.12 Other

A wide variety of biochemical and physiological responses to contaminants have been suggested as biomarkers, and it seems that new candidates are proposed in almost every environmental journal issue. It is beyond the scope of this chapter to discuss all of these candidate biomarkers, but a number of them have been covered in the publications cited previously.^{1-4,6,9} Many of them are included in Table 11.1 along with those covered in this chapter. Most of these approaches are not as well established as those that are covered in this chapter, and interested readers are referred to these publications.

There are two emerging areas of study that must be mentioned. One area that is developing rapidly in the human health area is genomics and the use of cDNA microarrays to detect the presence of mRNAs in response to disease or other challenges. Some mRNAs are now studied individually as biomarkers in wildlife. Examples are those for cytochromes P450, stress proteins, and vitellogenin. What is lacking is background information on DNA for wildlife species to permit development of gene arrays. To date, most work in genomics has pertained to humans and to human-health-related laboratory species. When genomic information is available for wildlife species, or closely related species, it will be feasible to make gene arrays to use in broad screens of wildlife status or response to environmental challenges of many kinds. Similarly, broad-based approaches to the synthesis of specific proteins (proteomics) in wildlife species have yet to be developed. Regardless of the quantitation method, enzyme activity, Western blot, etc., many of the current biomarkers evaluate the presence of a single protein or a class of related proteins. Current separation techniques and analytical software present the potential for examining multiple proteins simultaneously. Basically, this would be the simultaneous assessment of multiple gene products that would arise from the mRNA responses described in the preceding paragraph, but would not require the genomic information. Early work of this type utilized two-dimensional electrophoresis followed by visualization and computer-based pattern comparisons, but arrays of antibodies for specific proteins are currently under development.

Table 11.1 Presently Used and Possible Bioindicators^a

Bioindicator	Description	Stressor
Protein-related		
Proteomics	Broadly encompasses quantity and functioning of any protein; approaches being developed that may be protein equivalency of DNA arrays	Specificity will depend upon contaminant and technique
Enzymes	Many proteins are enzymes, and the quantities and activities and many of them are impacted by contaminants; some of the major ones follow	Specificity as indicated
ALAD	Change in the measurable activity of δ -aminolevulinic acid dehydratase	Lead
Cholinesterase	Assess acetylcholinesterase inhibition in brain; acetylcholinesterase and butrylcholinesterase inhibition in serum or plasma	Activity inhibited by carbamate and organophosphorus pesticides
Conjugating enzymes	Phase 2 metabolizing enzymes such as glutathione-S-transferase.	Increases may be caused by (PAHs), halogenated PAHs, and heavy metals
Cytochromes P450	Changes, generally increases, in various families of cytochromes P450 measured in any tissue by a variety of methods	Increases generally caused by polycyclic aromatic hydrocarbons (PAHs), halogenated PAHs; may be inhibited by heavy metals
Metallothionein	Increase in class of -SH rich polypeptides in tissues such as liver, kidney, and testes	Caused by heavy metals
Stress proteins glucose-regulated proteins heat stress proteins	There are several families of stress proteins that differ in molecular weight and effectors	Relatively low specificity, differs with family
DNA-related		
Genomics	A wide variety of factors impact DNA transcription and DNA structure	Specificity dependent upon contaminant and technique
DNA modifications	DNA transcription can be affected by most contaminants; measurements can be from one particular mRNA or from an array of dozens, hundreds, or thousands	Specificity dependent upon contaminant and mRNAs that can be assessed; the use of arrays in contaminant studies is under development
	Contaminant-induced changes in DNA include adduct formation, sister chromatid exchange, flow cytometry	Can have many causes; specificity varies with contaminant and evaluation technique
Reproduction- and growth-related		
Eggshell changes	There are many possible effects ranging from slight changes to lethal effects. Depending upon species and nature of reproduction, may be due to direct impact on developing organism or to impact on parent organism	Specificity depends upon the species and the life stage where exposure to contaminants occurs and the contaminant itself
	Thinning or weakening of eggshells	Caused by DDT and other halogenated organics

Table 11.1 Presently Used and Possible Bioindicators^a (Continued)

Bioindicator	Description	Stressor
Developmental problems — teratogenicity	Pertains specifically to failure of one or more organs or systems to develop properly.	Specificity depends upon the mechanism of action of the contaminant, time at which exposure occurs, and exposure level
Skeletal abnormalities	Greater than normal bilateral asymmetry	May be caused by halogenated polycyclic aromatic hydrocarbons
Growth rate	Reduced growth rate of young organisms	Nonspecific; can be due to direct effect on organism, effect on habitat, or effect on parent
Clinical-type measurements		
Blood chemistry	Change in levels of blood constituents that would be measured in typical human clinical testing; these include enzymes released by tissue damage, hormones (particularly corticosteroids, growth hormone, insulin and glucagon, reproductive hormones, thyroid hormones), vitamins (particularly vitamin A and its metabolites and vitamin C)	Many possibilities with varying specificities
Histopathologic	Impacts on a variety of tissues; can be detected by histochemistry	Specificity depends on contaminant, species, and tissue
Oxidant-mediated responses	Changes in levels of compounds such as glutathione (both oxidized and reduced and their ratios), ascorbate, and α -tocopherol, and in a variety of enzymes involved in radical scavenging, etc.	Caused by a wide variety of organic and inorganic contaminants
Porphyria	Disruption of normal porphyrin metabolism	Caused by halogenated PAHs and heavy metals
Bile metabolites	Metabolites of contaminants that are metabolized rapidly and may not be found as the parent chemicals in amounts that are readily measurable, may be found in measurable concentrations in bile	Variety of organic contaminants, but commonly used for rapidly metabolized PAHs
Immune competence	Impaired function of parts of immune process	Can be caused by chlorinated organics and heavy metals

^a Assignments to categories are arbitrary, some of the bioindicators could fit under several categories.

11.3 SUMMARY

Bioindicators of contaminant exposure presently used in environmental monitoring are discussed. Some have been extensively field-validated and are already in routine application. Included are (1) inhibition of brain or blood cholinesterase by anticholinesterase pesticides, (2) induction of hepatic microsomal cytochromes P450 by chemicals such PAHs and PCBs, (3) reproductive problems such as terata and eggshell thinning, and (4) aberrations of hemoglobin synthesis, including the effects of lead and of certain chlorinated hydrocarbons. Many studies on DNA damage and of histopathological effects, particularly in the form of tumors, have already been completed. There are presently numerous other opportunities for field validation. Bile metabolites of contaminants in fish reveal exposure to contaminants that might otherwise be difficult to detect or quantify. Bile analysis is beginning to be extended to species other than fishes. Assessment of oxidative damage and immune competence appear to be valuable biomarkers, needing only additional field validation for wider use.

The use of metallothioneins as biomarkers depends on the development of convenient, inexpensive methodology that provides information not available from measurements of metal ions. The use of stress proteins as biomarkers depends on development of convenient, inexpensive methodology and field validation. Gene arrays and proteomics hold promise as bioindicators for contaminant exposure or effect, particularly because of the large amount of data that could be generated, but they still need extensive development and testing.

12.1 INTRODUCTION

Organophosphorus (OP) and carbamate (CB) pesticides are used in domestic and natural environments for control of a wide variety of insect pests and disease vectors, other invertebrates, fungi, birds, and mammals; some CBs are used as avian repellents, and others have herbicidal properties. These two pesticidal classes, numbering about 200 OPs and 50 CBs, have been formulated into thousands of products that are available in the world's marketplace for varied applications to wetlands, rangelands, cultivated crops, forests, and rural and urban environs.¹⁻⁵ Except for mosquito control, these products are applied mostly on terrestrial landscapes. When applied according to the label, the active ingredient should be reasonably well contained within the intended treatment area. However, due to drift, runoff, or applicator error, the pesticide or toxic degradates are inevitably detected in water, soils, and vegetation outside the treated area — sometimes in toxic concentrations and for durations well beyond the expected residual life of the product. Off-site contamination of OPs and CBs has resulted in massive episodes of mortality of aquatic organisms,⁶ but the long-term implications of periodic transient mortality on ecosystem productivity has not been thoroughly evaluated. Free-ranging vertebrates have also suffered large-scale mortality from acute exposure to OP and CB insecticides within and peripheral to the treated area.⁷⁻¹⁰ OPs and CBs are acutely toxic to most animals with the potency of a chemical often widely variable among species.¹¹⁻²⁰

Most widely used OP and CB insecticides are highly toxic but relatively short-lived in nature (e.g., 2 to 4 weeks) and are readily metabolized and excreted by homoiothermic animals.^{2,3} These factors and broad-spectrum insecticidal efficacy favored OP and CB pesticides as replacements for the persistent and problematical mercurial and organochlorine compounds.²¹⁻²³ For example, certain organochlorine pesticides and metabolites bioaccumulate in food chains, inhibit proper eggshell formation, and severely jeopardize populations of fish-eating birds such as brown pelicans (*Pelecanus occidentalis*), bald eagles (*Haliaeetus leucocephalus*) and ospreys (*Pandion haliaetus*).²⁴ This type of chronic manifestation has not been demonstrated for OP or CB exposure, and it is not certain that OP- and CB-induced mortalities of nontarget vertebrates have critical effects at the population level. However, there is increasing evidence that mortality of raptorial birds from OP and CB poisoning may be affecting some species at the regional level.^{10,25}

The ecological hazard of OP and CB pesticides to wildlife is primarily from acute anticholinesterase toxicity but also includes species habitat association and foraging preference. Exposure may be directly from the pesticidal application, contact with or ingestion of contaminated water, soil or vegetation, or ingestion of contaminated prey or pesticide impregnated seeds or granules. Other factors also bear on wildlife tolerance of an OP- or CB-contaminated environment. For example, the prey base may be altered and affect foraging success; sublethal exposure may affect critical behaviors such as reproduction and migration; and proper balance between producer and consumer organisms in soil and aquatic systems may be disrupted.²⁶ Fish and other aquatic organisms also vary widely in tolerance of OP and CB exposure depending on inherent sensitivity and factors of water quality, chemistry, and temperature.²⁷

This chapter provides an overview of the hazard of organophosphorus and carbamate pesticides to avian and mammalian wildlife. Attention is given to practical environmental considerations rather than interpretation of laboratory studies that were detailed in the first edition of this book.²⁸ Invertebrates, fish, amphibians, and reptiles are exemplified as ecosystem components or for comparison with birds and mammals, but the toxicology of OP and CB pesticides to these taxa is presented in other chapters. The focus herein is on concepts of ecological toxicology of birds and mammals related to natural systems as affected by pesticidal application in agriculture and public health. The environmental fate of representative OP and CB pesticides, the availability of these pesticides to wildlife, and toxicology as related to ambient factors, physiological cycles and status, product formulations, and sources of exposure are discussed.

12.2 GENERAL TOXICOLOGY

12.2.1 Organophosphorus Pesticides

Organophosphorus chemicals comprise more than one third of the registered pesticides on the world market. Most registrations are for control of a large array of insect pests and disease vectors, but OPs effectively control many animal pests including other invertebrates and terrestrial vertebrates. Over 95% of the OP products presently in production are used in agriculture and mosquito control.²⁹ In the United States about 70 OPs are registered as the active ingredient (AI) in thousands of products, but only 10 to 15 of the chemicals account for over three fourths of the use. Examples of OPs that have been widely used in U.S. agriculture include azinphos-methyl, chlopyrifos, fonophos, malathion, methyl parathion, parathion, phorate, phosalone, and terbufos; OPs used extensively for mosquito control are fenthion, malathion, naled, and temephos. Many of these chemicals have been reviewed by regulatory agencies for environmental and public health concerns and are now classified as restricted-use pesticides in the United States; some uses have been cancelled. OPs registered for outdoor use have label warnings about toxicity to wildlife and application to wetlands.

The main concern about OPs is their acute lethal toxicity. Based on single-dose oral LD₅₀ tests, the above chemicals are among the most toxic OP pesticides to laboratory rodents and wildlife.^{11,13,15,16,30} Of the 12 chemicals, ten are classed highly toxic to birds (LD₅₀, <50 mg AI/kg body mass³¹), and seven are highly toxic to mammals. Only malathion is considered to be of a low order of acute toxicity to both birds and mammals (LD₅₀, >500 mg/kg). Chlorpyrifos and fenthion are moderately toxic (LD₅₀, 50 to 500 mg/kg) to mammals, and naled is moderately toxic to birds and mammals. Some OPs that have had most uses withdrawn or cancelled in the United States (e.g., dimethoate, EPN, monocrotophos, parathion, TEPP)⁵ remain available on the international market in spite of their demonstrated environmental hazard to human health and wildlife. In the U.S.S.R., pesticides with a single-dose oral mammalian LD₅₀ less than 50 mg/kg were banned in the 1960s; a few exceptions were permitted for use of granular formulations in agriculture.³²

The principal toxicity of OP pesticides is based on disruption of the nervous system by inhibition of cholinesterase (ChE; acetylcholinesterase, EC 3.1.1.7, and a mixture of nonspecific esterases) activity in the central nervous system and at neuromuscular junctions with death generally attributed to acute respiratory failure.³³ When OP binds to ChE, a relatively stable bond is formed and prevents the ChE from deactivating the neurotransmitter acetylcholine. This permits buildup of acetylcholine and overstimulation of the cholinergic nervous system. Some of the nonspecific signs following acute OP exposure of small mammals and birds include lethargy, labored breathing, excessive bronchial secretion, vomiting, diarrhea, tremors, convulsions, and death. These toxic indicators are useful when sick animals are found near an area of recent OP application, but the signs are not uniquely different from poisoning by other neurotoxic agents.^{1,16,33} In nature, notation of toxic signs is important in the investigation of a wildlife incident, while conclusive diagnosis depends on biochemical and chemical analyses for brain ChE inhibition and OP residues in the carcass.³⁴⁻³⁶ Biochemical diagnosis of OP and CB exposure is described in Section 12.4.7.

Two additional syndromes of single or very short-term OP exposure have been demonstrated in the laboratory. The first, referred to as an "intermediate syndrome," is a potentially lethal paralytic condition of the neck, limbs, and respiratory muscles.^{37,38} The paralysis from muscle necrosis follows an acute OP exposure by 2 to 3 days and is apparently initiated by depressed ChE activity and calcium accumulation in the region of the motor end-plate.^{38,39} This syndrome has not been identified as such in either laboratory or field studies of wildlife, but it could be an important factor in OP hazard in nature. For example, when flocking birds enter a hazardous OP-treated area, onset of acute toxicity often occurs within a few minutes in some birds, while others appear unaffected. If the intermediate syndrome plays a significant role, mortality away from the treated area could be much higher than generally believed. Examples of OP pesticides demonstrated to induce the

intermediate syndrome in mammals include fenthion, malathion, and monocrotophos.³⁸ Fenthion and monocrotophos have caused large-scale episodes of wildlife mortality; malathion has not. The possibility of intermediate syndrome from malathion has not been investigated.

The second syndrome of single-dose OP exposure is OP-induced delayed neurotoxicity (OPIDN) in which a relatively small dosage (e.g., 1/25 LD₅₀) of OP causes degeneration in the myelin sheath of long peripheral nerves and the spinal cord.⁴⁰ This debilitating malady develops in 1 to 3 weeks, causing a stumbling gait and incoordination. OPIDN has been demonstrated in a variety of laboratory animals including rodents, chickens, and mallards (*Anas platyrhynchos*); mallards do not appear to be as susceptible as chickens to OPIDN.⁴¹ Apparently, OPIDN is not related to anticholinesterase action of OPs.⁴² Most OPIDN-inducing pesticides are no longer on the market (e.g., leptophos and mipafox), but a few remain in use in some countries (e.g., cyanofenphos, EPN, methamidophos, trichlorfon, and trichloronate).^{38,42}

Subacute or subchronic exposure to repeated sublethal doses of OP have been demonstrated to affect birds and mammals in captivity^{28,43,44} and undoubtedly influences critical physiological functions in nature. However, validation of low-grade OP hazard to natural wildlife populations remains elusive. Some of the more likely sublethal effects on wildlife that live in or depend regularly on OP-contaminated forage and water include changes in response to ambient stressors, changes in foraging and reproductive behavior, and possible alteration in migration orientation. Whereas these effects appear related to anticholinesterase insult, other effects may be entirely independent of ChE inhibition. Examples include mutagenicity, carcinogenicity, and organ-specific toxicity to the heart and kidneys.⁴² Putative sublethal effects of OP exposure are discussed in Section 12.5.

12.2.2 Carbamate Pesticides

Fewer than one fourth of the registered carbamates in the world market are insecticides with significant anticholinesterase activity; the others are fungicides and herbicides with little acute hazard to birds and mammals. Of approximately 50 registered CB pesticides, only about eight (aldicarb, carbaryl, carbofuran, formetanate, methiocarb, methomyl, oxamyl, and propoxur) are used for insect control on crops, forests, and rangelands; methiocarb and methomyl are also used as avian repellents. Of these eight, carbofuran, methomyl, and carbaryl account for more than 90% of the use. As with OPs, CB insecticides have label warnings about toxicity to wildlife and application to wetlands.

CB insecticides exert their toxicity through acute ChE inhibition, and all of the above-named except carbaryl are classed highly toxic to birds and mammals.^{12,16} LD₅₀s are generally less than 20 mg/kg for both taxa and as low as 0.8 mg/kg for aldicarb with male laboratory rats and 0.5 mg/kg for carbofuran with male mallards. In contrast, the LD₅₀s for carbaryl are reported as 850 and >2,500 mg/kg for male rats and mallards.

Acute toxicity of CB insecticides including toxic signs are similar to that of OPs, except onset of and recovery from CB is faster than for equipotent exposure to OP insecticides.⁴⁵ The rapid reaction is partly because CB insecticides are direct ChE inhibitors that do not require metabolic activation for full potency as do most OPs. Rapid recovery is a product of near spontaneous reactivation of carbamylated ChE. Thus, an equipotent sublethal exposure of CB is generally less severe than OP exposure, and factors of delayed toxicity described for OPs do not occur with CBs.^{1,42}

12.2.3 Some Considerations

The toxicity of organophosphorus and carbamate pesticides varies considerably among vertebrates (Table 12.1). OPs and CBs do not bioaccumulate in food chains. Cumulative depression of ChE enzyme may occur and persist from repeated exposure to some OPs but generally not from CBs. CB and a variety of OP esters (e.g., acephate, monocrotophos, trichlorfon) are direct ChE inhibitors, but most OP pesticides (e.g., diazinon, malathion, parathion) must first undergo an

Table 12.1 Acute Response of Fish, Laboratory Rats, and Birds for Anticholinesterase Pesticides of Widely Variable Mammalian Toxicity

Pesticide	Rainbow Trout ^a	Bluegill ^a	Laboratory Rat ^{b,c}	Ring-Necked Pheasant ^{b,d}	Red-Winged Blackbird ^{b,e}

^a LC₅₀ = µg of active ingredient per liter of water calculated to kill 50% of test population during a standard 96-h exposure. Tests were conducted under static conditions (pH 7.2-7.5 at 10-13°C for trout or 20-22°C for bluegills), *n* = 50-60 per test.¹⁴

^b LD₅₀ = mg of active ingredient per kilogram of body mass calculated to kill 50% of test population.

^c Sherman strain male laboratory rats, 3 months old, *n* = 50 to 60 per test; dosage by gavage in peanut oil.^{11,12}

^d Farm-reared male and female ring-necked pheasants, 3 to 4 months old, *n* = 8 to 28 per test; dosage by gelatin capsule.¹⁶

^e Wild-captured pen-conditioned male and female red-winged blackbirds, adult, *n* = 8 to 28 per test; dosage by gavage in propylene glycol.¹⁵

oxidative desulfuration step for maximum anticholinesterase potency.^{2,33} This toxicating step is mediated by mixed-function oxidases (MFO) in the liver of vertebrates and in the fat body, malpighian tubules, and digestive tract of invertebrates. MFO activity varies widely among vertebrates in the following order: mammals > birds > fish.^{46,47} (The place of amphibians and reptiles in this ranking has not been determined.)^{48,49} The same physiologic system responsible for toxication of most OPs also has a primary role in their detoxication. Since OP and CB metabolism occurs primarily in the liver of vertebrates, the portal of entry into the circulatory system is important to acute toxicity. CBs and direct-acting OPs may be more hazardous through inhalation than through ingestion where substances are routed through the liver and first-phase metabolism. The environmental hazard of inhalation toxicity has not been thoroughly evaluated but is generally believed less important than ingestion. Likewise, percutaneous exposure to OP and CB pesticides has not been adequately studied in wildlife, but in nature the composite of inhalation, percutaneous exposure, and ingestion must all be considered in hazard prediction and understanding differences of species' response to OP and CB applications. It is important that OP toxication via oxidative desulfuration also occurs in nature as mediated by microbial metabolism in soils and by phytometabolism, but this process is slow compared to MFO metabolism in vertebrates.

The toxic consequences of OP or CB application to aquatic and terrestrial wildlife usually last only a few days. However, multiple applications of pesticide are the rule during the growing season; this extends the potential hazard to wildlife. In areas where a variety of crops are cultivated, exposure to a variety of pesticides and unexpected hazard may occur, especially to highly mobile wildlife. Other factors of variability must also be considered in hazard assessment of OP and CB pesticides. Predator-prey or competitor balance among invertebrates and aquatic vertebrates may be disrupted. Daily activity patterns, energy budgets, and various behaviors of terrestrial vertebrates may be affected. Repeated application of these biologically labile chemicals may cause cumulative physiological effects without a corresponding accumulation of chemical residues such as occurs for heavy metals and organochlorine pesticides. Recovery from anticholinesterase exposure may differ among pesticidal classes. For example, 1 to 3 weeks may be required for brain ChE activity to recover in vertebrates receiving a single exposure to OPs,^{50,51} but only a few hours may be necessary

to recover from CB exposure.⁵²⁻⁵³ Many of the confounding variables will become evident in the following section on environmental fate and hazard of several representative OP and CB pesticides.

12.3 ENVIRONMENTAL FATE AND HAZARD

The first considerations of environmental fate and hazard of organophosphorus and carbamate pesticides are agricultural crop, products formulation, rate and method of application, likelihood of wildlife exposure, and the biological and physical characteristics of any wetlands likely to receive runoff. OP and CB pesticides are comparatively labile in circumneutral environments and readily degrade under conditions of alkalinity, rain, sunlight, and temperature.^{2,3,54} Neither bioaccumulation nor biomagnification occurs to any important degree in aquatic or terrestrial food chains. The main hazard of OP and CB exposure to wildlife is from short-term, potentially lethal exposure to pesticidal treatment. This may include direct contact via inhalation and percutaneous routes or from ingestion of contaminated food and water. Classic secondary poisoning through biomagnification of highly lipid soluble pesticides, such as chlorinated hydrocarbons, does not happen with OP and CB compounds. Instead, predators are often poisoned by feeding on prey that had been contaminated by pesticidal application. For example, invertebrates and aquatic vertebrates adsorb OP and CB pesticide on their cutaneous surface or mucosal coating, which is then readily dissociated and absorbed when eaten by another animal.²⁸ Predatory birds have also been poisoned from eating insects that had ingested systemic OP and CB while foraging on vegetation.¹⁰ The stomach contents of poisoned birds and mammals may contain large concentrations of OP and CB that have proven toxic to predators and scavengers.⁵²

OP pesticides and anticholinesterase CBs have broad-spectrum toxicity to most animals with a cholinergic-dependent nervous system. OP and CB products are used as stomach and contact poisons for nearly any type of insect control; about 20% of OP and 40% of CB insecticides have systemic activity. They are also used as acaricides, nematocides, rodenticides, avicides, and bird repellents. As mentioned, a few OPs (e.g., butylate, EPTC, molinate) and many CBs have herbicidal properties, and some CBs receive wide use as fungicides (e.g., benomyl, maneb, mancozeb). In spite of their broad toxicity, OPs such as fenthion, naled, and malathion are widely used over wetlands and areas of human habitation for mosquito control.²⁹ ChE-inhibiting CBs are not as extensively applied on natural wetlands as are OPs, and CBs other than carbaryl are not applied extensively near human habitation.

Except for mosquito control, nearly all OP and CB application is on terrestrial landscapes. Nonetheless, pesticidal treatment of farmlands, forests, and cities results in the contamination of adjacent aquatic systems by some of the pesticide and its degradates. It has been theorized that all pesticidal chemicals will eventually enter an aquatic environment and affect a much larger number of species than originally intended.¹⁹ The hazard of OP and CB pesticides to nontarget life is a product of the amount, rate, and form of residual entering the aquatic system as well as the dynamics and chemistry of the system. For example, if runoff from a pesticidal application enters a stream, rapid dilution and dispersal may soon render the contamination ecologically innocuous. In contrast, if the same runoff enters an aquatic sink, such as a farm pond rich with detritus, the ecological consequences may be considerable to organisms at all levels including terrestrial species. In general, the residue levels of OP and CB compounds in natural waters are as follows: closed pond > free-flowing waters > lakes > estuaries > open sea.¹⁹

Contamination of small closed ponds has resulted in large incidents of mortality of waterfowl and predatory birds including northern harriers (*Circus cyaneus*) and golden eagles (*Aquila chrysaetos*) in the northern plains of the United States. In this example a granular formulation of phorate was incorporated into the soil for nematode control. Heavy rains occurred several months after application and facilitated the transport of phorate and degradates into small ponds, resulting in mortality of aquatic and terrestrial animals for 2 to 3 weeks following the storm event. Similar scenarios leading

to mortality from OP and CB leaching from granular formulations have been documented for agricultural application of pesticides such as parathion, diazinon, and carbofuran.⁶ Wildlife have been acutely poisoned by ingesting OP- and CB-impregnated granules and by foraging in areas treated with flowable and emulsifiable concentrate formulations and technical grade pesticide.^{4,6,10,52}

12.3.1 Organophosphorus Pesticides

Phosphorothioic acids contribute more than 90% of the OP pesticide use in the United States. These pesticides require metabolic activation for maximum anticholinesterase effect and vary widely in acute toxicity and chemical stability in the environment. Phosphoric acids, representing nearly all of the remaining OP pesticides, do not require metabolic activation for toxicity and, except for acephate and ethoprop, are presently of little importance in the United States. This is because voluntary withdrawal and regulatory restrictions have reduced the market for some previously widely-used and extremely toxic products such as dicrotophos, mevinphos, monocrotophos, and phosphamidon.⁵ The major phosphoric acid products on the U.S. market are acephate and ethoprop, while the others remain available on other world markets.

As discussed, OP pesticides are labile in natural environments, which generally limits their hazard to only a few days for vertebrates depending on a variety of ambient factors related to method of application and formulation of product. In contrast, a few OPs, such as phorate in the above example, have hazard potential to wildlife for a longer period due to systemic action and toxic degradates.

12.3.1.1 Case Study: Phorate

Phorate is one of a small but widely used group of highly efficacious insecticide-acaricide compounds whose environmental degradates are more toxic and stable than the parent chemical. This feature increases their potential hazard to wildlife but also increases their marketability as broad-spectrum systemic pesticides for foliar application and incorporation into the soil. Examples of these structurally similar OPs include phorate, (EtO)₂ PS.SCH₂ SEt; disulfoton, (EtO)₂ PS.SCH₂CH₂Set, and terbufos, (EtO)₂ PS.SCH₂ SBU.t55, are extremely toxic to mammals and birds (LD₅₀, <10 mg/kg).^{12,16} For comparison, the acute toxicity of methyl parathion and carbofuran has been reported as 14 and 11 mg/kg for rats¹² and 10 and 0.5 mg/kg for mallards.¹⁶ These pesticides are also highly toxic by the dermal route of exposure.^{5,12}

This group of pesticides has an additional oxidative pathway of toxication in the environment that is mediated primarily by UV irradiation in water and soil, to a lesser degree by microbial metabolism,⁵⁶ and by phytometabolism in plants.⁵⁷ As with the parent compound, the sulfoxide and sulfone degradates also require the oxidative desulfuration step to increase anticholinesterase potency.

With phorate as the model, several observations on environmental fate are important to the ecological hazard of these unique phosphorothioic acid pesticides. The fate of phorate in water is determined by pH, temperature, and photolysis.² Phorate is stable in water at about pH 5; its half-life in pH 6 water at 25°C is about 7 days.⁵⁸ The rate of hydrolysis increases about tenfold per pH unit under alkaline conditions. Irradiation by UV light oxidizes phorate within minutes to its more potent ChE-inhibiting sulfoxide and sulfone degradates.⁵⁶ Neither aquatic invertebrates nor fish tend to bioaccumulate phorate in model ecosystems,⁵⁹ but phorate is highly toxic to fish. For example, in comparable standardized 96-hour LC₅₀ tests, phorate is more than 100 times as toxic as methyl parathion and carbofuran to an array of both warm- and cold-water game fish.¹⁴

The fate of phorate in soil is affected by pesticide formulation, the method and rate of application, soil type, pH, temperature, moisture content, irrigation and water percolation, vegetation type and abundance, and microbial populations.^{60,61} Surface application of either granular or emulsifiable phorate results in 15 to 20% loss due to volatilization within 1 h; thereafter, nearly all the residual phorate remains bound to the soil particles but undergoes UV irradiation and oxidation to

sulfoxide and sulfone degradates within a few days. Up to 80% of these highly toxic degradates persist in various soil types for 1 to 2 months.⁶⁰ The terrestrial dissipation half-life of phorate in irrigated soils is 2 days in sandy loam and 9 to 15 days in silty loam. For sulfoxide and sulfone degradates, the half-life in sandy loam is 12 to 18 weeks.⁶² Phorate movement is more rapid in summer than in winter, but it is more stable in winter, probably due to lower microbial activity.⁶¹ Phorate is poorly soluble in water (~50 mg/L), and residues do not migrate extensively from the treated area. However, residues may be transported by erosion and runoff from agricultural fields into aquatic systems, where they have caused major episodes of fish and bird mortality.⁶

Soil-incorporated phorate is readily translocated through the roots and stems of plants and provides insecticidal protection to plants for a relatively long time because of the greater persistence of the sulfoxide metabolite.² The initial oxidation to sulfoxide proceeds rapidly in plants, whereas further oxidation to sulfone and desulfuration goes more slowly. Anticholinesterase activity increases as phorate oxidation proceeds to the most toxic sulfone. The oxon analog of each form is even more potent. Therefore, the anticholinesterase activity of phorate assimilated into plants increases for several days and only then gradually loses activity over 2 to 5 weeks.² Because of this systemic activity, phorate poses a potential hazard to herbivorous animals including wildlife and livestock.

In summary, phorate, like most widely used OP pesticides, is highly toxic to vertebrates. However, where most OPs rapidly degrade to biologically inert products, phorate degrades to more stable and potentially more potent anti-ChE products. This contributes to the systemic efficacy of phorate but also extends its hazard compared to other systemic OP insecticides. Examples of other systemic OPs include acephate, dicrotophos, oxydemeton-methyl, and phosphamidon; all are direct-acting ChE inhibitors.

12.3.2 Carbamate Pesticides

Carbamates with significant anticholinesterase activity were developed as analogs of alkaloid extracts of the calabar bean (*Physostigma venenosum*). Elimination of the polar moiety of the natural drug enhanced lipid solubility and penetration of the insect cuticle and nerve sheath, leading to broad-spectrum insecticidal activity.^{3,54} Most insecticidal products are phenyl N-methylcarbamates (e.g., carbaryl, carbofuran, propoxur); the others are oxime carbamates (e.g., aldicarb, methomyl, oxamyl).⁵⁵ Carbofuran and most oxime carbamates have significant systemic activity in plants. All CB insecticides are potent anticholinesterases and highly toxic to most invertebrates, and many are highly toxic to vertebrates. Birds and mammals receiving sublethal exposure to CB readily detoxicate the molecule and appear to fully recover within a few hours. There is little evidence that herbicidal and fungicidal CBs pose important hazard to terrestrial wildlife.⁴ For example, none of these CBs have significant anticholinesterase activity, and only one of the widely used products has a mammalian LD₅₀ of less than 1000 mg/kg (molinate, 720 mg/kg for laboratory rats), while most yield LD₅₀s above 2000 mg/kg for birds and mammals. However, some products are highly toxic to fish.¹⁴

Carbamate insecticides are generally short-lived as foliar applications (e.g., 1 to 4 weeks) and require several applications during growing seasons; when applied to soil, significant residues may persist 2 to 16 months.³ Little information is available on the biological hazard of multiple applications or on the importance of comparatively more persistent but less toxic degradates of CBs such as aldicarb and carbofuran. Both of these compounds are highly toxic to terrestrial animals^{3,4,6} and aldicarb is toxic to fish;¹⁴ carbofuran is not nearly as toxic as aldicarb in 96-hour LC₅₀ tests with freshwater fish.¹⁴ Toxic residues of aldicarb and its degradates (mostly aldicarb-sulfoxide and sulfone) have been detected in ground water and farm produce as long as a year after application.^{63,64} Due to extreme mammalian toxicity and hazard to farm workers, aldicarb is a restricted-use pesticide in the United States. Carbofuran is also a restricted-use pesticide, but it is still widely used in spite of regulatory concerns about its environmental hazard.^{6,65}

12.3.2.1 Case Study: Carbofuran

Carbofuran is used mostly in granular formulations for control of soil and foliage insects and agricultural nematodes. Flowable formulations were used extensively in the United States through the early 1970s and resulted in large-scale episodes of wildlife, mostly waterfowl, mortality. Thereafter, granular formulations were favored, but similar incidents of mortality continued.^{65,66} These incidents usually occurred within the first 2 to 3 days following approved pesticidal application to field crops. Additional incidents of mortality of both terrestrial and aquatic wildlife have also been documented subsequent to heavy rainfall for more than 6 months following application.

Carbofuran is the epitome of an acutely toxic environmental poison. That is, a trivial exposure (e.g., 0.1-5 mg/kg) may be lethal in less than 5 min, especially to some waterfowl and passerine birds.^{13,16} Other individuals exposed to the same and even higher dosages (e.g., > LD₅₀) may exhibit intense signs of poisoning within the same time frame and then abruptly recover and become fully alert and ambulatory within as little as 30 min posttreatment.^{45,67} In captivity, survivors of this initial toxicity appeared to recover fully; whether similar recovery would occur in nature is questionable. For example, on the day after an application of carbofuran on alfalfa both dead and living American wigeon (*Anas americana*) were in the field.³⁶ After a brief period of observation, the field was entered, and many of the birds flew to a nearby irrigation canal only to die soon thereafter. It was not known how long the wigeon had been in the field when approached or whether they were experiencing the onset of toxicity or were recovering from toxicity when flushed. However, during initial observations many normal appearing birds were noted feeding on the alfalfa in the same location where others had died.

It has been determined experimentally that birds may continue foraging on potentially lethal carbofuran-treated feed immediately upon recovery from a toxic episode, and without apparent effect.⁶⁸ In 5-day feeding studies with 1- to 21-day-old Japanese quail (*Coturnix japonica*), nearly all mortality and overt toxic signs from all graded exposures subsided within about 6 h of initial presentation of carbofuran. Both recovered, and apparently unaffected birds continued feeding on their carbofuran diets at the same rate and with comparable growth as controls on untreated diet. A few birds died later in the studies at most levels of exposures. Because these birds were tested in groups and not handled during treatment, it was not determined which individuals had previously shown overt toxicity. However, once toxicity occurred on day 3 or 4, the birds showed signs characteristic of acute poisoning and promptly died. In reference to the above wigeon example: (1) wild birds may initially recover from acute carbofuran exposure and then continue foraging on the same diet; (2) it is not certain that such recovered wild birds can also tolerate natural stressors such as fright response, extended flight, or adverse weather in the short term.

As mentioned, the most common hazard of carbofuran to wildlife is foraging in treated fields shortly after pesticidal application to foliage. Ambient factors of wind, rain, and UV irradiation rapidly reduce the hazard of readily available pesticide in its most toxic form within 2 to 3 days, even though systemic insecticidal activity may continue for more than a month.³ The availability of contaminated invertebrate prey diminishes precipitously immediately following a carbofuran treatment. Even for grazing waterfowl, such as the American wigeon and Canada goose (*Branta canadensis*), the hazard of carbofuran poisoning is greater immediately after treatment than after its incorporation into plant tissue. Another hazard that has been substantial to both aquatic and terrestrial life is periodic surges of pesticide into wetlands from runoff of heavy rainfall.⁶ In this situation the source of the carbofuran has often been granular product that had been incorporated in the soil. Though soil incorporation of granular would seem safe, wildlife mortality has occurred within a day following careful application of carbofuran according to the best available technology.⁶⁹ A form of secondary poisoning other than eating contaminated insects has also been documented for carbofuran. Predatory and scavenging birds and mammals have been poisoned by eating the entrails, including unabsorbed carbofuran in the stomachs of dead animals,^{69,70} sometimes as long as 6 months after application of pesticides for control of soil pests.⁷¹

General factors affecting the hazard of carbofuran to wildlife include formulation and application, its water solubility and potential for leaching and transport out of the treated area, and the likelihood of its entrance into wetlands. Carbofuran is soluble in water to about 700 mg/L and essentially stable in acidic medium.³ The fate of carbofuran in water is influenced by pH, photolysis, temperature, and trace impurities.⁷² The half-life of carbofuran in distilled water at 25°C and pH 5.5, 7, 8, and 9 is about 16 years, 1 month, 6 days, and 6 h, respectively.⁷³ The rate of hydrolysis is positively correlated with ambient temperature. Neither aquatic invertebrates nor fish tend to bioaccumulate carbofuran in slightly alkaline model ecosystems.⁷³⁻⁷⁵

The fate of carbofuran in soil is affected by pesticide formulation, rate and method of application, soil type, pH, rainfall and irrigation, temperature, moisture content, and microbial populations.^{3,76} Carbofuran decomposes rapidly in alkaline soil and is stable at pH 5.5; the hydrolytic half-life in soil at pH 7 is about 35 days.⁷³ Temperature and moisture content are positively correlated with degradation; maximum degradation to hydrolytic metabolites occurs at 27°C.⁷⁷ The terrestrial dissipation half-life of carbofuran in irrigated soils is 4 to 11 days in sandy loam, 1 month in loam, and less than 5 months in silty loam.⁶ Carbofuran is mobile and has been found in streams, surface water, and runoff sediments from treated watersheds.⁶ This suggests carbofuran may be quite stable in association with acid precipitation.²⁸ It is also suggested that carbofuran could leach into ground water, where it could persist at characteristically acidic pH, like aldicarb.^{64,65}

Carbofuran degrades within about 7 to 10 days on crops such as alfalfa sprayed with flowable formulations.⁷⁸ In-furrow application of granular formulation is readily translocated through the roots and stems with insecticidal activity continuing in foliage for 2 to 4 months.^{3,79} Even when granules are covered by soil, toxic carbofuran residues may be available to herbivorous animals.

Carbofuran is readily metabolized in living animals and is rapidly excreted. Toxicologically important bioaccumulation of either parent compound or degradates does not occur in either invertebrates or vertebrates.⁷³ Nonetheless, secondary hazard from carbofuran occurs in predatory vertebrates that feed on dead and struggling insects, earthworms, and small birds and mammals. As mentioned above and in the case study of phorate, this source of poisoning is most likely from unabsorbed carbofuran in the gut of the primary subject.

12.3.3 Wetlands

Organophosphorus and carbamate insecticides are generally not permitted for use on wetlands. An exception is a few OP products used for mosquito control, most notably malathion, but even this use is decreasing in favor of synthetic pyrethroids and biological control agents. However, wetlands are routinely contaminated during agricultural use of a wide array of OP and CB products. Drift, direct overspray, and runoff are sources of contamination when farmlands border natural wetlands, irrigation canals, and drainage ditches.⁶ Ground application of pesticide contaminates wetlands through volatilization, migration, and runoff, but drift from this source is not equal to that of aerial treatment. It has been estimated that downwind drift from aerial application is conservatively four times higher than produced by higher clearance ground sprayers.⁸⁰

Small streams and ponds are especially prone to OP and CB contamination from overspray, drift, and runoff. This is partly because they are difficult to avoid during aerial application when crops abut the wetlands. Of more importance, however, is the fact that these small wetlands, often less than a hectare in size and only 1 to 2 m deep, are not fully appreciated for their intrinsic value in regions dominated by expansive farmlands and monocultures. For example, in North America's prairie pothole region of south-central Canada and the north-central United States, about 65% of the original wetlands have been drained and put in cultivation.⁸¹ The remaining wetlands contribute more than 50% of North American's duck production.⁸² A very large proportion of these wetlands are near or surrounded by agricultural fields and are considered of high potential for excessive agricultural pesticide contamination.^{83,84} OP products constitute the majority of the pesticide use in the region.

Agricultural contamination of small and sometimes only seasonal wetlands is probably the most ecologically abusive use of OP and CB pesticides. Many of these wetlands are extremely productive in terms of biomass and wildlife dependence during critical spring and summer periods. These small ponds contain proportionally little volume to surface area for dilution and buffering of toxicity compared to larger ponds and lakes. OP and CB insecticides may seriously offset invertebrate populations for the short-term. However, most OP and CB products are inactivated within a few hours in circumneutral aquatic environments and within a few days to 1 to 2 weeks in more acidic systems. This rapid degradation is ecologically advantageous because most knocked-down invertebrate populations seem to recover rapidly from a single operational OP or CB treatment. The cumulative effects of multiple applications on species diversity, balance, abundance, and total biomass are not well understood for different product formulations or aquatic systems.

The U.S. Fish and Wildlife Service developed a comprehensive research plan in the mid-1980s to evaluate hazard of pesticides to aquatic invertebrates and waterfowl in the prairie pothole region of North America.⁸⁵ The studies focused on an array of "average" potholes of similar size and depth to determine the response of mallard and blue-winged teal (*Anas discors*) to "typical" treatments of parathion and methyl parathion on wheat and sunflowers. In both studies each of five broods was confined to a fenced pothole and permitted to roam throughout the pond and riparian zone to the edge of the treated crop that surrounded the pothole. Each pothole was believed to be of adequate size and quality to provide necessary cover, spatial, and nutritional requirements for simultaneous fledging of several mallard broods. (Details of this research initiative have been summarized in several case studies.⁸⁶)

In the study of spring wheat the first step was to treat all of the fields, including the ten potholes, with an aerial application of the herbicide 2,4-D (0.3 kg AI/ha), which is a standard practice in the region. One month later one half of the fields and ponds were treated by standard operational application of parathion (0.6 kg AI/ha), and other fields and ponds were treated with methyl parathion (0.3 kg AI/kg). All treatments were made from 1.5 to 2 m above the crop, which resulted in a spray swath of about 18 m. Three days prior to the insecticide treatments 10 to 12 3-week-old mallards and 10 to 12 3-week-old teal were released on each wetland. The ducklings were sampled at 2 and 7 days after the treatment, and then at about weekly intervals through 30 days posttreatment. Body mass, tissue residues of OP, and brain ChE activity were evaluated at each sample period. None of the ducklings died from OP poisoning, but within 2 days posttreatment, 27% of the ducklings on parathion-treated ponds and 29% of those on the methyl parathion treatment had significantly depressed ChE activity. Body mass was not affected. Behavioral and population studies did not indicate any differences in the number of wild broods or adults of either species on treated and control fields.

In the study of sunflowers an operational⁸⁷ aerial treatment of parathion was evaluated. The main differences from spring wheat studies were the use of younger mallards (1 to 3 days of age), the release of two broods of 10 to 12 ducklings with their hens in each pond, and near doubling of the rate of parathion treatment (1.12 kg AI/ha). This was the maximum recommended treatment for sunflowers in North Dakota. One half of the study wetlands were oversprayed to test the worst-case scenario. For the other half of the wetlands, the operator attempted to achieve complete crop coverage, while avoiding overspray of the ponds. Overall, more than 90% of the ducklings in the oversprayed ponds were dead within 3 days posttreatment. Brain ChE activity was inhibited an average of 76% compared with ducklings collected on control wetlands. In this study parathion residues were determined in several matrices (water, vegetation, insects, and snails) 1 day prior to spray and 1, 7, 14, and 29 days posttreatment. All prespray samples were clear of parathion. All samples contained parathion (mean residues: water, 0.12 µg/mL; insects, 0.29 µg/g; snails, 9.04 µg/g; and vegetation, 0.42 µg/g) 1 day posttreatment and by 7 days all samples were clear of detectable residues. Ground searching of the oversprayed ponds and their riparian zones yielded more than 30 dead birds with inhibited brain ChE activity. Over two thirds of the dead birds were juveniles of blue-winged teal, American coot (*Fulica americana*), red-winged blackbird (*Agelaius*

phoeniceus), and yellow-headed blackbird (*Xanthocephalus xanthocephalus*). For the wetlands where reasonable effort was made to avoid direct pond overspray while providing complete crop coverage, parathion was not attributed to the death of any of the ducklings. Likewise, there was not evidence of other birds having been acutely poisoned by the treatment. Wetland residues of parathion were also much less than for the oversprayed ponds. The mean residues for key wetland matrices 1 day posttreatment were also much less than for the oversprayed ponds. The mean residues for key wetland matrices 1 day posttreatment were: water, 0.01 µg/mL; insects, 0.13 µg/g; snails, 3.04 µg/g; and vegetation, 0.35 µg/g. The effort to avoid direct overspray of small wetlands eliminated OP-induced avian mortality and reduced parathion in water (> 90% and invertebrates 34 to 45%).

These studies were invaluable in demonstrating that: (1) standard commercial aerial application of flowable OP may be directly lethal to avian wildlife on small wetlands and (2) adjustment in application to avoid direct overspray reduced the inherent hazard of highly toxic OP to avian wildlife and critical components of the pothole ecosystem. Though an inconvenience to the applicator, the benefits of improved precision in broad-spectrum pesticidal application are clearly warranted in protection of North American waterfowl production. Similar studies, generally absent from the literature, are needed to identify practical problems and provide solutions. Even though OP and CB pesticides are not considered persistent in the same terms as organochlorine pesticides, there is ample evidence of wildlife mortality in wetlands as long as 6 months after application of granular formulations, e.g., phorate, fensulfothion, carbofuran.^{4,6,66,71} These mortalities were mostly delayed effects of leaching and pesticide availability in water killing waterfowl, which were then eaten by scavenging predatory birds and mammals. It has not been demonstrated that flowable formulations of either OP or CB insecticides produce the same long-term hazard as granular formulations.

12.3.4 Mosquito Control

Mosquito control is the only major use of organophosphorus pesticides on wetlands in the United States, and carbamates are not used in mosquito control. However, OPs and CBs are used extensively in mosquito control outside the United States. OP use is being supplanted by biological control agents such as BTI (*Bacillus thuringiensis israelensis*) and other subspecies (e.g., *B.t. darmstadiensis*, *B.t. kyushuiensis*, *B.t. galleriae*), fungus (e.g., *Lagenidium giganteum*) and anti-juvenile hormone enzymes.⁸⁸ This transition is in response to pesticides needed for wide-scale application to wetlands and areas of human habitation and is becoming necessary to overcome developing resistance of some mosquito species to chemical control agents.

Mosquito control routinely uses OPs throughout the world for suppression of nuisance mosquitoes and disease vectors. For example, under the threat of encephalitis epidemics following hurricanes and floods, thousands of hectares of contiguous bottomlands and major populated areas of the United States have been aerially sprayed with undiluted OPs, such as malathion, at rates as small as 219 mL/ha.²⁹ These ultra-low-volume treatments are efficient and comparatively safe for use wherever there is a need for rapid application of OP to large or remote lands.⁸⁹ Only a few OPs, such as malathion, naled, and fenthion, have been used extensively for mosquito control as ULV sprays, and none has been implicated in serious human health effects. This does not imply such treatments are without environmental hazard. In May 1969 undiluted fenthion was applied by helicopter at the recommended rate of 95 mL/ha to approximately 600 ha of a portion of the Red River and residential and park areas of Grand Forks, North Dakota.⁹⁰ Over the course of 2 days more than 450 birds representing 37 species were found dead or moribund within the fenthion-treated area. Most of the dead birds were warblers and other species that feed mainly on invertebrates. The mortality was finally estimated at more than 5000 birds in and around the city. In part because of this extreme incident of wildlife mortality from a standard mosquito-control application, many other studies have been conducted on fenthion mosquito control.²⁹ Though most studies resulted in avian mortality, fenthion remains a favored OP for use in mosquito control throughout much of the world.

Mosquito-control agents are normally used in areas of human activity and habitation and should not be either acutely toxic to mammals or induce serious side effects. The oral LD₅₀s for laboratory rats of favored mosquito-control agents in the United States, such as fenthion, malathion, temephos, chlorpyrifos, and naled, vary from about 150 (chlorpyrifos) to 8600 mg/kg (temephos).¹² Thus, LD₅₀s for these OPs are considered only moderately (chlorpyrifos, fenthion, and naled) to slightly (malathion and temephos) toxic to mammals, according to the acute toxicity ranking of Loomis and Hayes.³¹ However, all except malathion are classed highly toxic to birds. Fenthion may also induce potentially lethal “intermediate syndrome” in mammals.^{37,38} This syndrome has not yet been diagnosed in birds or wild mammals.

All of the above mosquito-control agents except temephos are broad-spectrum insecticides that are also widely used in agriculture. Temephos is used almost exclusively for mosquito, midge, and black-fly larvae control in lakes, ponds, and wetland habitats.⁴ All of the OPs are acutely toxic to susceptible invertebrates and fish within a few minutes of exposure but are poorly soluble and rapidly degraded in water (e.g., 2 to 72 h in circumneutral water) and have little potential for bioaccumulation in nature.⁹¹ For reference, except for temephos, all of these mosquito-control agents are generally more toxic to fish and aquatic invertebrates than are parathion or methyl parathion, are restricted-use pesticides in the United States, and are extremely toxic to natural pollinators such as honey bees (*Apis mellifera*).⁵ The potential hazard of these mosquito-control agents to bee pollinators is greater during general aerial application for nuisance and disease vector control than when applied to wetlands for larvae control.

In conclusion, malathion remains the primary OP adulticide for use in event of mosquito-transmitted disease epidemics in the United States, but with developing evidence of OP resistance in many mosquito populations its continued efficacy and large-scale use is being reconsidered. Development of alternative methods is in progress, and these alternative methods are generally believed to be less hazardous when used in wetlands. OP larvicides are likely to soon be replaced by alternative larvicides such as BTI and other biologicals. Such alternatives are expected to be safer in wetland applications.

12.4 FACTORS OF ACUTE HAZARD

Short-term life-threatening exposure is the principal hazard of organophosphorus and carbamate insecticides to aquatic and terrestrial wildlife. Nearly all applications of the more toxic products are on cultivated crops and, depending on the formulation and treatment, may remain potentially lethal to nontarget vertebrates for several days. These same treatments have sometimes contaminated nontarget wetlands. Such aquatic incidents usually involve large numbers and kinds of wildlife, often including birds and mammals. Sometimes aquatic toxicity lasts only a few hours depending on the system's capacity to dilute and degrade the contamination. In contrast, granular formulations, even when incorporated into the soil, have proved toxic to birds and mammals immediately posttreatment and again later when either granules or leachate become available to wildlife.⁷¹

Considering different scenarios of exposure and that multiple applications of insecticides are routine during a growing season, many forms of toxicity could manifest from OP and CB exposure. Perhaps they do, as will be discussed later, but the overwhelming effect is lethality. Most factors contributing to the acute toxicity of OP and CB insecticides in nature have been reasonably understood for at least two decades; therefore, only basic concepts are summarized here.

12.4.1 Comparative Toxicology

Organophosphorus and carbamate insecticides and product formulations vary widely in toxicity to different aquatic and terrestrial vertebrates.^{4,14,48,49,92} Those pesticides that are esters of carbamic acid and phosphoric acid are direct ChE inhibitors that invoke toxicity immediately upon absorption

into the circulatory system. Most OPs are esters of phosphorothioic acid and must undergo an oxidative desulfuration step for maximum anticholinesterase potency, as described earlier under general toxicology. Direct-acting ChE inhibitors may be more hazardous through inhalation and percutaneous exposure than are phosphorothioic acids.

Metabolic responses to OP and CB insecticides are similar for birds and mammals with any difference more quantitative than qualitative.⁹³ Several quantitative enzymatic differences between birds and mammals are important to differential response to acute toxic exposure. Birds generally have lower levels of hepatic metabolizing enzymes and A-esterase activity than do mammals, which tends to make birds more sensitive to acute anticholinesterase poisoning.^{46,47,94} However, the majority of widely used anticholinesterase pesticides are phosphorothioic acids that must be metabolically activated to their most potent analog. This step is mediated by the same hepatic enzymes as detoxication in birds and mammals.² This would suggest that mammals should toxicate phosphorothioic acids more efficiently than birds and be the more sensitive taxa. But this is not so, because activated OP analogs are substrates for A-esterase hydrolysis and are rapidly detoxified in the liver and blood. In a study of 14 species of birds, three species of laboratory mammals, domestic sheep, and humans, plasma A-esterase was at least 13 times higher in all mammals than in any of the avian species.⁹⁴ The importance of these enzymatic differences to birds was demonstrated with dimethoate, a phosphosothioic acid, in which adult ring-necked pheasants (*Phasianus colchicus*) and laboratory rats were compared. The toxic oxygen analog was rapidly formed and accumulated in pheasants but was rapidly degraded to inactive metabolites in the rats.⁹⁵ This undoubtedly contributed to the more than tenfold difference in the acute oral sensitivity of pheasants (LD₅₀, 20 mg/kg)¹⁶ and rats (LD₅₀, 215 mg/kg).¹²

In general, the array of domestic and wild bird species commonly studied in the laboratory are consistently more sensitive to acute oral toxicity of OP and CB insecticides than are laboratory mammals and wild mice (*Peromyscus* spp.) and voles (*Microtus* spp.).^{11-16,30} Though this generalization of differential acute sensitivity is convenient for preliminary risk assessments, it is not reliable for all species and pesticides.²⁶ For example, the acute toxicity of a series of phosphorothioic acid pesticides was compared for standardized LD₅₀ tests of adult male laboratory rats,¹² ring-necked pheasants,¹⁶ and red-winged blackbirds¹⁶ (Table 12.1). Pheasants and blackbirds were used because both species have general feeding habits but represent extreme body mass compared with rats (e.g., blackbirds, ~65 g; rats, ~200 g; pheasant, ~1000 g). The rat LD₅₀s were graded from 2.3 (phorate) to 8600 mg/kg (temephos). By most criteria for ranking acute mammalian toxicity, phorate is classed extremely toxic, and temephos is practically nontoxic. At the one extreme, though phorate is also highly toxic to pheasants (LD₅₀, 7.1 mg/kg), it is about three times more toxic to rats. At the other extreme, temephos is nearly 250 times more toxic to pheasants (LD₅₀, 35 mg/kg) than to rats. The original premise that birds are more sensitive to anticholinesterase insecticides was borne out for red-winged blackbirds, which were 2 to 200 times as sensitive as the laboratory rat.

The limited comparison of phosphorothioic acids has important implications for ecological risk assessment. First, avian mixed-function oxidase activity tends to be inversely related to body mass,^{46,47} and therefore red-winged blackbirds should be more tolerant of OP poisoning than is the ring-necked pheasant, but they are not. This may be partially explained by the fact that red-winged blackbirds (and possibly other small passerines) are particularly deficient in liver-detoxication enzymes, but it also may have been influenced by small birds having a much higher metabolic rate. Second, it was noted that OPs with rat LD₅₀s above 200 mg/kg were usually more than ten times as toxic to pheasants as to rats; but for OP LD₅₀s less than 200 mg/kg, rats were 2 to 20 times more sensitive than the pheasants (Table 12.1). This is especially important because rat LD₅₀s are often used as a primary source for preliminary risk assessments, and LD₅₀s above 200 mg/kg are considered only moderately toxic for wildlife.⁴ This conclusion would be erroneous for OPs such as dimethoate, fenitrothion, and temephos, all of which are classed highly toxic, with LD₅₀s of less than 50 mg/kg for many birds. In nature, fenitrothion applied at recommended rates on rangelands for grasshopper control resulted in bird mortality and decreases in breeding populations.⁴

Based on the foregoing, the laboratory rat is not a good model for prediction of acute anticholinesterase toxicity in birds. In contrast, laboratory rats and mice are conservative predictors of acute toxicity to wild rodents. In a study of the acute oral toxicity of a spectrum of pesticides including OPs to four species of voles and laboratory rats and mice it was determined that laboratory rodents are generally more sensitive to acute exposure than the most sensitive of the voles, (*Microtus canicaudus*).⁹⁶ Laboratory mice were also found to be more sensitive than deer mice (*Peromyscus maniculatus*), but the relationship was not consistent.³⁰

12.4.1.1 Acute Toxicity Testing

Acute exposure is the main hazard of organophosphorus and carbamate insecticides to wildlife, and of all standard toxicological tests, it is best represented by single-dose LD₅₀ study. Response to the dose of anticholinesterase is usually rapid, and, if not fatal, recovery normally occurs within a few hours. This test provides a sound method for quantification of naive sensitivity to OPs and CBs and comparisons such as differences between sexes, age classes, and formulated products. The test also provides characterization of the dose-response curve, which is essential for proper hazard evaluation and risk assessment. However, the acute test provides only an estimate of relative sensitivity based on a single potentially lethal exposure; whereas in the field exposure varies widely from repeated small doses during feeding (the degree of response depends on the level of contamination and susceptibility of the individual) to massive overdose from rapid ingestion of highly contaminated water or bolus of food. Therefore, a second “acute” test has also been developed to check the short-term response of birds and mammals to OP and CB-contaminated forage. The feeding trial is designed, replicated, and analyzed statistically the same as the single-dose acute test but provides graded levels of contaminant for 5 days. The critical statistic is the LC₅₀ (median lethal concentration). This feeding trial was developed in the 1960’s as an alternative to the acute test for highly persistent pesticides that were not acutely toxic.⁹⁷ As with the acute test, this feeding trial does not adequately represent field exposure of wildlife to OPs and CBs, but in combination the two tests provide insight into how wildlife may respond. Where the acute test provides information on inherent sensitivity to OP and CBs, the feeding trial provides information on response to repeated chemical exposures as may be encountered in nature. The use of these tests and their value in evaluation of ecological hazard has been critiqued in detail.^{97–100}

12.4.2 Acute Environmental Hazard

Low LD₅₀s indicate that most common organophosphorus and carbamate insecticides are extremely toxic to birds and mammals. However, only a small number of these pesticides are responsible for the majority of large-scale incidents of wildlife mortality. This is probably because certain uses are more likely to bring large numbers of wildlife in contact with a few of the more commonly used products. It is also likely that many incidents of wildlife mortality are not detected or reported. Most reported incidents are of three types: (1) a few dead songbirds in a neighborhood park or backyard, (2) an unusual concentration of dead flocking birds, or (3) large conspicuous water birds or special interest species such as raptors. In contrast, sometimes large flocks of birds were found dead and not reported because the discovery was believed to be part of an avian-control program. (Note: OPs and CBs have been used in wildlife damage and hazard control.)¹⁰¹ The prevalence of small mammals may range from common to abundant in many habitats routinely treated with OP and CB pesticides, but these mammals are rarely listed in reports of even large-scale terrestrial mortality. This omission is more likely due to difficulty in detection of small secretive species (e.g., shrews, mice, voles) than to any special tolerance. There has been comparatively little documentation of reptile and amphibian mortality from OP or CB pesticide treatments.^{48,49}

Prediction of acute OP or CB hazard to wildlife is confounded by many factors of anthropogenic and natural origin. A primary factor, and perhaps most easily addressed through limited additional

testing, is the influence of pesticidal formulations on availability and toxicity to wildlife. Regulatory agencies have only recently begun to consider the differential ecological hazard of finished product formulations, and then only after years of reported episodes of wildlife mortality from certain products.²⁶ Some of the other factors that may affect acute OP and CB hazard to wildlife to different degrees include the route, source, and timing of exposure and possible interactions with other chemicals, infectious diseases, and weather stressors.

12.4.2.1 *Confounding Variables*

Tolerance of anticholinesterase exposure may be affected by growth, maturation, gender, reproductive status, lineage, nutritional status, and exogenous and endogenous stressors. Few rigorous studies have been conducted on the influence of normal physiological factors on the sensitivity of wildlife to pesticides, or whether captive wildlife adequately represents nature. This is a critical uncertainty that must be attended to for reliable hazard and risk assessment. Even species raised commercially, such as quail and ducks, are not well understood, and they serve as the primary models for regulatory hazard assessment in North America and Europe.²⁶ Another uncertainty is the suitability of wild-captured animals for routine toxicity testing. Simple survival and weight maintenance for a few weeks in captivity may not reflect variables, such as nutritional imbalance or stress response, to confinement, isolation, or crowding.²⁸

Maturation alone does not always increase avian tolerance of anticholinesterase pesticides. For example, in a seminal study of acute toxicity with mallards at 1.5 days, 1 week, 1 month, and 6 months of age, LD₅₀s tended to follow different patterns for esters of phosphoric and phosphorothioic acid insecticides.¹⁰² LD₅₀s between 1 week and 6 months decreased by 45 and 53% for demeton and monocrotophos, while they increased by 60 and 190% for parathion and chlorpyrifos. Tolerance patterns for the two CBs tested — carbofuran and aldicarb — were similar to demeton and dicrotophos, both direct-acting OP insecticides. The apparently higher tolerance of young ducklings compared to adults was attributed to an immature nervous system being less sensitive to certain neurotoxic agents. The authors offered no explanation for the differences between direct-acting ChE inhibitors and those requiring metabolic activation for potency.

In contrast to single-dose LD₅₀ tests, dietary LC₅₀s typically increased with growth of precocial birds.^{68,103} The increase is probably due to larger (older) chicks eating less proportional to body mass, which reduces practical exposure to chemicals over the duration of the experiment. Physiological tolerance undoubtedly plays a role, but it was demonstrated that relative food consumption normally decreases about 60% for Japanese quail from hatch through 3 weeks of age.⁶⁸ Food consumption of controls in proportion to body mass averaged 48 g/100 g at 3 days of age, 31 g at 10 days, 24 g at 17 days, and 19 g at 24 days. This decreased energy requirement was correlated with an overall three- to fourfold increase of OP and CB LC₅₀s from hatch to 3 weeks of age. This study included chlorinated hydrocarbon and mercurial pesticides, which also yielded, increased LC₅₀s over age, but the differences between hatch and 3 weeks were consistently less than twofold. These differences indicate the more biologically labile and less hazardous nature of OP and CB pesticides compared to highly lipid soluble and cumulative products.

Historically, the sex of a bird or mammal was not considered important in studies of acute OP and CB exposure, unless the animal was in reproductive condition.¹⁰⁴ Therefore, to conserve resources for testing as many species and pesticides as possible LD₅₀ tests were designed for use of approximate statistical methods^{105,106} and reproductively quiescent animals.^{16,107} It was felt that routine tests reported for laboratory rats provided sufficient insight on sex effects for most hazard assessments.¹⁰⁴ For example, it was known that females in estrus were significantly more sensitive than males to about 30% of technical-grade OP and CB insecticides tested; males were more sensitive about 10% of the time.^{11,12} When sex differences were detected, females were usually 1.5 to 5 times as sensitive as males; when males were most sensitive, the difference was usually less than 50%. These relationships have not been verified for commercially reared mallards and quail

that are easily brought into reproductive status and are routinely used in regulatory decisions on ecological hazard. (Note: In the primary source on acute pesticide toxicity to wildlife, sexes are indicated, but most animals were reproductively quiescent.¹⁶) The need for such testing is critical because OP and CB pesticides are intensively applied throughout breeding seasons of many species. The importance of this variable was indicated by an acute test of fenthion in which ovulating northern bobwhites were over twice as sensitive as males.¹⁰⁸ This disproportional sensitivity to OP and CBs is potentially critical at the population level because females of most species are more important than males in population recruitment.

12.4.3 Routes of Exposure

Wildlife are most often exposed to organophosphorus and carbamate pesticides through ingestion of contaminated food and water. Inhalation and dermal exposure also occur but are believed to be less common and less hazardous to wildlife than is oral ingestion.¹⁰⁹ Accordingly, nearly all studies of anticholinesterase toxicity to wildlife involve oral administration of chemical, but such studies are usually based on technical grade chemical via gelatin capsule, gavage, or dry mash. Little is known about the toxicity of the finished formulated pesticide complexed with natural matrices or alternative routes and conditions of exposure.

As discussed earlier, the toxicity of OP and CB insecticides is primarily a function of hepatic metabolism regardless of the route of entry.¹¹⁰ Thus, esters of phosphoric and carbamic acids are potentially more potent if they enter the circulatory system by routes other than the alimentary canal, which shunts directly to the liver for first-pass metabolism and detoxication. Esters of phosphorothioic acids that require hepatic metabolism for activation (which includes most OP pesticides) are theoretically more toxic when ingested. Usually, however, pesticides are not rapidly absorbed through the skin and scales, the main alternative routes to ingestion. Percutaneous hazard depends on the rate (dose and time) at which chemical penetrates the skin and varies widely among chemical formulations, sites of application, and species.¹¹¹ An array of anticholinesterase pesticides have been tested by application to the wrapped feet (tarsometatarsis, phalanges, and webbing; ~12% of body surface) of adult mallards for 24 h,¹¹² and to a 1 cm² of a featherless skin under the wing joint of small passerine birds.¹¹³ At the same time, companion birds were dosed orally. Percutaneous and oral LD₅₀s were positively correlated in both studies (mallard, $n = 19$, $r^2 = 0.42$, $p < 0.01$; passerine, $n = 17$, $r^2 = 0.72$, $p < 0.01$). The LD₅₀s were consistently highest for percutaneous routes.

Though potentially more important because OP and CB insecticides readily cross the mucus membrane of the lung, inhalation toxicity is considered minor compared with deposition of chemical on the skin.^{109,114} This concept has not been rigorously tested on wildlife species. For example, it is not known to what degree bats are at risk when returning to their roost during morning twilight, the time considered optimal for aerial application of pesticides because wind is usually less of a factor.

12.4.4 Sources of Exposure

Wildlife are exposed to organophosphorus and carbamate pesticides by ingestion of contaminated water, soil, seeds, foliage, invertebrates, vertebrates, and formulated granular particles. All of these sources have killed large numbers of wild birds and mammals under varied environmental circumstances. Water is a common source of exposure that is poorly documented for terrestrial vertebrates. Potential OP and CB hazard is dependent on widely variable factors of ambient water quality, movement, and the solubility and stability of the product. Water soluble formulations usually remain available longest and tend to be the most acutely toxic.^{2,3} How these studies relate to waterborne exposure in nature is not clear because rates of feed and water consumption vary widely among wildlife species at different ages and seasons of the year. Smaller birds and mammals have a much higher water requirement relative to body mass than do larger species under similar ambient conditions.¹¹⁵ However, even closely related birds of similar sizes and feeding habits vary their

rates of free-water consumption from about 15 to 40% of their body mass per day at the ambient temperature of 25°C.¹¹⁶ Though aquatic wildlife undoubtedly contact and ingest more water through feeding, swimming, and wading than do terrestrial species that use water primarily for hydration, terrestrial species may opportunistically ingest large amounts of highly contaminated water, especially in arid regions.

Few studies of OP and CB pesticides in water have been reported for wildlife species. However, as previously mentioned, field applications of technical-grade fenthion in various formulations of 47 to 100 g of active ingredient per hectare over wetlands of various water depths killed a variety of passerine and water birds.^{90,117,118} The authors concluded that contaminated insects were an important source of fenthion in the avian mortalities, but the importance of contaminated water was not dismissed. Mortality of wildlife from puddling and run-off from agricultural fields has been documented for some of the more acutely toxic OP and CB pesticides, as discussed in Section 12.3.3.

OP and CB residues in foliage, whether by topical or systemic soil application, may be hazardous to wildlife in or near the treated area. Treatments to control insects in forests and orchards and on cultivated crops, such as small grains, alfalfa, and turf grasses, have all resulted in excessive mortality over the years. Foliar treatments may be especially hazardous when animals are in the spray zone during treatment and subject to multiple routes of exposure. Turf grass treatment with OPs (e.g., diazinon) has proven particularly hazardous to waterfowl such as American wigeon and the Canada goose.¹¹⁹ This unique hazard to grazing waterfowl resulted in the U.S. Environmental Protection Agency's issuing a cancellation notice for the use of diazinon products on golf courses and sod (turf) farms.¹²⁰

Seeds, like granular pesticides, are an important source of exposure to wildlife when the seeds are treated with pesticides for soil insect control.^{6,121,122} OP- and CB-treated seeds are readily eaten by small granivorous animals in spite of being brightly colored for safeguard of human health. This hazard is not limited to seeds on the surface of the soil or to small animals; large-scale mortality of greylag geese (*Anser anser*) was attributed to the uprooting and ingestion of germinating OP-treated seeds.^{123,124} It is not known whether phytometabolism of systemic OP and CB has contributed to wildlife mortality, but increased hazard to herbivores is plausible because metabolites are more persistent and may be as potent as the parent compound.

Contaminated arthropods have been proven lethal to wildlife after application of OP and CB insecticides such as terbufos, monocrotophos, dimethoate, fenthion, trichlorfon, and carbofuran.^{4,9,10,90,125,126} Such poisonings are most likely from insecticides adsorbed on the cuticle of the arthropods. An adsorbed chemical may be rapidly dissociated in the stomach of the consumer. However, pesticide ingested by arthropods may also contribute to a consumer's exposure. Recently, there was a documented incident of disulfoton-treated cotton seeds passing sufficient insecticide through the plant to grazing insects to be lethal to Swainson's hawks (*Buteo swainsoni*).¹⁰ In another incident as many as 3000 Swainson's hawks died from eating freshly-sprayed insects following monocrotophos treatment for grasshopper control.¹⁰ Monocrotophos is extremely toxic to birds with acute oral LD₅₀s consistently less than 5 mg/kg and as low as 0.8 and 0.2 mg/kg for California quail (*Callipepla californica*) and the golden eagle.¹⁶ Monocrotophos has been cancelled in the United States.⁵

Predatory and carrion-eating birds and mammals are known to have died from eating prey and carcasses contaminated with anticholinesterase pesticides such as monocrotophos, fenthion, mevinphos, phorate, famphur, and carbofuran.^{6,10,127} Most of these secondary poisonings were probably from eating unaltered chemical in the alimentary canal of prey or carcasses. The liver and kidneys may contain some biologically available anticholinesterase residues (e.g., oxons, sulfoxides, sulfones), but other postabsorptive tissues and fluids are not as hazardous as a source of secondary poisoning. For example, in an experiment with barn owls (*Tyto alba*) fed quail that had been killed with oral dosage of famphur, intact carcasses caused significant ChE inhibition in the owls, whereas owls fed quail with the entrails removed were unaffected.¹²⁸ Famphur presented a unique form of secondary poisoning because the product is applied directly on livestock for

vermin and parasite control. American magpies (*Pica hudsonia*) were poisoned by eating contaminated hair of cattle and possibly invertebrates in stockyards.¹²⁷

The potential for secondary poisoning from aquatic vertebrates has also been demonstrated.¹²⁹ Tadpoles exposed to parathion at 1 mg/L of water for 96 h were force-fed to 14-day-old mallards at the rate of 5% of body mass. A single meal was lethal to ducklings within 30 min. Because only parathion, and not its oxygen degradate, was found in the tadpoles and stomachs of the dead ducklings, it is likely that parathion concentrated in the protective outer mucus layer of the tadpoles and was almost immediately available for absorption upon ingestion by the ducklings. The treated tadpoles appeared healthy when fed to the ducklings.

Percutaneous, ocular, and inhalation exposure undoubtedly occur when wildlife are directly oversprayed by OP and CB pesticides, or when entering a freshly-sprayed area. The few studies conducted on these alternative routes of exposure have demonstrated that they may be important to toxicity in some circumstances, but most often ingestion is the primary source of poisoning.¹⁰⁹

12.4.5 Pesticide Formulations

Organophosphorus and carbamate residues on seed grains, vegetation, and formulated pesticide granules have killed large numbers of wildlife under varied environmental circumstances. Some of the kills were due to misuse, but some of the problem was due to general lack of information on the comparative toxicology of pesticidal formulations and hazard associated with various application techniques. Most often, potential hazard or risk to wildlife is estimated by comparison of the theoretical concentration of the active ingredient in a food item to results of standard acute tests of technical-grade chemical with northern bobwhites and mallards but without regard to the differential effects of finished product on absorption, fate, and toxicity.^{28,130}

Only rarely is technical-grade chemical applied in the field, and then only in very low volume, as described earlier for mosquito control. Instead, pesticides are normally applied as a formulated product that may differ substantially in acute toxicity compared to the technical-grade material tested. As a general rule, it has been determined that granular formulations are most often less toxic than technical-grade materials, whereas liquid formulations are usually more toxic than technical-grade products. This relationship was demonstrated with acute tests of northern bobwhites in which emulsifiable concentrates (48% AI) of diazinon and carbofuran were significantly more toxic than either technical-grade (99% AI) or granular formulation (14 to 15% AI).⁵² Sometimes the LD₅₀s among anticholinesterase formulations varied as much as fourfold. Aqueous solutions were consistently more toxic than oil-based ones. In contrast, pesticides were more toxic to mallard embryos when applied to eggs in an oil vehicle than when applied in an aqueous emulsifiable concentrate.^{131,132} Apparently, the oil medium retarded volatilization, increased the time of contact, and facilitated pesticide transport through the shell and membranes.

Though granular OP and CB insecticides may be less toxic in dosing studies than other formulations and are safer to handle during application, their potential environmental hazard is excessive.^{45,133,134} The hazard of granulars in nature depends on whether they are haphazardly or selectively ingested. If ingestion is haphazard, then the application rate is the more critical variable, but if ingestion is selective, then even the most stringent attempts to reduce granule availability may fail to reduce the hazard.⁶⁹ The color, size, texture, granule base, and application rate are all factors for consideration in reduction of granular hazard to wildlife.¹³⁵⁻¹³⁹ The substantial hazard to wildlife of granules leaching into wetlands is discussed in Section 12.3.3.

12.4.6 Toxic Interactions: Chemical and Environmental

Interaction among organophosphorus and carbamate pesticides and between anticholinesterase and other common environmental xenobiotics has not been thoroughly studied for wildlife species.

A few studies have been conducted on subchronic exposure of birds to expected field concentrations of persistent pesticides followed by acute challenge with OP or CB, or studies of simultaneous feeding on combinations of OPs for 5 days. Results of these studies are generally consistent with similar studies of laboratory mammals, but there are some differences that may affect ecological hazard assessment. For example, when laboratory rodents were pretreated with chlorinated hydrocarbon pesticides that increased hepatic mixed-function oxidase activity, their sensitivity to OP insecticides was reduced.^{140–142} In contrast, when the chlorinated hydrocarbon DDE was fed to Japanese quail for 3 months, the sensitivity to a single dose of parathion increased significantly.¹⁴³ When the quail were pretreated with chlordane, another chlorinated hydrocarbon, acute sensitivity to parathion was decreased. This latter relationship was also observed in similar studies with mice.¹⁴¹

In general, response of naive birds and rodents is additive when acutely challenged with paired anticholinesterases or anticholinesterases with chlorinated hydrocarbon pesticides.⁵² When more than additive effects are detected, the level of synergy is usually less than twofold, whether exposure is acute by oral dosage^{144–146} or short-term dietary presentation.¹⁴⁷ Little information is available on the effects of sequential exposures of wildlife, but the potential hazard may depend on the order in which the chemicals are encountered. When the initial exposure is to CB, some protection from OP may occur.¹⁴⁸ In contrast, when the initial exposure is to an OP, toxicity of subsequent exposure to either OP or CB may be increased.¹⁴⁹ Sequential exposure to different pesticides is a reasonable possibility in nature, especially for birds that are highly mobile and may forage among several crops.

Temperature extremes and season of the year are natural stressors that can affect the acute toxicity of anticholinesterase insecticides to wildlife. Abrupt changes in climate, particularly late spring cold fronts with heavy rains, may profoundly influence avian nesting success. Whether effects of OP exposure on thermoregulation so far demonstrated in the laboratory would exacerbate an already dramatic physiological challenge is not known. At the other extreme, heat stress was suggested as a contributor to dimethoate toxicity in an episode of sage grouse (*Centrocercus urophasianus*) poisoning in Idaho.¹⁵⁰ Environmental factors affecting OP and other xenobiotic toxicity in wildlife have been reviewed.^{44,151,152} Effects of seasonal changes on OP and CB toxicity are difficult to elucidate because many confounding endocrine changes are cued to photoperiod and temperature changes, with the more profound differences usually in females.

12.4.7 Diagnosis of Anticholinesterase Exposure

Organophosphorus and carbamate pesticides have resulted in hundreds of incidents of wildlife mortality from disease vector control and agriculture (including forest and range management) throughout the world. When many dead and moribund animals of mixed species are found in an area of known OP or CB treatment, the casual association may be evident but is not conclusive without biochemical and chemical confirmation. Proper diagnosis is then contingent upon demonstration of brain ChE inhibition consistent with levels indicative of toxicity or exposure and chemical detection of residues of the causative agent. This last step is sometimes difficult because neither OP nor CB residues tend to accumulate in postabsorptive tissues. However, a strong inferential diagnosis is possible by demonstrating depressed brain ChE activity and detection of a known anticholinesterase in either ingesta or tissues.^{34,36,123}

A conservative threshold of about 50% depression in whole brain ChE activity is generally considered diagnostic of death from anticholinesterase poisoning,³⁵ though depression of 70 to 95% is commonly reported for birds and mammals killed in nature by OP pesticides.³⁶ In contrast, when animals are killed in the field by CB pesticides, whole brain ChE activity may vary from near normal to depressions of only 60 to 70%.^{36,153} Apparently high levels of CB exposure kill by systemic neuromuscular blocking before significant penetration of the central nervous system has occurred.^{53,154} Also, lesser degrees of ChE inhibition may reflect spontaneous postmortem reactivation of carbamylated enzyme.⁶⁷ Brain ChE can be determined by many techniques,^{155,156} but either a laboratory norm must be developed for each species or a suitable enzyme reactivation technique

must be used to determine the degree of inhibition. In cases of poisoning by OP compounds ChE activity can be reactivated *in vitro* by the oxime 2-PAM (pyridine-2-aldoxime methyl chloride).³⁴ Carbamylated ChE is much less stable than phosphorylated ChE; therefore, simple *in vitro* heat reactivation will serve as a rapid indicator of carbamate exposure,³⁶ as will dilution techniques.¹⁵⁷ OP and CB reactivation techniques provide important guidance for analytical chemistry.

Blood plasma or serum ChE may be used as a nondestructive technique for detection of OP or CB exposure. As for brain ChE, the species-specific norm must be developed for diagnostic reference. If ChE depression exceeds the lower to end of normality, i.e., more than two standard deviations below the baseline mean, the subject is considered to have received significant exposure to anticholinesterase compound. Again, heat and 2-PAM reactivation may be used as provisional indicators of CB and OP ChE inhibition. These concepts have been reviewed in detail for wildlife including fish.¹⁵⁸

12.5 SUBLETHAL ENVIRONMENTAL HAZARD

12.5.1 Subchronic and Behavioral Effects

Wild birds and mammals are relatively tolerant of low-level exposure to organophosphorus and carbamate pesticides.^{43,44} This is partly because the chemicals are labile and readily excreted by warm-blooded animals. Also, low-grade exposure to anticholinesterase may stimulate changes in synaptic physiology, which may include reduction of both axonal release of acetylcholine transmitter and the density of postsynaptic acetylcholine receptors. This apparent tolerance was determined from laboratory studies that do not involve the rigors of nature that affect free-living animals, such as extreme weather and the ability to capture prey or avoid predation. For example, a single OP or CB dose of about 5% of its LD₅₀ (essentially nonlethal but induces significant brain ChE inhibition) may reduce the core temperature as much as 2°C in homoiothermic animals acclimatized to moderate ambient conditions of 25 to 30°C. If the ambient temperature is abruptly shifted to mimic a cold front, the core temperature may drop as much as 3 to 6°C from the same dose.¹⁵⁹⁻¹⁶¹ However, it has been demonstrated that even under these chilled ambient conditions the core temperature of OP-induced hypothermic animals returns to normal within about a day.⁴⁴ Generally, hypothermia occurs with brain ChE inhibition of about 50%, which is the degree of inhibition often associated with general physiologic deficit and sometimes death. Hypothermia is also associated with reduced metabolic efficiency, which in turn may slow metabolic degradation and excretion of OP and CB, thereby extending contact at receptor sites and enhancing toxicity.

Hypothermic animals are more sensitive to OP poisoning than normal.^{161,162} Young birds may be especially susceptible to anticholinesterase interference with thermoregulation because many species are not fully homoiothermous for 1 to 3 weeks after hatching.¹⁶³ Interaction between OP and ambient chilling was studied with 14-day-old northern bobwhites acclimatized to 35°C and then subjected to 27.5°C for 4 h.¹⁶⁴ Brain ChE inhibition from a single dose of chlorpyrifos in the chilled chicks was depressed about twice as much as in chicks continued at 35°C. Both nestling and precocial chicks could be further compromised because parental care may be affected when the female is exposed to anticholinesterase.^{165,166} Temperatures below 15°C are common throughout the breeding season of birds and small mammals in temperate climates. Mechanisms of thermoregulation and interaction with anticholinesterase have been thoroughly reviewed.^{43,151}

The ability of birds and mammals to capture prey or avoid predation after subacute exposure to OP and CB pesticides has not been properly evaluated. Controlled experiments are difficult to interpret. Treatment levels were usually based on some level of acute dosage that at least initially rendered the subject, predator or prey, critically ill and often immobile. The results tend to be predictable, i.e., predators will not hunt, and prey cannot escape. When levels are tested that do not indicate overt toxicity, predators and prey seem to respond normally. Field studies are hindered

by uncertainty of the subjects' exposure history and inability to follow movements and observe behavior of highly mobile or reclusive species. Radio tracking has provided some insight into effects of OP on northern bobwhite survival but not necessarily cause of death. One hundred ninety-seven wild quail were captured, equipped with a small radio transmitter, dosed once with either 0, 2, 4, or 6 mg/kg of methyl parathion, and their movements were monitored for 14 days.¹⁶⁷ Quail receiving the highest dosage had lower survival than did the controls; otherwise, there were no apparent treatment effects. The authors concluded that reduced survivability was due to increased OP-induced vulnerability to predation, perhaps due to reduced covey integrity. A similar study was conducted with wild northern bobwhites dosed with 0, 3, 5.6, or 21 mg/kg of terbufos and realized essentially the same results as for methyl parathion.¹⁶⁸

Subacute exposure of birds and mammals to various anticholinesterases has been shown to affect an array of behaviors, such as activity level, alertness, aggression, foraging and drinking, learning and memory, navigation, and reproduction.^{43,44,169,170} Though most of these behavioral studies were well planned and have important theoretical implications for survivability, laboratory studies are highly restrictive, and their projection to natural populations is speculative.¹⁷⁰ Or, as aptly stated, whereas behavioral tests seem desirable, there are two fundamental difficulties in the use of such tests: (1) the best-studied and most easily performed and quantified have the least environmental relevance and (2) the most relevant behaviors are the most strongly conserved against change.¹⁷¹

12.5.2 Chronic and Reproductive Effects

The chronic toxicity of organophosphorus and carbamate pesticides has not been extensively studied with wildlife because such chemicals were believed to be too labile in nature to pose a serious sublethal hazard. However, as discussed earlier, some OPs and CBs may remain available in the soil and vegetation for several months, and they may be applied to wildlife habitat several times during the growing season, which may coincide with critical periods of reproduction. Specially designed research is needed to evaluate: (1) intermittent exposure from repeated pesticide application, (2) exposure of naive animals to pesticide application at different stages in the reproductive cycle (e.g., courtship, onset of lay, incubation), (3) exposure to systemic pesticide in plant tissue, and (4) effects of potential interaction of tank mixtures and different anticholinesterase application on nearby crops.

Chronic studies of OP and CB pesticides with wildlife were usually some modification of the standard reproduction trial developed for pesticide registration. These tests were developed for evaluation of more persistent chlorinated hydrocarbons and heavy metals. The studies, usually of mallards or northern bobwhites, expose first-time breeders to constant rate of chemical from several weeks prior to lay through chick hatchability. Chicks were then observed for 2 weeks for evidence of mortality. Main effects noted in these studies included reduced feeding and corresponding weight loss in adults followed by predictable reduction in rate of lay and egg hatchability. Pharmacologic action on the endocrine system has also been demonstrated.^{43,44}

Some of the most acutely toxic OP and CB pesticides may also pose hazards to wildlife that have gone unnoticed. Monocrotophos has been implicated in some of the largest wildlife kills, but trivial residues have also been shown to depress egg production and hatchability in northern bobwhites.^{172,173} In another study with northern bobwhites the objective was to determine how reproductively active birds responded to decreasing concentrations of OP, as would be expected from a single application in nature.¹⁷⁴ Monocrotophos at concentrations of 0.1 to 1.0 mg/kg in diet were provided to breeding pairs. Then, at 3-day intervals the basic concentration was either continued or reduced so that at the midpoint and end of the 15-day study the concentrations were reduced by 50 and 75%. Finally, all birds were fed untreated diet for 2 weeks. Food consumption and egg production was negatively correlated with increased concentrations of OP. Inhibition of oviposition was not permanent, and time to recovery was dose-related. There was no evidence of

monocrotophos effect that could not be attributed to OP-induced anorexia. In studies of methyl parathion on avian reproduction, effects were also mediated by anorexia.^{175,176}

The most important effect of OP and CB pesticides on avian reproduction in nature, other than killing or incapacitating the parents, is the removal of the prey base.¹²² When prey is depleted, birds may abandon nests and leave the treatment area, or at least have more difficulty in caring for their young. Abandonment of the first nesting attempt is especially critical to population success because subsequent attempts are usually less successful.¹⁷⁶ Some of the subtle effects of sublethal parental poisoning have been studied for a variety of free-living birds. Female red-winged blackbirds were captured on their nests and given a single dose of methyl parathion (0, 2.4, or 4.2 mg/kg) and then observed for 5 h to document acute or gross behavioral responses including times spent incubating.¹⁷⁷ Each nest was then monitored through fledging. Females at the highest dose showed classic signs of acute anticholinesterase poisoning, but they all recovered, and there was no apparent effect on nest success. In a similar study¹⁷⁸ European starlings (*Sturnus vulgaris*) were induced to nest in artificial nest boxes. When nestlings were 10 days old, the male parent was eliminated, and the female parent was dosed once with dicrotophos at 2.5 mg/kg, and her activities were monitored at 2-hour intervals for the next 3 days. OP-dosed females made fewer trips in search of food for their young and stayed away from their nests longer than did the controls. Nestlings of treated females lost significant amounts of weight, which could have affected their postfledgling success.

Though the potential for reduced prey availability causing a negative effect on avian reproduction is evident, neither decreased nestling growth nor fledgling success was detected for free-living passerines in spite of 50 to 70% depletion of primary insect prey due to aerial application of fenthion¹⁷⁹ or trichlorfon.¹²⁵ The importance of relative depletion of insect prey probably varies widely depending on prey abundance at the time of pesticide application and the size, mobility, and energy demands of the insectivore.

Studies of nest attentiveness or other breeding behavior in wild birds gave mixed results when subjects were dosed with OPs at rates producing 10 to 50% brain ChE inhibition, but without causing observable signs of toxicity. Sharp-tailed grouse (*Tympanuchus phasianellus*) given a single dose of malathion at 200 mg/kg were less effective in defending breeding territories on leks.¹⁸⁰ One member per pair of incubating laughing gulls (*Larus atricilla*) was dosed once with parathion at 6 mg/kg, and incubation behavior was observed for 10-minute intervals throughout the day for 3 days. No effects on incubation were detected on the day of dosing, but parents dosed with parathion spent less time incubating on day 2 and the morning of day 3; activities appeared normal thereafter.¹⁸¹ This study was motivated by a natural event in which adult laughing gulls gathered parathion-poisoned insects in nearby cotton fields and either died leaving chicks to starve or returned and poisoned their chicks through presentation of parathion-contaminated insects.¹⁸²

OP and CB pesticides are not believed to pass through the parent to the egg in biologically important amounts, but such pesticides may be deposited on the egg from parents' feathers during incubation or from direct contamination by pesticide application. Effects of such topical exposures have been studied extensively with northern bobwhite and mallard eggs at day 3 of incubation. Eggs were immersed for 30 sec in aqueous emulsion or were dosed with a single topical application of pesticide in nontoxic oil. OPs were shown to be as much as 18 times more toxic when applied to the shell in oil than when immersed in water.¹³¹ Embryotoxicity and teratogenicity of OPs and CBs applied to bird eggs have been thoroughly reviewed.¹³²

12.6 CONCLUSIONS AND RECOMMENDATIONS

About 200 organophosphorus and 50 carbamate pesticides have been formulated into thousands of products that are available in the world's marketplace for application to forests, rangelands, wetlands, cultivated crops, cities, and towns. Though most applications are on field crops and other

terrestrial habitats, the chemicals often drift or otherwise translocate into nontarget aquatic systems and affect a much larger number of species than originally intended.

OP and CB insecticides, though acutely toxic to most animals, are readily metabolized by vertebrates and are quite labile in nature. Therefore, OPs and CBs have generally been underestimated as important environmental hazards beyond periodic incidents of short-lived mortality of fish and birds. These incidents, sometimes involving hundreds and even thousands of nontarget animals, were often justified philosophically by resource managers and regulators by equating them with mortality from natural phenomena such as storm fronts and infectious disease. This justification is inappropriate because wildlife populations evolved in coexistence with nature, but not with the extra burden of anthropogenic factors of habitat modification and reduction or application of potentially incapacitating or lethal chemicals during critical periods of reproduction.

OP and CB pesticides have not caused the type of population effects attributed to highly persistent chlorinated hydrocarbon pesticides, but there is increasing evidence that populations of some raptorial birds have been affected at the regional level. This is an important concept because prior to the mid-1980s predatory birds and mammals other than those foraging regularly on large insects were not generally believed to be subject to OP and CB hazard. It has since been determined that predators and carrion feeders are regularly poisoned by foraging on the OP- and CB-contaminated entrails of small birds and mammals, and small insectivorous species are often found dead in OP- and CB- treated habitats.

Granular formulations are another aspect of OP and CB hazard that has been increasingly documented for wildlife since the mid-1980s. Granulars were generally considered safer than flowable products, and controlled release granular formulations were highly efficacious. However, recurring incidents of toxicity were noted in association with rainfall and when granulars used in soil treatment were not properly buried. Sometimes, the hazard persisted as long as 6 months posttreatment.

Despite evidence that OP and CB toxicity to wildlife may persist well beyond the first few days posttreatment and that there are many uncertainties about their environmental hazard, regulatory controls of these widely used pesticides are almost exclusively based on incidents of aquatic and terrestrial wildlife mortality. Little information has been acquired to properly account for sublethal effects of multiple applications during the growing season or effects on ecosystem structure and productivity. Some areas in which aggressive research is needed are listed below:

1. Pesticidal formulations need to be tested for comparison to existing data on technical grade active ingredient. Technical grade pesticide is rarely used other than for emergency mosquito control. Finished-product and technical-grade chemicals are not equally absorbed by vertebrates, and differences of acute toxicity among formulations may exceed threefold.
2. The rate and method of pesticidal applications affect hazards to nontarget animals. Additional field studies of natural populations are essential and are critical to advance concepts of probabilistic risk assessment.
3. The stability and fate of finished product in nontarget habitats is critical. Studies are in progress on aquatic macrocosms, but little information is available for aquatic or terrestrial systems adjoining croplands.
4. OP and CB pesticides are applied at different intervals during the growing season depending on the crop and target pest. These treatments coincide with the reproductive cycle for many species. Information is generally lacking on wildlife behavior and productivity during this critical period.
5. Studies are needed to understand population effects relating to OP- and CB-induced mortality when coupled with natural wildlife mortality from climatic events and infectious diseases.

13.1 INTRODUCTION

13.1.1 Background

The discovery of the insecticidal properties of DDT that led to its subsequent use in pest control was hailed as a tremendous scientific achievement. Initial success with DDT in controlling human health pests during World War II and subsequent success in agricultural pest control stimulated synthesis and development of related organochlorine pesticides; their use increased exponentially following the war.¹ At first, evidence slowly accumulated that nearly all of these compounds were having widespread adverse effects on nontarget organisms. Later, a veritable mountain of evidence was amassed relating to their toxicity, persistence, and lipophilic characteristics that resulted in accumulation of residues, mortality, lowered reproductive success, and decline — even extirpation — of certain populations of wildlife.²⁻³ Ecotoxicological data for organochlorine pesticides are limited to relatively few countries where most research has been conducted. Despite documented damage of organochlorine pesticides to the environment a number of these compounds, particularly DDT, currently are used in a number of countries.⁴ It is likely that no other group of contaminants of anthropogenic origin has exacted such a heavy toll on the environment as have the organochlorine pesticides.

13.1.2 Objectives

The objectives of this review are to document the nature and extent of ecotoxicological problems resulting from use of organochlorine pesticides for over a half century and to discuss future relevance of these problems.

13.2 CHARACTERISTICS

13.2.1 Grouping

The five major groups of organochlorine pesticides are: DDT and its analogs, hexachlorocyclohexane (HCH), cyclodienes and similar compounds, toxaphene and related chemicals, and the caged structures mirex and chlordecone (Kepone®).⁵ This grouping is based on chemical structure; therefore, it is difficult to generalize group characteristics and their resultant toxic effects.

DDT and ten of its analogs include the commercial pesticides dicofol (Kelthane®), DDD (TDE), Bulan®, chlorfenethol (DMC), chlorobenzilate, chloropropylate, DFDT, ethylan (Perthane®), methoxychlor, and Prolan®. Some of these compounds have strikingly different properties; for example, the slow metabolism and marked storage of DDT and its metabolite DDE is in contrast to the rapid metabolism and negligible storage of methoxychlor.⁵ Most of these compounds will not be discussed in this paper because there are limited ecotoxicological data available, primarily because they were used sparingly.

Hexachlorocyclohexane (HCH) consists of eight steric isomers, including the well-known γ isomer — lindane. Like DDT and its analogs, the isomers have remarkably different properties.

Cyclodienes and related compounds include aldrin, isodrin, dieldrin, endrin, telodrin, heptachlor, isobenzam, chlordane, and endosulfan. This group contains the most toxic organochlorine pesticides (OCs), particularly in relation to acute poisoning.

The pesticide toxaphene is made up of a complex mixture of chemicals, many of which are still unidentified.

Mirex and chlordecone are slowly metabolized and are readily stored in the body.

13.2.2 Lipophilicity

One common characteristic of OCs is a generally high solubility in lipids or lipophilicity; this is expressed as the n-octanol/water partition coefficient.⁶ As a result, the highest concentrations of OCs are found in lipids; residues (presented on a wet weight basis unless otherwise indicated) may be stored in fat depots throughout the organism.² With decreases in body weight, as during times of stress, lipids and residues of organochlorines are mobilized into the blood.⁷ The residues may be transported to the brain or other compartments, where they may induce mortality or serious sublethal effects.⁸ Residues of organochlorines occur in lipids of biota throughout the world. Residues have decreased drastically in some areas, particularly in developed Western countries, due to banning of most problem organochlorines.³ In many undeveloped countries use persists, and there are few data available on residues or effects on the biota.⁹

13.2.3 Persistence

One of the best-known characteristics of organochlorine pesticides is their persistence in the environment. Persistence is based on the half-life both in the physical environment and in the organism.¹⁰ Half-lives range from months to years. Residues of some organochlorines may persist for decades — possibly centuries — in the environment;¹¹ but there are many physical factors that influence this including temperature, light, pH, and moisture.¹² Also, some microorganisms have the ability to break down organochlorine pesticides in the environment¹³ as well as in the living organism.¹⁴ Hibernation,¹⁵ reproductive activity,^{16–17} and other factors can influence the rate of loss of residues. Therefore, the range in half-life of an OC may vary dramatically according to existing physical and biological conditions. Persistence varies greatly among compounds. Several pesticides, including heptachlor and aldrin, are rapidly metabolized once inside the organism; however, their major metabolites, heptachlor epoxide and dieldrin, are indeed persistent and as toxic as the parent compound.¹⁸ Endrin and dicofol are relatively short-lived in organisms and the physical environment as well. Dicofol has no toxic metabolites of major significance. The highly toxic metabolite of endrin, 12-ketoendrin, is rarely found in birds but is important in a few mammalian species, including the laboratory rat.¹⁸

13.2.4 Bioaccumulation

The terminology related to buildup of OC residues in organisms is not standardized, and confusion exists as to the definition of the various terms.¹⁹ Definitions of the mechanisms and routes listed here follow Moriarty;² they are relatively straightforward and adequately define the processes.

Bioaccumulation is the characteristic that results in concentration of organochlorine pesticides in the biota, whether it be from water directly into an organism through gills, epidermis, and similar media (bioconcentration) or from food only (the food-chain effect or biomagnification). Bioaccumulation includes both biomagnification and bioconcentration; mirex residues bioaccumulated at a rate of 25×10^6 from water to eggs of birds.²⁰ Bioconcentration is the process whereby residues of certain organochlorines may be increased as much as 10^6 times from water to aquatic or marine organisms.²¹ American oysters (*Crassostrea virginica*) can bioconcentrate DDT from surrounding water up to 700,000 times.²² Matsumura²³ indicated that astronomical bioconcentration figures, such as those cited above, were misleading, primarily because of the method of calculation of biomagnification with respect to water. Moriarty² discussed problems and pitfalls in calculating and interpreting bioaccumulation; one major problem is comparing levels in whole bodies to individual tissues or eggs. Biomagnification is related to increases in various organochlorines to about 30- to 100-fold from prey to tissues and eggs of fish-eating birds including the herring gull (*Larus argentatus*), and brown pelican (*Pelecanus occidentalis*),^{16,24} and up to tenfold in terrestrial

organisms.²⁵ Harris et al.²⁶ calculated mean increases in residues of 42-fold (DDE) and 60-fold (DDT) from earthworms to eggs of American robins in orchards in Canada.

Evidence suggests that intake from food is not the major source of residues from persistent organic pollutants in aquatic species such as fish, oysters, and related organisms.^{2,21} For example, there is a linear correlation between concentrations in biota, particularly invertebrates, and those in water.²¹ Food is the principal source of persistent organochlorines for most trophic levels in terrestrial systems² and in certain aquatic species such as the Nile crocodile (*Crocodylus niloticus*) whose eggs contained total DDT residues that were tenfold higher than in fish.²⁷ There was a 37-fold increase in DDT and metabolites from whole bodies of fish to blubber of gray (*Halichoerus grypus*) and harbor seals (*Phoca vitulina*) in Norway.²⁸ There are also special cases that do not fit the usual bioaccumulation schemes in that the organisms are exposed to very high concentrations through ingestion, dermal absorption, or other routes of exposure that may lead to acute poisoning. Examples include control programs that use treated substrates such as bird perches,²⁹ spraying of bat roosts³⁰ or bird nesting areas,³¹ intentional use of treated seed³² or laced carcasses³³ for the specific purpose of killing nuisance wildlife, unintentional spillage of treated seed during transporting or planting operations, dumping of excess treated grain, and spills into bodies of water.^{34–36}

13.2.5 Toxicity

Molecules of organochlorine pesticides and other pollutants attach to and act upon receptors — molecules or parts of molecules — within the affected organism.² This combination of pollutant with receptor, termed the biochemical lesion,³⁷ is the first step before effects are manifested.³⁸ As an example, the biochemical lesion of DDT occurs in the axonic membrane of the nerve fiber,³⁹ but some of the details are still uncertain.⁴⁰ Matsumura²³ discussed modes of action of pesticides in some detail. Basically, OCs are neuroactive agents whose modes of action include effects on ion permeability (DDT and its analogs) or as agents for nerve receptors (cyclodienes and BHC).

Toxicity of organochlorines is determined by many factors, not the least of which is the chemical structure of the various compounds. All of these compounds can be absorbed through respiratory and dermal routes; the importance of the dermal route varies greatly among the toxicity of different pesticides.⁵ Toxicity of OC pesticides, as expressed by the LD₅₀ (calculated single oral dose that will kill 50% of exposed organisms), ranged from 1 mg/kg to > 2,080 mg/kg in birds⁴¹ and 8 to 6000 mg/kg in laboratory rats.⁴² The LC₅₀ (estimated dietary concentration that is lethal to 50% of the exposed animals) ranged from 14 to > 5000 µg/g in birds.⁴³ The 96-hour LC₅₀ (estimated concentration in water that is lethal to 50% of exposed fish or other aquatic organisms within 96 hours) ranged from <1 µg/L to 4300 mg/L.⁴⁴

In the environment mortality from organochlorines can occur within hours after exposure,⁴⁵ but usually death occurs after a buildup in residues after weeks or months. Determination of lethal brain residues of DDT in laboratory rats⁴⁶ and birds⁴⁷ and subsequently with the parent compound and the major metabolites DDE and DDD in experimental birds^{48–51} provided the mechanism whereby die-offs in the field were linked with the DDT group. Subsequently, diagnostic lethal residues in brains of experimental birds were determined for heptachlor epoxide, dieldrin, endrin, mirex, several chlordane-related compounds, and telodrin.^{52–58} It should be noted that some investigators have used residues in livers of birds and mammals to document mortality from OCs,² despite the fact that extensive research with lethal residues in brains and livers of experimental animals indicates that use of the brain for this purpose provides a more accurate diagnostic tool.^{47–57} Lethal residues are a diagnostic indicator of mortality — but not necessarily a direct measure of their effects on the action of the biochemical lesion that results in death.

Sex and age of vertebrates, repellency, type of exposure, formulation of the pesticide, interaction with other contaminants, and numerous other factors affect toxicity of pesticides.⁵⁹ Stresses such as shortage of food, weather extremes, migration, reproductive activities, hibernation, molting, and

disturbance also enhance toxicity.^{15,49,60–65} Species sensitivity is an important factor influencing toxicity of pesticides.^{43,66}

Resistance to DDT was reported as early as 1947. Genetic resistance to OCs has been reported in some frogs⁶⁷ and fish⁶⁸ and is commonly described in invertebrates,⁶⁹ but aside from documentation of apparent resistance to endrin in the woodland vole (*Microtus pinetorum*),⁷⁰ there are no other examples for mammals or birds in the field. Even in the woodland vole, genetic resistance was not verified because there were no consistent differences in population genetic indices in individuals from orchards with or without a history of endrin treatment.⁷¹ Deer mice (*Peromyscus maniculatus*) occupying a dieldrin “hotspot” were thought to have developed possible resistance to dieldrin,⁷² but there was no real evidence (see section on dieldrin). Cross-resistance may occur between and within classes of compounds; for example, DDT provides some cross-resistance to methoxychlor but not to lindane or dieldrin.⁷³

13.2.6 Physiological Responses

Metabolism is the effect of an organism, through its enzymes, on the chemical structure of foreign compounds or xenobiotics.¹⁸ Induction of microsomal enzyme activity by organochlorine pesticides was first discovered in laboratory mammals exposed to DDT or chlordane.^{74–75} Enzyme induction is, within normal physiological limits, not deleterious;² it may be thought of as a preparatory step for the liver to metabolize the xenobiotics. Wide interspecific differences occur in efficiency of the liver microsomal enzymes to metabolize organochlorine substrates. These affect persistence of lipid-soluble compounds and the rate of excretion of their water-soluble metabolites.⁶ For example, this enzyme system in the shag (*Phalacrocorax aristotelis*) is relatively inefficient in comparison to those of other species tested.⁵

DDT was the first OC demonstrated to exhibit estrogenic activity;⁷⁶ other OCs, including methoxychlor, chlordecone, and DDE, also exhibit estrogenic activity.³ Organochlorine pesticides stimulated production of liver microsomal enzymes that led to hydroxylation of steroids in experimental animals that may have adversely affected reproductive success.^{77,78} Peakall⁷⁸ demonstrated that DDT in experimental birds induced breakdown of sex hormones that regulate the mobilization of calcium. Hatchling and juvenile American alligators (*Alligator mississippiensis*) in Lake Apopka, Florida, exhibited a number of abnormalities in gonadal morphology and concentrations of sex steroids in both sexes.³⁶ Although these changes may have been related to residues of DDE and other contaminants, it was not possible to pinpoint the responsible pollutants. There are also adverse effects of OCs on thyroid secretion,⁷⁹ adrenal function,⁸⁰ migratory condition,⁸¹ biogenic amines,⁸² the immune system,⁶³ and many other physiological responses.^{1–3,23,29,38} Few of these physiological responses have received extensive study in the field; outstanding success has been achieved in quantifying effects of residues on endpoints like mortality, reproductive success, and eggshell thinning that are used in estimating degree of risk of OCs to the individual and the population.

13.2.7 Interactions

Organisms in the environment are frequently exposed to many OCs and other contaminants at the same time; residues of most OCs in animal tissues are positively intercorrelated.⁸⁴ As a result, synergism, potentiation, antagonism, or additivity of toxic effects may result.⁵⁹ Experimental studies have documented interactions of OCs and other stressors, but these are inadequate to make predictions to the field, where many complex factors are interacting.³ Prior treatment of birds with DDE enhanced the toxic effects of parathion to Japanese quail (*Coturnix japonica*), whereas prior treatment with chlordane was antagonistic to parathion toxicity but not to its metabolite paraoxon.⁸⁵ Northern bobwhites (*Colinus virginianus*) pretreated with chlordane for 10 weeks, followed by endrin, had greater accumulations of chlordane in their brains than did birds treated only with

chlordane.⁸⁶ Aldrin markedly increased storage of DDT in beagle dogs.⁸⁷ In an intensive study of over 100 combinations of eight OCs with organophosphorus and carbamate pesticides given to laboratory rodents, small or questionable potentiation was found between chlordane and methoxychlor, and a minor level of antagonism was noted between aldrin and trithion.⁸⁸ For industrial chemicals and pesticides, additivity seems the most common joint action.⁸⁹ Moriarty² concluded that for combinations of pollutants, the toxic unit (concentration of a pollutant producing a standard response) is considered to be additive. Experimental birds, dying while receiving DDT, DDD, or DDE in their diets, exhibited an approximately additive lethal ratio in their brains of 1:5:15 of DDT, DDD, and DDE, respectively.⁵⁰

13.3 SOURCES, USE, AND EFFECTS

13.3.1 DDT and Metabolites

DDT is the best-known organochlorine pesticide. It was synthesized in 1874, and discovery of its insecticidal activity by Paul Müller in 1939 subsequently led to his receiving the Nobel Prize.⁹⁰ Early work with heavy applications of DDT resulted in mortality of nontarget organisms,^{91–93} but it was not until the program to control Dutch elm disease was initiated that the lethal risk caused widespread concern. More than 90 species of birds, particularly American robins (*Turdus migratorius*), were found dead in neighborhoods where DDT was applied to trees.^{47,94–95} Subsequently, a large-scale mortality of insects and other invertebrates was discovered as well; earthworms accumulated high concentrations of DDT and metabolites that subsequently proved lethal to robins and other birds that ingested contaminated prey.²⁵

Determination of lethal brain residues of DDT and its metabolites in experimental animals^{46–51} provided the scientific evidence whereby these die-offs were linked with the DDT group.

It took several additional years to document the major sublethal risk of DDT; that is, the effects of its metabolite DDE on embryotoxicity, eggshell thinning, and related effects that adversely influence avian reproductive success. In Great Britain, Ratcliffe⁹⁶ initially documented eggshell thinning, depressed reproduction, and population declines of peregrine falcons (*Falco peregrinus*) and other birds. Experimental studies with birds verified that DDE was primarily responsible for thinning of eggshells and adverse effects on reproduction.^{97–99} Of the DDT group, DDE residues are usually highest and are found most frequently in environmental samples, particularly at higher trophic levels.¹⁰⁰ After application of DDT, DDE residues increase because of breakdown of the parent compound.^{11,100} The mode of action of DDE in eggshell thinning has been the subject of studies that should be consulted for further information on physiological relationships and structural changes.^{66,100,101} The latest information indicates that thinning is related to inhibition of prostaglandin synthetase in the eggshell gland mucosa.¹⁰²

Shortly after the initial work, many studies documented eggshell thinning in 18 families of wild birds in North America^{104–106} and throughout the world.^{101–107} In field studies, statistical analyses revealed that DDE was the contaminant primarily responsible for eggshell thinning^{108–110} and associated lowered productivity.^{111–112} Generally, thinning of 18 to 20% or more over several years is related to population decline.¹⁰⁴ Eggshell thinning and a number of other factors are related to adverse effects of DDE on productivity.¹¹² Despite the devastating effects of DDE on avian productivity and resultant population decreases described here, this metabolite has caused few documented mortalities in wild adult birds.^{113–114} Additionally, some segments of the avian fauna, including a raptorial species like the great horned owl (*Bubo virginianus*), a fish-eating species like the great blue heron (*Ardea herodias*), and the gray heron (*A. cinera*), showed minimal effects and no population declines even at the peak of usage of OCs.^{115–116}

The brown pelican is the most sensitive avian species to effects of DDE on reproduction; 3 µg/g in the egg is associated with near total reproductive failure.¹¹² Based on individual eggs,

residues are a more accurate indicator of nest success than eggshell thickness.¹¹⁷ The most extreme incidence of avian eggshell thinning was noted in 1969 on Anacapa Island in southern California; nearly all eggs of brown pelicans in the colony collapsed under incubating birds.^{118–120} Eggshell thinning of collapsed eggs was 53% compared with 34% in intact eggs. Only five young pelicans hatched from nearly 1300 nesting attempts in 1969.¹¹⁹ Eggshell thickness and reproductive success were only slightly higher at three colonies of brown pelican in northwestern Mexico in 1969.¹²¹ In comparison with other colonies, reproductive success and eggshell thickness were highest at three pelican colonies in the Gulf of California, but productivity was less than normal.¹¹⁸ Residues (lipid basis) in 1969 were extremely high and means ranged from 58 µg/g at Isla Piojo in the Gulf of California, 1310 µg/g at Coronados (northwestern Mexico) to 1818 µg/g at Anacapa Island.^{118,121} Residues largely originated from a DDT manufacturing plant near Los Angeles; residues remained high and pelicans experienced serious reproductive problems for many years.¹²² Except in Louisiana (see the endrin section), DDE was primarily responsible for declines of brown pelican populations in the United States and part of Mexico.^{112,121–123}

The peregrine falcon is considered sensitive to reproductive effects from DDE (but also see the section on dieldrin) because there were population declines associated with eggshell thinning and decreased productivity throughout much of its range.^{107,124–127} The sensitivity of the peregrine falcon to DDE depend not so much on the levels that adversely affect reproductive success as on its very high potential for bioaccumulation. The lowest level of DDE in peregrine eggs that adversely affects reproductive success was estimated at 15 to 20 µg/g.¹²⁶ However, a recent study more clearly defined this level at near 30 µg/g.¹²⁸ The peregrine is at the top of a complex food chain and has a far greater capacity to bioaccumulate residues of DDE and other OCs than a more sensitive species such as the brown pelican that is situated at a lower trophic level atop a less complicated food chain. Therefore, quantifying differences in species is complex; the above example with falcons and pelicans demonstrates that many factors affect toxicity of OCs to various segments of the biota.

Other examples of species that experienced widespread declines, primarily related to DDE, included the double-crested cormorant (*Phalacrocorax auritus*),^{129,130} osprey (*Pandion haliaetus*),^{132–133} bald eagles (*Haliaeetus leucocephalus*),^{134–135} merlins (*Falco columbarius*),¹³⁶ great cormorants (*Phalacrocorax carbo*),¹³⁷ Mexican free-tailed bats (*Tadarida brasiliensis*),¹³⁸ and other species.

The bald eagle seemed moderately sensitive to DDE with normal reproductive success when sample eggs contained ≤ 3 µg/g and nearly complete failure when eggs contained ≥ 16 µg/g.¹³⁵ The critical level of DDE in eggs of osprey that resulted in reproductive impairment was about 10 µg/g.¹³⁹ Although the evidence indicated that DDE was primarily related to these declines, some interaction with other contaminants is possible (see the section on dieldrin).

American kestrels (*Falco sparverius*) seemed tolerant of DDE in eggs; success was apparently unaffected when residues ranged from 5 to 100 µg/g.¹⁴⁰ Great blue herons produced fledglings from nests with sample eggs that contained up to 16 µg/g of DDE.¹⁴¹ Pipped great blue heron eggs with viable embryos contained as much as 78 µg/g.¹⁴² Viable herring gull eggs collected from an island in the Great Lakes in 1964 contained very high mean residues of DDT (19 µg/g), DDD (6 µg/g), and DDE (202 µg/g); however, productivity was reduced to only about 50% of the normal (pre-DDT) levels¹⁴³ and returned to normal in 1965, despite persistence of high residues.¹⁴⁴ Domestic chickens experienced few effects on eggshell thickness or reproductive success even at high dietary levels of DDT or DDE.^{145–146} Lundholm⁶⁶ characterized birds as very sensitive, moderately sensitive, or insensitive to effects of DDE on eggshell thinning that may persist for up to 1 year after dosage ceases.^{147–148}

Although ecotoxicological effects of DDT were demonstrated most often in birds, and to a lesser extent in mammals,¹⁴⁹ particularly bats,^{30,138} other segments of the biota have been affected. Lake trout (*Salvelinus namaycush*) fry that absorbed the yolk sac and died contained ≥ 2.9 µg/g of DDT;¹⁵⁰ this apparently had some adverse effect on the population.

Usage of DDT in the United States peaked in 1959 when 78×10^6 pounds were applied, but only one third that amount was used in 1970.¹ The primary reason for decline in use, before the ban of nearly all uses of DDT in the United States in 1972,¹⁵¹ was the development of resistance in major invertebrate pests. With the ban in the United States and many other countries, adverse effects of DDT on wildlife decreased, and depressed populations of brown pelicans,^{112,122} bald eagles,^{152,153} osprey,^{154,155} merlins (*Falco columbarius*),¹³⁶ double-crested cormorants,¹⁵⁶ great cormorants,¹³⁷ Mexican free-tailed bats,¹³⁸ and other species experienced full or partial recovery in much of North America, Europe, and certain other areas. Recent changes in peregrine falcon populations have ranged from small increases to essentially full recovery.¹⁵⁷

DDT proved more persistent than first estimated, particularly around sites of heavy contamination such as fruit orchards¹⁵⁸ other agricultural lands^{159,160} and manufacturing and formulating plants.^{122,161–163} DDT use continues in Brazil, Mexico, South Africa, and other countries,¹⁶⁴ where it is used primarily for mosquito control³ and in Zimbabwe and possibly other African countries, where it was used for tsetse fly (*Glossina* spp.) control.¹⁶⁵ Residues sufficient to induce eggshell thinning, reproductive effects, and mortality were documented recently in some avian populations including the white-headed black chat (*Thamnolaea arnoti*) in Zimbabwe.¹⁶⁵

Bald eagles were extirpated on Santa Catalina Island in California about 50 years ago. The current breeding population originated from a transplanting program initiated in the 1980s (first egg laid in 1987) and extending into the 1990s. Eggs of eagles on Santa Catalina contained high residues of DDE (25 to 67 $\mu\text{g/g}$) in 1990; all nests on the island failed.¹⁶⁶ The bald eagle transplanting program was initiated because brown pelicans in the Channel Islands were recovering from effects of DDT. In retrospect, it seems unreasonable to continue the transplanting program as long as the serious problems from DDE persist in bald eagles. This tale of response of two species to a pollutant in a common area further emphasizes the complexity of ecotoxicological research.

In Nevada in 1996 mean residues of 2.7 $\mu\text{g/g}$ of DDE in eggs of white-faced ibis (*Plegadis chihi*) were associated with decreases of 20% in productivity and 18% in eggshell thickness.¹⁶⁷ Residues in eggs of ibis were similar to those reported 10 years earlier; residues were apparently accumulated on the wintering ground. In 2000 another study of the white-faced ibis along the Colorado River in Arizona also revealed continuing problems from DDE. Average eggshell thinning of 15% were associated with DDE a mean residue of 2.2 $\mu\text{g/g}$ in eggs apparently was related to poor reproductive success.¹⁶⁸

In Canada from 1993 to 1995 American robins occupying fruit orchards were accumulating very high levels ($\bar{x} = 85 \mu\text{g/g}$) of DDE several decades after the last use of DDT in the orchards.²⁶ Although these high DDE levels had no demonstrable effect on reproductive success of the robins, predators consuming robins were probably at risk.¹⁶⁹ Another study (1988–1994) of DDE persistence in Canadian apple orchards revealed that eastern bluebirds (*Sialia sialis*) in Ontario were accumulating residues as high as 105 $\mu\text{g/g}$ in pooled egg samples.¹⁷⁰ There was some indication that organochlorine pesticides were associated with a reduction in reproduction of $\leq 14\%$ in 4 of 6 years; however, pooling of eggs for analysis probably confounded the conclusions.

From 1994 to 1995 some eggs of double-crested cormorants in Green Bay, Wisconsin contained DDE residues sufficient to reduce hatching success of some eggs; however, there was no apparent effect on cormorant population trends.¹⁷¹

A study of burrowing owls (*Athene cunicularia*) in 1996 in four areas in southern California revealed no effects of contaminants in eggs on reproductive success or the owls, even though DDE residues in one area averaged 7.5 $\mu\text{g/g}$ and eggshell thinning averaged 42%.¹⁷² The extreme thinning of burrowing owl eggshells appears anomalous and was apparently too high. Use of the pre-1947 mean thickness listed by Henny et al.,¹⁷³ compared to the data from California, indicated 12% thinning in the most contaminated area and 4% in the least contaminated areas.

The only major problem with DDD occurred in California when it was applied three times from 1949 to 1957 to Clear Lake to control gnats (*Haoporus astictopus*).^{174,175} Residues of DDD reached high levels in the biota, especially in western grebes (*Aeschmorporus occidentalis*), where

levels (lipid basis) were as high as 1200 $\mu\text{g/g}$ in body fat and 1007 $\mu\text{g/g}$ in eggs. The Clear Lake study was probably the first to document trophic level accumulation that proved so important in explaining the persistence of residues and residual effects of the OCs.¹⁷⁷ After the first application of DDD, the number of breeding pairs of western grebes decreased from 1000 in 1949 to none the following year. The western grebe breeding population had increased to only 165 pairs in 1967, and their reproductive success was still poor. The only other known environmental problem from DDD was mortality of a common loon (*Gavia immer*).¹⁷⁸

13.3.2 Aldrin/Dieldrin

These two closely related OCs are very toxic and were involved in numerous incidents of wildlife mortality. When aldrin is applied in the field, it is rapidly broken down to dieldrin; aldrin is found in biological samples only near application sites.¹⁷⁹

In 1960 and 1961 aldrin was applied in April to agricultural land in Illinois to control an infestation of Japanese beetles (*Popillia japonica*). The solid-block application of 2.2 kg/ha resulted in an estimated mortality of 25 to 50% of the adult ring-necked pheasants (*Phasianus colchicus*) within 1 month.¹⁸⁰ Reproduction of pheasants the year of application was severely depressed, as evidenced by the low numbers of chicks and the abnormally high proportion (52 to 56%) of broodless hens, the low ratio of young per adult in autumn, and reduced numbers of cock-calls the following spring. Reproduction on the treated area returned to normal the following year. Dieldrin residues ranged from 2.9 to 15 $\mu\text{g/g}$ in breast muscle of pheasants found dead and from 4.6 to 7.9 $\mu\text{g/g}$ in eggs.¹⁸⁰

In experimental studies as little as 1 $\mu\text{g/g}$ of aldrin in the diet caused mortality of 20% of adult ring-necked pheasants.¹⁸¹ Egg production ceased by 10 weeks in hens receiving only 1 or 2 $\mu\text{g/g}$ of aldrin in their diet.¹⁸⁴ Fulvous whistling-ducks (*Dendrocygna bicolor*), snow geese (*Chen caerulescens*), and a number of other birds and invertebrates died after ingesting aldrin-treated rice seed in Texas from the late 1960s until 1974, when this use of aldrin was banned.^{183,184} Brains of most waterfowl and other birds found dead contained lethal levels of dieldrin as determined by the lower diagnostic lethal level of 5 $\mu\text{g/g}$ in brains of experimental birds receiving dieldrin-contaminated diets.⁵² The fulvous whistling-duck population decrease was apparently related to aldrin use.¹⁸³ The whistling-duck population started to increase after the 1974 ban,¹⁸⁵ but the population estimates in the mid-1980s were still less than those of the early 1950s.¹⁸⁶

In one of the most vivid examples of the toxicity of dieldrin, Scott et al.¹⁸⁷ found virtual elimination or extreme mortality of most species of terrestrial mammals when dieldrin was applied in Illinois to control the Japanese beetle. Dieldrin was also used for a short time in the attempted eradication of the imported fire ant (*Solenopsis saevissima*) in the southeastern United States.¹⁸⁸

Dieldrin induced adverse effects on reproduction of birds in experimental studies,^{189,190} but there are few data from the field. Shags had low productivity when dieldrin residues reached 2 to 3 $\mu\text{g/g}$ in their eggs.¹⁹¹ Golden eagles (*Aquila chrysaetos*) in Scotland and brown pelicans in the southeastern United States seemed to have lowered productivity when dieldrin residues in sample eggs were ≥ 1 $\mu\text{g/g}$.^{111,192} However, further investigation seemed to indicate that at least the pelican relationship was spurious because brown pelicans in Louisiana had good productivity when dieldrin residues averaged nearly 1 $\mu\text{g/g}$ in their eggs.^{112,193,194} Such interpretive problems arise because many of the OC residues are positively intercorrelated; this may confound identification of effect levels of individual compounds because effects of multiple contaminants may or may not be additive. Dieldrin only induced up to 6% shell thinning in eggs of experimental birds;^{195,196} evidence from field studies also indicated that this OC is unimportant in eggshell thinning.^{109,132}

In the United States dieldrin killed 28 of 444 bald eagles analyzed from 1964 to 1977; however, it was concluded that DDE was the primary factor in the widespread population declines.¹³⁵ In contrast, several investigators have postulated that dieldrin, in concert with DDT, was responsible for population declines of certain birds including the Eurasian sparrowhawk (*Accipiter nisus*), the

merlin, and the peregrine falcon in Great Britain,^{17,197-199} and the peregrine falcon in the eastern United States.²⁰⁰ It was postulated that DDE adversely affected eggshell thickness and reproduction and that dieldrin and related cyclodienes (heptachlor and aldrin) induced mortality of adults in these populations. In the Eurasian sparrowhawk studies the role of dieldrin was emphasized because the population apparently crashed more quickly than could be accounted for by reproductive failure alone.²⁰¹ Secondary exposure of Eurasian sparrowhawks to dieldrin was mostly through ingestion of birds that had consumed treated seed.

A recent study²⁰² analyzed population trends of Eurasian sparrowhawks from 1963 to 1986; dieldrin accounted for 29% of sparrowhawks found dead. In conjunction with adverse reproductive problems related to DDE, it was postulated to cause a population decline of 20% per year. The population recovery of Eurasian sparrowhawks and merlins in Great Britain proceeded as residues of dieldrin and DDE declined.^{203,204}

Ratcliffe¹⁹⁸ concluded that the dramatic decline of the peregrine falcon population in Great Britain was related to the combined effects of dieldrin, aldrin, and heptachlor (cyclodienes) that were used as seed treatments, soil treatments, sheep dips, and other purposes. DDT was apparently of secondary importance because it was used years before onset of the decline that coincided more closely with initial use of the other three insecticides. Peregrines in the Scottish Highlands during 1962 to 1966 were reproducing well despite a high mean level (1.2 µg/g) of dieldrin in their eggs.²⁰⁵ This seems to reinforce the conclusion that if population declines were attributable to dieldrin, the critical aspect was mortality of adults. In addition, the population in Great Britain increased shortly after restrictions on the cyclodienes were imposed in 1962 and apparently reached the pre-1940 level by 1985.¹⁹⁸

Declines of peregrine populations occurred throughout Europe; lowest levels were found in the 1960s and early 1970s.²⁰⁶ Populations increased dramatically in most countries by 1985, but few populations were near pre-1940 levels. The pre-1940 population of 2000 to 3500 pairs in Fennoscandia decreased to a low of 65 pairs in 1975 and had increased to just 120 to 150 pairs by 1985.²⁰⁷ Newton²⁰⁶ concluded that the cyclodienes were primarily responsible for declines of peregrine populations throughout Europe; DDT played a secondary role in spite of adverse effects on eggshell thickness and reproductive success. In Fennoscandia, however, Lindberg et al.^{207,208} stressed the role of DDE and polychlorinated biphenyls (OC contaminants of industrial origin) in peregrine declines in that region.

Nisbet²⁰⁰ concluded that declines in peregrine falcon populations in some regions of North America were too rapid to have been caused by reproductive failure alone. Actual and potential exposure of peregrines to dieldrin was considered sufficiently high and widespread by the mid-1950s to have caused excessive adult mortality. Nevertheless, Nisbet²⁰⁰ concluded that the role of dieldrin in declines of the North American and British populations was based largely on circumstantial evidence and that other OCs may have been involved. Peakall and Kiff¹²⁷ concluded that DDE has been and continues to be the pollutant of primary importance adversely affecting peregrine falcon populations.

The gray bat (*Myotis grisescens*) population occupying a cave in Central Missouri experienced mortality from dieldrin (originating from agricultural applications of aldrin). Lethal levels of dieldrin in brains of gray bats were first noted in 1976, when the population contained 1800 individuals;²⁰⁹ the population was extirpated by 1979. Residues of dieldrin reached 89 µg/g in milk of lactating bats. Beginning in 1977 residues of heptachlor epoxide (heptachlor was intended as a substitute for aldrin) increased and also reached lethal levels in brains of some gray bats. After use of dieldrin and heptachlor was suspended, residues in the bats and their food decreased. Bats then returned to the colony, and the population increased from 8000 to 38,000 by 1994.¹³⁸ Gray bats at several other caves in central Missouri also died with lethal levels of dieldrin and heptachlor epoxide in their brains.

Except for limited use, aldrin and dieldrin were canceled in the United States in 1974;¹⁵¹ several other countries also banned these pesticides in the 1970s. As a result, problems from these pesticides largely dissipated in these areas. Nevertheless, wildlife mortalities from dieldrin persisted long after

the ban in the United States.²¹⁰ A dieldrin “hotspot” still persists at the Rocky Mountain Arsenal National Wildlife Refuge (RMANWR) near Denver, Colorado. Several pesticides and other toxic chemicals were manufactured at the site until 1987. A study of great horned owls from 1994 to 1996 revealed dieldrin-related deaths of a few adult owls and a dispersing juvenile. Although no adverse effects were noted during the nesting period, plasma samples from 9- to 10-week-old young that later died during the post-fledging period tended to have the highest residues of dieldrin.²¹¹

Carcasses and brains of big brown bats captured at the RMANWR in 1997 and 1998 contained elevated residues of dieldrin; however, the bats experienced no obvious adverse effects.²¹² High residues of dieldrin in soil apparently had no effect on deer mouse (*Peromyscus maniculatus*) populations at the RMANWR. Paradoxically, populations tended to be higher and greater proportions of females were reproductively active in the highly contaminated sites compared to a reference area.⁷² While genetic resistance of deer mice to dieldrin was mentioned as a possible mechanism for their success, absence of residue analysis in deer mouse tissues precludes any factual basis for resistance.

13.3.3 Endrin

Unlike most other OCs, endrin has a relatively short half-life in tissues of mammals^{213,214} and birds.^{215,216} Endrin rivals telodrin as the most acutely toxic OC pesticide.

In the United States the most extreme effect of endrin resulted from contamination of the Mississippi River from a plant at Memphis, Tennessee. The endrin moved downstream and killed millions of fish, especially the Gulf menhaden (*Brevoortia patronus*), near the mouth of the river.²¹⁷ Coincidentally, and without evidence of involvement by endrin, the large population of brown pelicans (estimated at 12,000 to 85,000 birds from 1918 to 1933¹²³) in the Louisiana estuaries was first noted undergoing a decline in 1958²¹⁸ and was extirpated by 1963.²¹⁹ The last breeding record was 1961 when a study of behavior was conducted at a small colony where the investigator was unaware of the plight of the population.²²⁰ From 1968 to 1980 a program was initiated to restore the brown pelican in Louisiana by transplanting about 1300 birds from Florida.^{221,222} The initial population growth was slow, and the short-term increase in use of endrin after the DDT ban, primarily on sugar cane, caused a die-off of about 35 to 45% of the total population of 400 to 459 pelicans in the mid-1970s.^{193,221} Brains of pelicans found dead in the mid-1970s contained endrin residues¹⁹³ similar to the lethal diagnostic residues ($\geq 0.8 \mu\text{g/g}$) established in experimental birds.⁵⁵ Their eggs contained elevated levels suggestive of possible effects¹⁹³ based on studies with experimental eastern screech owls (*Otus asio*).²²³ Once endrin use was discontinued in the area, endrin residues dropped dramatically and problems quickly dissipated,¹⁹³ and the breeding population of brown pelicans in Louisiana increased to about 700 pairs by 1984.²²²

In field experiments endrin was shown to cause reductions in populations of meadow voles (*Microtus pennsylvanicus*) over the short term and in deer mice (*Peromyscus maniculatus*) over the long term.²²⁴ Endrin use as a rodenticide in Washington State orchards killed many birds.^{45,225} Circumstantial evidence indicated that avian mortality may occur within hours after heavy applications in orchards despite a minimal time to death of several days in experimental studies.⁴⁵ Coveys of California quail (*Callipepla californica*) and chukars (*Alectoris chukar*) died after exposure to endrin spray. Use of endrin was restricted in 1979.¹⁵¹ Mortality of wildlife in Washington orchards dramatically declined after severe restrictions on endrin use were implemented in 1982 and other rodenticides, such as anticoagulants, were substituted.⁴⁵ In the Washington orchards endrin was applied postharvest in late fall or early winter, so there were no effects on reproductive success. Residues were present in some birds' eggs, but they were not high enough to impair reproduction.⁴⁵

In Montana relatively small quantities of endrin were applied to wheat fields to control insect pests.²²⁶ Residues of endrin were found in birds and mammals in Montana, but few detrimental effects were substantiated. In fruit orchards in New York, use of endrin as a rodenticide resulted in buildup of residues of endrin, but few adverse effects were noted.²²⁷

Endrin has one of the most interesting metabolic pathways of the OCs. In some mammals the pesticide is broken down into a metabolite, 12-ketoendrin, which is much more toxic than the parent compound. In laboratory rodents dying on endrin-contaminated diets residue analyses of rat brains revealed low levels of endrin but apparently lethal quantities of 12-ketoendrin (means ranged from 0.13 $\mu\text{g/g}$ ²²⁸ to 0.28 $\mu\text{g/g}$),²²⁹ whereas brains of mice contained lethal residues of endrin and little 12-ketoendrin.²²⁸ Experimental birds dying from dietary endrin had lethal levels of endrin in their brains, but only one of these contained 12-ketoendrin.^{228,230} There are no records of 12-ketoendrin residues in wild birds, even those dying from endrin poisoning.⁴⁵ In the field apparent deaths from 12-ketoendrin have occurred in an opossum (*Didelphis virginiana*) in New York²²⁷ and two deer mice in Montana.²²⁶ A montane vole (*Microtus montanus*) found dead after an endrin application in a Washington orchard contained a lethal level of endrin in its brain, but no 12-ketoendrin was detected.⁴⁵

13.3.4 Chlordane

Technical chlordane is a mixture of organochlorines that has been used as an insecticide since the late 1940s.²³¹ Chlordanes and their metabolites are ubiquitous in the environment; low concentrations are commonly found in environmental samples. Despite widespread use, persistence, and lipophilic properties, there was no firm evidence of either lethal or sublethal effects of chlordane on wild vertebrates when used in terrestrial systems^{54,231} until diagnostic lethal residues of heptachlor epoxide and oxychlordane were established in experimental birds given technical chlordane in the diet.⁵⁴ Residues of the two critical compounds in brains of experimental birds dying from chlordane ranged from 3.4 to 8.3 $\mu\text{g/g}$ for heptachlor epoxide and 1.1 to 5.0 $\mu\text{g/g}$ for oxychlordane. The lower ends of these ranges are imprecise. The residues of each compound should be weighed according to their individual lethal residues. For example, the lower limit of the lethal range is 8 $\mu\text{g/g}$ of heptachlor epoxide alone or 5 $\mu\text{g/g}$ oxychlordane alone in brains of birds.⁵⁴ Therefore, assuming straightforward additivity, examples of lethal combinations are 4 $\mu\text{g/g}$ of heptachlor epoxide and 2.5 $\mu\text{g/g}$ of oxychlordane or 2 $\mu\text{g/g}$ of heptachlor epoxide and 3.8 $\mu\text{g/g}$ of oxychlordane.

The first documented problems in the terrestrial environment occurred when three raptorial birds died with lethal combinations of the two toxic components of technical chlordane. One of the raptors also had a near-lethal level of dieldrin in its brain.²³² Other birds also died from chlordane poisoning.²³³ In New York State and New Jersey mortalities related to technical chlordane are recurring,^{210,234} even though the only registered use for chlordane from the late 1970s to 1988 was for termite control through subterranean applications.²³⁵ The persistence of chlordane problems in the United States seems unique to the New York-New Jersey area;^{210,234} however, routine analysis for residues of organochlorine pesticides in other areas probably have declined. Previously, chlordane was heavily used on lawns, golf courses, and certain crops. Continuing problems are related to these past uses. To support this a recent study in New Jersey in 1998²³⁶ verified that beetles were accumulating high residues of chlordane-related residues in areas formerly treated with chlordane; these residues were sufficient to account for mortality of over 400 birds in 1996 to 1997, including common grackles, (*Quiscalus quiscula*), European starlings (*Sturnus vulgaris*), American robins, and Cooper's hawks (*Accipiter cooperi*). Big brown bats (*Eptesicus fuscus*) and little brown bats (*Myotis lucifugus*) also died from chlordane.²³⁶

13.3.5 Heptachlor

Heptachlor was formerly a widely used insecticide; it was gradually phased out and most of its uses were withdrawn by 1983.¹⁵¹ One of its early uses that pointed toward its extreme toxicity to wildlife was an attempt to eradicate the imported fire ant in the southeastern United States. Excessive mortality of passerine birds and nontarget invertebrates on small plots²³⁷ resulted in its withdrawal for fire-ant control — but not until after several years of use.²³⁸

Treatment of wheat seeds with cyclodiene insecticides, including heptachlor, aldrin, or dieldrin, resulted in mortality of a large number of wood pigeons (*Columba palumbus*) and other birds in England;²³⁹ nearly 6000 wood pigeons died on 600 ha in 1961.²⁴⁰ Experiments verified that cyclodiene seed treatments were lethal to birds.²⁴¹

Heptachlor seed treatments resulted in the death of about 1300 foxes (*Vulpes vulpes*) in England during the winter of 1959–1960.²⁴² Livers of dead foxes contained 10 to 90 $\mu\text{g/g}$ heptachlor epoxide and 3 to 13 $\mu\text{g/g}$ dieldrin. The foxes were feeding on wood pigeons that had ingested the treated wheat seed; captive foxes died within 1 to 2 weeks after ingesting three to six contaminated wild wood pigeons.²⁴² Heptachlor also induced mortality of gray bats in central Missouri and, along with dieldrin, may have caused extirpation of one colony (see section on dieldrin).^{138,209}

In the late 1970s in Oregon and Washington, heptachlor seed treatments were associated with mortality, lowered reproductive success, and decline of a local population of Canada geese (*Branta canadensis*).^{34–35} American kestrels that fed on prey that had ingested treated wheat seed also experienced lowered reproductive success and some adult mortality.¹⁴⁰ Kestrels seemed more sensitive to heptachlor epoxide than geese; nest success of geese was adversely affected when sample eggs contained $> 10 \mu\text{g/g}$ compared with $< 3 \mu\text{g/g}$ for kestrels.^{35,140} Once heptachlor seed treatments were banned in the area and another OC, lindane, was used as a replacement, die-offs of birds ceased. Following the ban, reproductive success improved; and the local Canada goose breeding population doubled in size in less than a decade.³⁵ Most of the treated grain was made available to geese from spillage during planting or transporting operations and from intentional dumping of excess grain.³⁵

13.3.6 Hexachlorocyclohexane (HCH)

This pesticide, also known by the misnomer benzene hexachloride (BHC), consists of a mixture of five isomers; the gamma isomer (lindane) is the main insecticidal component.²³⁵

Several isomers of HCH impart an unpleasant flavor to food, crops, and poultry products consumed by humans;¹ therefore, its use in the United States was voluntarily canceled by the principal manufacturer in 1978. The alpha and beta isomers also had some repellency to wildlife when used as a seed treatment, particularly to ring-necked pheasants.²⁴³ Lindane is odorless and tasteless, but the technical formulation contains other isomers that impart repellency.²⁴⁴ After ingestion, lindane is rapidly metabolized to water-soluble chlorophenols and chlorobenzenes that are readily excreted. Other characteristics of lindane that reduce its hazard to wildlife are a much lower half-life in tissues and eggs of birds than most OCs^{215,245} and rapid degradation after application in the field.²⁴⁶ Although high levels of lindane in the diet inadvertently given to domestic pigeons (*Columba livia*) resulted in some mortalities²⁴⁷ and lindane seed treatment was suspected of being hazardous to wild birds,²⁴⁸ lindane has not been implicated in any problem with populations in the field,²⁴⁹ except for a population of greater horseshoe bats (*Rhinolophus ferrumequinum*) in Dorset in Britain that occupied 3200 km² of habitat. This population was thought extirpated by lindane, but there were no residue data available. After roosts in buildings were sprayed in 1953 with a 1% solution of lindane, 15,000 bats died; mortality and reproductive failure were noted for 26 years following the single application (summary by Clark and Shore¹³⁸). Die-offs of bats in Britain also occurred in Cornwall; high residues of dieldrin were noted in timber samples after this material was applied as a chiroptericide.

When lindane was substituted for heptachlor as a seed treatment in the northwestern United States (see heptachlor section), problems dissipated and residues of lindane in tissues or eggs were rarely found in seed eaters^{35,250} and were never found in predators of seed eaters.^{140,251} For these reasons, lindane is one of the few OCs that is still widely used. Nevertheless, lindane is sufficiently hazardous under confined conditions that its uses for control of insect pests in poultry facilities or human habitation were banned. Also, experimental studies indicate that lindane in the diet of domestic chickens reduced hatchability and egg production, increased embryonic mortality, and

induced eggshell thinning of 8 to 18%.²⁵² Remarkably, Sauter and Steele²⁵² reported that effects at 0.1 µg/g in the diet were essentially the same as those at 1 or 10 µg/g. Ware and Naber²⁵³ found no effect of 10 µg/g dietary lindane on reproduction of domestic chickens, but only egg production and weight gain of hens were measured. Also, domestic chickens receiving 200 µg/g of lindane in the diet for 1 month laid eggs with normal eggshell thickness.²⁵⁴

13.3.7 Toxaphene

Toxaphene is a broad-spectrum pesticide that is produced by reacting camphene with chlorine in the presence of ultraviolet radiation and certain catalysts to yield a mixture of 177 chlorinated camphenes with a chlorine content of 67 to 69%.²³⁵ Toxaphene was first used in the United States in 1948; it was the most heavily used insecticide in 1980. Annual production exceeded 45 million kg, with primary use in agricultural crops, particularly cotton. Toxaphene use was canceled in the United States in 1982, but existing stocks could be used after that time.¹⁵¹

Residues of toxaphene were as high as 50 µg/g in livers of colonial waterbirds found dead at the Klamath Basin National Wildlife Refuges.^{175–255} The deaths could not definitively be attributed to toxaphene because high residues of DDT and its metabolites were present. A more convincing case against toxaphene occurred when Big Bear Lake in southern California was treated with toxaphene to control rough fish populations. Besides the large die-off of fish, over 200 birds were found dead.¹⁷⁵ Tissues of dead birds were not analyzed, but toxaphene residues in fat of ducks and water birds that were shot ranged from 12 to 1700 µg/g.¹⁷⁵ The lake was toxic to fish for over 1 year. Another die-off of birds also occurred in California after toxaphene was used to control grasshoppers on a shortgrass range; carcasses of birds contained from 0.1 to 9.6 µg/g.²⁵⁶ There are no experimental studies with lethal diagnostic residues of toxaphene to evaluate amounts in birds found dead, but circumstantial evidence indicated that it was the major mortality factor in the last two examples.

Experimental studies to determine effects of dietary levels of toxaphene on reproduction of birds indicated no effects at 50 ppm for black ducks (*Anas rubripes*)²⁵⁷ or 100 ppm for ring-necked pheasants.¹⁸² Some reproductive problems with the pheasants occurred at a dietary level of 300 ppm.¹⁸² Keith²⁵⁵ reported that some young American white pelicans (*Pelecanus erythrorhynchos*) died after 4 to 5 weeks on a diet that contained 50 ppm toxaphene, but there was also some mortality of young on clean food. Domestic chickens given dietary levels of 0.5 to 100 ppm toxaphene exhibited no significant effects on productivity; however, sternal or keel deformation was noted in birds fed 5 ppm, and renal lesions were detected in those fed 50 ppm.²⁵⁸

Considering the widespread use of toxaphene, there are few serious known effects on the biota other than problems associated with its use as a piscicide and effects on experimental birds — primarily at high levels.

13.3.8 Dicofol

Several million pounds of dicofol are used annually in the United States for control of phytophagous mites, with most being applied to cotton and citrus.²⁵⁹ Dicofol is produced from DDT as the starting material; therefore, there are a number of DDT-related contaminants in technical dicofol.^{260,261} In ring-neck doves (*Streptopelia risoria*) and laboratory mice, there are three fat-soluble metabolites of dicofol including dichlorobenzophenone, dichlorobenzhydrol, and monodechlorinated dicofol.^{261,262} These metabolites are generally less toxic than the parent compound. Some of the experimental birds given diets containing pure or nearly pure dicofol at concentrations ranging from about 5 to 93 mg/kg (dry weight) experienced eggshell thinning and adverse effects on reproductive success including feminization of male embryos^{263–266} (MacLellan et al. 1996). Reproduction of mammals and fish was also adversely affected by dicofol in experimental studies.²⁵⁹

Experimental studies indicate that dicofol has the potential to induce serious adverse effects when applied in the field because it and its metabolites accumulate in tissues and eggs of birds

given dietary dosages.^{262,265} However, in the best definition of the value of ecotoxicological studies there were no adverse effects from dicofol documented in field studies; moreover, residues are relatively rare in environmental samples. Residues of dicofol and metabolites were low in fish and eggs of birds, with maximum residues of about 5 µg/g (summarized by Clark²⁵⁹). In a later study in California and Texas, very low residues were detected in only one of 24 eggs of birds sampled in areas of high dicofol use. Several species of lizards in Texas contained low residues of dicofol and its metabolites, whereas lizards from California contained no residues.²⁶⁷ The legal sale and use of dicofol products that contained > 0.1% of DDT and metabolites ceased in early 1989.²⁶⁸

13.3.9 Telodrin

Telodrin is probably the most acutely toxic OC pesticide,²⁶⁹ but it was apparently never used in the United States and was used for only a short time in a relatively isolated area in Europe. This insecticide was involved in a decline in numbers of breeding pairs of Sandwich terns (*Sterna sandvicensis*) in The Netherlands from 40,000 in 1954 to 650 in 1965.^{270–272} After the telodrin factory at Rotterdam was closed in 1965 and subsequent improvements in the purification plant reduced output of the other pesticides,²⁷² the number of pairs of terns increased to > 4000 by 1974.²⁷³ Apparently, the Sandwich tern decline was unique to The Netherlands because there were no decided declines in breeding pairs in other western European countries.²⁷² Adverse effects from telodrin were not quantified; rather, the evidence suggested joint involvement with several OCs, including endrin and dieldrin.²⁷¹ Brains of several seabirds found dead contained lethal levels of endrin.²⁷⁴

13.3.10 Methoxychlor

This insecticide more or less replaced DDT in control of Dutch elm disease in American elms.²⁷⁵ American robins experienced a low rate of mortality when exposed to methoxychlor in either laboratory or field.²⁷⁶ Methoxychlor is rapidly broken down in warm-blooded animals, so that residues are rarely found in either wild birds in areas sprayed for Dutch elm disease²⁷⁶ or experimental birds given diets containing this insecticide.²⁷⁷ In American robin populations decimated by DDT numbers increased dramatically with use of methoxychlor.²⁷⁶

13.3.11 Mirex

Mirex was used as a replacement for dieldrin and heptachlor in attempts to control the imported fire ant in the southeastern United States²⁷⁸ and as a fire retardant in electronic components, fabrics, and plastics.²⁷⁹ Mirex accumulated in wildlife near the sites of application.²⁸⁰ Residues also were detected in migratory birds, mammals, and other biota throughout the United States and Canada.²⁷⁹ Mirex has potential for chronic toxicity because it is only partly metabolized and is eliminated slowly; there also may be a high rate of bioaccumulation of residues in fat, brain, eggs, and other tissues.²⁰ Although mirex was said to cause severe damage to fish and wildlife in the southeastern United States and the Great Lakes,²⁷⁹ the evidence supporting this claim is lacking. Adverse effects in experimental birds occurred only at very high dietary levels,^{53,281} and the field data only indicated possible effects.²⁷⁸ All uses of mirex in the United States were banned in 1978.²⁷⁹

13.3.12 Chlordecone

The major environmental problem from chlordecone resulted from illegal dumping from a manufacturing plant in Virginia.²⁸² Residues of chlordecone were found throughout the James River and environs; contamination also was found in Chesapeake Bay.²⁵² Chlordecone was also used to control fire ants in the southeastern United States.³ Chlordecone induced reversal of external sex

characteristics in experimental male ring-necked pheasants.¹⁸¹ Similar to mirex, chlordecone effects in experimental animals occur only at high dietary levels, but both closely related compounds are relatively persistent. Use of chlordecone in the United States was canceled in 1978.¹⁵¹

13.4 PROJECTIONS FOR THE FUTURE

Although most of the problem OCs have been banned in a number of countries, exposure, bioaccumulation, and ecotoxicological effects will be found far into the future because of the environmental persistence of many compounds and continued use in a fairly large area. The recent findings in the United States and Canada that DDE, dieldrin, and chlordane are still exerting important adverse effects on birds and other animals 20 to 30 years after use was discontinued reinforces concerns for the future. Worldwide sales of OCs dropped 20% from 1983 to 1986,¹⁶⁴ but the decline since then has probably leveled off faster than anticipated.

Recent developments include a proposed treaty that would instigate a global ban on persistent organic pollutants including DDT and other OCs.²⁸³ However, there is a debate about the retention of DDT for control of mosquitoes that carry the malaria parasite.⁹ In the Philippines in 1993 DDT was banned for all uses including mosquito control.⁴ Several replacement insecticides, primarily organophosphorus compounds, seemed to control the mosquitoes, but there are plans to resort to one insecticide — the synthetic pyrethroid ethofenprox.

The recent settlement of the lawsuit regarding DDT contamination in the California Bight for \$73 million²⁸⁴ provided the legal foundation for assessing past and continuing problems to the environment; the ecotoxicological foundation was established over 50 years ago.

13.5 CONCLUSIONS AND PERSPECTIVES

Organochlorine pesticides, although frequently regarded as uniformly highly toxic and persistent to the organism and the ecosystem as a whole, are a diverse group whose toxicity and persistence are highly variable. Toxicity of OCs is influenced by species, sex, age, stress of various kinds, formulations used, and numerous other factors. Sensitivity by species is highly variable among all taxa. Most OCs, but particularly DDT, telodrin, aldrin, endrin, dieldrin, and heptachlor, are too toxic for use in the environment; this is particularly true for the most sensitive species that are constantly at risk from these compounds. A few OCs, such as lindane and dicofol, that are still in widespread use present a low risk to the environment.

The eggshell-thinning phenomenon, depressed productivity, and mortality of birds in the field led to experimental studies with DDE and DDT and other OCs that are pertinent to actual environmental problems. In turn, experimental studies under controlled conditions resolve complex problems, such as the metabolism of endrin to 12-ketoendrin, that are impractical to study in the field. Results from controlled experiments are essential in interpreting field data that are correlative in nature. Such studies point the way to more productive work in the field; however, it is evident that experimental studies and more recent stringent registration and reregistration testing requirements have limitations in duplicating environmental conditions. In dealing with the OCs as well as other contaminants the ecotoxicologist must use a mix of data obtained from controlled experiments as well as those obtained from the field. Field experimentation, where the investigator controls certain variables and where check or reference areas are used as a comparison with the contaminated area,³⁵ present the best experimental design for obtaining accurate and pertinent results. It seems obvious that too much emphasis has been placed on obtaining large numbers of samples for residue analysis rather than using the best design to tie OC residues to important effects. As such, much of the residue data base is of doubtful scientific value, insofar as it can be used in defining ecotoxicological effects.² Controversies over whether DDE or dieldrin were more important

in causing declines of peregrine falcons and other raptors in Great Britain or whether endrin was responsible for declines of brown pelicans in Louisiana probably could have been resolved through use of the sample egg technique¹¹⁷ and other innovations.³⁵

14.1 INTRODUCTION

Crude petroleum, refined petroleum products, and individual polycyclic aromatic hydrocarbons (PAHs) contained within petroleum are found throughout the world. Their presence has been detected in living and nonliving components of ecosystems. Petroleum can be an environmental hazard for all organisms. Individual PAHs can be toxic to organisms, but they are most commonly associated with illnesses in humans. Because petroleum is a major environmental source of these PAHs, petroleum and PAHs are jointly presented in this chapter. Composition, sources, environmental fate, and toxic effects on all organisms of aquatic and terrestrial environments are addressed.

Petroleum spills raised some environmental concern during the early twentieth century when ocean transport of large volumes of crude oil began.¹ World War I caused a large number of oil spills that had a noticeably adverse effect on marine birds. The subsequent conversion of the economy of the world from coal to oil, followed by World War II, greatly increased the petroleum threat to marine life. Efforts to deal with a growing number of oil spills and intentional oil discharges at sea continued during the 1950s and 1960s.¹ The wreck of the *Torrey Canyon* off the coast of England in 1967 produced worldwide concern about the consequences of massive oil spills in the marine environment. Research on the environmental fate and biological effects of spilled petroleum increased dramatically during the 1970s. The *Exxon Valdez* oil spill in Prince William Sound, Alaska, in 1989, and the massive releases of crude oil into the Arabian Gulf during the 1991 Gulf War again captured international attention and resulted in an increase in environmental research. Despite considerable progress in developing methods to clean up spills, the adoption of numerous national and international controls on shipping practices, and high public concern (e.g., passage of the Oil Pollution Act of 1990 [33 USCA Sec. 2701-2761] in the United States), petroleum continues to be a widespread environmental hazard.

The association between skin cancer in chimney sweeps and exposure to contaminants in soot was made in England during the late eighteenth century. By the early twentieth century, soot, coal tar, and pitch were all known to be carcinogenic to humans. In 1918 benzo(a)pyrene was identified as a major carcinogenic agent; other PAHs have since been identified as carcinogenic or tumorigenic. Many toxic and carcinogenic effects of PAHs on humans, laboratory animals, and wildlife have been described in numerous reviews.²

14.2 COMPOSITION AND CHARACTERISTICS

14.2.1 Petroleum

Petroleum consists of crude oils and a wide variety of refined oil products. Crude oils vary in chemical composition, color, viscosity, specific gravity, and other physical properties. Color ranges from light yellow-brown to black. Viscosity varies from free flowing to a substance that will barely pour. Specific gravity of most crude oils varies between 0.73 and 0.95.³ Refined oil products most often spilled in large quantities are aviation fuel, gasoline, No. 2 fuel oil (diesel fuel), and No. 6 fuel oil (bunker C). Fuel oils (Nos. 1 to 6) become increasingly dense and viscous and contain increasingly fewer volatile compounds as their numeric classification proceeds from one to six.

Crude oil is a complex mixture of thousands of hydrocarbon and nonhydrocarbon compounds. Hydrocarbons comprise more than 75% of most crude and refined oils; heavy crude oils can contain more than 50% nonhydrocarbons.^{3,4} Hydrocarbons in petroleum are divided into four major classes: (1) straight-chain alkanes (n-alkanes or n-paraffins), (2) branched alkanes (isoalkanes or isoparaffins), (3) cycloalkanes (cycloparaffins), and (4) aromatics (Figure 14.1). Alkenes occur in crude oil, but they are rare. A variety of combinations of the different types of compounds occur. Low-molecular-weight members of each class predominate in crude oils. Aliphatic hydro-

Figure 14.1 Types of molecular structures found in petroleum.³ Hydrogen atoms bonded to carbon atoms are omitted.

carbons have the carbon atoms arranged in an open chain (straight or branched). Aromatic hydrocarbons have the carbon atoms arranged in ring structures (up to six), with each ring containing six carbon atoms with alternating single and double bonds. The aliphatic hydrocarbons (except alkenes) have maximum hydrogen content (saturated), whereas the aromatic hydrocarbons do not have maximum hydrogen content (unsaturated) because of the alternating double bonding between carbon atoms. Nonhydrocarbons in petroleum are compounds containing oxygen (O), sulfur (S), nitrogen (N) (Figures 14.1 and 14.3), or metals, in addition to hydrogen and carbon, and can range from simple open-chain molecules to molecules containing 10 to 20 fused aromatic and cycloalkane carbon rings with aliphatic side chains. The largest and most complex nonhydrocarbons are the resins and asphaltenes.

Crude oils are classified according to physical properties or chemical composition.^{3,5} Specific gravity determines whether oil is classified as light, medium, or heavy. Crude oils also can be partitioned into chemical fractions according to boiling point. The relative amounts of compounds in various categories are sometimes used to classify oil (e.g., paraffinic, naphthenic, high or low sulfur).

14.2.2 PAHs

Polycyclic aromatic hydrocarbons are aromatic hydrocarbons with two or more fused carbon rings that have hydrogen or an alkyl ($C_n H_{2n+1}$) group attached to each carbon. Compounds range from naphthalene ($C_{10} H_8$, two rings) to coronene ($C_{24} H_{12}$, seven rings) (Figure 14.2). Crude oils contain 0.2 to 7% PAHs, with configurations ranging from two to six rings; PAH content increases with the specific gravity of the oil.⁶⁻⁸ In general, PAHs have low solubility in water, high melting and boiling points, and low vapor pressure. Solubility decreases, melting and boiling points increase, and vapor pressure decreases with increasing molecular volume. Investigators assessing biological effects sometimes group true PAHs with compounds consisting of aromatic and nonaromatic rings, or compounds with N, S, or O within the ring (heterocycle) or substituted for attached hydrogen (Figure 14.3).

Figure 14.2 Examples of PAH compounds without attached alkyl groups.¹⁶ Hydrogen atoms bonded to carbon atoms are omitted.

14.3 SOURCES

14.3.1 Petroleum

During the early 1970s about 35% of the petroleum hydrocarbons in the marine environment came from spills and discharges related to marine transportation; the remainder came from offshore oil and gas production, industrial and municipal discharges, stormwater discharges, river runoff, atmospheric deposition, and natural seeps^{9,10} (Figure 14.4). Transportation spills and discharges probably accounted for less than 35% of the total oil discharged onto land and freshwater environments.¹⁰ Estimates for the late 1970s indicated that about 45% of the petroleum hydrocarbons in the marine environment came from spills and discharges related to marine transportation.¹¹ In heavily used urban estuaries, the contribution of transportation spills and discharges to total petroleum hydrocarbon input can be 10% or less.^{12,13} By contrast, the largest source of petroleum in coastal or inland areas removed from urban or industrial centers is petroleum transportation. In the 1980s and 1990s, war, terrorism, vandalism, and theft became additional, and sometimes major, causes of petroleum discharges into water and land environments.^{14,15}

Figure 14.3 Examples of PAH compounds with attached alkyl groups and aromatic compounds with nitrogen, sulfur, or oxygen.⁸ Except for the alkyl groups, hydrogen atoms bonded to carbon atoms are omitted.

14.3.2 PAHs

Most PAHs are formed by a process of thermal decomposition (pyrolysis) and subsequent recombination (pyrosynthesis) of organic molecules.¹⁶ Incomplete combustion of organic matter produces PAHs in a high-temperature (500 to 800°C) environment. All forms of combustion, except flammable gases well mixed with air, produce some PAHs. Subjection of organic material in sediments to a low-temperature (100 to 300°C) environment for long periods of time produces PAHs as coal and oil deposits within sedimentary rock formations (a.k.a. diagenesis).^{7,17} Although the PAH compounds formed by high- and low-temperature processes are similar, the occurrence of alkylated PAHs is greater in the low-temperature process.¹⁴ Biological formation of PAHs occurs in chlorophyllous plants, fungi, and bacteria.^{2,8}

Natural sources of PAHs include forest and grass fires, oil seeps, volcanoes, plants, fungi, and bacteria. Anthropogenic sources of PAHs include petroleum, electric power generation, refuse incineration, and home heating; production of coke, carbon black, coal tar, and asphalt; and internal combustion engines.^{2,7} The primary mechanism for atmospheric contamination by PAHs is incom-

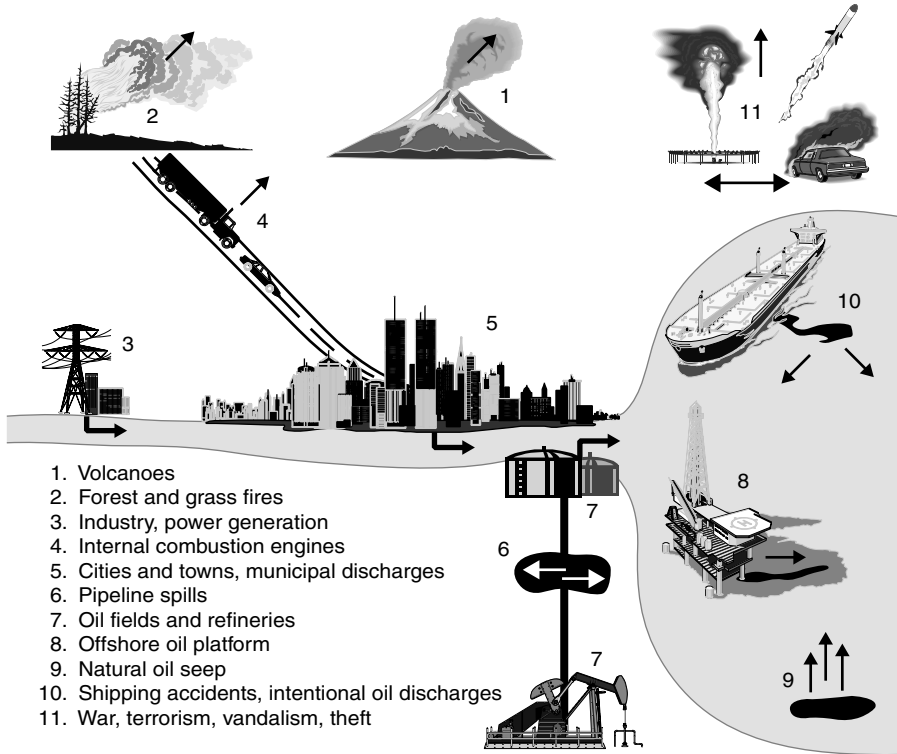

Figure 14.4 Sources of petroleum and PAHs in the environment. Arrows indicate the initial movement of PAH and petroleum into the air, water, and soil.

plete combustion of organic matter from previously mentioned sources.¹⁵ Aquatic contamination by PAHs is caused by petroleum spills, discharges, and seepages; industrial and municipal wastewater; urban and suburban surface runoff; and atmospheric deposition.² Land contamination by PAHs is caused by petroleum spills and discharges, forest and grass fires, volcanoes, industrial and municipal solid waste, and atmospheric deposition.

14.4 ENVIRONMENTAL FATE

14.4.1 General Considerations

Petroleum is monitored as a liquid composed of a diverse array of thousands of compounds, but PAHs are monitored as a group of individual compounds with similar molecular structures. Polycyclic aromatic hydrocarbons from low- or high-temperature pyrolysis and pyrosynthesis of organic molecules have similar fates in the environment. Whereas PAHs from crude and refined oils and coal originate from a concentrated hydrocarbon source, PAHs produced by high temperature (combustion or industrial processes) are dispersed in the air, scattered on the ground, or included as a component of liquid waste and municipal sewage discharges.

14.4.2 Physical and Chemical

Petroleum discharged on water spreads quickly to cover large areas with a layer of oil varying from micrometers to centimeters thick. Some oils, especially heavy crudes and refined products,

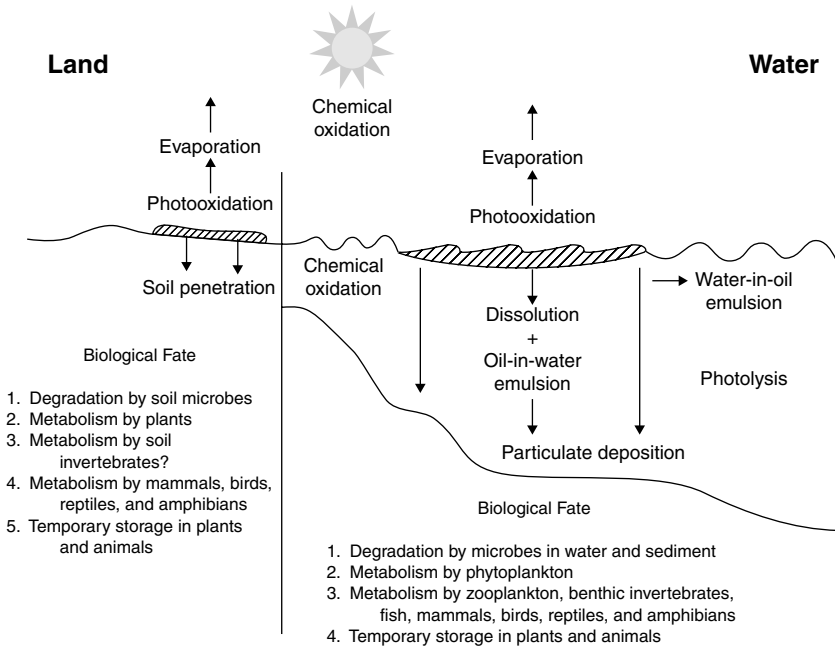

Figure 14.5 Chemical and biological fate of petroleum and PAHs in water and on land.

sink and move below the surface or along the bottom of the water body. Wave action and water currents mix the oil and water and produce either an oil-in-water emulsion or a water-in-oil emulsion. The former increasingly disperses with time, but the latter resists dispersion. Water-in-oil emulsions have 10 to 80% water content; 50 to 80% of emulsions are often described as “chocolate mousse” because of the thick, viscous, brown appearance. Oil remaining on the water eventually forms tar balls or pancake-shaped patches of surface oil that drift ashore or break up into small pieces and sink to the bottom.

Polycyclic aromatic hydrocarbons released into the atmosphere have a strong affinity for airborne organic particles and can be moved great distances by air currents. The molecules are eventually transported to earth as wet or dry particulate deposition.¹⁸

Crude and refined oil products begin to change composition on exposure to air, water, or sunlight³ (Figure 14.5). Low-molecular-weight components evaporate readily; the amount of evaporation varies from about 10% of the spilled oil for heavy crudes and refined products (No. 6 fuel oil) to as much as 75% for light crudes and refined products (No. 2 fuel oil, gasoline). Less than 5% of a crude oil or refined product (primarily low-molecular-weight aromatics and polar nonhydrocarbons) dissolves in water. Hydrocarbons exposed to sunlight, in air or water, can be converted to polar oxidized compounds (photooxidation). Degradation of hydrocarbons in water by photolysis occurs when oxygen is insufficient for photooxidation; high-molecular-weight aromatic hydrocarbons are particularly likely to be altered by this mechanism.⁷ Chemical oxidation of aromatic hydrocarbons can result from water and wastewater treatment operations⁷ and chemical reactions in the atmosphere.¹⁸

14.4.3 Biological

The movement of oil from the water surface into the water column by dissolution and emulsion exposes the molecules and particles of oil to degradation and transport by organisms. Microbes

(bacteria, yeast, filamentous fungi) in the water metabolize the light and structurally simple hydrocarbons and nonhydrocarbons.^{3,19} Heavy and complex compounds are more resistant to microbial degradation and eventually move into bottom sediments. Oil particles and individual hydrocarbons (petroleum or recent pyrosynthesis) also adhere to particles (detritus, clay, microbes, phytoplankton) in the water and settle to the bottom, where a variety of microbes metabolize the light and structurally simple compounds. About 40 to 80% of a crude oil can be degraded by microbial action.³

Oil and anthropogenic PAHs are ingested by a variety of invertebrate and vertebrate organisms, in addition to microbes. Mammals, birds, fish, and many invertebrates (crustaceans, polychaetes, echinoderms, insects) metabolize and excrete some of the hydrocarbons ingested during feeding, grooming, and respiration.^{2,20-24} Although bivalve mollusks and some zooplankton are either unable or marginally able to metabolize oil, they can transport and temporarily store it. Terrestrial plants and aquatic algae can assimilate and metabolize hydrocarbons.^{2,25,26} Some soil invertebrates could be capable of metabolizing oil and anthropogenic PAHs, but evidence is absent from the literature.

Accumulation of hydrocarbons is usually inversely related to the ability of the organism to metabolize hydrocarbons.^{2,6} For example, bivalve mollusks have a poorly developed mixed function oxygenase (MFO) capability and accumulate hydrocarbons rapidly. After acute exposure, depuration of light for structurally simple hydrocarbons, especially aliphatic hydrocarbons, is more rapid than for heavy hydrocarbons, especially aromatic hydrocarbons.^{2,8,27,28} Hydrocarbons accumulated by bivalves through chronic exposure are depurated slowly.^{8,29} Organisms, such as fish and some crustaceans, that possess a well-developed MFO system (microsomal monooxygenases) are capable of metabolizing hydrocarbons and only accumulate hydrocarbons in heavily polluted areas.² Aquatic environmental factors that reduce the potential for hydrocarbon uptake and retention include high levels of dissolved or suspended organic material and warm water temperatures. Increases in PAH accumulation have not been observed in the trophic levels of aquatic ecosystems.^{8,30} Aquatic and terrestrial mammals, birds, reptiles, and amphibians have well-developed MFO systems, but enzyme induction by hydrocarbons in these species is not as well described as in fish and some aquatic invertebrates.³¹ Phytoplankton can accumulate aromatic hydrocarbons from water.² Terrestrial plants are poor accumulators of soil PAHs, presumably because PAHs strongly adsorb to soil organic material. Most of the PAHs detected in terrestrial plants appear to be derived from the atmosphere; PAHs adhere to or are absorbed by plant tissue. Following the death of vegetation, PAHs are deposited into the surface litter of soil.^{2,27,32}

Organisms with high lipid content, a poor MFO system, and that exhibit activity patterns or distributions that coincide with the location of hydrocarbon pollution are most likely to accumulate hydrocarbons.^{2,8} Once assimilated, heavy aromatic hydrocarbons (four or more benzene rings) are the most difficult group of hydrocarbons to excrete, regardless of MFO capability.^{2,33}

14.4.4 Residence Time

Residence time for petroleum in water is usually less than 6 months. Residence time for petroleum deposited on nearshore sediments and intertidal substrate is determined by the characteristics of the sediment and substrate. Oil-retention times for coastal environments range from a few days for rock cliffs to as much as 20 years for cobble beaches, sheltered tidal flats, and wetlands.³⁴⁻³⁸ Microbes in the sediment and on the shoreline metabolize petroleum compounds; microbial degradation is reduced considerably by anaerobic conditions.^{39,40} In cold climates ice, low wave energy, and decreased chemical and biological activity cause oil to remain in sediments or on the shore longer than in temperate or tropical climates; sheltered tidal flats and wetlands can be expected to retain oil for long periods of time.^{41,42} Total petroleum hydrocarbons or individual PAHs in undisturbed estuarine subtidal sediments can remain as identifiable deposits for many decades.⁴³

Oil spilled on land has little time to change before it penetrates into the soil. Oil spilled on lakes and streams usually has less opportunity to change before drifting ashore than oil spilled on the ocean because the water bodies are smaller. Petroleum spilled directly on land is degraded by evaporation, photooxidation, and microbial action. Residence times for hydrocarbons in terrestrial soils are less well documented than for sediments but are determined by the same conditions (substrate type, oxygen availability, temperature, surface disruption) that determine residence times in intertidal sediments. Total petroleum hydrocarbons and individual PAHs can persist in soils of cold or temperate regions for at least 20 to 40 years; persistence of PAHs increases with increase in the number of benzene rings.^{32,44-46}

14.4.5 Spill Response

Petroleum spills are sometimes left to disperse and degrade naturally,⁴⁷ but cleanup efforts are initiated when economically or biologically important areas are threatened. Oil-response actions include mechanical removal, chemical treatment, enhanced biodegradation, and restoration.^{48,49} The addition of chemicals to floating oil for purposes of gelling, herding, or dispersing the oil can modify the expected effects of the oil. The chemicals themselves often have some toxicity, and in the case of dispersants, movement of oil into the water column is greatly accelerated. Enhanced biodegradation practices are evolving through experimentation, but the most common practice is the stimulation of indigenous microbial populations through application of supplemental nitrogen or phosphorus to oil on land or water. The addition of nitrogen and phosphorus to oiled shorelines in Prince William Sound, Alaska, accelerated biodegradation and did not increase toxicity or environmental effects of the oil.⁵⁰ The literature on oil-spill response procedures, cleanup methods, and restoration methods is extensive; the interested reader is encouraged to consult literature cited in references⁴⁷⁻⁵⁰ and other sources for a more comprehensive treatment of this topic.

14.5 EFFECTS ON ORGANISMS

14.5.1 General

Petroleum can adversely affect organisms by physical action (smothering, reduced light), habitat modification (altered pH, decreased dissolved oxygen, decreased food availability), and toxic action. Large discharges of petroleum are most likely to produce notable effects from physical action and habitat modification. The aromatic fraction of petroleum is considered to be responsible for most of the toxic effects.

Polycyclic aromatic hydrocarbons affect organisms through toxic action. The mechanism of toxicity is reported to be interference with cellular membrane function and enzyme systems associated with the membrane.⁷ Although unmetabolized PAHs can have toxic effects, a major concern in animals is the ability of the reactive metabolites, such as epoxides and dihydrodiols, of some PAHs to bind to cellular proteins and DNA. The resulting biochemical disruptions and cell damage lead to mutations, developmental malformations, tumors, and cancer.^{2,6,51} Four-, five-, and six-ring PAHs have greater carcinogenic potential than the two-, three-, and seven-ring PAHs.^{2,7} The addition of alkyl groups to the base PAH structure often produces carcinogenicity or enhances existing carcinogenic activity (e.g., 7,12-dimethylbenz[a]anthracene). Some halogenated PAHs are mutagenic without metabolic activation,⁵² and the toxicity and possibly the carcinogenicity of PAHs can be increased by exposure to solar ultraviolet radiation.^{53,54} Cancerous and precancerous neoplasms have been induced in aquatic organisms in laboratory studies, and cancerous and noncancerous neoplasms have been found in feral fish from heavily polluted sites.^{2,7,55,56} However, sensitivity to PAH-induced carcinogenesis differs substantially among animals.^{2,7}

In water the toxicity of individual PAHs to plants and animals increases as molecular weight (MW) increases up to MW 202 (fluoranthene, pyrene). Beyond MW 202 a rapid decline in solubility reduces PAH concentrations to less than lethal levels, regardless of their intrinsic toxicity. However, sublethal effects can result from exposure to these very low concentrations of high MW compounds.⁷ Except for the vicinity of chemical or petroleum spills, environmental concentrations of PAHs in water are usually several orders of magnitude below levels that are acutely toxic to aquatic organisms. Sediment PAH concentrations can be much higher than water concentrations, but the limited bioavailability of these PAHs greatly reduces their toxic potential.² In general, caution should be employed when assessing the aquatic “toxicity” of biogenic or anthropogenic PAHs because bioavailability (solubility, sediment sequestration, mechanism of exposure) and chemical modification determine how much toxicity is realized.

14.5.2 Plants and Microbes

Reports of the effects of petroleum spills or discharges on plants and microbes contain accounts of injury or death to mangroves,^{57,58} seagrasses,⁵⁹ and large intertidal algae;^{60,61} severe and long-lasting (> 2 years) destruction of salt marsh vegetation^{38,62–64} and freshwater wetland vegetation;^{65,66} enhanced or reduced biomass and photosynthetic activity of phytoplankton communities;^{67,68} genetic effects in mangroves and terrestrial plants;^{69,70} and microbial community changes and increases in numbers of microbes (Table 14.1).^{71–73} Differences in species sensitivity to petroleum are responsible for the wide variation in community response for phytoplankton and microbes.

Recovery from the effects of oil spills on most local populations of nonwoody plants can require from several weeks to 5 years, depending on the type of oil, circumstances of the spill, and species affected. Mechanical removal of petroleum in wetlands can markedly increase the recovery time.^{74,75} Complete recovery by mangrove forests could require up to 20 years.⁷⁶ Phytoplankton and microbes in the water column of large bodies of water return to prespill conditions faster than phytoplankton and microbes in small bodies of water because of greater pollutant dilution and greater availability of colonizers in nearby waters.⁷⁷ Lethal and sublethal effects are caused by contact with oil or dissolved oil, systemic uptake of oil compounds, blockage of air exchange through surface pores, and possibly by chemical and physical alteration of soil and water, such as depletion of oxygen and nitrogen, pH change, and decreased light penetration.

The effects of petroleum on marine plants, such as mangroves, sea grasses, saltmarsh grasses, and micro- and macroalgae, and microbes have been studied with laboratory bioassays, experimental ecosystems, and field experiments and surveys (Table 14.1).^{78–87} Petroleum caused death, reduced growth, and impaired reproduction in the large plants. Microalgae were either stimulated or inhibited, depending on the species and the type and amount of oil; response was expressed as changes in biomass, photosynthetic activity, and community structure. In response to petroleum exposure, community composition of indigenous bacteria was altered and total biomass increased.

The effects of petroleum on freshwater phytoplankton, periphyton, and microbes have been studied with laboratory bioassays and field experiments.^{88–93} Petroleum induced effects similar to those described for marine microalgae and bacteria. Domestic and wild plants have been exposed to oiled soil in laboratory experiments^{94–96} and tundra vegetation has been subjected to an experimental spill of crude oil.⁹⁷ Inhibition of seed germination, plant growth, and fungal colonization of roots was demonstrated in the laboratory bioassays. Death of herbaceous and woody plants and long-term community alteration were caused by the experimental tundra spill.

Individual PAHs, mostly two- and three-ring compounds, at low concentrations (5 to 100 ppb) can stimulate or inhibit growth and cell division in aquatic bacteria and algae. At high concentrations (0.2 to 10 ppm) the same PAHs interfere with cell division of bacteria and cell division and photosynthesis of algae and macrophytes; they can also cause death.^{2,7}

Table 14.1 Effects of Petroleum or Individual PAHs on Organisms

Effect ^a	Type of Organism					
	Plant or Microbe	Invertebrate	Fish	Reptile or Amphibian	Bird	Mammal ^b

^a Some effects have been observed in the wild and in the laboratory, whereas others have only been induced in laboratory experiments or are population changes estimated from measures of reproduction and survival.

^b Includes a sampling of literature involving laboratory and domestic animals.

^c Populations of microalgae, microbes, soil invertebrates, and parasitic invertebrates can increase or decrease in the presence of petroleum, whereas populations of other plants and invertebrates and populations of vertebrates decrease.

14.5.3 Invertebrates

Reports of the effects of aquatic oil spills or discharges and oil-based drill cuttings often contain accounts of temporary debilitation, death, population change, or invertebrate community change for marine water column,^{98,99} deepwater benthic,^{100,101} nearshore subtidal,^{102–105} intertidal,^{64,106,107} coastal mangrove organisms,^{102,108} and stream^{109,110} and lake¹¹¹ organisms. For a review of the effects of petroleum on marine invertebrates, see Suchanek.¹¹² Observed effects are caused by smothering; contact by adults, juveniles, larvae, eggs, and sperm with whole or dissolved oil; ingestion of whole oil or individual compounds; and possibly by chemical changes in the water, including oxygen depletion and pH change. Accounts of the effects of petroleum spills or discharges on terrestrial invertebrates have not been published.

Recovery from the effects of oil spills on local populations of invertebrates can require as little as a week for pelagic zooplankton or as much as 10 years, or more, for nearshore subtidal meiofauna. Uncertainty of recovery time is particularly evident for intertidal, nearshore subtidal, and coastal mangrove biota; the prognosis for recovery is a function of the size of the spill, type of oil, season of year, weather, characteristics of affected habitat, and species affected. Chronic input of petroleum from natural seeps or anthropogenic sources produces communities of biota that are adapted to the hydrocarbon challenge; preexisting or continuing chronic input can complicate estimates of inver-

tebrate recovery from ephemeral input. Aggressive cleaning of shorelines can retard recovery.¹¹³ Zooplankton in large bodies of water return to prespill conditions faster than zooplankton in small bodies of water (isolated estuaries, lakes, stream headwaters) because of greater pollutant dilution and greater availability of colonizers in nearby waters.⁷⁷

Much work has been done on the effects of petroleum on marine invertebrates with laboratory bioassays, mesocosms, enclosed ecosystems, and field experiments and surveys.^{82,114–124} Less work has been conducted on freshwater invertebrates with laboratory bioassays and field experiments.^{88,125–129} Among the effects reported are reduced survival, altered physiological function, soft-tissue abnormalities, inhibited reproduction, altered behavior, and changes in species populations and community composition.

Soil contaminated with petrochemicals has been associated with a reduced number of species and reduced species abundance of rodent parasites.¹³⁰ In contrast, petrochemical contamination of soil increased the abundance of isopods,¹³¹ and chronic exposure to low concentrations of PAHs appeared to stimulate populations of several groups of soil invertebrates.¹³² In soil remediation studies earthworms have been found to be a sensitive indicator of soil quality.¹³³

In short-term exposure trials (24 to 96 h) on selected aquatic invertebrates, individual PAH compounds had LC₅₀ values in water ranging from 0.1 to 5.6 ppm.^{2,7} Eggs and larvae are more sensitive than juveniles or adults to dissolved PAHs. Larvae with a high tissue burden of PAHs from maternal transfer are likely to be at risk for increased toxicity from ultraviolet radiation.¹³⁴ Sublethal effects include reduced reproduction, inhibited development of embryos and larvae, delayed larval emergence, decreased respiration and heart rate, abnormal blood chemistry, and lesions.^{2,7}

14.5.4 Fish

Adult and juvenile fish, larvae, and eggs are exposed to petroleum through contact with whole oil, dissolved hydrocarbons, particles of oil dispersed in the water column, or ingestion of contaminated food and water.^{135,136}

Death of fish in natural habitat usually requires a heavy exposure to petroleum. Consequently, it is unlikely that large numbers of adult fish inhabiting large bodies of water would be killed by the toxic effects of petroleum. Fish kills usually are caused by large amounts of oil moving rapidly into shallow waters.^{137,138} However, fresh and weathered crude oils and refined products vary considerably in their composition and toxicity, and the sensitivity of fish to petroleum differs among species. Petroleum concentrations (total petroleum hydrocarbons) in water of less than 0.5 ppm during long-term exposure¹³⁹ or higher concentrations (several to more than 100 ppm) in moderate- or short-term exposures can be lethal.^{140–143} Sublethal effects begin at concentrations of less than 0.5 ppm and include changes in heart and respiratory rates, gill structural damage, enlarged liver, reduced growth, fin erosion, corticosteroid stress response, immunosuppression, impaired reproduction, increased external and decreased internal parasite burdens, behavioral responses, and a variety of biochemical, blood, and cellular changes.^{136,142,144–154}

Eggs and larvae can suffer adverse effects, including death, when exposed to concentrations of petroleum in water ranging from less than 1 ppb (total PAHs) up to 500 ppb (total PAHs or total petroleum hydrocarbons).^{155–158} Eggs, larvae, and early juveniles are generally more vulnerable than adults to oil spills and discharges because they have limited or no ability to avoid the oil, and they reside in locations that receive the most severe exposures (near the water surface or in shallow nearshore areas and streams). Effects of oil on eggs and larvae include death of embryos and larvae, abnormal development, reduced growth, premature and delayed hatching of eggs, DNA alterations, and other cellular abnormalities.^{136,156–161} Evidence of continued adverse effects on the viability of pink salmon (*Oncorhynchus gorbuscha*) embryos for 4 years after the *Exxon Valdez* oil spill in Prince William Sound, Alaska, presented the possibility of gametic damage to exposed fish.¹⁶²

Assessing the effect of petroleum spills and discharges on fish populations has been attempted with a variety of approaches, including taking fish samples from oiled and control areas after a

spill,¹⁶³ monitoring postspill fish harvest and recruitment,¹³⁸ aerial surveys of fish stocks before and after spill events,¹⁶⁴ translating abundance of benthic prey into estimates of demersal fish biomass,¹⁰⁴ using a life-history model to estimate effects on a species,¹⁶⁵ measuring differences in fish community composition above and below a discharge site on a stream,¹⁴⁹ and evaluating the potential of deleterious heritable mutations induced by a one-time spill event to produce measurable population change.¹⁶⁶ Several of these attempts revealed likely effects of petroleum on fish populations.

Also, the potential effects of oil spills on regional pelagic fish populations were evaluated with an extensive modeling effort of the Georges Bank fishery off the northeastern coast of the United States.^{167,168} Unfortunately, normal variation in natural mortality of eggs and larvae for such species as Atlantic cod (*Gadus morhua*), haddock (*Melanogrammus aeglefinus*), and Atlantic herring (*Clupea harengus*) is often larger than mortality estimates for the largest of spills. Consequently, direct field observations would not be able to distinguish the effect of a major oil spill on a single year class from natural variation in recruitment. The authors concluded that a comprehensive recruitment model was needed to separate the effect of spilled oil from expected natural mortality.

In general, it is difficult to determine the effect of an ephemeral petroleum discharge on fish populations in large bodies of water. It is beneficial to have before-and-after data, and some modeling appears necessary to identify effects that are difficult to measure. Also, time and geographic scale are important considerations in any population assessment.

In short-term exposure trials (24 to 96 h) on selected species of fish, individual PAH compounds had LC₅₀ values in water ranging from 1.3 to 3400 ppb.² The primary target organ for toxic action is the liver. Sublethal effects on eggs, larvae, juveniles, and adult fish² are generally similar to those previously described for exposure to fresh or weathered petroleum and separate aromatic fractions but with greater emphasis on neoplasm induction and DNA alteration.

Induction of precancerous cellular changes in laboratory studies with PAHs and high frequencies of lesions and cancerous and noncancerous neoplasms in bottom-dwelling fish from areas contaminated with PAHs provide support for a causal relation between PAHs in sediment and the presence of cancer in several species of bottom-dwelling marine fish.^{7,33,55,56,169–171} Fish from Puget Sound, Washington,¹⁷² tributaries of southern Lake Erie, Ohio,^{55,173,174} and the Elizabeth River, Virginia,¹⁷⁵ had cancerous and noncancerous skin and liver neoplasms, fin erosion, and a variety of other external abnormalities. Concentrations of total PAHs in the sediment were sometimes > 100 ppm and 50 to 10,000 times greater than in reference areas.^{2,55,173,175}

There is evidence that exposure to high concentrations of PAHs can affect fish populations and communities. Lesion frequency, overall health assessment, and population age structure were useful biological measures for differentiating a population of brown bullheads (*Ameiurus nebulosus*) in an industrialized urban river (Schuylkill River, Philadelphia, Pennsylvania) from a population in a nonindustrialized suburban pond (Haddonfield, New Jersey).¹⁷⁶ Analysis of fish community structure revealed lower species diversity for contaminated Lake Erie tributaries (Black and Cuyahoga Rivers, Ohio) than for a reference stream (Huron River, Ohio).¹⁷⁴

Metabolism of PAHs by feral fish in areas chronically contaminated with multiple pollutants is poorly studied; studies such as van der Oost¹⁷⁷ are rare. Also lacking is information on dose-effect and temporal aspects of *in situ* exposure to carcinogens.^{33,55} Species differences in PAH metabolism and incidence of neoplasms, even among closely related species,³³ further complicate efforts to generalize about findings from individual studies.

14.5.5 Reptiles and Amphibians

The response of reptiles and amphibians to petroleum exposure is not well characterized. Various species of reptiles and amphibians were killed by a spill of bunker C fuel oil in the St. Lawrence River (E.S. Smith, New York Department of Environmental Conservation, Albany, NY, unpublished report). Sea snakes were presumed to have been killed by crude oil in the Arabian Gulf.¹⁷⁸ Petroleum could have been a contributing factor in the deaths of sea turtles off the coast of Florida,¹⁷⁹ in the

Gulf of Mexico following the *Ixtoc I* oil spill,¹⁸⁰ and in the Arabian Gulf after the Gulf War oil spills,¹⁸¹ but the cause of death was not determined. Ingestion of oil and plastic objects has been reported for green (*Chelonia mydas*), loggerhead (*Caretta caretta*), and Atlantic Ridley (*Lepidochelys kempi*) turtles.^{179,180,182}

Experimental exposure of juvenile loggerhead turtles to crude oil slicks revealed effects on respiration, skin, blood characteristics and chemistry, and salt gland function.¹⁸³ Juvenile loggerhead turtles were exposed to artificially weathered crude oil for 4 days followed by an 18-day recovery period; blood abnormalities and severe skin and mucosal changes from exposure were reversed during the recovery period.¹⁸⁴ Atlantic Ridley and loggerhead embryos died or developed abnormally when the eggs were exposed to oiled sand; weathered oil was less harmful to the embryos than fresh oil (T.H. Fritts and M.A. McGehee, Fish and Wildlife Service, Denver Wildlife Research Center, Denver, CO, unpublished report).

Bullfrog tadpoles (*Rana catesbeiana*) were exposed to amounts of No. 6 fuel oil that could be expected in shallow waters following oil spills; death was most common in tadpoles that were in the late stages of development, and sublethal effects included grossly inflated lungs, fatty livers, and abnormal behavior.¹⁸⁵ Larvae of the wood frog (*Rana sylvatica*), the spotted salamander (*Ambystoma maculatum*), and two species of fish were exposed to several fuel oils and crude oils in static and flow-through tests; sensitivity of the amphibian larvae to oil was slightly less than that of the two species of fish.¹⁴⁰ Exposure of green treefrog (*Hyla cinerea*) embryos and larvae and larval mole salamanders (*Ambystoma opacum* and *A. tigrinum*) to used motor oil in natural ponds, field enclosures, or laboratory containers caused reduced growth or reduced food (algae) densities and prevented metamorphosis of green frogs at high exposure.^{186,187}

The injection or implantation in amphibians of perylene or crystals of benzo(a)pyrene and 3-methylcholanthrene induced cancerous and noncancerous tissue changes.² It has been suggested that amphibians are more resistant to PAH carcinogenesis than mammals because of the demonstrated inability of the hepatic microsomes of the tiger salamander (*A. tigrinum*) to produce mutagenic metabolites.¹⁸⁸ The toxicity and genotoxicity of benzo(a)pyrene and refinery effluent to larval newts (*Pleurodeles waltlii*), in the presence and absence of ultraviolet radiation, was established in a series of experiments by Fernandez and l'Haridon.¹⁸⁹

14.5.6 Birds

Birds can be affected by petroleum through external oiling, ingestion, egg oiling, and habitat changes. External oiling disrupts feather structure, causes matting of feathers, and produces eye and skin irritation. Death often results from hypothermia and drowning.^{1,190–192} Bird losses in excess of 5000 individuals are common for moderate to large petroleum spills. Birds that spend much of their time in the water, such as alcids (*Alcidae*), waterfowl (*Anatidae*), and penguins (*Spheniscidae*), are the most vulnerable to surface oil.

Petroleum can be ingested through feather preening, consumption of contaminated food or water, and inhalation of fumes from evaporating oil. Ingestion of oil is seldom lethal, but it can cause many debilitating sublethal effects that promote death from other causes, including starvation, disease, and predation. Effects include gastrointestinal irritation, pneumonia, dehydration, red blood cell damage, impaired osmoregulation, immune system suppression, hormonal imbalance, inhibited reproduction, retarded growth, and abnormal parental behavior.^{192–203}

Bird embryos are highly sensitive to petroleum. Contaminated nest material and oiled plumage are mechanisms for transferring oil to the shell surface. Small quantities (1 to 20 μL) of some types of oil (light fuel oils, certain crude oils) are sufficient to cause death, particularly during the early stages of incubation.^{204,205} Eggshell applications of petroleum weathered for several weeks or longer are less toxic to bird embryos than fresh or slightly weathered petroleum.^{206,207}

Petroleum spilled in avian habitats can have immediate and long-term effects on birds. Fumes from evaporating oil, a shortage of food, and cleanup activities can reduce use of an affected area.^{208,209}

Long-term effects are more difficult to document, but severely oiled wetlands and tidal mud flats are likely to have altered plant and animal communities for many years after a major spill.^{62,82}

The direct and indirect effects of oil spills are difficult to quantify at the regional or species level. Death from natural causes and activities of humans (e.g., commercial fishing), weather, food availability, and movement of birds within the region can obscure the effects of a single or periodic catastrophic event. Regional population assessments in the northern Gulf of Alaska for bald eagles (*Haliaeetus leucocephalus*) and common murre (*Uria aalge*) after the *Exxon Valdez* oil spill in March 1989 failed to identify population changes attributable to the spill.^{210–212} During the last 50 years seabird populations of western Europe have increased or decreased without apparent relation to losses from oil spills.^{213,214}

Effects of oil spills are most likely to be detected at the level of local populations. Also, measures of survival, reproduction, and habitat use of numerous individual birds can be extrapolated to local or regional populations. The *Exxon Valdez* oil spill in Prince William Sound, Alaska caused the loss of an estimated 250,000 to 375,000 birds.^{215,216} Adverse effects of this spill have been described for individuals of several species of seabirds or wintering waterfowl in Prince William Sound and extrapolated to populations.^{217–220} Wiens et al.²¹⁸ also combined the species effects into assessments of avian community composition. Marine bird population declines have also been reported after the 1996 *Sea Empress* spill off the coast of England²²¹ and the 1991 Arabian Gulf oil spill.²²² Most of the changes in performance measures or local population size were no longer detectable by 2 years after the spill; exceptions were described by Wiens et al.,²¹⁸ Esler et al.,²²¹ and Symens and Suhaibani.²²²

The consequences of direct and indirect effects of oil spills on seabird populations have also been estimated with simulation models.^{223–226} Models have shown that (1) an occasional decrease in survival of breeding adults will have a greater effect on seabird populations than an occasional decrease in reproductive success, (2) long-lived seabirds with low reproductive potential will have the most difficulty recovering from a catastrophic oil spill, and (3) recovery of a seriously depleted population of long-lived seabirds will be greatly hindered if adult survival and reproduction show small, but sustained, decreases. The overall recovery potential for a species depends on the reproductive potential of the survivors and the immigration potential from surrounding areas.^{227,228}

Much of the available information on effects of PAHs on birds was produced by studies of the effects of petroleum on eggs. Experiments have shown that the PAH fraction of crude and refined oils is responsible for the lethal and sublethal effects on bird embryos caused by eggshell oiling.²⁰⁵ Further, the toxicity of PAHs to bird embryos is a function of the quantity and molecular structure of the PAHs.²²⁹ Brunstrom et al.²³⁰ injected a mixture of 18 PAHs (2.0 mg/kg of egg) into eggs of the chicken (*Gallus domesticus*), turkey (*Meleagris gallopavo*), domestic mallard (*Anas platyrhynchos*), and common eider (*Somateria mollissima*) and found the mallard to be the most sensitive species and benzo[k]fluoranthene (four rings) and indeno[1,2,3-cd]pyrene (five rings) to be the most toxic of the PAHs tested. The most toxic PAHs were found to have additive effects on death of embryos, and the cause of toxicity was proposed to be a mechanism controlled by the Ah receptor.²³¹ Naf et al.²³² injected a mixture of 16 PAHs (0.2 mg/kg of egg) into chicken and common eider eggs and reported that > 90% was metabolized by day 18 of incubation (chicken), with the greatest concentration of PAHs in the gall bladder of both species. Mayura et al.²³³ injected fractionated PAH mixtures from coal tar (0.0625 to 2.0 mg/kg of egg) into the yolk of chicken eggs and found that death, liver lesions and discoloration, and edema increased as the proportion of five- and > five-ring aromatics, compared to the proportion of two- to four-ring aromatics, increased in the mixture.

Studies with adults and nestlings revealed a variety of sublethal toxic effects induced by PAHs. Male mallard ducks fed 6000 ppm of a mixture of 10 PAHs combined with 4000 ppm of a mixture of 10 alkanes for 7 months in a chronic ingestion study had greater hepatic stress responses and higher testes weights than male mallards fed 10,000 ppm of the alkane mixture.²³⁴ Nestling herring gulls (*Larus argentatus*) were administered single doses (0.2 or 1.0 mL) of crude oils, their aromatic

or aliphatic fractions, or a mixture of crude oil and dispersant.^{235,236} Retardation of nestling weight gain and increased adrenal and nasal gland weights was attributed to the PAHs with four or more rings. Immune function and mixed-function oxidase activity of adult European starlings (*Sturnus vulgaris*) were altered by subcutaneous injections (25 mg/kg body weight) of 7,12-dimethylbenz[a]anthracene, a four-ring PAH, every other day for 10 days.²³⁷ Oral doses in adult birds (25 mg/kg body weight) and nestlings (20 mg/kg body weight) also altered immune function. The coefficient of variation of nuclear DNA volume of red blood cells from wild lesser scaup (*Athya affinis*) was positively correlated with the concentration of total PAHs in scaup carcasses.²³⁸

14.5.7 Mammals

Marine mammals that rely primarily on fur for insulation, such as the sea otter (*Enhydra lutris*), polar bear (*Ursus maritimus*), Alaska fur seal (*Callorhinus ursinus*), and newborn hair seal pups (*Phocidae*), are the most likely to die after contact with spilled oil.^{22,239,240} Oiled fur becomes matted and loses its ability to trap air or water, resulting in hypothermia. Adult hair seals, sea lions (*Eumetopias jubatus*, *Zalophus californianus*), and cetaceans (whales, porpoises, dolphins) depend primarily on layers of fat for insulation; thus, oiling causes much less heat loss. However, skin and eye irritation and interference with normal swimming can occur. Skin absorption of oil has been reported for seals and polar bears.

Oil ingested in large quantities can have acute effects on marine mammals. However, marine mammals, such as seals and cetaceans, are capable of rapid hydrocarbon metabolism and renal clearance.²³⁹ Ingested oil can cause gastrointestinal tract hemorrhaging in the European otter (*Lutra lutra*);²⁴¹ renal failure, anemia, and dehydration in the polar bear;²⁴² pulmonary emphysema, centrilobular hepatic necrosis, hepatic and renal lipidosis, increased nuclear DNA mass, altered blood chemistry, and possible gastric erosion and hemorrhage in sea otters,^{243–245} and altered blood chemistry and reduced body weight in river otters (*Lontra canadensis*).²⁴⁶ Inhalation of evaporating oil is a potential respiratory problem for mammals near or in contact with large quantities of unweathered oil.^{239,247} Some of the previously described disorders are thought to be caused by hypothermia, shock, and stress rather than direct toxic action; distinguishing between the two types of causes can be difficult.²⁴⁸

Effects of the *Exxon Valdez* oil spill on populations of sea otter, harbor seals (*Phoca vitulina*), Stellar sea lions, killer whales (*Orcinus orca*), and humpback whales (*Megaptera novaeangliae*) in Prince William Sound, Alaska, are summarized in the overview provided by Loughlin et al.²⁴⁵ Sea otters and harbor seals were the most affected, with loss estimates in the thousands for otters and in the hundreds for seals. Age distributions of dead sea otters systematically collected from oiled areas of western Prince William Sound between 1976 and 1998 revealed a reduction in the survival rate of otters during the 9 years after the spill (1990–1998).²⁴⁹ Aerial counts of harbor seals at seven sites affected by the oil spill and 18 unaffected sites in central and eastern Prince William Sound revealed a 28% population reduction during the period 1990–1997; however, harbor seal populations on the survey route were declining prior to the 1989 spill.²⁵⁰ Effects of the Gulf War oil spills on cetaceans in the Arabian Gulf were thought to be minimal.²⁵¹ Overall, the consequences of local effects (acute, chronic, and indirect) of catastrophic oil spills on regional populations of marine mammals have proven difficult to determine because of a lack of prespill population information, movement of animals within the region, and natural fluctuations in survival and reproduction.

Documentation of the effects of oil spills on wild nonmarine mammals is less than for marine mammals. Large numbers of muskrats (*Ondatra zibethica*) were killed by a spill of bunker C fuel oil in the St. Lawrence River (E.S. Smith, New York Department of Environmental Conservation, Albany, NY, unpublished report). Giant kangaroo rats (*Dopodomys ingens*) in California were found dead after being oiled,²⁵² beaver (*Castor canadensis*) and muskrats were killed by an aviation kerosine spill in a Virginia river,²⁵³ and rice rats (*Oryzomys palustris*) in a laboratory experiment

died after swimming through oil-covered water.²⁵⁴ Oil field pollution in wooded areas in Russia affected blood characteristics, organ indices, species composition, relative abundance, and population age and sex structure of small mammals.²⁵⁵ Cotton rats occupying old petrochemical sites were characterized by increased cell apoptosis in the ovary and thymus,²⁵⁶ and rodent populations and assemblages on the same types of sites were altered compared to nearby reference sites.²⁵⁷ The literature on effects of crude or refined petroleum on laboratory and domestic animals is substantial; recent examples are Lee and Talaska (DNA adduct formation in mouse skin),²⁵⁸ Feuston et al. (systemic effects of dermal application in rats),²⁵⁹ Khan et al. (clinical and metabolic effects in dosed cattle),²⁶⁰ and Mattie et al. (pathology and biochemistry of dosed rats).²⁶¹

The effects of major oil spills on the environment of mammals could include food reduction, an altered diet, and changed use of habitat.^{262,263} These effects could be short- or long-term and would be most serious during the breeding season, when movement of females and young is restricted.

The metabolism and effects of some PAHs have been well documented in laboratory rodents and domestic mammals but poorly documented in wild mammals. Acute oral LD₅₀ values for selected PAHs in laboratory rodents range from 50 to 2000 mg/kg body weight.² Target organs for PAH toxic action are skin, small intestine, kidney, and mammary gland; tissues of the hematopoietic, lymphoid, and immune systems; and gametic tissue. Nonalkylated PAHs are rapidly metabolized; hence, accumulation is less likely than for alkylated PAHs.² Partially aromatic PAHs, alkylated fully and partially aromatic PAHs, and metabolites of nonalkylated, fully aromatic PAHs have the greatest potential to alter DNA and induce cancerous and noncancerous neoplasms in epithelial tissues of laboratory and domestic mammals.² Species differences in sensitivity to carcinogenesis appears to be a function of differences in levels of mixed-function oxidase activities. Background exposure concentrations of PAHs and studies on mixtures of PAHs in mammals are needed to accurately assess the potential hazard of exposure to multiple PAHs in polluted environments.²

Although PAHs can produce systemic effects, DNA alterations, and cancer, concerns about the carcinogenic and mutagenic potential predominate, especially for human health. Consequently, PAHs that are carcinogenic or mutagenic are most studied.² With regard to wild mammals, a few investigations have documented the presence of PAH adducts on DNA of marine mammals,²⁶⁴⁻²⁶⁶ and participants of a recent workshop on marine mammals and persistent ocean contaminants²⁶⁷ described PAHs as a “less widely recognized” contaminant that should be further studied because of potential mutagenic and genotoxic effects.

14.5.8 The *Exxon Valdez* and Arabian Gulf Oil Spills

The 1989 *Exxon Valdez* oil spill (EVOS) in Prince William Sound, Alaska and the Gulf War oil spills (GWOS) in the Arabian Gulf in 1991 are worthy of special comment. Each was significant for different reasons, and reports of the fate and effects of these spills dominated the petroleum pollution literature during the 1990s.

The EVOS consisted of 36,000 metric tons of crude oil released in just a few days into a high-latitude, relatively pristine marine ecosystem. Although many times smaller than the Gulf War oil discharges, the scientific and societal response was immediate and intense. The spill resulted in a massive oil-removal effort,²⁶⁸ a thorough crude oil mass balance determination spanning the period 3/24/89 to 10/1/92²⁶⁹ and the largest wildlife rescue and rehabilitation effort ever attempted (at a cost of \$45 million).²⁷⁰

In the United States, the Clean Water Act and the Comprehensive Environmental Response, Compensation, and Liability Act determined the response requirements for trustees (federal, state, tribal) of affected natural resources. Trustees initiated research that sought evidence of “injury” to natural resources, and Exxon Corporation initiated research that sought to demonstrate minimal injury and subsequent restoration of affected resources. This adversarial legal process discouraged cooperation among scientists and delayed public access to the results of the studies for several years.²⁶⁸ Two books containing studies sponsored mostly by Exxon²⁷¹ and Trustees²⁷² provide many

examples of conflicting interpretations of the effects of the spill; Wiens²⁷³ provides a discussion of the effects of advocacy on investigations of the effects of the spill on birds. The EVOS is rapidly becoming the most studied oil spill in history; a stream of scientific reports continues to be generated by scientists assessing the biological consequences.

The GWOS consisted of 240 million metric tons of crude oil released into the northern Arabian Gulf over a 6-month period; the Gulf had a previous history of petroleum pollution from oil production activities and warfare. The spillage was caused by acts of war, and scientific coverage of the progression of the spill and its biological effects was delayed until hostilities ended and munitions were cleared from areas affected by discharged oil. Investigators from a number of countries performed assessments of the effects of the oil, which appear to have been less severe on plants and animals of aquatic and coastal environments than the effects reported for the EVOS. In contrast, the contamination of terrestrial environments caused by destruction of oil wells and pipelines was severe and is likely to affect terrestrial plants and animals for many years to come.^{274,275}

14.5.9 Conclusions

The effects of petroleum on organisms are as varied as the composition of petroleum and the environmental conditions accompanying its appearance. Petroleum can cause environmental harm by toxic action, physical contact, chemical and physical changes within the soil or water medium, and habitat alteration. Oil spills have caused major changes in local plant and invertebrate populations lasting from several weeks to many years. Effects of oil spills on populations of mobile vertebrate species, such as fish, birds, and mammals, have been difficult to determine beyond an accounting of immediate losses and short-term changes in local populations. Reptiles and amphibians need further study. Knowledge of the biological effects of petroleum in freshwater environments continues to increase but still lags behind comparable information for saltwater environments.

Concentrations of individual PAHs in air, soil, and water are usually insufficient to be acutely toxic, but numerous sublethal effects can be produced. The induction of lesions and neoplasms in laboratory animals by metabolites of PAHs and observations of lesions and neoplasms in fish from PAH-contaminated sites indicate potential health problems for animals with a strong MFO system capable of metabolizing PAHs. Although evidence linking environmental PAHs to the incidence of cancerous neoplasms in wild vertebrates is primarily limited to fish, the growing quantities of PAHs entering our environment are a cause for concern.

14.6 SUMMARY

Petroleum and individual PAHs from anthropogenic sources are found throughout the world in all components of ecosystems. Crude and refined oils are highly variable in composition and physical characteristics and consist of thousands of hydrocarbon and nonhydrocarbon compounds. Polycyclic aromatic hydrocarbons are aromatic hydrocarbons with two to seven fused benzene rings that can have alkyl groups attached to the rings. Less than half of the petroleum in the environment comes from spills and discharges associated with petroleum transportation. Most of the petroleum comes from industrial, municipal, and household discharges; motorized vehicles; natural oil seeps; and acts of war, terrorism, vandalism, and theft. Most PAHs are formed by a process of thermal decomposition and subsequent recombination of organic molecules (pyrolysis and pyrosynthesis). Low-temperature processes produce the PAHs in coal and oil. High-temperature processes can occur naturally (forest and grass fires, volcanoes) or can be caused by anthropogenic activities (oil, coal, and wood combustion; refuse incineration; industrial activity). Most high-temperature PAHs enter the environment as combustion emissions or components of liquid waste effluents from industrial sites and municipal sewage plants.

Crude and refined petroleum spreads rapidly on water and begins to change composition upon exposure to air, water, or sunlight. Anthropogenic aromatic hydrocarbons are dispersed by air currents and movement of waters receiving wastewater effluents. Hydrocarbons are primarily degraded by microbial metabolism; mammals, birds, fish, and many macroinvertebrates can also metabolize ingested hydrocarbons. Hydrocarbons are also degraded by photooxidation, photolysis, and chemical oxidation.

Organisms with high lipid content, activity patterns or distributions that coincide with the location of the hydrocarbon source, and a poor mixed-function oxygenase system are most likely to accumulate hydrocarbons. Trophic-level increases in accumulation have not been observed. Residence time for petroleum in the water column is usually less than 6 months. Coastal environments can retain oil from several days to 20 years, depending on the configuration of the shoreline, type of substrate, and climate. High-molecular-weight hydrocarbons, particularly aromatics, can persist for long periods of time (> 20 years) in sediments and terrestrial soils.

Petroleum can have lethal or sublethal effects in plants and microbes. Recovery from the effects of oil spills requires as little as a few weeks for water column microalgae up to 5 years for most wetland plants; mangroves could require up to 20 years. Individual PAHs at low concentrations can induce positive or negative sublethal effects in aquatic bacteria and algae; high concentrations can lead to death.

Oil spills often have pronounced effects on local populations of invertebrates; recovery could require a week for zooplankton or 10 years for intertidal populations of mollusks. A large and diverse amount of experimental and survey research, performed with saltwater and freshwater invertebrates, has demonstrated lethal and many sublethal effects as well as population and community effects. Individual PAHs can be lethal at high concentrations and cause sublethal effects at low concentrations.

Eggs, larvae, and early juvenile stages of fish are more vulnerable to oil because they have limited or no ability to avoid it. Large losses of adult fish are usually limited to situations where a large quantity of oil rapidly moves into shallow water. Many sublethal effects of oil on fish have been documented. Effects of oil spills on fish populations in large bodies of water are difficult to determine because of large natural variation in annual recruitment. Laboratory studies of PAH metabolism and lesions and tumors in fish collected from areas heavily contaminated with PAHs imply that PAH exposure can cause cancerous and noncancerous tissue changes in feral fish. Uncertainties about the interactive effects of multiple pollutants at heavily contaminated sites and inadequate knowledge of dose-effect responses and temporal aspects of *in situ* exposure to carcinogens complicate efforts to link environmental PAHs to neoplasms or local population changes.

Adult reptiles and amphibians can be killed and their eggs and amphibian larvae killed or sublethally affected by petroleum. However, available information is inadequate to compare their sensitivity to petroleum or individual PAHs to that of other vertebrates.

Birds are often killed by oil spills, primarily because of plumage oiling and oil ingestion. Birds that spend much of their time on the water surface are the most vulnerable to spilled oil. Ingested oil can cause many sublethal effects. Effects of oil spills are more likely to be detected at the level of local populations than at the regional or species level. When the quantity of data is large, investigators often extrapolate responses of individual birds to local and regional populations. Population modeling studies have shown that long-lived birds with low reproductive success will have the most difficulty recovering from a major oil spill. Recovery potential for a species is a function of the reproductive potential of the survivors and the immigration potential at the spill site. Experiments with individual or groups of PAHs and bird eggs, nestlings, and adults have revealed a variety of toxic responses and shown that PAHs are responsible for most of the toxic effects attributed to petroleum exposure.

Mammals that rely on fur for insulation (polar bear, otters, fur seals, muskrat) are the most likely to die from oiling. Mammals that rely on layers of fat for insulation (seals, cetaceans) are infrequently killed by oil. Ingested oil is rapidly metabolized and cleared, but it can cause many

sublethal effects. Effects of spilled oil on local and regional populations of marine mammals have proven difficult to determine because of a lack of prespill population information, movement of animals within the region, and natural fluctuations in survival and reproduction. Laboratory mammals, but not wild mammals, have been extensively used to study the toxic and carcinogenic potential of individual PAHs. Partially aromatic PAHs, alkylated, fully and partially aromatic PAHs, and metabolites of nonalkylated, fully aromatic PAHs have the greatest potential to cause neoplasms in tissues of laboratory and domestic mammals. Investigations involving mixtures of PAHs are especially needed.

In general, petroleum negatively affects living organisms through physical contact, toxic action, and habitat modification, whereas individual PAHs have toxic effects. Partially metabolized and alkylated PAHs can induce genetic damage, developmental abnormalities, and cancerous and noncancerous tissue changes. Evidence linking environmental concentrations of PAHs to induction of cancer in wild animals is strongest for fish. Although concentrations of individual PAHs in aquatic environments are usually much lower than concentrations that are acutely toxic to aquatic organisms, sublethal effects can be produced. Effects of spills on populations of mobile species have been difficult to determine beyond an accounting of immediate losses and, sometimes, short-term changes in local populations.

15.1 INTRODUCTION

Lead (Pb) is a nonessential, highly toxic heavy metal, whose known effects on biological systems are always deleterious. Lead is very soft (< 35 diamond pyramid hardness) and dense (11.34 g/cm³) and occurs as an important constituent of more than 200 minerals. The average concentration in the earth's crust is 0.016g Pb/kg soil,¹ making it a relatively rare metal. Small amounts of lead are released into the environment by natural processes, including the weathering of rocks, igneous activity, and radioactive decay. Present anthropogenic lead emissions have resulted in soil and water lead concentrations up to several orders of magnitude higher than naturally occurring concentrations.²

Lead exists in both inorganic forms (Pb[II] and less frequently Pb[IV]), in organic forms. Significantly more inorganic lead is cycled globally than organic lead. However, organolead compounds may contribute significantly on a local scale.³ Both the chemical and physical forms of lead influence its distribution and behavior within the environment and its potential for absorption by and toxicity to living organisms. Solubility and particle size are particularly important, as they affect the intercompartmental and geographical distributions of lead, its adsorption onto sediments, and absorption by living organisms.

Lead is one of the easiest metals to mine, and smelting requires only moderate temperatures. Consequently, lead has been exploited by humans for millennia. Over 7000 years ago the Egyptians used lead for weights and anchors, cooking utensils and piping, solder, and pottery glaze. The Romans also used lead extensively. The solubilization of lead from cooking pots used for preparing grape syrup for wine and preserved fruit by the aristocracy has been suggested as a major reason behind the fall of the Roman Empire. The high lead content of exhumed bones of Roman aristocrats has lent credibility to this hypothesis.⁴

Although the use of lead has a long history, demand increased greatly during the industrial revolution of the 18th and 19th centuries, and again following the adoption of organic lead compounds as antiknock agents in gasoline (initially in 1923,⁵ then proliferating following World War II). Anthropogenic uses of lead, particularly over the last century, have altered the availability and distribution of lead, locally and globally, more than for any other toxic element. High lead emissions from urban centers have resulted in urban lead concentrations several thousand times higher than in pretechnological times, and the small lead particles present in most atmospheric emissions may be transported globally by trade winds. Consequently, rural environments also have elevated lead levels. Even the most recently deposited ice layers at the North Pole have lead concentrations one to two orders of magnitude higher than in prehistoric times. At the South Pole the deposition rate of lead is 3 to 5 times higher than in pretechnological times.² World lead production in 1987 was 2,110,000 metric tons: USSR 506,000 metric tons, Australia 485,000 metric tons, Canada 422,000 metric tons, United States 317,000 metric tons, Mexico 190,000 metric tons, and Peru 110,000 metric tons.⁶ In 1994 world production was 2,800,000 metric tons primary production and 5,400,000 metric tons from secondary production (recycling).⁷ The principal uses of lead are for storage batteries, tetraalkyl lead for gasoline, cable coating, pigments and chemicals, building and construction, and caulking.⁸ Principal use patterns for lead in Europe, the United

States, and Japan are illustrated in Table 15.1. Use patterns are changing along with national and international restrictions on many of the uses of lead (e.g., as an additive in gasoline). By 1992 the shift in lead usage was obvious; batteries accounted for 63% of the total use and paint pigments (12.8%) and gas additives (2.2%) declined precipitously.⁷ Most anthropogenic lead emissions result from the mining, smelting, and refining of lead and other metal ores; vehicle emissions; and industrial emissions resulting from the production, use, recycling, and disposal of lead-containing products. The United States recycles an estimated 50,000 tons annually and discards an additional 25,000 tons into landfills nationwide.⁹

Lead poisoning has occurred for at least 2500 years,¹⁰ and the adverse health effects of lead have been widely recognized for centuries. Benjamin Franklin, in a letter to a friend in 1786, mentioned the adverse human health effects of lead and stated that “the Opinion of this mischievous Effort from Lead is at least above Sixty Years old; and you will observe with Concern how long a useful Truth may be known and exist, before it is generally received and practiced on.”¹¹ However, today, due to stricter industrial health control measures, the acute effects of lead poisoning to which Franklin was referring are rare and are generally only associated with specific localized sources of exposure. For many years, the major concern has been over health effects associated with continuous exposure to low levels of lead (i.e., chronic exposure, which does not always produce overt signs of poisoning). Particular concern has focused on the effects of lead upon intelligence quotient and behavior in children. A wide range of studies has been conducted since the 1940s,¹²⁻¹⁵ and it is now understood that juveniles, including human children, are more susceptible than adults to lead poisoning. This is a consequence of higher lead uptake, incomplete development of detoxifying metabolic pathways, and age-related differences in the permeability of the blood-brain barrier.¹⁶ In the United States, blood lead levels in 9% of the children aged 1 to 5 years exceeded 100 µg/L; blood lead levels exceeding 1000 µg/L have been reported in children living near lead smelters in undeveloped Asiatic and eastern European countries.¹⁷

As the technological capability to measure ever-lower concentrations of lead has increased, levels at which physiological effects have been measured have continued to decrease. Langford¹⁸ noted that “the concept of differentiating lead absorption from lead poisoning is no longer tenable, and it has been suggested that it may be more useful to speak in terms of its chemical toxicity (without symptoms) and clinical toxicity (with symptoms), recognizing that one merges into the other.”

It is significant to note that lead appears to be the only toxic chemical pollutant to have accumulated in humans to average concentrations that approach the threshold for potential clinical poisoning.¹⁹ Although there are increasingly strict controls on the uses of lead and lead emissions, general environmental exposure still induces a wide range of health effects in animals, and specific sources of lead still result in animal mortality. Sources of lead, environmental concentrations, uptake by living organisms, and health effects in animals will be discussed in this chapter.

15.2 SOURCES OF LEAD IN THE ENVIRONMENT

Anthropogenic emissions of lead into the environment may be directly into air, water, and soil. Although emissions into these media can be easily quantified, there is a continuous intercompartmental exchange of lead among them. The geographical distribution of atmospheric lead, relative to the point of emission, is largely dependent upon particle size. Most airborne lead is eventually deposited onto some surface, including plants, soil, bodies of water, artificial surfaces, and the respiratory tracts of animals, by dry or wet deposition processes. Dry deposition is either by gravitational settling of larger particles ($> 10 \mu\text{m}$)²⁰ or impaction of particles of all sizes (especially smaller particles). Wet deposition results either from the incorporation of particles into water droplets within clouds or from the accumulation of particles by falling precipitation. Industrial discharges, highway runoff, and sewage effluent are responsible for much of the lead in water, with some wet deposition of atmospheric lead, and direct dry deposition, which is more significant for large bodies of water. The distribution of lead in water depends upon the chemical form of the lead. Lead in soils results mainly from dry and wet deposition of atmospheric lead, particularly close to emission sources, and the disposal of sewage sludge, often onto agricultural land. Lead in soils is relatively immobile compared to that in other environmental media, and soils and, ultimately, ocean bed sediments are the “sinks” for anthropogenically emitted lead.

Metallic lead also enters the environment from human activities. Hunting, fishing, and target shooting produces “hot spots” of metallic lead that have been responsible for the deaths of a number of species, ranging from ducks to eagles.^{21,22} Using stable lead isotope ratios, it is possible to determine the source of the lead in a variety of matrices, including avian bone. Juvenile herring gulls (*Larus argentatus*) from the Canadian Great Lakes had lead isotope ratios similar to that of lead originating from combustion of Canadian gasoline, whereas waterfowl and eagles had lead ratios most similar to the ratios found in lead shot and sinkers.²³ Additionally, the isotope ratios for all species were higher than those derived from lead from mining or smelting.

15.2.1 Atmospheric Emissions

Estimated total lead emissions into the atmosphere from natural sources (1979 to 1984) ranged from (Table 15.2) 8.6 to 54.1×10^9 gm/year.²⁴ Atmospheric lead emissions resulting from anthropogenic activities are estimated to be at least one to two orders of magnitude greater than from natural sources (Table 15.2). The most important source of atmospheric lead is the combustion of fuels containing tetraalkyl lead antiknock agents. This category by itself exceeds all of the natural emissions of lead. The lead from automobile exhaust is typically in the form of fine particulates. However, lead profiles in dated sediment cores and atmospheric aerosols show a decline since 1970, presumably reflecting the reduction in the use of lead in gasoline.²⁵ Other than gasoline-derived lead, most sources are point sources, resulting in locally elevated atmospheric lead concentrations.

15.2.1.1 Vehicular Emissions

The useful properties of tetraalkyl leads as antiknock agents (i.e., agents that allow for high engine compression ratios without spontaneous air/gasoline ignition in the cylinder) were first discovered in 1923.²⁶ Lead is added to gasoline in organic tetraalkyl forms, as tetraethyl lead, tetramethyl lead, and mixed alkyls of triethylmethyl lead, diethyldimethyl lead, and ethyltrimethyl lead. During fuel combustion in the cylinder lead alkyls are converted to oxides, which foul spark plugs and remain in the cylinder. To prevent this, ethylene dichloride and ethylene dibromide are added to scavenge the lead. The lead chlorides and bromides consequently formed are relatively volatile and allow for approximately 70 to 75% of gasoline lead to be emitted into the atmosphere with exhaust fumes. These inorganic lead salts are emitted as very small particles, of approximately $0.015 \mu\text{m}$ aerodynamic diameter, that are considered to increase in size rapidly in the atmosphere by coagulation with other particles.²⁷ A small amount of lead may also be emitted as larger particles

(5 to 50 μm) resuspended from the exhaust system.²⁸ The atmospheric lifetime of emitted lead depends upon particle size, topography, and weather conditions. Particles > 10 μm are usually deposited rapidly close to the emission source (e.g., within 30 m of roads), either through gravitational settling or turbulent deposition. Due to their longer atmospheric residence time smaller particles can be carried by winds and deposited over very large areas.

Although most organic leads in gasoline are converted to inorganic forms during combustion, evaporation and incomplete combustion can release organic leads in the vapor phase into the atmosphere. Tetraalkyllead is relatively stable in the atmosphere, since it is not readily attacked by oxygen or light, and probably accounts for 1 to 6% of total lead at urban sites and possibly a similar percentage at inland rural sites.²⁸ Most organic lead in the environment results from gasoline additives. Leaded gasoline usually contains 0.15 to 0.40 g Pb/L, and unleaded < 0.01 g Pb/L. Exhaust fumes may contain 2000 to 10,000 μg Pb/m³ when leaded gasoline is used.²⁸ These fine particles tend to persist in the atmosphere and can be transported long distances; their small diameter further enhances their absorption into the bloodstream.²⁹

15.2.1.2 Fossil Fuel Combustion

The combustion of fossil fuels contributes only a small percentage of total lead emissions to the atmosphere, even relative to natural emissions (Table 15.2). However, this source of lead may be important locally. Coal contains, on average, approximately 25 ppm lead, with 17 ppm lead in British coal compared with 35 to 44 ppm in the United States.^{30,31} During combustion most lead in coal becomes deposited in fly ash, which may have lead concentrations an order of magnitude higher than the initial fuel. Little fly ash reaches the atmosphere during domestic coal combustion, although high chimney gas velocities may result in some loss of fly ash during industrial combustion. The amount lost depends upon the efficiency of control devices used. Modern electrostatic precipitators have greatly reduced atmospheric lead emissions from this source. However, other environmental media may become contaminated through the disposal of fly ash. Crude petroleum oil contains relatively less lead than coal, generally 0.001 to 0.2 ppm, with maximum concentrations reaching 2 ppm.³¹ During fractionation, most of the lead becomes concentrated in heavy fuel oils or residues, and total lead emissions are low.

15.2.1.3 Industrial Emissions

Elevated lead emissions may be recorded in the vicinity of lead and other metal mines, primary and secondary smelters, and many industries that produce, use, recycle, or dispose of lead-containing products. These include the pigment and dye industry,³² car battery manufacture,³³ the manufacture of tetraalkyl additives for gasoline,³⁴ and municipal waste incinerators.

15.2.1.4 Dusts

Many sources contribute to lead in dusts, and concentrations may become elevated in urban environments, including within dwellings. A large proportion of lead in dusts probably results from aerial deposition, although paint (sanding and scraping of buildings) or other sources may be the major contributors. Household dusts usually contain < 1000 ppm dry weight (d.w.⁴⁸) Pb³⁵ and urban and street dusts 500 to 5000 ppm d.w.³⁶

15.2.2 Lead Emissions into Water

Present-day lead concentrations in marine water are probably up to an order of magnitude greater than natural concentrations. Table 15.3 illustrates industrial inputs of lead annually into all oceans. These inputs are some 2.6 times higher than estimated preindustrial inputs. However, most industrial and domestic lead inputs to waterways occur in urban or coastal areas, and in rural areas the natural mineralization of parent rock may provide the most significant contribution of lead into the aquatic environment.

Using isotopic lead ratios and lead/calcium atomic ratios, the lead in teeth of California sea otters (*Enhydra lutis*) from Alaska have increased 2- to 15-fold over otters from 2000 years ago. The lead in preindustrial otters was derived from natural sources, whereas the lead in recent animals is derived from aerosols or industrial lead waste deposits.^{37,38} Likewise in birds, lead burdens are derived from recent anthropogenic sources, primarily gasoline combustion or recently manufactured lead shot and lead sinkers.²³

Anthropogenic inputs of lead into water include dry and wet deposition of atmospheric lead, which act globally, or at least hemispherically, and point sources of emission, which influence the environment more locally and often involve effluents with high lead concentrations. Point sources include discharges from sewage works and direct industrial and mine works discharges. In addition to such point sources, lead may be leached from soils and mine tailings, and highway runoff frequently reaches local waterways. Lead in freshwater often becomes adsorbed onto sediment and ultimately reaches oceans.

Table 15.3 Approximate Lead Input to All Oceans

Input	Tons/Year
Industrial inputs	
Aerosols (gasoline)	37,000
Aerosols (smelters, forest fires)	3,000
Rivers/sewers (soluble, mainly aerosols)	60,000
Rivers/sewers (solids)	200,000
Preindustrial inputs	
Aerosols	1,000
Rivers (soluble)	13,000
Rivers (solids)	100,000

15.2.2.1 Vehicular Emissions

Although the contribution of gasoline lead in water is mainly indirect, through dry and wet deposition of atmospheric lead and highway runoff, it remains very important. Trefry et al.³⁹ found that lead inputs into the Gulf of Mexico from the Mississippi River in the United States had decreased by 40% 10 years after the introduction of regulations reducing the lead content of gasoline. The Mississippi carries over half the total water and sediment carried by all U.S. rivers, and the 40% decrease in lead transported was comparable to the decrease in the use of leaded gasoline over that period.

Gasoline lead deposited onto roads constitutes the most important source of lead in urban runoff.^{40,41} The amounts of lead deposited on road surfaces from vehicles in urban areas depend upon a wide range of factors including traffic intensity, driving mode, weather and climatic factors, road surface area, etc. Runoff water is usually either directed to sewage treatment plants, in which case only a small proportion will reach waterways in the short term, or transported directly to local water courses. Small amounts of gasoline lead may also reach water directly, through combustion by boat engines, although only 9 to 31% of gasoline lead is found in boat exhaust water.⁴²

15.2.2.2 Lead in Sewage Effluent

The amount of lead released into water from sewage treatment plants depends upon the range and nature of effluents received by the plant and the treatment process. Sewage treatment plants may receive, in addition to domestic wastewater, certain industrial discharges and highway runoff, particularly following storms. A large proportion (80 to 100%) of lead present in the effluent is incorporated into sewage sludge during treatment,⁴³ and the remaining effluent is discharged into waterways.

15.2.2.3 Leaching and Seepage

Lead may reach waterways by leaching from fly ash and from soils that have been subject to additions of lead (e.g., sewage sludge) and by leaching and seepage from wastedumps, mine tailings, and tailing pond decant. Lead is relatively immobile in soils; therefore, leaching is only likely to contribute a small amount of lead in water. A certain amount of lead may be leached from the fly ash resulting from fossil fuel combustion. It has been reported that distilled water can leach 3.4% of the total lead in fly ash in 48 h.⁴⁴

15.2.2.4 Other Sources

Certain industrial discharges directly entering waterways result in increased lead concentrations and local contamination, and accidental releases of lead from industrial and other sources can cause considerable water contamination. Lead also reaches water in less obvious ways such as through the use of lead plumbing systems. In areas of soft water, where no calcium layer coats the inside of plumbing systems, elevated lead concentrations can accumulate in static water, for example, overnight.

15.2.3 Lead in Soils and Sediments

The major natural source of lead in soils is the weathering and mineralization of parent material, and in rural areas receiving little lead pollution, there is often a strong relationship between lead concentrations in soil and parent material. Naturally high soil lead concentrations can be found in local areas of high mineralization, but even these rarely approach those resulting from anthropogenic activities around urban areas. Emitted lead reaches soils via a wide range of pathways. This may occur on a local scale from point sources, such as the application of sewage sludge to land or land

disposal of mine wastes and fly ash, or universally through the deposition of atmospheric lead. By one pathway or another, the vast majority of atmospheric lead, and much lead in water, eventually becomes associated with soils or sediments, due to the strong binding capacities of many soil components for metals.

Lead mine tailings comprise a localized but significant source of lead-bearing sediments. These sediments wash far down exposed waterways, where they are ingested by wildlife, especially waterfowl.⁴⁵ This venue constitutes one of the few instances where wild birds have died of lead poisoning without having ingested lead shot.⁴⁶

15.2.3.1 Intercompartmental Lead Transfer to Soils

The extent of dry deposition of airborne lead onto soils from point emission sources is related to the atmospheric lead concentration, particle sizes, weather, wind direction, and soil surface characteristics. Gravitational and turbulent settling of large particles is high near the emission source, decreasing with distance. Deposition of smaller particles by impaction, or diffusion mechanisms (e.g., Brownian diffusion), takes place over a much larger geographical area and is related to surface characteristics. Deposition tends to be lowest on smooth surfaces, with concentrations of lead up to eight times higher on rough or hairy leaf surfaces than on smooth leaf surfaces.⁴⁷ Lead deposited onto plant surfaces may finally reach the soil when plants die, if they are not grazed or cropped. In addition, lead reaching plant and other natural and artificial surfaces via dry deposition may be washed off and reach the soil in water.

Water plays a very important role in the transport of lead to soils and sediments. Dry deposition of atmospheric lead gives rise to contamination close to emission sources, whereas wet deposition through precipitation is universal. Both are thought to deposit approximately similar amounts of lead in rural areas.²⁸ Rain and dew also transport lead to soils by washing deposited lead off plant surfaces, roads, and other artificial surfaces. The movement of lead-contaminated leachates and seepage water contributes locally to soil contamination, as does accidental flooding with water contaminated by industrial processes, sewage processing plants, and waste dumps.

15.2.3.2 Sewage Sludge

As the sludge from sewage treatment facilities is rich in plant nutrients, particularly nitrogen and phosphorus, its addition to agricultural land as fertilizer is considered a convenient and useful means of disposal. Sewage sludge contains variable amounts of lead, depending upon the effluent types received by the treatment plants. Most sewage sludges contain within the range of 120 to 3000 ppm d.w., and surveys in the United Kingdom have found sludges to contain from as low as 19 to as high as 45,400 ppm d.w. of lead.^{49,50} Although heavy-metal concentrations are often high in sludge, agricultural use has been permitted under the premise that most lead becomes immobilized within soils and sediments and is unavailable for uptake by plants. However, in cases of surface sludge application, grazing animals may ingest sludge deposited on the surface of, or along with, plants. The U.K. government has regulated the maximum permissible concentrations of lead and other metals in sludge to be applied in this way (2000 ppm d.w. for Pb), along with maximum concentrations to be disposed over a given period of time.¹⁹

15.2.3.3 Other Sources

Local soil contamination may occur around storage battery reclamation plants, near mines and waste, dumps, and around mainly older buildings where leaded paint has been used and is flaking. An additional source of lead in soils is lead ammunition.^{51,52} The production of lead ammunition, both for military purposes and for hunting, has continued to increase throughout the last three

centuries. Today, lead shot is regularly and widely distributed in the environment, mainly by hunters. Although lead shot is relatively stable in most soils, it has resulted in significant soil-pollution problems at specific sites, and the ingestion of spent ammunition causes large-scale avian mortality. However, the use of lead in ammunition has declined or, in the case of lead shot for waterfowl, been banned. After 6 years of the ban, an estimated 1.4 million ducks were spared from lead poisoning in 1997.⁵³

15.3 INTAKE AND UPTAKE OF LEAD

Amounts of lead entering and being assimilated by plants and animals from the atmosphere, soil, and water are not always directly related to environmental concentrations. Lead intake and uptake depends upon many factors including its chemical and physical form, exposure route, and the biology of the exposed organism. Lead reaches plants via wet and dry deposition onto plant surfaces, including road and soil splash, and by uptake from roots. Inorganic lead reaches terrestrial animals mainly via inhalation and ingestion, and absorption through the skin or gills is important for aquatic animals. Organic lead may be absorbed through the skin of all animals, although such uptake is generally insignificant.

15.3.1 Plants

15.3.1.1 Aquatic Plants

The availability of lead (and other metals) for uptake by aquatic plants is related to a wide range of chemical and physical variables, including the chemical form of lead, the pH of water, the presence and quantity of calcium and magnesium ions (water hardness) and nutrients, and the quantity and nature of suspended material. Lead from water usually enters plants in an ionic form, and uptake by aquatic plants can be from water, soil, air, or a combination of the three depending upon the type of plant (rooted/submerged, etc.). Crowder⁵⁴ reviewed lead uptake by plants. Of wetland plants, the submergent macrophytes generally tend to have the highest lead concentrations, although uptake is species-specific. Subterranean parts tend to accumulate the highest lead concentrations, and senescent foliage can contain higher lead concentrations than live foliage. Under certain conditions lead concentrations in aquatic plants have been correlated with sediment lead concentrations, and plant lead concentration may be negatively correlated with water pH. Under experimental conditions, pH and electrode potential (Eh) interact to influence lead uptake.⁵⁴

In experimental studies with rooted macrophytes, lead was rapidly taken up from solution containing 1.0 mg Pb²⁺/L via passive mechanisms.⁵⁵ A large proportion of lead taken up within one hour by shoots of *Elodea canadensis* was released within 2 weeks of transfer to clean water, although 10% appeared to remain irreversibly bound.

There has been concern over the uptake of lead deposited as gunshot by aquatic and terrestrial plants. Plants can take up large amounts of lead from spent gunshot deposited in acidic soils and sediments (maximum of 24,892 µg/g d.w. — T. Elkington, pers. comm.). However, most wetland sites are not particularly acidic, and Behan et al.⁵⁶ found similar lead concentrations in plants collected from heavily hunted wetlands and from refuges. In spite of this some lead from deposited shot may become available for uptake, and these authors found that 3 years after seeding a 0.17-ha pond with 227 kg lead shot, the roots and shoots of aquatic plants had significantly higher lead concentrations than controls. However, this amount of shot is at least an order of magnitude higher than that found in most heavily shot-over wetlands. The exception to this is the fall zone from shotgun target ranges, where lead shot density ranged from 4.15 x 10⁶ to 3.70 x 10⁹ pellets/ha.⁵⁷

15.3.1.2 Terrestrial Plants

Quantities of lead accumulated on plant surfaces are related to atmospheric concentrations, particle size, topography, climate, and surface characteristics of plants. Little is known of the movement of aerosol lead following deposition on plant surfaces or in stomata, although it appears that most deposited lead is immobile, perhaps being embedded in the cuticle. Although foliar transport of aerosol lead appears limited in most species, Rule et al.,⁵⁸ using a solution of ^{210}Pb , illustrated foliar absorption and translocation of lead to the youngest leaves of lettuce and the storage roots of white icicle radish plants. Translocation of atmospherically derived lead within some species has been confirmed using similar ^{210}Pb tracer studies.⁵⁹

The contribution of atmospheric lead to total plant lead may be high both in areas of low soil and low atmospheric lead concentrations as well as in areas with high atmospheric lead concentrations. Tjell et al.⁶⁰ found that > 90% of total lead in grass in rural areas of Denmark resulted from atmospheric deposition. Plants with rough foliar surfaces tend to retain more lead than those with smooth or waxy surfaces,⁶¹ and surface characteristics may also influence the amount of lead removed by precipitation. Large seasonal fluctuations in the lead concentrations of foliar parts of plants have been recorded, with values sometimes an order of magnitude higher in winter than in summer months. Increased concentrations in winter are thought to be related to higher deposition rates resulting from increased thermal stability in winter,⁶² possible higher lead uptake by dead and decaying material due to cuticular breakdown increasing permeability and facilitating lead access,⁶³ and slower winter pasture turnover rates.

The availability of soil lead for uptake by plant roots depends upon physical and chemical soil characteristics. Lead is generally strongly adsorbed onto solid soil components with high organic matter cation exchange capacity and high percentage silt or clay. Under such conditions little ionic lead is available in the aqueous phase for uptake by plant roots. When soils are low in the components described and under conditions of poor drainage, low soil pH, and low concentrations of iron oxides and phosphorus, the availability of lead to plant roots increases. The application of calcium or phosphate to soils can reduce lead availability to plants through the formation of lead hydroxide, carbonate, or phosphate compounds of low solubility.⁶⁴ Lead uptake by roots can be passive⁶⁵ or active,⁶⁶ and uptake is influenced by species, cultivar, age, and growth rate. Metal uptake by roots can be accelerated in species in which roots release solubilizing agents or carriers into the rhizosphere, as some of these may act as ligands or chelate metals.⁵⁴ Transport of lead between roots and foliar parts of plants tends to be limited, and it has been suggested that lead may be precipitated in vesicles that fuse with cell walls in roots, immobilizing and inactivating it.⁶⁶ However, although most lead taken up from soil appears to accumulate in roots, Rolfe⁶⁷ found that significant concentrations of lead also accumulated in the leaves and stems of eight tree species within one growing season in soils of high lead content.

The high binding capacity of soil for lead, its limited transport from roots, and the tendency for lead to accumulate at xylem sites within the plant all act as natural barriers against the movement of lead to foliar parts.⁶⁸ Although total plant lead concentrations are generally higher with high soil lead concentrations, the increase in plant lead is generally small proportional to that in soils. The Ministry of Agriculture, Food and Fisheries (MAFF)⁶⁹ investigated lead concentrations in plants grown in a variety of soils and found that, in soils with up to 25 times background lead concentrations, plant lead concentrations did not more than double.

15.3.2 Animals

15.3.2.1 Aquatic Animals

Lead uptake by aquatic organisms is via water (absorption through skin, gills, intestine, etc.) and food. The chemical form of lead and other elements present both in water and diet, along with

species and other biological and environmental factors, influences lead uptake. Lead uptake by certain freshwater fish, such as the pumpkinseed sunfish (*Lepomis gibbosus*) and rainbow trout (*Salmo gairdneri*), has been shown to increase as water pH decreases.^{70,71} As in many terrestrial animals, calcium appears to have an important influence on lead transfer. Lead uptake and retention in the skin and skeleton of coho salmon (*Oncorhynchus kisutch*) was reduced when waterborne or dietary Ca was increased.⁷²

Organic lead compounds, which accumulate in lipids, tend to be taken up and accumulated by freshwater teleosts more readily than inorganic lead compounds. Organic lead compounds are generally more toxic than inorganic compounds to aquatic organisms, and toxicity increases with the degree of alkylation.⁷³ A wide range of aquatic organisms can absorb and accumulate very high lead concentrations, and the residence time of lead appears to be related to the route of administration.⁷⁴

15.3.2.2 Terrestrial Animals

Ingestion and inhalation are the most important exposure routes of lead to terrestrial animals. The relative contributions of those routes to total body burden will vary according to environmental concentrations, other environmental factors, and biological considerations such as species, age, sex, and diet.

15.3.2.2.1 Inhaled Lead

Most atmospheric lead is present as particulate inorganic salts, which, following inhalation, may be exhaled, deposited in the lungs and lower respiratory tract, or deposited in the windpipe and subsequently swallowed. Maximum lung retention occurs when particle sizes are 1.5 to 2.5 μm aerodynamic diameter.⁷⁵ Although deposition rates vary in relation to air lead concentration, particle size, and respiration rates, approximately 50% of inhaled lead is deposited in the lungs, even when atmospheric lead concentrations are relatively high.⁷⁶ Practically all lead deposited in the lungs is absorbed into the bloodstream. Half-lives of removal of lead from the lungs have been estimated at 6 h for humans⁷⁷ and 12 h in dogs.⁷⁸ Very little lead is thought to remain in the lungs after 3 days. Although most atmospheric lead is inorganic, a similar proportion of organic lead may be absorbed.⁷⁹

15.3.2.2.2 Ingested Lead

Lead is usually ingested along with food and water but may be ingested independently. Examples of nonfood ingestion include the ingestion of spent lead gunshot and anglers weights by waterfowl and ingestion of paint chips and soil by children and other young animals, known as “pica” (the compulsive active ingestion of nonfood objects). Contaminated sediments adhering to food items not only contribute to the body burden but may reach toxic levels when sediment distribution is restricted but lead content is high. Sediments in the Coeur d’Alene river system have been implicated in numerous lead poisoning instances in tundra swans.⁴⁵

Following the ingestion of lead in the diet, a large proportion is eliminated directly with the feces. The proportion of ingested lead absorbed from the intestine is small relative to the proportion of inhaled lead absorbed and varies according to a wide range of factors, primarily dietary. Absorption of ingested lead is reduced when ingestion occurs along with food or if food is already present in the intestine.⁸⁰ It is believed that certain dietary constituents may either inhibit lead absorption through the intestinal wall or stimulate the excretion of lead into feces, or both.⁸¹ The strong influence of dietary and other factors on intestinal lead absorption is such that values given in the literature for intestinal lead absorption in humans vary by up to an order of magnitude.

However, the majority of studies have found an 8 to 18% absorption of ingested lead, and 10% is most frequently quoted.^{16,82,83} In other animals gastrointestinal absorption efficiencies are different, and even within species large variations are recorded.

15.3.2.2.1 Factors Influencing Lead Absorption in the Intestine — The amount of lead absorbed from the intestine depends upon a range of factors including the chemical form of lead ingested. As early as 1923 Hanzlik and Presho⁸⁴ illustrated experimentally that metallic lead was more toxic to pigeons than similar amounts of lead as lead chloride, iodide, sulfide, carbamate, or acetate. They suggested that this might result from reduced lead solubility and, consequently, reduced intestinal uptake when other elements were present along with the lead. The physical as well as chemical form of lead also influences absorption, and smaller lead particles (<180 µm) may be absorbed from the intestine more rapidly than larger ones.¹

As discussed, only a small proportion of inorganic lead ingested is absorbed into the body. This is considered to account for approximately 10% of ingested lead in humans⁸³ and may be as low as 1 to 2% in cattle and sheep.⁸⁵ Studies in which animals have been fed various forms of lead have shown widely different tolerances between species. Absorbed lead normally bypasses the soft tissues and is sequestered in the bones; nutritional status also plays an important role in this process.⁸⁶ Differences in response are probably attributable to interspecific differences in abilities to absorb, store, detoxify, and excrete lead. These factors appear to be largely related to diet as well as physiological and environmental factors. Age differences in susceptibility to lead poisoning have been widely studied. Although uptake and storage of lead does vary in many species with age, increased toxicity of lead to young animals is related more to an increased lead sensitivity of certain body systems during early stages of development. In some young birds increased storage of lead by juveniles in the developing bones may serve to reduce the toxic effects of a given lead exposure over those of adults. In addition, the bones of female birds exposed to lead frequently have more elevated concentrations than those of males.^{87,88} This is related to an increased calcium metabolism and turnover in bones of females, necessitated by eggshell production.

In a nationwide survey of lead-poisoned waterfowl, hepatic lead levels were independent of age and sex; lead-poisoned ducks tended to have higher hepatic lead levels than geese or swans, but the difference could be attributed to differences in body weight rather than kinetic differences between species.⁸⁹ Differential absorption and sensitivity to lead may be genetically based as well. Black ducks (*Anas rubripes*) and mallards (*A. platyrhynchos*) were not different in their response to dosing with lead shot, and there was no seasonal effect.⁹⁰ However, there was a significant difference in vulnerability; the wild-caught birds exhibited greater mortality and weight loss, probably due to captive-related stress. Lead accumulation in bone and blood of smelter workers was varied and apparently related to the allele they carried for delta-aminolevulinic acid dehydratase (ALAD).⁹¹ Further analysis has linked response and accumulation to alleles not only for ALAD but also the vitamin D receptor gene and the enzyme aminolevulinic acid.⁹²

A considerable amount of research related to lead absorption has been carried out in laboratory studies using the rat. As early as 1939 a component of apples — probably pectin — inhibited lead assimilation in growing rats.⁹³ Researchers also found higher lead retention in growing than adult rats. Milk in the diet has been found to influence lead absorption in rats. Dietary calcium appears to be one of the most important factors influencing lead absorption and toxicity. Lead uptake, toxicity, and soft tissue storage are increased in lead-exposed animals fed low-calcium diets. This has been illustrated in a wide range of birds and mammals including waterfowl, rats, dogs, horses, and sheep.⁹⁴⁻⁹⁷ In sheep low-calcium diets adequate in other minerals fed to lambs along with 400 mg Pb/kg resulted in death within 5 weeks. With adequate dietary calcium, lambs survived for up to 10 months.⁹⁸ Other dietary factors that have been shown to influence lead uptake or toxicity are phosphorus, zinc, iron, ascorbic acid, vitamin D, and protein. Iron-, calcium-, phosphorus-, zinc-, and protein-deficient diets tend to result in increased lead uptake and toxicity, and dietary supplements of these constituents tend to decrease lead uptake or alleviate signs of lead poisoning in

many species.^{8,95-99} However, the interactions between lead and other dietary constituents are very complex, and under certain circumstances, and in some species, dietary excess of many elements, including those listed above, may exacerbate lead toxicity.

In some animals there appears to be a seasonal peak in lead poisoning. In children, cattle, and dogs, lead-poisoning cases are most common in spring or summer months.^{97,100,101} Although this remains largely unexplained, it is thought that this might be related to increases in vitamin D levels, stimulated by increased sunlight. Vitamin D appears to be associated with intestinal lead absorption, and increased levels of dietary vitamin D tend to increase lead absorption and retention in some animals.¹⁰² The seasonal incidence of lead poisoning in some animals may also be related to other physiological factors such as dehydration¹⁰² or differential access to lead-contaminated dietary material.

When nonfood ingestion of lead occurs, similar factors will influence absorption and retention, although most animals usually rapidly egest large lead objects. However, this is not the case with waterfowl and other birds ingesting lead shot or anglers weights. Waterfowl actively ingest grit, which is retained in their muscular gizzard to help grind up and breakdown ingested material. Small ingested lead objects may be similarly retained and ground down within the gizzard. The retention and absorption of ingested shot by waterfowl is related to the quantity of food ingested and its physical characteristics as well as its chemical characteristics, as described above. Smaller, softer foods, especially those low in fiber, generally pass more rapidly through the intestine,¹⁰³ possibly increasing the expulsion rate of ingested shot and any lead particles eroded from the shot's surface. However, an increased shot expulsion rate does not always imply decreased absorption. Mourning doves (*Zenaida macroura*) fed a seed diet had lower shot retention rates but higher tissue lead concentrations than those on a pelleted diet, probably due to differences in lead absorption related to the chemical constituents of the diets.¹⁰⁴ Lead absorption rates from ingested gunshot are lowest when physical characteristics of diet facilitate the rapid passage of lead through the intestine and chemical components reduce lead absorption. Large-scale avian mortality has occurred due to shot ingestion.^{105,106}

15.4 LEAD CONCENTRATIONS

15.4.1 Plants

Lead concentrations in plants depend upon a wide range of factors and may vary between different parts of the plant.^{62,107} Plants grown in uncontaminated environments generally contain < 1 ppm fresh weight lead (dry-weight values are commonly 2 to 20 times fresh-weight values depending upon plant/part of plant sampled). Some plants have been found to accumulate very large quantities of lead. Extreme examples are *Potamogeton* sp. growing in a tailings pond in Missouri recorded to have 11,300 ppm d.w. lead¹⁰⁸ and certain aquatic bryophytes recorded with maximum lead concentrations of 14,825 ppm d.w.⁵⁴ Lead concentrations in a wide range of aquatic and terrestrial plants have been related to their distance from a lead-emission source, suggesting their use as biological indicators of lead pollution. The analyses of mosses and lichens for lead has been used for decades to monitor airborne pollution.¹⁰⁹ Concentrations of lead in plants are illustrated in Table 15.4 and have been reviewed by Jenkins¹⁰⁸ and Eisler.⁸

15.4.2 Animals

15.4.2.1 Distribution and Concentrations of Lead within the Body

Following absorption, lead moves into the bloodstream. Most inorganic lead (> 90%) is transported by the circulatory system attached to the surfaces of red blood cells.¹¹⁰ Only part of the

absorbed lead remains in the bloodstream, the rest being deposited within minutes in soft tissues, primarily the liver and kidney, and in bone.

In the kidney, lead tends to be deposited in the nuclei of cells, particularly in proximal convoluted tubule cells of the renal cortex. This lead is bound to dense proteinaceous structures forming acid-fast intranuclear inclusion bodies.¹¹¹ It has been suggested that these bodies may act as an immobile storage system for lead, reducing its cellular toxicity. Intranuclear inclusion bodies have been reported in a wide range of bird species^{110,112,113} as well as in bats, rats, rabbits, dogs, swine, cattle, and primates.^{111,114-117} Intranuclear inclusion bodies have also been reported in plant cells.¹¹¹

In humans, lead has a half-life of 20 days in blood and 600 to 3000 days in bone.²⁸ Lead-retention time in bones is related to the medullary content, retention times being greater in bones with a high medullary content.^{118,119} Sex and physiological condition influence lead kinetics in avian bone, as medullary bone undergoes sequences of formation and destruction in relation to calcium storage and liberation for eggshell formation.⁸⁸ Residence times of lead in soft tissues vary from several weeks to 6 or 7 months. Half-lives vary interspecifically but are of a similar order of magnitude. Blood lead remains in a fairly mobile equilibrium with that in soft tissues. In most vertebrates blood, liver, or kidney lead concentrations indicate recent absorption of inorganic lead, whereas bone lead concentrations indicate both recent and anterior absorption. Bone lead concentrations, therefore, generally tend to be higher in older individuals.

Table 15.5 Lead Concentrations in the Tissues of Exposed Birds (ppm, wet weight)

Tissue	Lead Concentration (ppm w.w.)				
	Trimethyl Lead		Trialkyl Lead Dunlin ^b	Total Lead (Inorganic Lead)	
	Starlings ^a			Bald Eagle ^c	Canada Geese ^d
	AI	All

Liver	3.70	32.4	10.10	16.60	7.80
Kidney	5.38	30.2	13.80	6.00	—

^a Starlings *Sturnus vulgaris*. Experimental study in which birds were given a low (AI = 200 ug/day) and high (All = 2mg/day) dose of trimethyl lead. 6 birds in each group (Osborne et al.²⁴¹).

^b Dunlin *Calidris alpina*. Wild birds from the Mersey estuary, U.K., 1979, after being poisoned with alkyl lead from a petrochemical works. 10 birds (Bull et al.²²¹).

^c Bald eagles *Haliaeetus leucocephalus*. Four captive birds that died following dosage with 10+ lead shot (Pattee et al.²⁴²).

^d Canada geese *Branta canadensis*. Four wild birds that died following shot ingestion (Bagley et al.²⁴³).

Exposure regime (acute or chronic) influences the distribution of lead within an animal. For example, an animal suffering acute poisoning may have higher lead concentrations in soft tissue than bone, whereas chronic poisoning is likely to result in higher bone lead concentrations. Wild urban pigeons (*Columbia livia*) accumulated very high tissue lead concentrations without several of the signs usually associated with acute lead toxicity in experimental studies.¹²⁰ The results of this study similarly suggest that exposure regime may influence the subcellular distribution and thus the toxic effects of lead.

Organic lead in the bloodstream is more evenly distributed than inorganic lead between the plasma and red blood cells. Organic lead disappears rapidly from the bloodstream and is converted in the liver to trialkyl lead, some of which may reappear in the blood 5 to 10 h after initial absorption.²⁸ The high liposolubility of organoleads results in their accumulation in nonbony tissues such as the liver, kidney, and brain. Example lead concentrations in different tissues of wild and captive avian species following exposure to inorganic and organic lead are provided in Table 15.5.

The high liposolubility of organolead compounds may partly explain the generally higher toxicity of organic than inorganic forms of lead to animals. However, regardless of the higher toxicity of organoleads, most lead accumulation and toxicity events in animals results from inorganic lead. For example, American kestrels (*Falco sparverius*) fed for 60 days on a diet containing 48 ppm d.w. of biologically incorporated lead (cockerels fed lead acetate for 4 weeks) exhibited only minor effects besides increasing tissue lead burdens; there were no signs of lead intoxication, significant changes in weight, or development of anemia.¹²¹

15.4.2.2 Lead Concentrations in Relation to Exposure

In most species of wild vertebrates from uncontaminated areas (both aquatic and terrestrial), blood lead concentrations are generally < 30 µg/dL, liver lead concentrations are usually < 10 ppm d.w. (often < 5 ppm d.w.), and bone lead concentrations are usually < 20 ppm d.w. In exposed individuals these values may increase by an order of magnitude, although many species will not tolerate such burdens and may die before they are achieved. Elevated bone lead concentrations are more frequently observed, as bone lead reflects lifetime absorption and is relatively immobile.

Earthworms are widely studied invertebrates in relation to lead accumulation as they are ubiquitous and a food source for a wide range of animals, especially birds. Beyer and Cromartie¹²²

investigated total body levels in different species of earthworms from natural and lead-contaminated sites. They found that from nine natural sites with low soil lead concentrations (5 to 14 ppm d.w.), lead levels in earthworms ranged from 1.4 to 2100 ppm d.w., and concentrations in different species varied considerably within the same site. Earthworms of *Noïdes* accumulated large amounts of lead, even at uncontaminated sites (2100 ppm d.w.). They suggested that if earthworms are used as indicators of environmental contamination, it is important to identify the species and collect similar earthworms from uncontaminated soil with similar characteristics for comparison. Gish and Christensen¹²³ sampled earthworms (mainly *Allolobophora trapezoids* and *A. turgida*) from soil near two major highways in the United States, and found good correlation between whole body lead concentrations, lead concentrations in soil, and distance from highway.

Toads were fed a diet of earthworms containing 10 ppm w.w. total lead (5.6 ppm available lead); a second group was maintained on a diet containing 308 ppm lead w.w. (93 ppm available lead) for 4 weeks followed by 816 ppm w.w. (65 ppm available lead) for 4 weeks. Feeding rates were controlled and were not significantly different between the two groups.¹²⁴ Table 15.6 illustrates lead concentrations in different tissues of the two groups. Toads on the high lead diet accumulated lead in all tissues examined, with particularly high levels in bone, kidney, and liver. Toads on the high lead diet also had significantly reduced activity of the heme-biosynthetic enzyme ALAD in erythrocytes. The soft tissue lead levels were sufficient to pose a hazard to predators. However, these concentrations were far lower than those recorded in the earthworms being eaten by the toads.

Lead concentrations in a range of small mammals living adjacent to roads with high and low traffic density were highest in those mammals living close to highways of high traffic density (Table 15.6). There was some evidence of a relationship between feeding habits and tissue lead in those species restricted to roadsides by habitat requirements.¹²⁵ However, the elevated tissue concentrations found in the most contaminated environments were not as high as those considered to result in toxic effects in mammals, and the biological significance of the levels recorded is uncertain.

Animal tissue lead levels have been shown to be derived from a variety of lead polluting sources. Table 15.6 illustrates the breadth of the sources and of the animals impacted. Examples include box turtles (*Terrapene carolina*) living close to and far from primary lead smelters, songbirds living in urban and rural environments, and flounder (*Platichthyes flesus*) from two different areas. Hardisty et al.¹²⁶ also demonstrated an age-related increase in total body lead of flounder from the two sites.

Several species have been suggested as indicators of lead contamination in human environments. The pigeon (or rock dove), which is ubiquitous and typically feeds on the ground in urban environments where it encounters substrates likely to be contaminated with lead-rich dust, has often been used as an indicator of urban lead contamination. Significantly elevated lead concentrations have been found in the tissues of urban pigeons in many countries.^{87,127–129} Tissue lead concentrations in Tokyo pigeons decreased following a reduction in the use of leaded gasoline.¹²⁹ Whole body burdens of lead in fish collected throughout the United States declined steadily between 1976 and 1984, suggesting a reduced influx of lead to the aquatic environment following stricter regulatory measures.¹³⁰ The level of lead exposure and tissue lead concentrations are not always correlated. This also applies to the relationship between tissue lead concentrations and effects, as mechanisms of storage and detoxification render some individuals or species more susceptible to lead toxicity than others.

15.4.2.2.1 The Passage of Lead through the Food Chain

Biological magnification (i.e., a progressive increase in concentrations from the source of exposure through the trophic levels of living organisms), with primary producers having the lowest concentrations and predatory consumers the highest, does not appear to occur with lead. Namminga et al.⁷⁰ studied the distribution of lead in a pond ecosystem and found concentrations of 0.0013 mg/L, 281 ppm d.w., 37 ppm d.w. and 11.5 ppm d.w. in water, plankton, benthos, and fish (*Gambusia*

affinis), respectively. Using a laboratory continuous-flow system, Vighi⁷⁴ studied the transfer of lead between a primary producer, the algae *Selenastrum capricornutum*; a primary consumer, the zooplanktonic crustacea *Daphnia magna*; and a secondary consumer, the fish *Poecilia reticulata*. Vighi found that lead accumulated within the trophic chain with a decreasing concentration factor from the lowest to highest trophic levels. Similar results were reported by Leland and McNurney⁷¹ in a river ecosystem. Increasing concentration factors were reported by Parslow et al.,¹³¹ with concentrations of 0.03 ppb w.w. lead in unpolluted seawater, < 0.002 ppm w.w. in fish, (sand-eels and herrings *Ammodytes* spp. and *Clupea* spp.), and 0.036 ppm w.w. in the puffin *Fratercula arctica*, a fish predator. However, because many different sources of lead may have contributed to the lead body burden of the puffin, no conclusions can be drawn as to the part that biomagnification may have played.

15.5 EFFECTS OF LEAD

Most organic lead compounds are found as contaminants of aquatic environments, and there is some evidence that certain microorganisms in soils and lake sediments can biotransform inorganic lead to organic leads.^{132,133} Although organic lead is much less frequent than inorganic lead contamination, organic lead is generally more readily absorbed and more toxic. Lead also influences community structure and biological diversity. For example, although certain aquatic organisms can develop a tolerance to long-term chronic lead exposure, macroinvertebrate and floral diversity is reduced in rivers with elevated lead concentrations.¹³⁴⁻¹³⁶

15.5.1 Plants

The toxicity of lead to plants is related to its chemical form, availability for and mechanisms of uptake, translocation and storage/detoxification, and physiochemical characteristics of the plant's direct environment. Although lead is toxic to plants under experimental conditions, little lead is generally available for uptake by plants in soils and sediments, and very high soil/sediment lead concentrations are often required before toxic effects upon plants are observed. In addition, many plants appear to have mechanisms of storing lead in an insoluble form, or for limiting its translocation within the plant. Toxic effects of lead in plants are most likely to occur near point sources of lead emission, where environmental concentrations are very high, or when the availability of lead for uptake by plants is high (e.g., under conditions of low soil or water pH, low soil calcium and phosphate, etc.).

Interspecific differences in lead toxicity to plants may be related to lack of translocation of lead within the plant due to physical or chemical isolation of the lead. In plant tissues lead has been reported to precipitate with intracellular orthophosphate.¹³⁷ The chemical isolation of lead within insoluble phosphate granules may reduce lead toxicity and its penetration into cells and cellular organelles.^{66,138} The immobilization of lead by binding to cell walls, particularly in roots, has also been reported.¹³⁹ Silverberg¹⁴⁰ found that in the cells of *Stigeoclonium tenue* (Chlorophyceae), lead was present in an insoluble form in the cytoplasmic vacuoles and was not observed in the lead sensitive sites of cell metabolism (mitochondria, plastids, nuclei). Lead tolerance by lichens, which may accumulate and tolerate very high concentrations, may be related to an ability to precipitate extracellular lead, possibly as lead hydrocerussite.¹⁴¹

The existence of lead-tolerant ecotypes of a common grass species was demonstrated as early as 1952 by Bradshaw,¹⁴² and lead tolerance has since been demonstrated in many species growing in areas of high lead concentration. In roadside plant populations lead tolerance decreases with distance from the road. Such tolerance is determined genetically and may be related to morphological changes and tolerance to other metals.¹⁹ Of all aquatic biota, algae appear the most resistant to lead toxicity, although this observation may be influenced by the methods of toxicity testing used.¹⁴³

Lead has been reported to have a wide range of effects in plants including disruption of cell membranes and mitosis; inhibition of plant growth; ATP (adenosine triphosphate) synthesis and structural protein formation; reduction of photosynthesis, water absorption, and transpiration rates; increase in generation time; and decrease in pollen germination and seed viability.^{139,143-147}

Koepe and Miller¹⁴⁵ studied the effects of lead upon mitochondrial respiration in corn *Zea mays*. They concluded that if sufficient phosphate is present, lead will precipitate, and enzymatic reactions in corn mitochondria are not likely to be affected. However, it was suggested that plant growth could be dramatically reduced by lead under conditions of phosphate deficiency. Lead has been shown to inhibit respiration and photosynthesis in phytoplankton (*Phaeodactylum tricornerutum*), with the magnitude of effect directly related to lead concentration and duration of exposure.¹⁴⁸ Dayton and Lewin¹⁴⁶ found that lead exposure increased the generation time of *P. tricornerutum* and *Phaeodactylum tricornerutum*, with the magnitude of effect directly related to lead concentration and duration of exposure.¹⁴² Reduced photosynthesis and transpiration (by 10 to 25%) was recorded in 7-week-old seedlings of loblolly pine (*Pinus taeda*) and autumn olive (*Elaeagnus umbellata*) 4 weeks after exposure to 320 ppm lead (PbCl₂) in potting medium.¹⁴⁷ The simultaneous decline in transpiration and photosynthesis suggests that the leaf stomatal resistance to CO₂ and water vapor diffusion had changed.

Krishna and Bedi¹⁴⁴ found a decrease in the percentage pollen germination and seed viability in *Cassia* spp. growing near a highway. These improved as distance from the highway increased. The life-cycle period was also reduced in relation to lead accumulation in plants growing near the highway. It is possible that atmospheric lead may have played a part in the decline of European spruce forests, as the lead concentration in needles and litter was significantly higher where tree decline was most pronounced.¹⁴⁹ The effects of lead in plants are reviewed in Jaworski.¹⁵⁰

15.5.2 Animals

Lead is a nonspecific toxicant at the molecular level and inhibits the activities of many enzymes necessary for normal biological functioning. The most widely studied effects of lead are those upon the hematological system, the brain and nervous system, learning and behavior, and reproduction and survival. Research into the effects of lead upon animals was considerably stimulated in the 1950s when it was suggested that learning ability and coordination in children might be affected by lead. Subsequent research has suggested that young animals are more susceptible than adults to certain of the neurological and behavioral effects, as lead may affect the developing brain and nervous system.¹⁵⁰ Lead may act upon both nervous system structure and function, resulting in impairment of intellectual, sensory, neuromuscular, and psychological functions.^{4,8}

Large inter- and intraspecific differences are observed in lead toxicity in relation to mechanisms and factors that influence lead absorption, retention, detoxification, and elimination. Diet is the most important variable influencing lead absorption; age, sex, physiological condition, and environmental factors also influence lead toxicity. Increases in tissue lead concentrations are normally associated with the toxic effects of lead, but it is difficult to determine tissue threshold concentrations for effects, as many factors, such as exposure regime and subcellular distribution, influence toxicity (Table 15.7).^{4,8,95,150}

Table 15.7 documents effects of lead exposure upon animals. Although such experiments form an essential part of our understanding of metal toxicity, they should not be directly extrapolated as predictors of effect upon wild animals, as many biological and environmental factors may influence the absorption and distribution — and thus toxic effects — of lead under natural conditions. In addition, under experimental conditions animals are often only exposed to the contaminant under investigation, whereas in the natural environment they will be exposed to multiple contaminants, which may act antagonistically or synergistically.

Before discussing selected aspects of lead toxicity in different groups of animals, the hematological effects of lead will be considered in some detail, as they are common to most vertebrates.

Table 15.7 Effects of Lead upon Selected Animals in Experimental Studies

Pelleted commercial duck ration	No mortality	
Cracked corn	100% mortality	
10 Mallard drakes in each of 4 groups with different diets fed 1 No. 6 lead shot. No mortality occurred in controls fed no shot.		247
Corn diet	60% mortality	
Mixed grain diet	60% mortality	
Small grains, tame rice and smartweed seed	10% mortality	
Coontail and mixed grains	No mortality	
Mallards (7M, 7F) fed 1 No. 4	One month after dosing, lead shot (ca. 200 mg Pb) ALAD activity reduced 75% in blood, 42% in liver, 50% in cerebellum, and 35% in cerebral hemisphere	151
200 μg trialkyl Pb chloride/days (ca. 28 mg/kg/days) given to Starlings, <i>Sturnus vulgaris</i>		241
Triethyl lead	Reduced respiratory rate and labored breathing; abnormal head and body posture; fluffed feathers; altered feeding activity; reduced body weight, liver weight, and pectoral muscle.	
Trimethyl lead	Lack of coordination; impaired balance; tremors; fluffed feathers; inability to fly; bright green watery droppings; altered feeding activity; reduced body weight, liver and kidney weight, and pectoral muscle. 100% mortality within 6 days for both groups. However, pre-death symptoms more severe with trimethyl Pb.	
Mammals		
Rats		
4% lead carbonate fed to lactating females resulting in 46 ppm Pb in milk to young	Growth retardation and paraplegia 26 to 30 days after birth. 85 to 90% mortality in 2 weeks.	95
Young rats weaned at 25 days on milk as above, and fed 4% Pb carbonate for 5 more days	Urinary incontinence at 22 to 24 days, caudal paraplegia 2 to 4 days later. Restricted growth and delayed maturation of brain cells.	95
Lead acetate administered to adult (100 days) and weanling (22 days) rats via intraperitoneal injections (0 to 1.2 mg/100 g) for 21 days pretest and 16 days testing.	Urinary ALA excretion increased in all exposed rats. At highest dose some clinical signs of poisoning and mortality. No behavioral effects measured.	95

Table 15.7 Effects of Lead upon Selected Animals in Experimental Studies (Continued)

Dose	Response	Reference
Lead acetate (0.8 mg/100 g) administered to pregnant rats for 21 days intraperitoneally.	100% reproductive failure	95
3.5 mg Pb/100 g given by gavage to lactating dam.	Impaired T-maze learning in weanlings nursed by dams dosed 1–10, but not 11–20 days postpartum	95
Lactating rats fed 35 mg/kg Pb ²⁺ /kg for 1–10 days postparturation.	Pups receiving lead from mothers milk exhibited decreased learning ability that persisted into adulthood.	248
Sheep		
Adult sheep fed powdered elemental Pb (4.5 mg/kg/days) for 6 months prior to birth of lambs. Blood lead was 34 µg/dl in adults and 24 µg/dl in 2-week-old lambs. Postnatally, lambs were exposed only to Pb in ewe's milk.	Between 5 and 15 months, lambs trained on a simultaneous, 2-choice, nonspatial visual discrimination task. Significant increase in days required by dosed group to master visual discrimination test.	95
Primates		
Lead acetate given orally to infant rhesus monkeys, 0.5–9.0 mg/kg.	Seizures occurred with blood Pb of 300 ug/dl, but stopped when exposure ceased. With blood Pb 60–100 ug/dl monkeys were hyperactive, insomniac, and hemoglobin and hematocrit gradually declined.	95
Lead acetate in drinking water 20 mg/kg resulting in blood Pb of 135 µg/dl in juvenile monkeys.	No behavioral changes.	95
Lead acetate 250–500 mg/kg three times weekly to 5- to 6-month-old rhesus monkeys resulting in blood Pb 30–1000 ug/dl.	Overt toxicosis after 7–16 weeks: anorexia; lethargy; muscular weakness; convulsions.	95
Lead chloride intravenously 1.61 mg/kg/day to baboons.	Two individuals died, at 68 and 85 days with blood Pb 1500 and 950 µg/dl.	88
Lead fed to infant rhesus monkeys at 3–4 mg/kg/day for 5 weeks or 9–10 mg/kg/day for 3 weeks.	Behavior of experimental animals differed markedly from controls. Infant monkeys more susceptible to Pb-induced behavioral effects than adolescents and adults.	249
Rhesus monkey infants fed 0.5 mg/kg diet for 4 weeks. Adults given 20 mg/L Pb in drinking water for 4 weeks.	Hyperactivity, insomnia and abnormal social behavior in infants, no effect in adults.	250

Unlike many of the other effects of lead, hematological effects can be quantified in wild animals as precisely as those used in controlled experiments. Several parameters are useful as indicators of lead contamination in wild populations.

15.5.2.1 Effects of Lead in the Bloodstream

The first measurable effects of lead following absorption occur in the bloodstream. Lead inhibits several heme-biosynthetic enzymes, notably ALAD and heme synthetase. ALAD is the most lead-sensitive erythrocyte enzyme, and lead is a relatively specific inhibitor of ALAD activity. ALAD activity becomes inhibited within hours of lead absorption and, depending upon the level and duration of exposure, may remain inhibited for several weeks or several months after cessation of exposure. Inhibition of erythrocyte ALAD activity following lead exposure has been reported in many species of freshwater and marine fish, in birds, and many mammals including mice, rats, rabbits, sheep, cattle, swine, and humans.^{8,143} The sensitivity of ALAD to low concentrations of lead has been demonstrated in a wide range of avian species including mallard, black duck (*Anas rubripes*), canvasback (*Aythya valisineria*), American kestrels, bald eagles (*Haliaeetus leucocephalus*), barn swallows (*Hirundo rustica*), pheasants (*Phasianus colchicus*), Japanese quail (*Cortunix*

japonica), and other species.^{112,151–158} Inhibition of ALAD activity has been recorded at blood lead concentrations of < 5 µg/dL in some avian species,¹⁵² and in most species > 90% inhibition occurs when blood lead concentrations exceed 120 to 150 µg/dL. Interspecific differences in the sensitivity of ALAD to lead have been recorded in birds.¹⁵⁹ Lead affects fish in a similar way to birds and mammals, interfering with the activities of enzymes, notably those of the heme-biosynthetic pathway, and affecting a wide range of body systems resulting in impaired growth, reproduction, and survival. ALAD activity in cattle and humans appears to be more sensitive to *in vitro* lead inhibition than that of pigs or dogs.¹⁶⁰ Lead inhibition of erythrocyte ALAD activity may be accompanied by a corresponding inhibition of ALAD activity in the brain, liver, and kidney of birds and mammals.^{151,154,161,162}

Inhibition of ALAD activity results in the accumulation of amino levulinic acid (ALA), which is excreted in the urine in abnormal concentrations when blood lead is > 40 µg/dl in humans,¹⁶³ and high urinary ALA concentrations are characteristic of lead poisoning.¹⁴³ In many animals significant inhibition of ALAD activity can occur without a corresponding decrease in heme production, possibly related to a compensatory increase in ALAD production. Many animals can compensate for the inhibition of ALAD activity, and dogs fed sufficient lead to inhibit most ALAD activity may remain apparently healthy.¹⁶⁴ In some avian species ALAD activity may be inhibited by up to 80% by lead, and this inhibition can be sustained over several months without the occurrence of anemia.¹⁶⁵

Another enzyme in the heme-biosynthetic pathway influenced by lead is heme synthetase, responsible for the incorporation of ferrous iron Fe₂₊ into protoporphyrin 9 (PP9) for heme production. Inhibition of heme-synthetase activity results in elevated levels of metal-free erythrocyte porphyrin (FEP) and zinc protoporphyrin (ZPP), in which zinc becomes incorporated into PP9 instead of iron. Elevated concentrations of PP9 (FEP or ZPP) in the blood following lead exposure have been reported in many animals including humans, rabbits, small mammals, and birds.^{152, 166–170} Both FEP and ZPP fluoresce when actuated by specific wavelengths of light, and this fluorescence is used for the quantitative estimation of protoporphyrin concentration. Both FEP/ZPP concentrations and ALAD activity have been used as indicators of lead exposure in many species of fish, birds, and mammals.⁸

In cases of acute or long-term chronic lead exposure, the inhibition of heme-biosynthetic enzymes may result in a reduction in total blood hemoglobin concentration and anemia. Lead may also cause anemia by impairing red blood cell production or initiating premature cell degradation, particularly in cases of acute exposure. Pain and Rattner¹⁷¹ reported significant decreases in both hemoglobin concentration and hematocrit of black duck within 3 days of ingesting one No. 4 lead shot. Anemia is a classic sign of lead poisoning and has been reported in fish, birds, and mammals.^{8,143,172}

Other hematological features associated with lead poisoning include reticulocytosis,^{173,174} basophilic stippling of erythrocytes,^{175,176} and a high degree of variability in erythrocyte morphology, including characteristic “tear-drop” shaped cells in waterfowl.^{103,177} Morphological alterations in red blood cells may result in increased hemolysis and, consequently, contribute to anemia.

15.5.2.2 Aquatic Animals

The effects of lead upon aquatic organisms vary according to species, duration of exposure, development of tolerance, lead concentration, and environmental factors, such as water hardness and pH, that influence lead solubility. For example, the LC₅₀ (concentration of total lead required to kill 50% of individuals) for *Daphnia magna* exposed for 96 h varies from 612 µg Pb/LL with a water hardness of 54 mg CaCO₃/L to 1910 µg Pb/L with water hardness 152 mg CaCO₃/L.¹⁷⁸ A similar increase in LC₅₀ with increasing water hardness has been reported for minnows (*Pimephales promelas*), rainbow trout, and bluegills (*L. macrochirus*), although the relationship between water hardness and lead toxicity was not constant across species.¹²⁷

Lead-tolerant strains of the isopod *Asellus meridianus* have been reported with an LC₅₀ of 280 µg Pb/L (48-h exposure) for a nontolerant strain compared with 3500 µg Pb/L for a strain from a lead-contaminated river.¹⁴³ Lead tolerance may be either genetically controlled or achieved by acclimation during the animal's lifetime. Evidence of the former has been provided by Brown¹⁷⁹ in *A. meridianus* and the latter by Fraser¹⁸⁰ in *A. aquaticus*. Although tolerance to the lethal effects of relatively high concentrations of lead can and does develop in certain aquatic organisms, rivers affected by lead mine waste support few macroinvertebrates and flora. Demayo et al.¹⁴³ suggested that the observed sublethal effects of lead at concentrations > 20 µg Pb/L on invertebrates may be sufficient to extinguish some populations.

The chemical form of lead influences its toxicity, with organic forms tending to produce toxic effects at lower concentrations than Pb²⁺, as is illustrated by the LC₅₀ concentrations in plaice (*Pleuronectes platessa*) (Table 15.7). Although the concentration of lead resulting in lethality varies considerably with the chemical form of lead and composition of the water, a variety of sublethal effects can occur at very low water lead concentrations (7 µg/L¹⁴³), and the activity of certain hematopoietic enzymes can be inhibited by water Pb concentrations of 10 µg/L.¹⁸¹ Elevated water lead concentrations may result in anemia, reduced egg hatching, darkening of the dorsal tail region and degeneration of the caudal fin, and scoliosis (lateral curvature of the spine).¹⁴³ Lethal solutions of lead cause increased mucus formation, which coagulates over the gills and body resulting in death by anoxia.^{182,183} Certain fish appear to be more sensitive to the effects of lead when exposed at the egg or young hatchling stage, possibly due to an increased sensitivity of the developing nervous system or an increased ability to take up lead relative to older fish. Reduced community diversity and general absence of fish in parts of a river with higher lead content in suspended and bed sediments were reported by Leland and McNurney,⁷¹ although lead was not the only factor influencing community structure, as oxygen levels also affected the biota.

15.5.2.3 Amphibians

Lead exposure has resulted in a range of effects in amphibians including decreased red and white blood cells; neutrophils and monocytes; sloughing of the skin; excessive bile excretion; hypertrophy of liver, spleen, and stomach; decreased muscle tone and loss of normal semierect posture; salivation, excitement, and muscular twitching; and delayed metamorphosis.^{8,184} LC₅₀ values vary between species and according to water chemistry, but in soft water (99 mg CaCO₃/L), an 8-day exposure to 1.4 mg Pb/L was sufficient to cause mortality in some salamanders (*Ambystoma opacum*).⁸ Surface water runoff from the fall zone of a shotgun range (total lead ranged from 840 to 3150 µg/L) was toxic pickerel frog (*Rana palustris*) tadpoles but not to bullfrog (*Rana catesbeiana*) tadpoles.¹⁸⁰ Green frogs (*Rana clamitans*) on a shotgun target range had femur lead levels of 1728 µg/g, nearly 1000-fold higher than a nearby neighbor.¹⁸¹

15.5.2.4 Birds

15.5.2.4.1 The Ingestion of Lead Gunshot and Bullets

The effects of lead upon wild birds have perhaps been observed more frequently than for any other group of wild animals. This results primarily from the widespread exposure of avian species to spent lead gunshot. The two main groups of birds that become poisoned from this source are those feeding in substrates in shot-over areas, such as wetlands, clay-pigeon shoots, firearms training facilities,¹⁸⁵ and upland game areas; and those species that ingest shot while feeding on animals carrying shot in their flesh. Waterfowl, waders, rails, coots, pigeons, and doves fall into the first category, and raptors (including eagles, buzzards, harriers, and vultures) into the second.¹⁸⁶

Lead poisoning from gunshot ingestion is considered to be directly responsible for the deaths of millions of wild birds each year.^{105,251} In the United States, before the widespread use of nontoxic

gunshot, 1.6 to 2.4 million waterfowl were estimated to die annually as a direct result of gunshot ingestion.²⁵² Lead poisoning threatens waterfowl worldwide,¹⁸⁷ with particularly high levels of exposure in some parts of Europe, such as Mediterranean wetlands,^{188–190} where other waterbirds, such as the greater flamingo (*Phoenicopterus ruber roseus*), have also suffered lead-poisoning mortality.¹⁹¹ Several waterfowl species classified as globally threatened,¹⁹² including the marbled teal (*Marmaronetta angustirostris*) and the white-headed duck (*Oxyura leucocephala*), are susceptible to lead poisoning in Spain.¹⁹³ Historical analyses of ringing recoveries from x-rayed mallards has shown reduced survival in birds carrying ingested shot.¹⁹⁴

Both predatory and scavenging raptors are vulnerable to lead poisoning.^{195–201} Elevated tissue lead levels and mortality have been reported, for example, in bald (*Haliaeetus leucocephalus*) and golden eagles (*Aquila chrysaetos*) from Canada;¹⁹⁵ in Steller's sea eagles (*Haliaeetus pelagicus*) from Japan;¹⁹⁶ in white-tailed sea eagles (*Haliaeetus albicilla*) from Japan, Austria, and Germany;^{196,202,203} in golden eagles from California;¹⁹⁷ in bald eagles from the great plains of North America; in golden and bald eagles from the upper Midwest¹⁹⁸ (United States); in bald and golden eagles from Idaho;^{199–201} in marsh harriers (*Circus aeruginosus*) from France and Spain;^{204, 205} in Griffon vultures (*Gyps fulvus*) from Spain;²⁰⁶ and California condors (*Gymnogyps californianus*).²⁰⁷

For example, the Raptor Center at the University of Minnesota treated 654 golden and bald eagles from 1980 to 1995; 138 were lead poisoning cases.¹⁹⁹ More than 170 bald eagle deaths from lead poisoning have been documented by the National Wildlife Health Research Center (United States, pers. comm.). Several globally threatened raptor species are exposed to lead gunshot or bullet fragments in their prey including the Spanish imperial eagle²⁰⁸ and the California condor.²⁰⁷ The remnant wild population of California condors exhibited a rapid population decline in the 1980s, largely as a result of lead poisoning through ingesting bullet fragments in carrion, and this remains a problem for birds released in the 1990s subsequent to a successful captive breeding program.²⁰⁹

External signs of lead poisoning in birds following shot ingestion were first recognized in 1876 in pheasants (*Phasianus colchicus*), emaciated and with paralyzed legs, the feet being held in a similar manner to the “drop-hand” condition typical of lead-poisoned humans.²¹⁰ Lead-poisoned birds are frequently emaciated, have a prominent keel, and are weak and unable to walk or fly. The muscular paralysis caused by lead poisoning results in characteristic signs such as abnormal carriage of wings by waterfowl (either wing-droop or carriage in a hat-shaped position) and “kinky” necks in swans following the ingestion of lead fishing sinkers. Wing-droop has also been reported in Laysan albatross (*Diomedea immutabilis*) chicks after ingesting paint chips containing lead.²¹¹ Jacobsen et al.²¹² noted that bald eagles were unable to maintain an upright position following shot ingestion.

Not all birds exposed to shot die, as shot retention and lead absorption and distribution within the body vary according to a wide range of factors, including age, sex, environmental factors, and diet. The importance of diet upon lead toxicity is illustrated in mallards in Table 15.7. Waterfowl that die following shot ingestion may die within several days of ingesting a large number of shot (e.g., ten), with little loss of weight and few external signs of poisoning. However, more frequently, waterfowl die several weeks after the ingestion of a smaller number of shot. At necropsy, birds that have died from lead poisoning are often underweight, lacking subcutaneous fat reserves. Substantial weight losses, occasionally of > 50% of body weight, have been recorded in many species of waterfowl, game birds, raptors, and passerines.^{105,112,174,213,214} Tissues of dead birds are generally anemic, the gall bladder is often distended and bile-filled, and the gastrointestinal tract may be impacted with food. Intestinal impaction due to muscular paralysis may result in death from starvation.

15.5.2.4.2 Nonammunition Sources

Lead poisoning of mute swans (*Cygnus olor*) and other species has occurred due to the ingestion of lead fishing sinkers.^{186,215} Concern over Mute swan mortality resulted in the banning of most lead fishing sinkers in the United Kingdom in 1986. Lead poisoning from lead fishing weights has

been identified as a source of mortality in common loons (*Gavia immer*); 16 of 31 dead loons examined died of lead poisoning,²¹⁶ and 21% of 105 loons found dead in New York from 1972 to 1979 had ingested lead fishing weights.²¹⁷

An additional source of lead poisoning, although rarely reported in wild birds, is leaded paint. Ingestion of chips of flaking paint from a deserted military base on Midway Atoll resulted in mortality of Laysan albatross chicks in 1983.²¹¹ Cases of lead poisoning from leaded paint are more often reported in caged birds.¹⁸⁶ Birds are exposed to many sources of environmental lead contamination, and elevated tissue lead concentrations and associated physiological effects are frequently found in birds occupying or feeding in urban areas, industrial areas, or waste dumps.^{87,218} These sources of lead contamination usually result in sublethal effects in birds and other animals, the biological significance of which is difficult to quantify. However, recent work in the United States has shown that in areas where sediment has become lead contaminated (e.g., through mining or smelting) sediment ingestion is an important route of lead contamination in waterfowl.^{219,220}

Although most avian mortality from lead poisoning results from the ingestion of lead objects, sporadic cases of mass avian mortality from other sources do occur. One example is the deaths of several thousand shorebirds and gulls in the Mersey Estuary, United Kingdom, in 1979 and the early 1980s following the ingestion of prey contaminated with organic lead from a petrochemical works.²²¹ Signs of lead poisoning following exposure to organic lead compounds are presented in Table 15.7.

15.5.2.5 Mammals

From experimental studies, the toxic effects of lead in mammals have included blindness, histopathology of liver and kidney, hemorrhaging, depressed food intake and anorexia, anemia, inhibition of ALAD activity and increased protoporphyrin concentrations, reduced brain weight and cerebral pathology, lack of coordination, convulsions, impaired motor skills, impaired visual discrimination and learning behavior, abnormal social behavior, increase in aggression, hyperactivity, disturbed sleep patterns and insomnia, reproductive impairment, increased fetal deaths and abortions, and reduced survival and longevity.^{8,143,222}

The minimum level of lead intake that results in sublethal lead poisoning or death in cattle has been shown to be 5 to 7 mg ingested Pb/kg body weight/day.^{8,223} However, lower lead doses have resulted in toxic effects in some experiments, and the form of lead administered, age, and physiological state of test animals and diet all appear to influence the minimum toxic dose. A dose of 5 mg Pb/kg/day over a 10- to 20-day period resulted in some clinical lead poisoning and mortality in calves, whereas 2.7 mg/kg body weight given as lead acetate to calves for 20 days on a milk diet resulted in mortality.²²⁴ Mortality in horses has resulted from the ingestion of 2.4 mg Pb/kg body weight/day.¹⁴³ Only a percentage of lead administered orally is absorbed, and toxic effects of lead are observed at much lower doses when lead is administered via intraperitoneal or intramuscular injection. Even when no clinical signs of lead poisoning are apparent, lead may increase the susceptibility of animals to disease. Hemphill et al.²²⁵ illustrated that by exposing mice to lead nitrate at concentrations that provoked no clinical signs of poisoning. Their susceptibility to infection by the bacteria *Salmonella typhimurium* increased.

Controlled studies in a wide range of mammals, including rats, sheep, and primates, have illustrated various effects of lead on learning and behavior (Table 15.7). A common finding of these studies is that the age at exposure to lead is critical; prenatal and very early postnatal lead exposure is more likely to affect animals than exposure at later stages.¹⁵⁰ Maternal or dual-parent exposure to lead has been shown to influence learning and behavior in offspring of rats^{226,227} and sheep.²²⁸ Transfer of lead from mother to young is both via the placenta and milk. Lambs from pregnant ewes fed 4.5 mg Pb/kg/days for 6 months prenatally required more days to learn visual discrimination processes than controls (Table 15.7).^{228,229} No data are available concerning the effects of lead upon learning and altered social behavior in wild animals.

Cases of lead poisoning and mortality in domestic and wild mammals usually result from feeding in areas contaminated by industrial lead operations, near disposal sites of lead containing waste, or in areas where leaded paints have been used.²³⁰ Mortality from lead poisoning has been reported in horses and cattle in the vicinity of a California lead smelter,²³¹ and lead poisoning has been reported in buffalo and cattle in the vicinity of a plant that recycles lead from old batteries.²³² Lead toxicity has also been reported in cattle consuming silage cut from fields that had been used for clay-pigeon shoots.^{233,234} Frape and Pringle²³³ reported soluble lead concentrations in shot-contaminated silage of 3800 ppm d.w. soluble lead (pH was 3.9 to 4.4). Affected cows showed lack of appetite and coordination as well as stiff and swollen joints; in addition, a large number of stillbirths or abortions occurred. Many zoo animals have suffered lead poisoning including primates, bats, foxes, ferrets, panthers, and a bear.²³⁵ In almost every case the source of lead poisoning was lead-containing paint.

15.6 CONCLUSIONS

Anthropogenic uses of lead have probably altered its availability and environmental distribution more than any other toxic element. Consequently, lead concentrations in many living organisms may be approaching thresholds of toxicity for the adverse effects of lead. Such thresholds are difficult to define, as they vary with the chemical and physical form of lead, exposure regime, other elements present and also vary both within and between species. The technological capability to accurately quantify low lead concentrations has increased over the last decade, and physiological and behavioral effects have been measured in wildlife with tissue lead concentrations below those previously considered safe for humans.^{8,236} Consequently, lead criteria for the protection of wildlife and human health are frequently under review, and “thresholds” of lead toxicity are being reconsidered. Proposed lead criteria for the protection of natural resources have been reviewed by Eisler.⁸

Uptake of lead by plants is limited by its generally low availability in soils and sediments, and toxicity may be limited by storage mechanisms and its apparently limited translocation within most plants. Lead does not generally accumulate within the foliar parts of plants, which limits its transfer to higher trophic levels. Although lead may concentrate in plant and animal tissues, no evidence of biomagnification exists.

Acid deposition onto surface waters and soils with low buffering capacity may influence the availability of lead for uptake by plants and animals, and this may merit investigation at susceptible sites. The biological significance of chronic low-level lead exposure to wildlife is sometimes difficult to quantify. Animals living in urban environments or near point sources of lead emission are inevitably subject to greater exposure to lead and enhanced risk of lead poisoning.

Increasingly strict controls on lead emissions in many countries have reduced exposure to lead from some sources, and the reduction of lead in gasoline has resulted in lower tissue lead concentrations in humans and wildlife from many, particularly urban, locations.²³⁷ However, it has been suggested that increasing use of organic lead compounds as catalysts for the production of plastics and as wood preservatives and biocides could adversely affect wildlife.⁸

The most significant source of direct wildlife mortality from lead is spent gunshot and fishing sinkers. Elevated mortality from shot ingestion in avian species resulted in the introduction of nontoxic (steel) shot zones along certain flyways in the United States in the mid-1970s and a total ban on the use of lead for waterfowl and coot hunting nationwide by 1992.^{251,252} Several other countries are now following suit and have either banned or are in the process of restricting the use of lead shot for waterfowl hunting.²³⁸ In the United States it has been estimated that since the 1986 hunting season, when the use of nontoxic shot became widespread, over 6 million ducks have not been lost to lead poisoning.²³⁹ Raptors, especially eagles, have also apparently benefited, although lead poisoning from ingestion of bullet fragments remains a problem for the critically threatened California condor.²⁰⁹ Quantifying reductions in lead mortality rates would be difficult since eagle

populations throughout North America are rapidly recovering from other anthropogenic perturbations, especially organochlorine pesticides.

16.1 INTRODUCTION

This chapter describes selected aspects of the behavior of mercury in the environment and examines the ecotoxicology of this highly toxic metal. The widespread geographic extent and

adverse consequences of mercury pollution continue to prompt considerable scientific investigation. Furthermore, the environmental sources, biogeochemistry, transformations, transport, fate, and effects of mercury in the environment are subjects of frequent symposia, workshops and a large, steadily expanding body of scientific literature. We characterize the environmental mercury problem, critically review the ecotoxicology of mercury, and describe the consequences of methylmercury contamination of food webs. We discuss processes and factors that influence exposure to methylmercury, the highly neurotoxic form that readily accumulates in exposed organisms and can biomagnify in aquatic and terrestrial food webs to concentrations that can adversely affect organisms in upper trophic levels, including humans. Emphasis is given to aquatic food webs, where the problem of methylmercury contamination is greatest.¹ When available, recent reviews have been cited for readers interested in more detailed coverage.

Concerns about environmental mercury pollution and contamination of aquatic food webs stem largely from the human health risks of dietary exposure to methylmercury, the dominant form of mercury in the edible flesh of fish and aquatic mammals.²⁻⁴ The human health risks associated with mercury in surface waters and aquatic biological resources are not reviewed here but have been critically examined in several case studies and recent reviews.⁵⁻¹⁶ Nonetheless, our discussion of processes and factors affecting exposure of fish and wildlife to methylmercury is directly relevant to the issue of human exposure to methylmercury, which results largely from consumption of fish, shellfish, and aquatic mammals and birds.^{10,12,17}

16.2 EVOLUTION OF THE ENVIRONMENTAL MERCURY PROBLEM

Humans have been using mercury for more than 2000 years for a wide variety of applications,^{18,19} and centuries of emissions and reemissions of anthropogenic mercury have caused widespread environmental contamination over large regions of the globe.^{20,21} Cinnabar, $\text{HgS}_{(s)}$, the principal mercury ore, was used as a red pigment long before the process for refining mercury ore to recover elemental mercury, Hg^0 , was discovered. Since the advent of refining cinnabar, five mining areas have dominated the historical global production of elemental mercury: the Almadén district in Spain, the Idrija district in Slovenia, the Monte Amiata district in Italy, the Huancavelica district in Peru, and the state of California in the United States.^{18,22} At Almadén, Spain, mercury was first mined about 430 B.C.,²³ and during the next 25 centuries the Almadén mines produced more than 280,000 metric tons of the estimated total global production of about 800,000 tons.²² The mining and smelting of cinnabar and other mercury ores have caused substantial contamination of air, soil, water, biota, and sediment in the vicinity of such operations, and mercury-containing wastes at mining and smelting sites continue to emit mercury, including methylmercury, to the environment for decades or centuries after operations cease.^{22,24-30}

From 1550 to 1930 an estimated 260,000 tons or more of mercury were released globally from mining operations that used the mercury-amalgamation process to recover gold and silver.³¹ In the United States, gold mining was the primary use of mercury during the latter half of the 1800s, and the demand created by gold and silver mining stimulated mining for mercury as well.^{18,32} The mining of mercury deposits (primarily cinnabar) along 400 km of the Coast Range of California, for example, was stimulated by the California gold rush in the mid-1800s.^{28,33,34}

Gold or silver was mined throughout much of North America, and large quantities of mercury were used for precious-metal mining in California, Nevada, and South Dakota.^{31,34} Contaminated tailings and alluvium originating from mining sites are consequently widespread in North America and elsewhere.^{29,31,35-37} Emissions of mercury from contaminated mine tailings and lands include volatilization of Hg^0 to the atmosphere, aqueous dissolution by infiltrating water and entrainment with stream flow, and physical erosion and downstream transport of mercury-enriched geologic materials.³⁷⁻⁴² Contaminated tailings can remain a source of mercury emissions for decades or centuries after mining operations have ceased.^{31,37} In some drainage basins, exemplified by the

Carson River (Nevada), contaminated sediment originating from historic mining sites has been transported, deposited, and redistributed far downstream, causing persistent contamination of stream and river channels, river banks, floodplains, and reservoirs along extensive reaches of the watershed.^{33,35–38,40,41,43,44} The natural burial of such mercury-contaminated deposits by more recent, “clean” sediments may mitigate these settings only temporarily, given that large floods can reexpose the underlying, contaminated deposits.³⁶

Since the early 1970s there has been a resurgence of gold-mining operations that use the mercury-amalgamation process, particularly in South America, Southeast Asia, China, and parts of Africa.^{31,37,45–47} These ongoing mining activities, which seem to be stimulated partly by economic recession,⁴⁶ are widely dispersed in hundreds to thousands of operations — often small and in remote areas — involving millions of people worldwide.^{31,45,46} Total emissions from these operations are now and could remain a globally significant source of new anthropogenic mercury for decades.^{31,37,39,45} Recent emissions to the global environment from this “new gold rush” may total as much as 460 metric tons per year (about 10% of annual, anthropogenic global emissions),⁴⁸ with roughly two thirds of this total emitted to the atmosphere and one third emitted to land or water.³¹ In Brazil, gold mining has become the major source of anthropogenic mercury emissions.⁴⁵

Mercury also has a long history of usage in industrial applications, particularly in chlor-alkali plants and pulp and paper mills, and pollution from these sources has been well documented in recent decades.^{21,25,49,50} The most publicized industrial releases occurred in Minamata and Niigata, Japan, in the 1950s and 1960s, when many humans were poisoned by methylmercury after eating fish that were highly contaminated by mercury from direct industrial sources.^{5,8} These tragedies focused global attention on environmental mercury pollution⁵¹ and prompted efforts, beginning around 1970 in the United States, Canada, and many other industrialized countries, to identify industrial sources of mercury pollution and to reduce intentional discharges of mercury into surface waters.^{25,45} As a result, mercury levels in fish and sediments in such industrially affected waters typically declined in subsequent years and decades.^{25,52–60} In many cases, the concentrations of mercury in fish decreased by 50% or more during the first decade after discharges were reduced, and the rate of decrease in concentration then slowed considerably, or concentrations leveled off, to values that were elevated relative to lesser contaminated waters nearby.^{25,52,53,55,58,61} At some mercury-contaminated sites, however, the decline in concentrations of mercury in fish has been slow or delayed in the affected aquatic ecosystem.^{25,62,63}

In industrially polluted Clay Lake, Ontario, mercury concentrations in gamefish have declined from peak levels but remained substantially above the Canadian mercury limit of 0.5 µg/g wet weight nearly three decades after operations ceased at the industrial source, a chlor-alkali plant near Dryden that operated from 1962 to 1970.^{52,64} Mercury concentrations in axial muscle of 50-cm walleye (*Stizostedion vitreum*) from Clay Lake decreased rapidly after operations ceased at the chlor-alkali plant — from about 15 µg/g wet weight in 1970 to about 7.5 µg/g in 1972 — and then declined gradually to about 3.5 µg/g in 1983.⁵² Concentrations apparently declined little during the next 15 years, given that total mercury averaged 2.7 µg/g in a sample of 14 walleyes (mean fork length, 53 cm) taken from Clay Lake in 1997 and 1998.⁶⁴ Persistent problems with methylmercury contamination of aquatic biota at historically contaminated sites may result from continuing, unintended emissions of mercury from the source area, from recycling and methylation of the mercury present in contaminated sediments, from temporal increases in the bioavailability of mercury or in the habitability of highly contaminated zones within the ecosystem, from changes in food-web structure, from atmospheric deposition of mercury from other sources, or from a combination of these and other factors.^{25,50,62,65–69} Indeed, the physical and chemical properties that made mercury so useful in industrial applications (e.g., liquid state at ambient temperature, high volatility, and ease of reduction) also make this metal very difficult to contain and recover from the environment.²⁵

The growing awareness of the hazards of mercury exposure led to widespread discontinuation or phased reductions in usage of the metal in a variety of applications and consumer goods beginning

in the late 1960s.^{18,19,29} For example, the use of mercurial fungicides in seed grain, which began in the 1940s, had severe consequences for humans and wildlife. Thousands of humans were poisoned, and hundreds died, when methylmercury-treated grains were eaten (rather than planted) by Iraqi farmers and their families.^{6,7,9} Incidents of high mortality of wild birds were reported after planting of seeds treated with alkylmercury compounds,⁷⁰ and both seed-eating birds and their predators were poisoned.⁷¹ The use of mercury compounds as seed dressings was decreased or banned in Sweden, Canada, and the United States in the 1960s and 1970s.

Mining of mercury decreased abruptly in response to rapidly declining demand and prices. Mercury production in the United States, for example, had peaked in 1877 at more than 2700 metric tons per year, and as recently as 1969 there were more than 100 active mercury mines in the country.¹⁸ The mercury-mining industry in the United States collapsed in the early 1970s. Fewer than ten mines remained in production in late 1976, and the last mine in the country to produce mercury as its principal product closed in November 1990.¹⁸

In the late 1970s and 1980s, concentrations of mercury exceeding 0.5 or 1.0 $\mu\text{g/g}$ wet weight — sufficient to prompt fish-consumption advisories — were reported in predatory fishes from aquatic ecosystems lacking substantive, on-site anthropogenic or geologic sources of mercury.^{72–76} Subsequent investigations have shown that in certain aquatic systems concentrations of methylmercury in aquatic invertebrates, fish, and piscivorous wildlife are commonly elevated — a situation frequently reported for humic and low-alkalinity lakes (including low-pH lakes),^{77–83} newly flooded reservoirs,^{84–88} and wetlands or wetland-influenced ecosystems.^{67,89–91} Many such environments can be characterized as lightly contaminated systems in which the amount of inorganic Hg(II) being converted to methylmercury is sufficient to contaminate food webs supporting production of fish and wildlife.^{92–100}

Reliable records of temporal trends in mercury deposition can be obtained by analyses of dated cores of depositional sediments from lakes or reservoirs, of peat from ombrotrophic bogs, and, in some cases, of glacial ice.^{20,59,101–106} At a site in northwestern Spain about 600 km northwest of the Almadén mines, substantive anthropogenic emissions of mercury to the atmosphere are reflected in peat deposited more than 1000 years ago in a core from an ombrotrophic bog.²³ The oldest anthropogenic mercury in this core was deposited about 2500 years ago, coinciding with the start of mining at Almadén and accounting for about 10 to 15% of the total mercury deposited in peat at that time.²³ In remote and semiremote areas of North America, Greenland, and Scotland that lack on-site sources of anthropogenic mercury, the rate of mercury accumulation in many lacustrine sediments has increased by a factor of 2 to 4 since the mid-1800s or early 1900s, based on analyses of sediment and peat cores.^{101,102,104,107–110} Moreover, some cores from semiremote sites show evidence of recent declines in atmospheric mercury deposition associated with decreasing regional emissions of anthropogenic mercury into the environment.^{102,103,106,109} Much of the mercury deposited onto terrestrial catchments is stored in soils, and the sediments in lakes that receive substantial inputs of mercury from their catchments may be slow to reflect declines in rates of atmospheric deposition of mercury.¹¹⁰

Many remote and semiremote ecosystems are contaminated with anthropogenic mercury deposited after long-range atmospheric transport from source areas.^{20,109,111,112} Qualitatively, it can be reasonably inferred that a significant fraction of the methylmercury in the aquatic biota of remote or semiremote regions, including marine systems, is derived from anthropogenic mercury entering the aquatic ecosystem or its watershed in atmospheric deposition.^{20,94,101,111,113–118} In northern Wisconsin, for example, the total annual atmospheric deposition of mercury to an intensively studied, semiremote seepage lake with no surface inflow and very little groundwater inflow averaged about 0.1 g/ha during 1988 to 1990, an input sufficient to account for the mass of mercury in water, fish, and depositing sediment.^{94,114,119}

Concentrations of methylmercury in aquatic biota at remote and semiremote sites have probably increased globally during the past 150 years in response to anthropogenic releases of mercury into the environment. Substantial increases in methylmercury contamination of marine food webs in the North Atlantic Ocean, for example, were revealed by analyses of feathers from two fish-eating

Figure 16.1 Historical trends of increasing methylmercury concentrations (mean \pm 1 standard error, with sample size denoted near the bottom of each bar) in feathers of two species of fish-eating seabirds obtained from the North Atlantic Ocean during 1885 to 1994.¹¹⁸ Monteiro and Furness¹¹⁸ determined organic mercury in feathers from museum specimens of the birds to avoid potential errors associated with postmortem contamination of the museum samples with inorganic mercury.

seabirds sampled from 1885 through 1994 (Figure 16.1).¹¹⁸ The long-term increase in concentration of methylmercury averaged 1.9% per year in Cory's shearwater (*Calonectris diomedea borealis*) and 4.8% per year in Bulwer's petrel (*Bulweria bulwerii*).¹¹⁸ Monteiro and Furness¹¹⁸ attributed these increases to global trends in mercury contamination, rather than local or regional sources. Mercury concentrations have also increased during the past century in other species of seabirds.¹¹⁶

Quantitatively assessing the relative contributions of anthropogenic and natural emissions to the methylmercury burdens accumulated in biota at remote and semiremote sites is an enormous scientific challenge, partly because of spatial variation in (1) the contribution of natural sources and (2) the biogeochemical transformations and transport of mercury on the landscape.⁴² The drainage basins onto which anthropogenic mercury is deposited can vary spatially in many respects. First, there is variation in the natural geologic abundances of mercury in bedrock, soils, sediments, and surface waters.¹²⁰⁻¹²² Second, surface waters within a region can differ spatially and temporally in the extent to which they receive total mercury and methylmercury exported from the drainage basin.^{92,93,101,107,108,123-125} Third, the extent to which inorganic mercury present in aquatic ecosystems is converted to methylmercury can vary considerably, even on spatial scales of a few kilometers to tens of kilometers.^{68,92,97,126} To overcome such complexities, new investigations involving the application of stable isotopes of mercury^{127,128} are being employed to examine the biogeochemical cycling, bioaccumulation, and food-web transfer of "old" vs. newly deposited mercury in ecosystems.¹²⁹

16.3 GLOBAL-SCALE ENVIRONMENTAL CYCLING AND FATE

Our understanding of the biogeochemical cycling of mercury (sources, pathways, and pools) in the environment has increased markedly during the past 10 to 15 years, whether considered in the context of mass balances,^{48,130,131} concentrations in environmental media,^{20,132,133} or important

Figure 16.2 A simplified view of the biogeochemical cycling of mercury in an aquatic ecosystem, depicting pathways and processes that influence exposure of biota to methylmercury. In this illustration, mercury enters the ecosystem largely as inorganic Hg(II) in atmospheric deposition. The mercury cycle includes a complex set of biogeochemical processes, of which methylation is most important from an ecotoxicological perspective. Methylmercury is readily bioaccumulated and transferred in food webs and can biomagnify to high concentrations in predatory fish and wildlife. Biotic exposure to methylmercury in the ecosystem is strongly influenced by the net balance between processes that yield methylmercury and make it available to aquatic biota vs. processes that degrade methylmercury or decrease its bioavailability for uptake.

chemical reactions and rates.^{134–140} The environmental mercury cycle (Figure 16.2) has four strongly interconnected compartments: atmospheric, terrestrial, aquatic, and biotic. The atmospheric compartment is dominated by gaseous elemental mercury (Hg^0), although Hg(II) dominates the fluxes to the aquatic and terrestrial compartments. The terrestrial compartment is dominated by Hg(II) sorbed to organic matter in soils. The aquatic compartment is dominated by Hg(II) -ligand pairs in water and Hg(II) in sediments, and the biotic compartment is dominated by methylmercury. Mercury is quite reactive in the environment and cycles readily among compartments.

At the global scale, atmospheric processes and pathways dominate the transport of mercury from sources to receptors. The global mercury cycle can be envisioned as a two-way exchange process, in which sources emit elemental mercury (Hg^0) in the gas phase and various species of Hg(II) to

the atmosphere and the atmosphere loses mercury via oxidation of Hg^0 to $\text{Hg}(\text{II})$ and the rapid removal of gaseous and particulate species of $\text{Hg}(\text{II})$ by wet and dry deposition.^{48,139–142} This simple conceptual model reflects the following understanding of atmospheric pathways and processes: (1) that many important sources affecting global mercury cycles (including oceans, fossil fuel combustion, and municipal and medical waste incinerators) emit mostly gaseous Hg^0 and, to a lesser extent, gaseous and particulate species of $\text{Hg}(\text{II})$;^{10,143,144} (2) that gaseous and particulate forms of emitted $\text{Hg}(\text{II})$ are subjected to local and regional removal in dry and wet deposition,^{139–141,145} limiting their long-range transport; (3) that divalent mercury can be readily reduced to Hg^0 by natural processes in both terrestrial and aquatic ecosystems;^{135,146} and (4) that Hg^0 can be oxidized in the atmosphere to $\text{Hg}(\text{II})$, which is efficiently removed in wet and dry atmospheric deposition.^{139–142,145}

Mercury deposited onto the land surface in atmospheric deposition is sequestered in terrestrial soils, largely as species of $\text{Hg}(\text{II})$ sorbed to organic matter in the humus layer.^{131,147,148} Globally, the inventory of mercury in surface soils far exceeds that in the aquatic and atmospheric compartments. The vast majority (947 Mmol) of the estimated total mass of mercury released into the environment during the past century resides in surface soils, compared to 17 Mmol in the atmosphere and 36 Mmol in the oceans.⁴⁸ The residence times of mercury in the atmosphere and the oceans are considerably shorter (a year to a few years) than the residence time of mercury in soils. Yet soils should be considered a potential long-term source — as well as a sink — for mercury in the environment, given that the $\text{Hg}(\text{II})$ in soils can be reduced and emitted to the atmosphere as Hg^0 or slowly exported to aquatic systems located down gradient.^{110,147}

Recent advances in our understanding of mercury in the environment have highlighted the dominant influence of human activities — particularly since the industrial revolution — on the redistribution of global mercury pools, the size of actively cycling pools, and the importance of atmospheric pathways to a global pollution problem.^{20,48,106} Anthropogenic emissions have greatly increased the mass of mercury now cycling at the earth's surface and in the atmosphere,^{48,106,107,109} causing widespread contamination of terrestrial soils and aquatic sediments.^{48,102,133,148,149} Mason et al.⁴⁸ estimate that two thirds of the mercury in modern global fluxes is from anthropogenic sources, and the remaining one third is from natural emissions. Soil and sediment are considered to be the dominant sinks for atmospherically derived mercury; however, detailed studies have shown that these enriched pools are susceptible to remobilization via volatilization, leaching, or erosion.^{21,50,69,100,110,141} Investigators often find that the more closely they look, the more reactive the existing mercury pools appear to be; for example, St. Louis et al.¹⁵⁰ found that soil-canopy-atmosphere transfer rates were up to three times greater than prior estimates, Friedli et al.¹⁵¹ showed that forest fires can release mercury from burned areas, and Lalonde et al.¹⁵² showed that recently deposited snow can rapidly lose mercury via reevaporation to the atmosphere.

The importance of apportioning between natural and anthropogenic mercury emissions is recognized but very difficult to achieve.^{20,48,131,141,153} Initially, the estimated ratio of natural to anthropogenic emissions of mercury may have been underestimated.¹⁴¹ In Europe, for example, estimated natural emissions of mercury during 1995 were in the range of 250 to 300 tons, only slightly less than the estimate of 342 tons for anthropogenic emissions.¹⁴⁴ In addition, emissions of Hg^0 from areas that are geologically enriched with mercury or affected by mining activities can be substantial.^{42,153} The estimation of natural emissions from diffuse sources is greatly complicated by the fact that original sources — whether natural or anthropogenic — cannot presently be distinguished after mercury has been released into the atmosphere and has entered the global biogeochemical cycle.^{21,141}

16.4 MERCURY SPECIATION AND ENVIRONMENTAL CONCENTRATIONS

Scientific understanding of mercury speciation in the environment, although far from complete, has increased considerably because of steadily improving analytical and field methods during the

past two decades. Mercury exists in the environment in three oxidation states — Hg(0), Hg(I), and Hg(II) — and for each valence many chemical forms can occur in the solid, aqueous, and gaseous phases. The environmental chemistry of mercury is very complex, and subtle changes in chemical, physical, biological, and hydrologic conditions can cause substantial shifts in its physical form and valence state over time scales ranging from hourly to seasonal.^{136,138,152} Here we briefly summarize selective aspects of mercury speciation in the atmospheric, aquatic, and terrestrial environments, focusing on aspects most pertinent to the ecotoxicology of mercury, such as the formation and abundance of methylmercury.

16.4.1 Atmosphere

In most locations, mercury in the atmosphere is mostly (> 95%) gaseous elemental Hg⁰, with the remainder composed largely of particulate ionic Hg(II), gaseous divalent mercury (commonly termed “reactive gaseous mercury”), and, on occasion, trace amounts of methylmercury.^{141,145} Particulate and reactive gaseous mercury have relatively short travel distances (up to tens of kilometers) and residence times in the atmosphere, whereas gaseous elemental mercury has global-scale transport and an average atmospheric residence time of about 1 year.⁴⁸ Recent analyses of air in northern Europe showed that total gaseous mercury averaged 1.98 ng/m³, whereas particulate mercury and reactive gaseous mercury averaged 56 and 22 pg/m³, respectively.^{154,155} Monovalent mercury is stable only as the dimer (Hg₂²⁺), which rapidly disproportionates to Hg⁰ and Hg²⁺ and is probably only detectable in atmospheric samples at extremely low levels.¹³⁵ Over the open oceans concentrations of gaseous elemental mercury increase from the southern hemisphere (~1 ng/m³ at 60° south) to the northern hemisphere (~3 ng/m³ at 60° north),^{156,157} reflecting the stronger sources of mercury in the northern hemisphere, which is more industrialized and heavily populated than the southern hemisphere.

Reactive gaseous mercury is generally assumed to be HgCl₂, although recent research has shown the existence of Hg(NO₃)₂·H₂O in the gas phase.¹⁵⁸ After polar sunrise gaseous Hg⁰ in the Arctic and Antarctic atmospheres is rapidly depleted via oxidation to reactive gaseous mercury, which increases rapidly in abundance as Hg⁰ is depleted.^{139,140,159,160} During April and May 2000, reactive gaseous mercury often comprised more than 60% of the total gaseous mercury measured in air over Barrow, Alaska.¹⁶⁰ Reactive gaseous mercury is rapidly removed from the atmosphere via both wet and dry deposition^{140,155,160} and is considered to be available for methylation once deposited.¹⁴⁰

16.4.2 Aquatic Environments

The methylation of mercury and subsequent exposure of biota to methylmercury are greater in aquatic environments than in terrestrial environments. Many recent investigations of mercury in surface waters have determined methylmercury, gaseous elemental mercury (Hg⁰), and total mercury (defined as the sum of all mercury species recovered from a strongly oxidized sample).¹⁶¹ A fraction termed “reactive mercury,” which is generally equivalent to mercury reducible by stannous chloride, has also been measured; however, such fractions are often poorly defined and difficult to relate to other environmental factors or processes. The recent development of methods for separating colloidal and truly dissolved fractions of inorganic mercury and methylmercury should advance understanding of aqueous-solid phase partitioning of mercury species and possibly bioavailable fractions.¹⁶² Dimethylmercury has been observed in the marine environment, but only at extremely small concentrations (averaging 0.016 ng/L in the North Atlantic).¹⁶³ Dimethylmercury has not been confirmed in fresh waters, however, and its overall importance in the mercury cycle is unknown. We limit this discussion to the three fractions — total mercury, Hg⁰, and methylmercury — that are most commonly reported for water.

Except under rare geochemical conditions, or in the vicinity of strong geologic or anthropogenic mercury sources, the concentrations of all forms of mercury in most natural waters are very low

(picograms to nanograms per liter). Most naturally occurring mercury compounds have very low solubility, although mercury complexes with dissolved organic matter are much more soluble.¹⁶⁴ Among surface waters or within a given lake or stream, the abundances of methylmercury and total mercury can vary widely, and the accurate quantification of their aqueous concentrations requires the steadfast application of trace-metal clean techniques to minimize sample contamination during collection, handling, and analysis, coupled with the application of highly sensitive analytical methods.^{132,165} When proper sample collection and preservation protocols are followed, inter-comparisons among laboratories that use accepted analytical methods for total mercury and methylmercury yield similar results.¹⁶⁶

The speciation of mercury in water is most strongly influenced by the aqueous chemical conditions — most notably redox, pH, organic ligands, and inorganic ligands.¹⁶⁵ Inorganic divalent mercury, Hg(II), and methylmercury are strongly influenced by the chemical makeup of the host water and almost entirely form ion pairs with ligands in the aquatic environment.¹⁶⁷ In most oxic, circumneutral surface waters, ion-pair formation for Hg(II) and methylmercury is dominated by dissolved organic matter and chloride.^{168,169} Under anoxic conditions, which can occur in sediment porewaters and in the hypolimnia of certain lakes, or anywhere reduced sulfur species are appreciable, inorganic Hg(II) and methylmercury will dominantly be present as sulfide or sulfhydryl complex ion pairs.^{50,168,170} The complexation of Hg(II) with sulfide can substantially affect the availability of mercury for methylation by microbes.¹⁷¹

Concentrations of total mercury in unfiltered water samples from lakes and streams lacking substantive, on-site anthropogenic or geologic sources are usually in the range of 0.3 to 8 ng/L.^{133,172,173} In waters influenced by mercury mining or industrial pollution, concentrations of total mercury are greater, often in the range of 10 to 40 ng/L.^{33,133,173–175} Surface waters with high concentrations of humic substances can also have high concentrations of total mercury, demonstrating the importance of natural organic material on solubility and aqueous transport of the metal.^{115,123,127,176,177} Surface waters draining areas with high geologic abundances of mercury or with contaminated tailings from mercury or gold mining can exceed 100 or even 1000 ng/L in total mercury.^{3,26–28,33,38,41,165,178}

In oxic waters, concentrations of methylmercury are typically within the range of 0.04 to 0.8 ng Hg/L.^{33,41,68,93,97,123,124,133,173,179,180} However, concentrations of 1 to 2 ng Hg/L can occur in surface waters affected by either industrial pollution (e.g., chlor-alkali plants)^{174,181} or mercury mine drainage.^{28,133} The fraction of total mercury present as methylmercury is generally higher in fresh waters than in estuarine or marine systems,¹⁸² which may result from inhibition of methylation by the abundant sulfide in pore waters of brackish water systems¹⁷¹ or from the generally low level of dissolved organic matter in marine settings.¹²⁷ Within a given drainage basin or geographic area the concentrations and yields of methylmercury, as well as the fraction of total mercury present as methylmercury, are typically highest in surface waters that drain wetlands.^{68,93,123–125,133,183} The biogeochemical processes contributing to the methylmercury-wetland association are under investigation; however, it is evident that biogeochemical conditions in wetlands are favorable for methylation and that complexation of methylmercury with the abundant natural organic matter in wetlands can facilitate its export to waters downstream. Methylmercury generally accounts for about 0.1 to 5% and seldom exceeds 10% of the total mercury present in oxic surface water.^{123,133,179} Under anoxic conditions, however, methylmercury can be one of the dominant species of mercury present, and concentrations can exceed 5 ng Hg/L.^{96,100,179,184}

Early measurements of Hg⁰ in fresh waters showed concentrations ranging from about 0.01 to 0.10 ng/L, which led to a conclusion of pronounced super saturation of Hg⁰ in the water column, usually by a factor of 100 to 500, relative to the overlying air,¹⁸⁵ yielding high estimated rates of Hg⁰ volatilization to the atmosphere. More recent investigations involving diel measurements have generally shown strong correlations between, on the one hand, instantaneous Hg⁰ in the water column and solar intensity and, on the other, a reequilibration with the atmosphere after sundown, with much lower concentrations of Hg⁰ in water at night (about 0.005 ng/L).^{138,186} Moreover, the

rapid reoxidation of Hg^0 in surface water has also been demonstrated¹⁸⁷ and, when taken into account, greatly decreases estimated volatilization rates of Hg^0 from surface waters.¹⁸⁸ In marine ecosystems, the evasion of Hg^0 appears to be a geochemically significant efflux of mercury.^{48,189}

16.4.3 Terrestrial Environments

Comparatively few data are available on the abundances of total mercury and methylmercury in soils and groundwater in upland settings relative to the substantive information available for surface water, sediment, and peat in aquatic environments. Yet recent estimates indicate that terrestrial soils contain the largest inventories of mercury from natural and anthropogenic emissions.^{48,131} In addition, the toxicity, solubility, and volatility of mercury depend highly on its speciation, and such information for soils is scant. Various reductive processes can yield appreciable emissions of Hg^0 from contaminated soils, and the mercury in soils may be cycling more actively than previously thought.^{147,153,190,191}

The speciation of mercury in most upland soils is probably dominated by divalent mercury species that are sorbed primarily to organic matter in the humus layer and secondarily to mineral constituents in soil.^{131,147} Nater and Grigal,¹⁴⁸ who studied forest soils across the upper Midwest of the United States, found that concentrations of total mercury in humus ranged from about 100 to 250 ng/g dry weight, whereas the mineral horizon just below the humus layer contained about 15 to 30 ng/g. In locations near point sources, especially cinnabar (HgS_s) deposits or abandoned placer mines, mercury concentrations can be considerably higher — generally in the $\mu\text{g/g}$ range.^{26,153,192,193} The speciation of mercury in such highly contaminated soils depends on the origin of the mercury itself (most likely Hg^0 used for placer mining and chlor-alkali plants, or HgS_s) as well as the chemistry and texture of the soil. Barnett et al.,¹⁹⁴ for example, observed that liquid Hg^0 released to anaerobic, hydric soils resulted in the formation and long-term stabilization of mercuric sulfide. Cinnabar, on the other hand, seems to be more stable when exposed to the surface as mine tailings or transported down gradient from mining operations, generally maintaining its HgS_s stoichiometry, although surface coatings of secondary mercury compounds have also been observed on weathered cinnabar.¹⁹⁵ Little is known about the relative stability and reactivity of mercury amalgam; however, it probably behaves similarly to elemental mercury in the environment.

Published information on concentrations and speciation of mercury in upland soils is sparse, especially for methylmercury. Forest soils have been rarely analyzed for methylmercury, and reported concentrations are generally low — about 0.2 to 0.5 ng/g in the humus layer and < 0.05 ng/g in the mineral-trophic layer.^{150,196,197} Although data are few, the very low concentrations of methylmercury in soils, runoff, and groundwater in upland environments suggest that little methylmercury is produced in upland landscapes.^{125,131,198}

16.5 MERCURY METHYLATION IN THE ENVIRONMENT

The methylation of inorganic $\text{Hg}(\text{II})$ is the most toxicologically significant transformation in the environmental mercury cycle because it greatly increases the bioavailability and toxicity of mercury and increases the exposure of wildlife and humans to methylmercury. It is not surprising that variation in mercury concentrations in fish of a given size (or age) and trophic level among surface waters lacking direct, on-site sources of mercury can be attributed largely to processes and factors that affect the net production and abundance of methylmercury.^{92,96,97,126} Mercury *methylation* is the conversion of inorganic $\text{Hg}(\text{II})$ to methylmercury by a methyl-group donor. The conversion of methylmercury to inorganic mercury, regardless of the mechanism, is termed *demethylation*. In general, both of these processes (methylation and demethylation) operate simultaneously in aquatic systems. The detection of methylmercury in sediment samples generally indicates a positive net rate of methylation, i.e., the rate of methylation exceeds that of demethylation; however, the

abundance of methylmercury is not necessarily a good predictor of *in situ* methylation rate, given that influxes of methylmercury from external sources can be significant in some settings. In this section, we review the current understanding of methylating and demethylating agents as well as the locations where these processes operate in the environment.

Mercury can be methylated through biotic and abiotic pathways, although microbial methylation is generally regarded as the dominant pathway in the environment.^{134,199,200} More specifically, sulfate-reducing bacteria are considered to be the most important methylating agents in aquatic environments,^{97,134,199–202} and the most important sites of methylation by sulfate-reducing bacteria are thought to be oxic-anoxic interfaces in sediments^{203,204} and wetlands.^{93,97,123,198,205} Methylation also occurs in aerobic marine and freshwaters,^{206,207} floating periphyton mats and the roots of some floating aquatic plants,^{208,209} the intestines of fish,²¹⁰ and the mucosal slime layer of fish;²¹¹ however, these sites are considered to be much less important quantitatively than are anaerobic sediments and wetlands.²¹² In sediments, the microbial methylation of mercury is most rapid in the uppermost 5 cm of the sediment profile, where the rate of sulfate reduction is typically greatest; comparatively little methylmercury is produced in deeper sediments.^{27,65,97,202,213,214}

To be methylated by sulfate-reducing bacteria Hg(II) must first cross the cell membrane of a methylating bacterium, presumably as a neutral dissolved species.^{170,171} Thus, the speciation of inorganic mercury in aqueous and solid phases controls the fraction of the total mercury pool that is available for microbial methylation.^{170,171} At certain concentrations, for example, chloride and sulfide seem to increase bioavailability because they bind Hg²⁺ as the neutrally charged species HgCl₂ or HgS;^{170,215} however, at higher ligand concentrations these ion pairs become charged (e.g., HgCl₃⁻), and availability for methylation is decreased. Likewise, when Hg²⁺ is bound to large molecules of dissolved organic matter or to particulates (either organic matter or clay), it is considered unavailable for biotic methylation.⁶⁵ Within microbial cells methylation can be facilitated through enzymatic and nonenzymatic pathways, which are distinguished by the presence or absence of active microbial metabolism, although both pathways call upon methylcobalamine as the active methyl donor to the Hg²⁺ ion.^{216,217} Methylcobalamine is produced by many microbes in the environment and reacts with Hg(II) to form methylmercury outside of cells in anaerobic or aerobic conditions,²¹⁸ although Choi et al.²¹⁹ found that the process is catalyzed enzymatically and that production rates are much higher within cells.

Comparatively little is known about abiotic methylation, which in simple chemical terms implies the existence in the environment of a methyl donor. Several methyl-donating compounds that are attributed largely to industrial sources can methylate mercury abiotically,^{220,221} but anthropogenic methyl donors have been documented for few environmental settings. At high concentrations methylated tin and lead compounds can transfer a methyl group to Hg(II) to produce methylmercury,²²² but these situations are very limited in extent. Most of the literature on abiotic methylation consequently suggests that the most important methyl donors in the environment are humic acids,^{223,224} although this topic has been studied little. In most cases, abiotic formation of methylmercury has been strongly linked to temperature, and at ambient conditions the methylation rates reported for most abiotic pathways are small. Falter and Wilken²²⁵ have shown that small amounts of methylmercury can be formed abiotically in sediments at ambient temperatures. Their results have had implications for the analytical procedures being used in many laboratories to determine methylmercury because methylmercury can be formed as an artifact while processing samples with high concentrations (generally in the µg/g range) of inorganic Hg(II).^{226,227}

Although two processes — methylation and demethylation — ultimately control the abundance of methylmercury, the process of demethylation has received comparatively little study.²²⁸ Demethylation, or methylmercury degradation, can occur via a number of abiotic and biotic pathways in the environment. Like methylation, demethylation can occur in near-surface sediments via microbial pathways²²⁹ and in the water column via microbial and abiotic pathways.^{137,199}

Much of the early literature suggested that the microbial degradation of methylmercury involved a two-step, enzyme-catalyzed process by microbes encoded with the *mer*-operon gene sequence,

also referred to as the *mer* detoxification pathway. The *mer*-operon is widespread in nature and has been found for both Gram-negative and Gram-positive bacteria and under both aerobic and anaerobic conditions,²³⁰ although most investigators have found that this process operates in aerobic conditions.²²⁸ The first step of the *mer* pathway involves cleavage of the carbon-mercury bond by the organomercurial lyase enzyme (encoded by the *mer B* gene) to yield methane and Hg^{2+} . A second step involving the mercury-reductase enzyme (*mer B* encoded) reduces Hg^{2+} to Hg^0 , yielding a mercury species that can evade from the system.^{228,231}

More recently, an oxidative demethylation pathway has been proposed and confirmed by the presence of CO_2 as the end product of the methyl-group breakdown and does not appear to involve the secondary mercury-reductive step.^{229,232} These authors^{229,232} have proposed that this pathway is similar to the degradation of methanol or monomethylamine by methanogens. The oxidative pathway has been demonstrated in a wide range of environments including freshwater, estuarine, and alkaline-hypersaline sediments and in both aerobic and anaerobic conditions.²³³ In anaerobic sediments of the Everglades, methanogens and sulfate reducers have been identified as the principal anaerobes in the oxidative-demethylation process, and maximal rates are observed in near-surficial sediments, where maximal methylation rates are collocated.²³³ The precise mechanisms and triggers that induce the oxidative-demethylation pathway remain unclear because demonstration of the process in pure culture remains elusive. However, examination of both the *mer*-detoxification and the oxidative demethylation pathways across a wide range of mercury-contamination gradients suggest that the *mer*-detoxification pathway predominates in severely contaminated systems, whereas the oxidative pathway is more important in lightly contaminated environments.

The abiotic process of photodegradation of methylmercury in surface waters has been recently examined at a few sites.^{125,137,234} It has long been known that methylmercury ion pairs are capable of adsorbing light at appreciable levels and are subject to photolytic breakdown;²³⁵ however, the significance of the photodemethylation process was not recognized until photodemethylation was shown to be quantitatively important in the methylmercury budgets of lakes.^{125,234,236} The specific mechanisms causing the degradation of methylmercury in surface waters as well as the factors limiting this process, are unknown, but experimental work suggests that singlet oxygen and peroxide radicals are responsible for the reaction.²³⁷ The mercury end products of photodemethylation have not been determined, and theoretical considerations indicate that any of the three oxidation states are possible.^{135,138} Identification of mercury end products is needed to assess the overall effect of photodegradation, given that $\text{Hg}(\text{II})$ could be methylated again, whereas Hg^0 could evade from the lake to the atmosphere.

16.6 MERCURY-SENSITIVE ECOSYSTEMS

Some aquatic ecosystems can be classified as mercury-sensitive because seemingly small inputs or inventories of total mercury (e.g., in the range of < 1 to 10 g Hg/ha) can cause significant contamination of fish and wildlife in upper trophic levels with methylmercury. Known mercury-sensitive ecosystems include most wetlands,^{93,97,124} low-alkalinity or low-pH lakes,^{79,92,94,238} surface waters with upstream or adjoining wetlands,^{93,124,239} waters with adjoining or upstream terrestrial areas subjected to flooding,^{84,85,96,240} and dark-water lakes and streams.^{92,93} One common attribute of mercury-sensitive systems is the efficient conversion of inorganic $\text{Hg}(\text{II})$ to methylmercury.^{85,92,96,97,133,241} In some cases, concentrations of mercury in game fish inhabiting such ecosystems can equal or exceed concentrations observed in fish from waters heavily contaminated by wastes from industrial point sources such as chlor-alkali plants (Table 16.1).

A recent, but growing, body of evidence indicates that wetlands are mercury-sensitive ecosystems. Wetlands can be important sources of methylmercury on the landscape, given that production and yields of methylmercury in wetland areas can greatly exceed that in other aquatic and terrestrial habitats.^{123,124} The production of methylmercury in wetlands can increase greatly during flooding,⁹⁶ a periodic event in many wetland systems. A number of ecosystem characteristics probably enhance

Table 16.1 Elevated Mercury Concentrations in Axial Muscle Tissue of Selected Freshwater Game Fishes in North American Waters

Aquatic Environment	Mercury Concentration ($\mu\text{g/g}$ wet weight)	
	Range in Means	Range in Maxima
Waters polluted by chlor-alkali plants ^a	1–5	2–15
Newly flooded reservoirs ^a	0.7–3	2–6
South Florida wetlands ^b	0.4–1.4	2–4
Low-alkalinity lakes ^a	0.5–0.9	1–3

Note: Values shown are based on data reported for northern pike (*Esox lucius*), walleye (*Stizostedion vitreum*), largemouth bass (*Micropterus salmoides*), and smallmouth bass (*Micropterus dolomieu*).

the microbial methylation of inorganic Hg(II) in wetlands, including an abundance of labile carbon substrates and dissolved organic matter, anaerobic sediments, high microbial activity, and seasonal water-level fluctuations that can cause oscillating redox cycles.^{85,92,96,123,126,133,179,242,243} Yet the quantitative effect of methylmercury production and export from wetland areas on contamination of aquatic food webs in downstream waters supporting fish production, piscivorous wildlife, and recreational fisheries has received little study. Wetlands may differ considerably in their methylmercury-producing potential, and the influence of wetland type on methylmercury yield and the identification of associated controlling mechanisms are areas of needed investigation.

Variation in ecosystem sensitivity to mercury inputs is exemplified in Figure 16.3, which depicts tenfold variation in the mercury content of whole yellow perch (*Perca flavescens*) sampled in 1989 from three nearby lakes in northcentral Wisconsin. The three lakes differed chemically, spanning a spatial gradient in mean pH from about 5 to 7, reflecting the variation in the chemistry of lakes in northcentral Wisconsin, an area with hundreds of lakes with low acid-neutralizing capacity.²⁴⁴ The three lakes were small seepage basins (no surface inlets or outlets) in rural, mostly forest-covered watersheds having no identifiable on-site anthropogenic or enriched geologic sources of mercury. The low-pH seepage lakes in this area receive very little groundwater inflow; rather, nearly all (> 95%) of their hydrologic inflow is from precipitation falling directly onto the lake surface.²⁴⁵ Surficial sediments in lakes of the area are enriched with mercury, relative to deeper preindustrial sediments,²⁴⁶ and the mercury-accumulation rate in sediments deposited about 1990 was three to four times that in the mid-1800s.¹⁰⁷ The three lakes can be regarded as lightly contaminated, with inventories of total mercury in surficial sediments (uppermost 5 cm) ranging from 1.6 to 5.8 g/ha²⁴⁷ and annual atmospheric inputs of mercury (wet plus dry deposition) averaging about 0.1 g/ha from 1988 to 1990.¹¹⁴ The yellow perch is one of the more widespread and abundant fishes in area lakes and is an important link in the trophic transfer of mercury in lakes of the region.^{248,249} Mercury concentrations in walleyes (a regionally important gamefish) and chicks of common loons (*Gavia immer*, a fish-eating bird) are elevated in area lakes with low pH or low acid-neutralizing capacity,^{78,238,250} reflecting variation among lakes in contamination of yellow perch, their preferred prey.^{251,252}

16.7 BIOACCUMULATION, BIOMAGNIFICATION, AND BIOLOGICAL EFFECTS

16.7.1 Biomagnification in Food Webs

Aquatic organisms can obtain methylmercury from food, water, and sediment, and they bioaccumulate methylmercury with continued exposure because elimination is very slow relative to the rate of uptake.²⁵³ Methylmercury readily crosses biological membranes and can biomagnify to high

Figure 16.3 Variation in ecosystem sensitivity to mercury inputs, illustrated by differing concentrations (upper panel) and burdens (lower panel, in logarithmic scale) of mercury in whole yellow perch from three nearby seepage lakes in forest-covered watersheds in Vilas County, Wisconsin. Fish in low-pH lakes in this and many other geographic areas have much higher concentrations of mercury than fish in nearby circumneutral-pH lakes that receive similar inputs of mercury in atmospheric deposition. (From: unpublished data for fish sampled in May 1989 by J. G. Wiener, R. G. Rada, and D. E. Powell, University of Wisconsin-La Crosse, River Studies Center, La Crosse, Wisconsin.)

concentrations in aquatic food webs, despite its seemingly low concentrations (< 1 ng Hg/L) in most surface waters.^{57,173,254–256} Concentrations of methylmercury in fish, for example, commonly exceed those in ambient surface water by a factor of 10^6 to 10^7 .^{94,254,256,257}

Most of the mercury in surface waters and sediments is typically inorganic Hg(II), yet the mercury accumulated in fish and higher trophic levels of aquatic food webs is almost entirely methylmercury.^{2–4,258–260} Some species of fish-eating seabirds and aquatic mammals exhibit highly variable amounts of inorganic mercury in their internal organs, particularly the liver and kidneys.^{258,260–263} The presence of inorganic mercury in piscivorous birds and mammals is generally attributed to the ability of these species to convert methylmercury to the less toxic inorganic mercury via demethylation.^{260–263} The presence of inorganic mercury in internal organs and tissues does not indicate dietary uptake or bioaccumulation of inorganic mercury by these organisms.

Biomagnification, defined as the increasing concentration of a contaminant with increasing trophic level in a food web, has been widely documented for methylmercury in aquatic ecosystems.^{57,257,264} Patterns of methylmercury biomagnification in aquatic food webs are similar, even among aquatic systems that differ in ecosystem type, mercury source, and pollution intensity. This is illustrated in Table 16.2, which summarizes information from three geographically distant, markedly different aquatic environments: one a coastal marine embayment in Western Australia that was contaminated with mercury from a point source, the second a small seepage lake in northern Wisconsin that received mercury almost entirely via atmospheric deposition, and the third a tropical lake in a remote area of New Guinea. Two patterns characteristic of mercury concentrations in food

Table 16.2 Biomagnification of Methylmercury (MeHg) in Food Webs in Three Substantially Different Aquatic Environments: Princess Royal Harbor, a marine embayment on the south coast of Western Australia that was contaminated with mercury from a super-phosphate plant over a 30-year period;^{57,61} Little Rock Lake, a small, temperate seepage lake (no inflowing or outflowing streams) in northern Wisconsin (USA) that received mercury largely from atmospheric deposition directly onto the lake surface;⁹⁴ and Lake Murray, a tropical lake in the remote Western Province of Papua New Guinea²⁵⁷

Food-Web Component	Australian Marine Embayment ^a		Wisconsin Seepage Lake ^b		Tropical Lake ^c

^c Data for the planktonic food web, from Bowles et al.²⁵⁷

webs are evident in Table 16.2. First, the concentration of methylmercury increases up the food web from water and lower trophic levels to fish. Second, the fraction of mercury present as methylmercury increases with increasing trophic level.

In aquatic invertebrates, methylmercury is much more readily assimilated and bioaccumulated than is inorganic mercury.^{265–269} In aquatic organisms in trophic levels below fish, the fraction of total mercury present as methylmercury can vary considerably.^{67,87,264,270,271} In 15 northern Wisconsin lakes, for example, percent methylmercury ranged from 9 to 82% in aquatic insects and from 46 to 97% in five taxa of crustacean zooplankton.²⁶⁴ Mean percent methylmercury varied seasonally in net plankton from 12 lakes in northeastern Minnesota (U.S.), increasing from 20% in spring to 52% in autumn.²⁷² Percent methylmercury in benthic aquatic insects in two hydroelectric reservoirs in northern Quebec, classified by diet, ranged from 20–25% in detritivores, 30–40% in grazers, 60–85% in grazers–predators, and 95% in predatory dragonflies.²⁷⁰

The greatest increase in methylmercury concentration in pelagic food webs, relative to concentrations in water, occurs in the phytoplankton or seston (small living plankton and nonliving particulate matter).^{240,257,264,273} Bioaccumulation factors for methylmercury between seston and water, for example, ranged from $10^{4.9}$ to $10^{5.6}$ in tropical Lake Murray, New Guinea,²⁵⁷ and from $10^{4.8}$ to $10^{6.2}$ in 15 northern Wisconsin lakes.²⁶⁴ Bioaccumulation factors for methylmercury between herbivorous zooplankton and seston are much smaller, averaging 2.5 ($10^{0.4}$) in 12 northern Wisconsin lakes²⁶⁶ and about 9 ($10^{0.95}$) in natural lakes and the La Grande 2 reservoir in northern Quebec.²⁴⁰

Bioaccumulation factors between concentrations of mercury (largely methylmercury) between piscivorous fish and their prey are also small relative to the orders-of-magnitude increases in methylmercury concentration between seston and water. Ratios of mercury concentrations in piscivorous fish (axial muscle) to those in coexisting prey (whole fish) are typically less than 10, with values ranging from ~4 to 9 in freshwater lakes.^{256,274–276} Bioaccumulation factors for mercury reported for seabirds (from analysis of contour feathers) and their prey (from analysis of regurgitated food) are considerably greater, ranging from 125 to 225 and averaging more than 150 in six species of seabirds from the Azores archipelago.²⁷⁷

The entry of methylmercury into the base of the food web and its subsequent trophic transfer in the lowest levels are poorly understood. The uptake of inorganic mercury by sulfate-reducing bacteria in the ecosystem is an essential step in the methylation of mercury and a prerequisite to the bioaccumulation and trophic transfer of methylmercury.^{255,278} The abundance of methylmercury in the lower trophic levels appears to be strongly linked to the net production or supply of methylmercury (i.e., methylation minus demethylation), with the production of methylmercury being tightly coupled to the rate of sulfate reduction by sulfate-reducing bacteria.^{97,202,279}

The dominating influence of methylmercury supply on the contamination of an aquatic food web was illustrated by a flooding experiment in the Experimental Lakes Area of Ontario, Canada.^{96,98,100} Experimental flooding of the wetland surrounding Lake 979 was followed by decomposition of inundated vegetation,²⁸⁰ which rapidly depleted dissolved oxygen and imposed anoxic conditions over the inundated wetland surface, stimulating microbial sulfate reduction and mercury methylation.^{96,100} The abundance of methylmercury in surface water, seston, and zooplankton in the lake increased rapidly and markedly (tenfold or greater) in response to increased methylmercury production.^{96,98} Concentrations of methylmercury in seston and zooplankton were strongly correlated with those in water, and concentrations in zooplankton were strongly correlated with those in seston as well (all $r^2 \geq 0.85$).⁹⁸ Bioaccumulation factors for methylmercury in zooplankton (ratio to concentrations in water) were similar before and after flooding, despite the large changes that occurred in water chemistry, waterborne methylmercury concentration, and zooplankton community structure,⁹⁸ indicating that the increased contamination of the planktonic food web resulted directly from the increased supply of methylmercury. This conclusion is further supported by a comparison of the biomagnification of methylmercury in planktonic food webs in the La Grande 2 reservoir to that in natural lakes in northern Quebec.²⁴⁰ In Lake 979, concentrations of methylmercury also increased after flooding in benthic insects, caged fish (finescale dace, *Phoxinus neogaeus*, which

fed primarily on benthic invertebrates), and nestling tree swallows (*Tachycineta bicolor*, which fed primarily on emergent dipterans).^{87,99,281}

Within a given fish population or community, variation in trophic position accounts for much of the variation in methylmercury concentration, both within and among species.^{257,282,283} In species with omnivorous feeding habits, such as adult lake trout (*Salvelinus namaycush*), trophic position can vary substantially — even within a single life stage.²⁸⁴ Thus, concentrations of methylmercury in adult lake trout are strongly correlated with the trophic position in the pelagic food web.^{282,283} Moreover, concentrations of methylmercury in organisms at the top of aquatic food webs increase concomitantly with increasing length (number of trophic levels) of the food chain below.

Unlike methylmercury, inorganic mercury is not readily transferred through successive trophic levels and does not biomagnify in aquatic or terrestrial food webs.^{254,264,266,285} Consequently, reliance on data from total-mercury determinations for trophic levels below fish (including water, seston, plants, and invertebrates) can produce misleading assessments of food-web contamination and erroneous estimates of potential methylmercury transfer to fish and higher trophic levels.^{57,265,286}

16.7.2 Fish

The bioaccumulation of mercury has been more intensively studied in fish than in other aquatic organisms, probably because fish are the primary source of methylmercury in the human diet.^{6,12} Nearly all of the mercury in fish muscle and in whole fish is methylmercury.^{2,3,57,77,287} There is very little inorganic mercury in either freshwater or marine fish,^{2,3,57,77,287} even in aquatic ecosystems with high concentrations of dissolved inorganic mercury.²⁸⁸ Fish assimilate inorganic mercury much less efficiently than methylmercury from both food and water, and if absorbed, inorganic mercury is eliminated much more rapidly than is methylmercury.^{253,289–294}

Dietary uptake probably accounts for more than 90% of the total uptake of methylmercury in wild fishes,^{295–298} and fish probably assimilate from 65 to 80% or more of the methylmercury present in the food they eat.^{291,294,296} In the laboratory, fish can accumulate high concentrations of methylmercury directly across the gills when exposed to abnormally high concentrations of waterborne methylmercury.^{292,299,300} Many of the published laboratory studies on bioaccumulation have exposed test fish to methylmercury concentrations that greatly exceed concentrations of methylmercury in surface waters.^{79,173} The mode of uptake (food vs. water) in bioaccumulation experiments, however, seems to have little influence on the distribution of methylmercury among most internal organs and tissues, except that concentrations in the gills are much higher after waterborne (than dietary) exposure and concentrations in the intestines are higher after dietary exposure.^{253,300–302}

After crossing the fish gut, methylmercury binds to red blood cells and is transported via the circulatory system to all organs and tissues, readily crossing internal membranes.^{294,300,301,303} There is a dynamic internal redistribution of assimilated methylmercury among the tissues and organs of fish exposed to methylmercury in both laboratory and field studies. The masses in the blood, spleen, kidney, liver, and brain decline after exposure to either waterborne or dietary methylmercury ceases, and much of the methylmercury in the body eventually relocates to skeletal muscle, where it accumulates bound to sulfhydryl groups in protein.^{290,301–303} Wiener and Spry¹⁷³ hypothesized that storage of methylmercury in skeletal muscle serves as a protective mechanism in fishes, given that sequestration in muscle reduces the exposure of the central nervous system to methylmercury.

Within a given fish population, concentrations of methylmercury in muscle tissue or whole fish typically increase with increasing age or body size, a pattern that has been observed repeatedly in surveys of mercury in fishes.^{173,253} The increasing concentration with size or age results from the very slow rate of elimination of methylmercury by fish relative to its rapid rate of uptake.^{253,293} In a critical analysis of experimental data on methylmercury elimination by fish, Trudel and Rasmussen²⁹³ showed (1) that short-term experiments (< 90 days) substantially overestimate elimination rate, (2) that elimination rate is negatively correlated with body size ($r = -0.65$), (3) that

elimination rate is positively correlated with water temperature ($r = 0.77$) in long-term (> 90 days) experiments, with a Q_{10} of 1.9, and (4) that the concentration or burden of methylmercury in the fish does not influence the rate of elimination.

The bioaccumulation of methylmercury in fish is influenced by an array of biotic, ecological, and environmental variables. Much of the modern spatial variation in fish mercury levels (within a given trophic level) is attributed to differences among lakes and their watersheds in biogeochemical processes and transformations that control the abundance of methylmercury. The production of methylmercury via the microbial methylation of inorganic Hg(II) in the environment is a key process affecting mercury concentrations in fish.^{86,92,97,126,242} It follows logically that factors and processes affecting the microbial production of methylmercury on the landscape will also influence the methylmercury content of fish residing in the ecosystem. Some of the variation in mercury concentrations in fish among northwestern Ontario lakes, for example, is caused by the effect of temperature, or lake size, on the microbial net production of methylmercury in the epilimnia.¹²⁶ Mean concentrations in axial muscle of walleye and northern pike (*Esox lucius*) ranged from about 0.7 to 1.1 $\mu\text{g Hg/g}$ wet weight in small (89–706 ha) lakes but were less than 0.4 $\mu\text{g/g}$ in nearby lakes that were larger (2219–34,690 ha) and colder.¹²⁶ Specific rates of mercury methylation in the lakes were positively correlated with water temperature, whereas specific rates of methylmercury demethylation (microbial destruction of methylmercury) were negatively correlated with temperature.³⁰⁴

The dietary uptake of methylmercury in fish is influenced by their size, diet, and trophic position.^{274,283,305–307} In piscivorous species, such as the walleye and lake trout, the methylmercury content of the diet and associated rate of mercury accumulation can increase with age, accelerating abruptly when the fish become large enough to switch from a diet of invertebrates to prey fish.^{274,306} In adult fish, females often contain higher mercury concentrations than males because they must consume more food than males to support the energy requirements of egg production.^{308,309} The increased feeding rates in females cause greater dietary uptake of methylmercury, and only a small fraction of the accumulated methylmercury is transferred to the egg mass and eliminated during spawning.^{287,310,311}

The relative contamination of aquatic food webs with methylmercury can be assessed with information on mercury concentrations in fish of a given species and age,^{77,80,81,312–314} particularly if the trophic position of the fish analyzed varies little among the water bodies studied. Within a number of geographic areas of North America, mean concentrations of mercury in same-age yellow perch, for example, vary several fold among midcontinental lakes (and presumably receiving similar rates of mercury deposition). Moreover, mean concentrations of mercury in yellow perch are inversely correlated with lake pH and related chemical variables.^{77,81,313,315} Similarly, estimated mercury concentrations in 3-year-old largemouth bass (*Micropterus salmoides*) from 53 Florida lakes varied from 0.04 to 1.53 $\mu\text{g/g}$ wet weight and were correlated with lake pH and related chemical factors.⁸⁰

Methylmercury is neurotoxic and can be very harmful to the central nervous system. In the laboratory, long-term dietary exposure of fishes to methylmercury has caused incoordination, diminished appetite or inability to feed, diminished responsiveness and swimming activity, starvation, and mortality.^{173,316,317} Adult fishes were adversely affected in at least two cases of extreme industrial mercury pollution during the past century — Minamata Bay (Japan) and Clay Lake (Ontario). In Minamata Bay, coincident with the poisonings of humans and other organisms, resident fish exhibited symptoms of methylmercury intoxication^{318,319} that have been subsequently reported in laboratory experiments.^{300,316,317} These symptoms included mortality, severely diminished locomotor activity, impaired escape behavior, emaciated condition, and lesions in the brain.³¹⁹ Mercury concentrations in axial muscle of “enfeebled” fishes found floating in seawater in the bay averaged 15 $\mu\text{g/g}$ wet weight and ranged from 8.4 to 24 $\mu\text{g/g}$ in six species.³¹⁸

In grossly polluted Clay Lake in the English-Wabigoon River system (northwestern Ontario), northern pike varying in age from 3 to 8 years had mercury concentrations ranging from 6 to 16 $\mu\text{g/g}$ wet weight in axial muscle tissue.³²⁰ Compared with northern pike from a relatively uncontaminated reference lake, fish from Clay Lake were emaciated, had low hepatic fat stores, exhibited

symptoms of starvation (low levels of total protein, glucose, and alkaline phosphatase in blood serum), and had low serum cortisol levels.³²⁰ After 1 year, contaminated northern pike transplanted from Clay Lake into the reference lake had serum concentrations of total protein, alkaline phosphatase, and cortisol intermediate to those in Clay Lake and reference-lake fish, suggesting partial recovery. Lockhart et al.³²⁰ did not attribute the poor condition of Clay Lake fish directly to effects of methylmercury; however, similar symptoms have subsequently been observed in fish exposed to dietary methylmercury in a laboratory experiment.³¹⁷

Wiener and Spry¹⁷³ derived the following critical tissue concentrations in *adult* fish, based on a review of mercury concentrations associated with toxic effects in freshwater fish. In the brain, concentrations of 7 µg/g wet weight or greater probably cause severe, potentially lethal, effects. In mercury-sensitive species, brain-tissue concentrations of 3 µg/g wet weight or greater probably indicate significant toxic effects. For axial muscle tissue, field studies indicate that concentrations of 6 to 20 µg/g wet weight are associated with toxicity. The range for laboratory studies is similar, with sublethal effects or death associated with concentrations in muscle of 5–8 µg/g in walleyes and 10–20 µg/g in salmonid species. Whole-body concentrations associated with sublethal or lethal effects are about 5 µg/g wet weight for brook trout (*Salvelinus fontinalis*) and 10 µg/g for rainbow trout (*Oncorhynchus mykiss*), whereas estimated no-observed-effect concentrations in salmonid species are 3 µg/g for the whole body and 5 µg/g for brain or axial muscle tissue. However, Wiener and Spry¹⁷³ cautioned that the toxicity of methylmercury to fish is influenced by factors such as interspecific and intraspecific variation in sensitivity to methylmercury that contribute uncertainty to estimates of critical tissue concentrations. Moreover, the rate of accumulation seems to affect the toxicity of methylmercury in fish.²⁹² If methylmercury is accumulated slowly, fish can clearly tolerate higher tissue concentrations of mercury, presumably due to the internal transfer and binding of methylmercury to proteins in skeletal muscle (the primary storage site), which decreases exposure of the central nervous system.¹⁷³

Given the high neurotoxicity of methylmercury, the exposure levels causing adverse behavioral effects are probably much lower than exposure levels associated with overt toxicity.¹⁷³ Many fish behaviors are sensitive and ecologically relevant indicators of contaminant toxicity, affected at exposure levels much lower than those causing direct mortality.^{321–323} The ability of mosquitofish (*Gambusia affinis*) to avoid predation by largemouth bass, for example, was greatly diminished by aqueous exposure to 10, 50, and 100 µg Hg/L (administered as mercuric chloride), concentrations that otherwise did not influence mortality.³²¹ The neurotoxic effects of exposure to sublethal concentrations of methylmercury can impair the ability of fish to locate, capture, and ingest prey and to avoid predators.^{324–326} For example, Fjeld et al.³²⁵ showed that the feeding efficiency and competitive ability of grayling (*Thymallus thymallus*), exposed as eggs to waterborne methylmercuric chloride for 10 days and having yolk-fry with mercury concentrations of 0.27 µg/g wet weight or greater, were impaired when fish were tested 3 years later.

In a critical review, Wiener and Spry¹⁷³ concluded that reduced reproductive success was the most plausible effect of mercury on wild fish populations at contemporary exposure levels in aquatic ecosystems with methylmercury-contaminated food webs. They also suggested, based on the limited information available, that the margin of safety between existing and harmful exposure levels may be small for some fish populations. Methylmercury can impair reproduction of fishes by affecting gonadal development or spawning success in the adults or by reducing the hatching success of eggs and the health and survival of embryolarval stages.^{64,300,327,328} The embryolarval and early juvenile life stages of fish are typically most sensitive to toxic contaminants,³⁰⁰ and exposure of embryos to methylmercury can impair competitive ability and foraging efficiency throughout the lifetime of the fish.³²⁵

Nearly all of the mercury in the developing eggs of fish is methylmercury derived from maternal transfer.^{64,287,311} The amount of methylmercury transferred from the female to the developing egg is small relative to the burden of the metal in the adult, yet the methylmercury content of eggs is strongly related to that of the maternal fish.^{64,287,311}

Recent experiments showing diminished reproductive success or fitness of fish exposed to environmentally realistic concentrations of methylmercury indicate that some fish populations may be adversely affected by methylmercury.^{64,328} Latif et al.⁶⁴ examined the effects of both maternally transferred and waterborne methylmercury on embryos and larvae of walleyes from industrially polluted Clay Lake and two atmospherically contaminated lakes in Manitoba. In their study, the hatching success of eggs and the heart rate of embryos decreased with increasing environmentally realistic concentrations of waterborne methylmercury (range, 0.1–7.8 ng/L), whereas methylmercury concentrations in eggs from maternal transfer did not significantly affect egg-fertilization success, egg-hatching success, or the heart rate of embryos. The growth of larval walleyes (measured 8 days after hatching) and the incidence of larval deformities were unrelated to either maternal or waterborne methylmercury in their study.⁶⁴

Hammerschmidt et al.³²⁸ fed fathead minnows (*Pimephales promelas*) diets containing concentrations of methylmercury present in contaminated food webs, maintained the fish through sexual maturity, and examined the effects of dietary and maternally transferred methylmercury on several reproductive variables. In their study, dietary methylmercury affected the overall reproductive performance of adult fathead minnows, whereas maternally transferred methylmercury did not measurably affect the embryos and larvae produced. In the adults, exposure to dietary methylmercury reduced spawning success, delayed spawning, decreased the instantaneous rate of reproduction, and reduced gonadal development (as reflected by the gonadosomatic index) and reproductive effort of females. These responses were caused by dietary concentrations of methylmercury that are equaled or exceeded in the prey of some piscivorous and invertivorous fish inhabiting low-alkalinity lakes and flooded reservoirs.³²⁸ In contrast, the growth and survival of adult fathead minnows in this study were unrelated to dietary methylmercury. Fertilization success, hatching success, 7-day survival, and 7-day weight of larval fathead minnows varied considerably, but these biological endpoints were not correlated with concentrations of mercury in either the diets or carcasses of parental fish.³²⁸

16.7.3 Birds

The threat of mercury to birds is now largely an aquatic one, given that the probability of exposure of terrestrial birds to high concentrations of organomercurials has diminished substantially since the use of mercury compounds in seed dressings was discontinued. Fimreite⁷¹ reviewed information on bird poisonings caused by mercurial seed dressings. The bioaccumulation and toxic effects of mercury in birds have been reviewed more recently.^{329–331} The biomagnification of mercury in aquatic food webs often leads to high concentrations in fish-eating birds.^{263,332–334} Moreover, there is evidence that concentrations of methylmercury have increased in some seabirds during the past century and in the past few decades (Figure 16.1).^{116,118}

Consumption of fish is the main pathway of methylmercury exposure for birds.³³⁵ Methylmercury, one of the most harmful of contaminants to birds, can adversely affect adult survival, reproductive success, behavior, and cell development.³³⁶ It can also cause teratogenic effects.^{337,338} Methylmercury readily crosses the blood-brain barrier^{339,340} and is passed from the mother to the eggs.^{341–343} When transferred to eggs, nearly 100% of the mercury remains in the methylmercury form and about 85 to 95% is deposited into the albumen.³⁴¹

Incorporation of methylmercury into growing feathers and excretion in the feces are the major routes of mercury elimination in birds,³⁴⁴ although deposition of mercury into eggs is also an important route for reproducing adult females.^{341,343,345} Stickel et al.³⁴⁶ reported a half-life of mercury in whole bodies of adult male mallards (*Anas platyrhynchos*) of about 12 weeks, and the growth of new feathers toward the end of their 12-week period of study seemed to be responsible for most of the loss. Young birds also excrete methylmercury into their developing feathers.³⁴⁷

The concentration of mercury in feathers has been advocated as an indicator of mercury in other avian tissues.³⁴⁸ Scheuhammer et al.³⁴⁹ reported significant correlations between mercury in

the feathers and blood of chicks of common loons. Caldwell et al.,³³⁵ who failed to find good correlations between mercury concentrations in chick feathers with those in blood, other tissues, and eggs of double-crested cormorants (*Phalacrocorax auritus*), suggested that more information is needed to establish the dynamics of mercury in feathers vs. other tissues. Unlike fish, in which older, larger individuals tend to have higher concentrations of mercury,¹⁷³ birds can annually eliminate much of their body burden of methylmercury through the formation of new feathers.³⁵⁰

Fish-eating seabirds seem to be able to demethylate methylmercury, mainly in the liver.²⁶² The rank order of concentrations of methylmercury in various tissues, averaged over several species of seabirds, was liver > kidney > muscle, and the mean percentages of total mercury present as methylmercury were 35% in liver, 36% in kidney, and 66% in muscle. Furthermore, the percentage of total mercury present as methylmercury decreases as the concentration of total mercury increases.

In double-crested cormorants from Caballo reservoir in New Mexico, where prey fish contained from 0.05 to 0.21 $\mu\text{g Hg/g}$ wet weight, cormorant eggs contained a mean of 0.30 $\mu\text{g Hg/g}$ wet weight, and nestlings that were about 7 to 10 days old had concentrations of 0.36, 0.40, 0.18, and 3.54 $\mu\text{g/g}$ wet weight in blood, liver, muscle, and primary feathers, respectively.³³⁵ Kim et al.,²⁶² who studied nine species of seabirds, found that both total mercury and methylmercury in nearly all species were higher in liver than in feathers, kidney, and muscle; among these latter three tissues there were no consistent relations. With feathers, it is desirable to know when new feathers were formed because mercury in the diet and body burdens at that time seem to control the deposition of methylmercury into developing feathers.³⁵⁰ In controlled laboratory studies, where continuous methylmercury diets have been fed, species such as chickens (*Gallus gallus*), ring-necked pheasants (*Phasianus colchicus*), and mallards tend to accumulate the highest concentrations of mercury in liver and kidney, with muscle and brain containing lesser concentrations.^{343,351,352}

16.7.3.1 Field Studies on Birds

Observations of high concentrations of mercury in fish-eating birds have prompted field studies to assess effects of methylmercury exposure in wild birds. Mortality and impaired reproduction are two effects observed in controlled laboratory experiments with methylmercury that could decrease exposed populations of wild birds. A number of field studies have shown associations between high mercury levels in the diets or tissues of fish-eating birds and suspected harm. In southern Florida, for example, methylmercury exposure may have contributed to deaths from chronic diseases in great white herons (*Ardea herodias occidentalis*).³⁵³ The livers of herons that died of acute causes, such as collisions with power lines or vehicles, had a mean mercury concentration of 1.77 $\mu\text{g/g}$ wet weight, whereas birds that died showing signs of chronic disease had livers with a mean of 9.76 $\mu\text{g/g}$ mercury. Spalding et al.³⁵³ cautioned that little was known about the history of methylmercury exposure in the dead birds examined in their study. In such cases, the wasting of muscle in sick birds could result in the release of mercury from muscle and its further accumulation in liver.²⁶³

In the Netherlands, many grey herons (*Ardea cinerea*) died during the winter of 1976.³⁵⁴ The mercury concentration in the livers of 41 of these dead herons averaged 95.5 $\mu\text{g/g}$ dry weight (~ 27 $\mu\text{g/g}$ wet weight), with a maximum of 773 $\mu\text{g/g}$ dry weight. Necropsies were performed on 26 of the dead herons, and most were severely emaciated. Van der Molen et al.³⁵⁴ experimentally exposed herons to methylmercury, and lethality was associated with mercury concentrations in the liver that averaged 500 $\mu\text{g/g}$ and ranged from 415 to 752 $\mu\text{g/g}$ dry weight. Only two of the analyzed dead herons from the field had hepatic mercury levels within this lethal range; however, van der Molen et al.³⁵⁴ postulated that the observed mortality was caused by the sublethal effects of mercury combined with the stress of cold weather and undernourishment. The authors estimated that mercury levels in livers of 20% of the 26 herons examined were sufficiently high to have caused either lethal or serious sublethal effects. In eastern Canada, Scheuhammer et al.²⁶³ reported that the livers and kidneys of common loons found dead or in a weakened, emaciated condition contained levels of mercury that were high enough to have contributed to their ill health, although the authors noted

that the wasting of muscle and other tissue in the sick and dead loons could have increased the concentrations of mercury in the remaining tissue. The authors also pointed out that, because only low levels of the mercury in the liver were in the methylmercury form, it was questionable whether the loons were affected by methylmercury toxicity.

The embryos of birds and other vertebrate organisms are much more sensitive than the adult to methylmercury exposure.^{6,355} The dietary concentrations of methylmercury that significantly impair avian reproduction are only one-fifth of those that produce overt toxicity in the adult,³⁵⁵ and possible reproductive impairment of wild birds has been reported in a number of field studies.

Newton and Haas³⁵⁶ examined the levels of several pollutants, including mercury, in eggs of the merlin (*Falco columbarius*). Concentrations of mercury in eggs from wild merlins were related to the number of young raised by the adults, and higher concentrations were associated with fewer young. Nearly all of the mercury in eggs is methylmercury.^{341,357,358} The relation between production of young merlins, and mercury exposure was statistically significant but not clear-cut; for example, some of the most contaminated clutches produced 3 or 4 young, whereas some of the nests with low concentrations of mercury in eggs failed completely. Newton and Haas³⁵⁶ attributed such variable results to variation in individual sensitivity to methylmercury and to the influences of other environmental factors on reproductive success.

Reproductive failure in common loons, a piscivorous aquatic bird, was attributed to dietary mercury exposure linked to contamination of food webs from industrial mercury pollution of the English-Wabigoon River system. Fimreite³³² observed that young common loons were absent along highly contaminated reaches where mercury concentrations were high in adult loons and other aquatic birds. In a comprehensive field study in the same river system, Barr³⁵⁷ showed a strong negative correlation between the successful use of breeding territories by common loons and mercury concentrations in lakes in a 160-km reach downstream from a chlor-alkali plant. Barr³⁵⁷ observed that reductions in egg laying and territorial fidelity were associated with mean mercury concentrations of 0.3 to 0.4 $\mu\text{g/g}$ wet weight in prey organisms and with mean concentrations of 2 to 3 $\mu\text{g/g}$ wet weight in loon eggs and the adult brain. Reproductive effects were more severe when concentrations of mercury in prey fish exceeded 0.4 $\mu\text{g/g}$ wet weight.³⁵⁷

The North American breeding range of the common loon includes many semiremote and remote lakes in regions where reported mercury concentrations in fish commonly exceed 0.3 to 0.4 $\mu\text{g/g}$ wet weight, the dietary threshold values for reproductive effects estimated by Barr.³⁵⁷ These regions include the northcentral and northeastern United States and the eastern Canadian provinces of Ontario, Quebec, New Brunswick, and Nova Scotia. Scheuhammer and Blancher,³⁵⁹ for example, estimated that as many as 30% of the lakes in central Ontario contained prey fish with mercury levels high enough to impair reproduction in common loons, based on the dietary threshold of 0.3 to 0.4 $\mu\text{g/g}$ estimated by Barr.³⁵⁷

In northern Wisconsin, another area with many methylmercury-contaminated fish populations, Meyer et al.⁸² examined reproductive success of common loons in relation to mercury levels in blood and feathers. Adults and chicks were studied on 45 lakes (mostly seepage lakes) in an area where atmospheric deposition is the dominant mercury source.³⁶⁰ The mean concentration of mercury in eggs sampled from nests at these lakes was 0.9 $\mu\text{g/g}$ wet weight,⁸² an exposure level that has been associated with reproductive impairment in laboratory experiments with mallards.³⁴³ Production of loon chicks was lowest at the lakes where mercury in the blood of chicks was highest. The concentration in chick blood was negatively correlated ($r^2 = 0.56$) with lake pH,⁸² a pattern also observed in the methylmercury content of prey fish (Figure 16.3) and game fish in small lakes of the study area.^{78,250}

Descriptive field studies typically yield correlational results, which alone are generally insufficient for establishing a causal linkage between toxicant exposure and a biological response, such as reproductive success, because of the potential confounding influence of other, covarying factors.³⁶¹⁻³⁶³ For this reason, Meyer et al.⁸² did not conclude a cause-and-effect relation between high methylmercury exposure and low production of loon chicks on northern Wisconsin lakes. They

indicated the need to first critically test an alternative hypothesis concerning reproductive success of common loons in northern Wisconsin lakes: that the lower production of loon chicks on low-pH lakes resulted from lesser prey abundance in the low-pH lakes.

Fish assemblages of small seepage lakes used by nesting loons in northern Wisconsin are characterized by low species richness and numerical dominance by a few species, particularly sunfishes (*Lepomis* spp.) and yellow perch.^{74,248,249,364,365} The yellow perch, the preferred prey of the common loon,²⁵² is ubiquitous and typically abundant in these seepage lakes, ranking second in relative numerical abundance (based on catch per unit of effort) only to the bluegill (*Lepomis macrochirus*).^{74,248,249,365} Moreover, the yellow perch is an acid-tolerant species, and self-sustaining populations occur in Wisconsin lakes with pH as low as 4.4 standard units.^{249,364} Intensive, standardized fish surveys in 12 small lakes in northcentral Wisconsin (fixed sampling effort per lake with four gear types) yielded catches of yellow perch ranging from 285 to 969 fish (mean, 597) in six lakes with low pH (range, 5.1–6.0) and catches ranging from 38–1030 fish (mean, 370) in six lakes with circumneutral pH (range, 6.7–7.5).⁷⁴ Two other potential prey-fish species, bluegill and pumpkinseed (*Lepomis gibbosus*), are also abundant in the low-pH lakes.⁷⁴ Thus, it is highly improbable that the low production of loon chicks observed by Meyer et al.⁸² on low-pH lakes in northern Wisconsin resulted from lesser prey-fish abundance in such lakes. We infer that high methylmercury exposure is a more defensible explanation for the low production of loon chicks on these low-pH lakes.

In Georgia (U.S.), Gariboldi et al.³⁶⁶ measured mercury levels in prey items regurgitated by nestling wood storks (*Mycteria americana*) at four colonies. The estimated mean concentration in the diet of nestlings at individual colonies ranged from 0.10 to 0.28 $\mu\text{g/g}$ wet weight, equaling or exceeding a lowest observed adverse effect concentration (LOAEC) of 0.1 $\mu\text{g/g}$ wet weight, a value recommended by Eisler³³⁶ as a maximum tolerable dietary concentration for sensitive avian species. The LOAEC of 0.1 $\mu\text{g/g}$ wet weight was derived from laboratory experiments showing that the reproduction and behavior of mallards were affected by a diet containing 0.5 $\mu\text{g Hg/g}$ dry weight (~ 0.1 $\mu\text{g/g}$ wet weight), administered as methylmercury dicyandiamide. The mean concentration in prey of nestling wood storks was highest (0.28 $\mu\text{g/g}$ wet weight) in an inland colony, where an average of 1.9 young wood storks were fledged per nest — lower than the averages of 2.6 and 2.5 birds fledged per nest at the two coastal colonies, where mean dietary mercury concentrations were 0.10 and 0.19 $\mu\text{g/g}$ wet weight, respectively.³⁶⁶ Gariboldi et al.³⁶⁶ stated that it was difficult to separate the effects of dietary mercury exposure from other potential stressors on wood storks such as differences in the abundance of prey among colonies. These authors also noted the uncertainty associated with extrapolating a LOAEC derived from laboratory studies with mallards to wild, fish-eating wood storks. Mercury levels in eggs of wood storks were not measured in this study.

In the English-Wabigoon River system, Fimreite³³² reported a mercury concentration of 3.65 $\mu\text{g/g}$ wet weight in eggs of common terns (*Sterna hirundo*) nesting in Ball Lake, Ontario, where estimated hatching success was less than 27%. In lesser contaminated Wabigoon Lake, mercury averaged 1.0 $\mu\text{g/g}$ in eggs of terns, only seven unhatched eggs were found, and a “large number of fledged young” were observed. The reproductive measurements in this study were made during two visits to each colony and were not systematically collected; however, Fimreite³³² associated the impaired reproduction in terns from Ball Lake with high methylmercury exposure.

The embryos of herring gulls (*Larus argentatus*) seem to be much less sensitive than embryos of the common tern to methylmercury, based on results of Vermeer et al.,³⁶⁷ who measured mercury in a single egg taken from each of 18 herring gull nests and monitored the subsequent hatching success of the remaining eggs. Mercury levels in whole eggs varied from 2.3 to 15.8 $\mu\text{g/g}$ wet weight. In four eggs, yolk and albumen were analyzed separately, yielding concentrations ranging from 0.9 to 3.5 $\mu\text{g/g}$ in the yolk and from 3.5 to 22.7 $\mu\text{g/g}$ in the albumen. All but two of the remaining eggs in the 18 nests hatched, and those two eggs were in nests where the sampled eggs contained 7.9 and 8.1 $\mu\text{g/g}$ of mercury.³⁶⁷

Henny et al.³⁶⁸ assessed the influence of high concentrations of mercury in eggs on bird reproduction at five national wildlife refuges in the western United States. Concentrations in some

eggs of ducks exceeded 3 $\mu\text{g/g}$ dry weight (~ 0.6 to 0.8 $\mu\text{g/g}$ wet weight), a concentration near that causing reproductive impairment in laboratory studies with mallards.³⁴³ It was not feasible to relate mercury residues measured in a single egg taken from each duck nest to hatching success of the remaining eggs because of heavy predation on the nests. A small sample of eggs from the nests was, therefore, incubated in the laboratory; eggs with more than 3 $\mu\text{g Hg/g}$ (dry weight) hatched as well as eggs with concentrations less than 3 $\mu\text{g/g}$.³⁶⁸

16.7.3.2 Laboratory Experiments on Birds

An inherent limitation of ecotoxicological field studies stems from the difficulty in isolating the biological effects of methylmercury exposure from the effects of other variables. The presence of other environmental contaminants, for example, can complicate the identification of biological responses to methylmercury. Controlled laboratory experiments are useful for addressing the uncertainties inherent in even the best field studies. A principal objective of many laboratory experiments has been to determine the concentrations of methylmercury in the avian diet or in avian tissues and eggs that are associated with mortality or reproductive failure.

Koeman et al.³⁶⁹ dosed mice with methylmercury dicyandiamide and fed the mice, which contained about 13 $\mu\text{g Hg/g}$ wet weight, to Eurasian kestrels (*Falco tinnunculus*). Methylmercury poisoning in the kestrels became evident after about 15 days, and mortality began after 21 days. The kestrels suffered demyelination of the spinal cord, a symptom of methylmercury poisoning. Concentrations of mercury in the kestrels that died or were sacrificed after showing signs of mercury poisoning ranged from 49 to 122 $\mu\text{g/g}$ wet weight in the liver and from 20 to 33 $\mu\text{g/g}$ in the brain.³⁶⁹ Methylmercury poisoning and mortality also occurred in goshawks (*Accipiter gentilis*) and red-tailed hawks (*Buteo jamaicensis*) fed chicken flesh containing about 4 to 13 $\mu\text{g Hg/g}$ on a wet-weight basis, as methylmercury.^{370,371} Livers of the dead goshawks contained from 103 to 144 $\mu\text{g Hg/g}$ wet weight, and brains contained 36 to 51 $\mu\text{g/g}$.³⁷⁰ Livers of poisoned red-tailed hawks contained about 19 to 20 $\mu\text{g/g}$ of mercury.³⁷¹

Finley et al.³⁷² estimated the concentrations of mercury in tissues associated with the death of birds by feeding 40 $\mu\text{g Hg/g}$, as methylmercuric dicyandiamide, to European starlings (*Sturnus vulgaris*), common grackles (*Quiscalus quiscula*), red-winged blackbirds (*Agelaius phoeniceus*), and brown-headed cowbirds (*Molothrus ater*). After 5 of the 14 birds of each species had died from methylmercury poisoning, 5 survivors were sacrificed, and mercury concentrations in tissues of the dead and surviving birds were compared. The sacrificed birds showed no overt symptoms of methylmercury intoxication. Concentrations in tissues of most dead birds exceeded, but did not differ statistically from, concentrations in the survivors. This study suggested that there is no specific, single concentration of methylmercury in tissues associated with death of the organism. Although no such threshold concentration was evident in their study, Finley et al.³⁷² considered 20 $\mu\text{g Hg/g}$ wet weight in the tissues as a hazardous concentration.

In another study to determine harmful tissue levels of mercury, Scheuhammer³⁷³ fed diets containing 5 $\mu\text{g Hg/g}$ dry weight, as methylmercuric chloride, to zebra finches (*Poephila guttata*) for 76 days. One fourth of the birds died, and 40% of the survivors exhibited overt neurological signs of methylmercury poisoning including lethargy and difficulty in balancing on their perches. Mercury levels in the brains of finches that died were no higher than levels in birds that showed overt signs of poisoning but did not die. Finches that survived the 76-day exposure period without exhibiting overt symptoms of methylmercury poisoning typically had less than 15 $\mu\text{g Hg/g}$ wet weight in the brain, whereas birds with symptoms had at least 15 $\mu\text{g/g}$ in the brain. Scheuhammer³⁷³ concluded from these and other data that tissue levels of methylmercury associated with neurological effects are similar in birds of different species, size, and dietary mercury level.

In Pekin ducks (*Anas platyrhynchos*) fed 15 $\mu\text{g Hg/g}$ (as methylmercuric chloride), overt signs of mercury poisoning (loss of appetite, decreased mobility, and leg paralysis) appeared in males

after 5 weeks and in females after 8 weeks.³⁷⁴ Mercury concentrations did not differ between the sexes at death or at the end of the 12-week exposure period; livers of males and females contained 88 and 92 $\mu\text{g/g}$ wet weight, respectively, and brains contained 20 and 23 $\mu\text{g/g}$.³⁷⁴ In mallards fed methylmercuric chloride, Pass et al.³⁷⁵ saw no clear delineation between mercury concentrations in the brains of birds that had developed microscopic lesions in the brain (range, 3.2 to 27.2 $\mu\text{g/g}$ wet weight) and those without detectable lesions (1.8 to 22 $\mu\text{g/g}$).

Heinz³⁷⁶ tabulated published concentrations of mercury in the internal tissues of birds that were poisoned, dead, or asymptomatic. He estimated that wet-weight concentrations of mercury associated with harmful methylmercury exposure in adult birds were 15 to 20 $\mu\text{g/g}$ in the brain, 20 to 60 $\mu\text{g/g}$ in the liver, 20 to 60 $\mu\text{g/g}$ in the kidney, and 15 to 30 $\mu\text{g/g}$ in muscle tissue.

The embryos and young of birds are more sensitive to methylmercury than are the adults. Heinz and Locke³⁴⁰ fed breeding mallards 3 $\mu\text{g Hg/g}$ as methylmercury dicyandiamide, and mercury was accumulated in eggs to mean concentrations between ~5.5 and 7.2 $\mu\text{g/g}$ wet weight in 2 consecutive years. Reproductive success was impaired, and some ducklings died from methylmercury poisoning after hatching. The brains of dead ducklings had mercury concentrations ranging from ~4.9 to 8.7 $\mu\text{g/g}$ wet weight and exhibited demyelination and necrosis characteristic of methylmercury poisoning.³⁴⁰ Reproduction of black ducks (*Anas rubripes*) fed 3 $\mu\text{g Hg/g}$ as methylmercury dicyandiamide was similarly impaired, with post-hatching mortality of ducklings associated with mercury concentrations between 3.2 and 7.0 $\mu\text{g/g}$ wet weight in the brain.³⁷⁷

Concentrations of methylmercury in the maternal diet and in eggs associated with adverse reproductive effects in birds have also been estimated in laboratory studies. Tejning³⁴¹ fed chickens a diet containing about 9.2 $\mu\text{g Hg/g}$ dry weight as methylmercury dicyandiamide. Within 3 weeks mercury concentrations in eggs increased to about 25 $\mu\text{g/g}$ wet weight in egg whites and 2 $\mu\text{g/g}$ in egg yolk, and hatching success of exposed eggs decreased to about 10%, relative to about 60% in unexposed controls. When the maternal diet contained about 4.8 $\mu\text{g/g}$ of mercury, administered as methylmercury dicyandiamide, egg whites and yolks contained about 17 and 2 $\mu\text{g/g}$, and hatching success was 17%.³⁴¹ Fimreite³⁴² fed ring-necked pheasants a diet containing about 3.7 $\mu\text{g Hg/g}$ as methylmercury dicyandiamide. After 12 weeks hatching success was about 10%, compared to about 50 to 55% for controls. In eggs, decreased hatchability was associated with mercury concentrations between 0.5 and 1.5 $\mu\text{g/g}$ wet weight.³⁴² Borg et al.,⁷⁰ who fed breeding pheasants a diet with 15 to 20 $\mu\text{g Hg/g}$ dry weight as methylmercury for 9 days, observed a significant decline in hatching success (55%) relative to controls (74%). Mercury residues in whole eggs associated with this decline ranged from 1.3 to 2.0 $\mu\text{g/g}$ wet weight,⁷⁰ in close agreement with the findings of Fimreite.³⁴²

The diagnosis of methylmercury poisoning in birds based on measured residues of mercury in tissues may be complicated by the influence of other, co-occurring elements that alter the toxicity of methylmercury.³⁷⁸ In particular, it has been generally believed that selenium protects vertebrate organisms against methylmercury poisoning, even though mercury accumulation in tissues may be increased by selenium.³⁷⁹

A notable exception to the presumed protective action of selenium against methylmercury poisoning in wildlife was observed in mallards fed a combination of selenomethionine and methylmercuric chloride.³³⁸ In this experiment, Heinz and Hoffman³³⁸ showed that the toxic effects on the developing bird embryo were much greater when selenium and methylmercury were added jointly to the maternal diet than when methylmercury was added without selenium. In the same experiment, dietary selenium decreased methylmercury toxicity in the adult mallard.³³⁸ Thus, selenium does not seem to protect against reproductive effects of methylmercury.

Few controlled laboratory experiments have been done on the fish-eating birds that are at greatest risk due to methylmercury exposure in the wild. Reproductive experiments with fish-eating birds exposed to dietary methylmercury are urgently needed, given the uncertainties in extending experimental results for laboratory test species to wild, fish-eating birds. Even with laboratory species (such as the mallard, pheasant, and chicken), there is much uncertainty in the threshold concentra-

tions of methylmercury in the maternal diet and in the eggs that elicit reproductive problems. Obtaining information on the reproductive sensitivity of wild, fish-eating birds to methylmercury exposure is perhaps the most pressing research need concerning the avian ecotoxicology of mercury. The combined effects of exposure to methylmercury and other contaminants (particularly selenium and organochlorines), as well as other environmental stressors encountered by wild birds, also merit critical study.

16.7.4 Mammals

Mercury intoxication in wild mammals was first reported in association with the widespread use of organomercurial fungicides as seed dressings during the 1950s and 1960s, when individuals of various wild avian and mammalian species, particularly granivores and their predators, were killed from dietary exposure to high concentrations of mercury.⁷⁰ Later, methylmercury intoxication was reported as the cause of death of a wild mink (*Mustela vison*) near a mercury-contaminated river³⁸⁰ and of a wild otter (*Lutra canadensis*) near a lake contaminated with mercury from a chlor-alkali plant.³⁸¹ These cases involved outright mortality of adult mammals, probably in response to high dietary exposure to methylmercury. The sources of mercury that caused these past exposures (i.e., emissions from pulp and paper mills and chlor-alkali plants and usage as seed dressings) have largely been discontinued or greatly reduced. As described earlier in this chapter, however, other regionally and globally significant sources of anthropogenic mercury remain, and the methylation of mercury in the environment and biomagnification of methylmercury to high concentrations in food webs continue. Consequently, piscivorous and other top predatory mammals still risk elevated methylmercury exposure in some aquatic environments.

In this section, we review the effects of dietary methylmercury exposure in wild mammals, the *in vivo* demethylation of methylmercury, and interactions between mercury and selenium in mammals. We discuss evidence linking recent methylmercury exposure to toxic effects in certain wild mammal species and in certain environments of North America. For earlier reviews of mercury toxicology in wild mammals, the reader is referred to Wren,³⁸² Heinz,³⁷⁶ Thompson,³²⁹ and Wolf et al.³³⁰

16.7.4.1 Effects of Methylmercury in Mammals, and Critical Concentrations in Tissues and Diets

Data on tissue concentrations of mercury and methylmercury toxicity are more plentiful for otter and mink than other wild mammals. Combined evidence from wild otter and mink that died after exhibiting signs of methylmercury poisoning^{380,381} and from controlled, dietary-dosing experiments on these two species^{383–385} indicate that total mercury concentrations in the range of 20 to 100 $\mu\text{g/g}$ wet weight in liver, or > 10 $\mu\text{g/g}$ wet weight in brain, indicate potentially lethal exposure to methylmercury. Reported values for other predatory mammals also fall within these ranges. For example, a fox (*Vulpes vulpes*) that was found staggering and running in circles and that later died had 30 $\mu\text{g/g}$ wet weight of total mercury in its liver and kidneys, and a marten (*Martes martes*) with similar symptoms of methylmercury intoxication had 40 $\mu\text{g Hg/g}$ wet weight in its liver and kidneys.⁷⁰ Liver tissue from a Florida panther (*Felis concolor coryi*) suspected of dying of methylmercury poisoning had 110 $\mu\text{g/g}$ wet weight of total mercury.³⁸⁶ Total mercury concentrations ranging from 37 to 145 $\mu\text{g/g}$ wet weight were found in the livers of feral, domestic cats that died from methylmercury toxicosis.³⁸⁷ Generally, in the studies cited above only total mercury in tissue was measured, and it was assumed that all or most of the mercury was present as methylmercury, the dominant form to which the animals were exposed. Mammals that die from methylmercury intoxication first exhibit characteristic neurological signs, including some combination of lethargy, weakness, ataxia, paralysis of limbs, tremors, convulsions, and visual impairment.

Chronic exposure to dietary methylmercury concentrations of 1 $\mu\text{g/g}$ wet weight or greater causes neurotoxicity and mortality in adult mink^{384,385,388} and otter.³⁸⁹ Mink die after 3 to 11 months of exposure to 1 $\mu\text{g Hg/g}$ wet weight of methylmercury in the diet.^{384–385} Higher dietary concentrations ($> 2 \mu\text{g/g}$ wet weight) hasten the appearance of toxic signs and mortality; however, tissue concentrations of individual mink and otter dying of methylmercury exposure were similar regardless of the methylmercury concentration in the diet, and higher dietary methylmercury concentrations mainly influenced the time required to accumulate toxic tissue concentrations.^{388,389} Dietary methylmercury levels of $\leq 0.5 \mu\text{g Hg/g}$ wet weight are generally not lethal to mink, and consumption of such diets has not caused obvious neurological signs of methylmercury intoxication in mink in controlled feeding experiments.^{384,385,390,391}

Comparatively few studies have examined more subtle, sublethal effects of methylmercury in wild mammals. Two studies that examined the effects of dietary methylmercury on reproduction in mink concluded that sublethal exposures (dietary concentrations $\leq 0.5 \mu\text{g Hg/g}$) did not adversely affect reproductive variables such as fertility, number of kits born per female, and the survival and growth rates of kits.^{385,392} We are unaware of any studies of subtle neurological or neurobehavioral effects of low-level methylmercury exposure in wild mammals such as mink or otter; however, such studies have been done on small mammals used in medical research. Burbacher et al.,³⁹³ who reviewed the medical toxicological literature, concluded that brain-mercury concentrations of 12 to 20 $\mu\text{g/g}$ wet weight during postnatal development are associated with blindness, spasticity, and seizures in small mammals (e.g., rats, mice, and guinea pigs) experimentally exposed to methylmercury; these effects have also been reported in methylmercury-intoxicated mink and otter with similar concentrations in the brain. Lower mercury concentrations (3 to 11 $\mu\text{g/g}$ wet weight) in the brains of small experimental mammals cause behavioral deficits during postnatal development, such as increased activity, poorer maze performance, abnormal auditory startle reflex, impaired escape and avoidance behavior, abnormal visual evoked potentials, and abnormal performance on learning tasks.³⁹³ Similarly, Wobeser et al.³⁸⁸ concluded that mercury concentrations exceeding 5 $\mu\text{g/g}$ wet weight in the brain, when combined with neurological signs, were consistent with methylmercury toxicity in mink. Mercury concentrations in the brains of free-living otter and mink trapped in Wisconsin and in Manitoba, Ontario, and Quebec were generally in the range of 0.1 to 1.0 $\mu\text{g/g}$ wet weight, although some individuals had 5 to 10 $\mu\text{g/g}$ wet weight.^{260,394–397} Results from medical toxicological studies with small mammals indicate that such concentrations in the brain may cause subtle visual, cognitive, or neurobehavioral deficits. Impaired vision and learning ability could be life-threatening to wild, visual predators, given that such dysfunctions could significantly impair ability to catch prey, causing malnutrition, increased susceptibility to disease, or reduced reproductive success.

16.7.4.2 Demethylation and Relationship with Selenium

Information on concentrations of total mercury in certain commonly analyzed tissues, such as the liver, is not sufficient for diagnosing methylmercury toxicity in wild mammals. Methylmercury is the primary and most toxic form of mercury in the diets of piscivores and other top mammalian predators that are associated with aquatic food webs. However, some wild mammals can demethylate methylmercury to varying degrees, and inorganic mercury often accounts for a significant and highly variable fraction of the total mercury present in the liver, kidney, and brain in such species.^{260,389,396} Mammals have also been shown to demethylate methylmercury in controlled experiments. In guinea pigs (*Cavia porcellus*), for example, inorganic mercury accounted for 30 and 60% of total mercury in the liver and kidneys, respectively, after 3 weeks of administration of methylmercury.³⁹⁸

The inorganic mercury produced by *in vivo* demethylation of methylmercury can gradually accumulate to very high concentrations in association with selenium in certain tissues without

causing any apparent toxicity. Thus, liver-mercury concentrations that would probably be toxic if composed mainly of methylmercury ($> 20 \mu\text{g/g}$ wet weight) may not be toxic if present primarily as Hg-Se complexes. Methylmercury generally predominates when total mercury concentrations in livers of predatory mammals are less than $\sim 9 \mu\text{g/g}$ wet weight; however, with greater mercury accumulation, an increasingly high proportion of total mercury is often present as inorganic mercury. In marine mammals and aquatic birds that have accumulated high concentrations of mercury in the liver (10 to $> 30 \mu\text{g/g}$ wet weight), more than 85% of total mercury is typically present as inorganic mercury associated with selenium in a molar ratio approximating 1:1.^{263,399} Thus, observations of elevated concentrations of total mercury in the liver or kidneys of dead mammals are not sufficient for diagnosing methylmercury intoxication because of demethylation and the subsequent formation of Hg-Se complexes that have relatively low toxicity. Ideally, such diagnoses should be based on information on total mercury, methylmercury, and selenium in the liver, kidneys, and brain. Determination of total mercury in skeletal muscle would also be useful in such assessments because very little demethylation occurs in muscle tissue. In the absence of clinical signs of methylmercury intoxication (e.g., for animals found dead), a mercury concentration exceeding $20 \mu\text{g/g}$ wet weight in the liver, combined with a concentration exceeding $12 \mu\text{g/g}$ wet weight in muscle, indicates probable methylmercury intoxication.^{383,388,389} Conversely, the same or higher mercury concentration in the liver, in conjunction with low mercury concentrations in muscle, would not be indicative of methylmercury intoxication.

The antagonistic relation between mercury and selenium in biological systems is well known;³⁷⁹ however, the biochemical mechanisms underlying this antagonism are poorly understood. Studies with rats have demonstrated that selenium protects against or delays the toxicity of methylmercury. Animals that received co-administration of selenium salts with methylmercury had lower mortality, fewer neurological signs of methylmercury intoxication, and better growth rate and weight gain than animals given only methylmercury.⁴⁰⁰⁻⁴⁰⁴

In wild mammals, the association between mercury and selenium has been most intensively studied in dolphins. Rawson et al.⁴⁰⁵ described pigment granules containing high concentrations of mercury in lysosomes of liver cells of Atlantic bottlenose dolphins (*Tursiops truncatus*). All animals with mercury-containing granules had concentrations of total mercury in the liver exceeding $61 \mu\text{g/g}$ wet weight, whereas animals without pigment had concentrations of less than $50 \mu\text{g/g}$. Rawson et al.⁴⁰⁵ did not suggest that these mercury-containing pigments were composed of Hg-Se-protein complexes; however, other studies have demonstrated the presence of such compounds, both as Hg-Se-protein complexes and as insoluble HgSe (tiemannite) granules, in liver cells of dolphins.⁴⁰⁶⁻⁴⁰⁹ As reported for other mammals with high mercury accumulation, dolphins with the highest concentrations of total mercury in the liver ($> 100 \mu\text{g/g}$ wet weight) typically have the lowest percentages of methylmercury (< 10 percent of total mercury) and also have high selenium concentrations in the liver.⁴¹⁰ These Hg-Se compounds, which are much less toxic than methylmercury, are very stable and have a long biological half-life, accumulating to high concentrations in older individuals.^{405,411} Low concentrations of mercury in the liver of dolphins, and perhaps other marine mammals, are present primarily as methylmercury; however, there is an apparent threshold above which the speciation of mercury is altered by *in vivo* demethylation and concurrent accumulation of selenium with mercury in stable, insoluble complexes.⁴⁰⁹ Such Hg-Se complexes have apparently not been reported or studied in otter or mink.

Evans et al.²⁶⁰ measured concentrations of total mercury and methylmercury in the brain, kidney, liver, and fur of apparently healthy wild otter and mink from Ontario, Canada and reported a greater percent of inorganic mercury in otter than in the same tissues in mink. Mink and otter had comparable levels of total mercury (e.g., in liver, 0.85 to $3.5 \mu\text{g/g}$ wet weight in mink and 0.87 to $2.3 \mu\text{g/g}$ in otter), but the mercury in soft tissues of mink was from 80 to 90% methylmercury, whereas the methylmercury fraction ranged from 56 to 81% in otter, leading Evans et al.²⁶⁰ to suggest that otter are more able than mink to demethylate methylmercury. Wren et al.³⁹⁶ also reported higher proportions of methylmercury in liver tissue of otter, relative to mink, in animals

collected throughout Ontario. Concentrations of mercury and selenium were not correlated in the livers of Ontario otter.³⁹⁶

16.7.4.3 Hazard Assessment Studies

Environmental mercury exposure has occasionally been implicated as a possible contributing factor to population declines in mink and otter. Osowski et al.,⁴¹² who noted that mink were completely absent in parts of the Atlantic coastal plain of Georgia, North Carolina, and South Carolina (southeastern United States), where they were historically abundant and where high-quality habitat remained available, assessed the potential role of 17 environmental contaminants in population declines of mink. Mercury (along with PCBs, DDE, and dieldrin) emerged as a potentially important contaminant influencing mink populations. Concentrations of total mercury in kidneys of mink from areas of concern were as high as 25 µg/g wet weight, compared to < 4 µg/g wet weight in reference areas.⁴¹² Notably, the higher mercury levels reported in this study were toxic to mink in controlled feeding experiments.³⁸⁸

Giesy et al.⁴¹³ conducted a hazard assessment of mercury and other contaminants in mink above and below hydroelectric dams on three rivers flowing into the North American Great Lakes. Based on an assumed dietary no-observed-adverse-effect concentration of 0.05 µg Hg/g wet weight for mink, the hazard assessment concluded that the calculated hazard indices were not high, although mercury levels in fish upstream from the dams were higher than those downstream. Mercury was deemed to be less important than PCBs as a factor potentially affecting Great Lakes mink populations, and Giesy et al.⁴¹³ concluded that concentrations of mercury in fish in the rivers examined were probably too low to cause any population-level effect on mink.

Two studies have attempted to assess the risk of adverse effects in otter and mink from environmental mercury and PCB contamination in the Clinch River and Poplar Creek watersheds in Tennessee.^{414,415} Mercury in small fish collected in areas of concern averaged about 0.2 to 0.4 µg/g wet weight.⁴¹⁵ Results of Monte Carlo simulations estimating total daily intakes of mercury, integrated with dose-response curves to estimate risks, led Moore et al.⁴¹⁵ to conclude that dietary methylmercury exposure posed a moderate risk to female mink (a 24% probability of at least 15% mortality) within the areas of concern. Similarly, Sample and Suter⁴¹⁴ concluded that there was an 85% probability that mercury exposure in otter in some of the affected sites exceeded the estimated lowest observed adverse effect level for methylmercury.

16.8 DEGRADATION OF ECOSYSTEM GOODS AND SERVICES

As a “good” produced by aquatic ecosystems, fish are a high-quality food resource — high in protein, low in saturated fat, and a source of beneficial omega-3 polyunsaturated fatty acids and antioxidants such as vitamin E.⁴¹⁶ Mercury contamination has clearly diminished the economic, nutritional, and cultural values of the fishery resources produced by many freshwater and marine ecosystems.^{417–420} The growing awareness of the mercury problem has prompted increasing efforts to survey mercury contamination of fish, producing information that has, in turn, prompted issuance of additional advisories concerning the consumption of sport fish. In Canada, mercury contamination accounted for more than 97% (2572) of all fish-consumption advisories listed in 1997.⁴²¹ Most of the Canadian advisories pertained to surface waters in Quebec and Ontario, whereas New Brunswick and Nova Scotia had province-wide advisories in effect for mercury. In the United States, methylmercury contamination accounted for 79% of all fish- and wildlife-consumption advisories in 2000.⁴²¹ Out of 50 states, 41 had advisories attributed to mercury, and the number of statewide fish-consumption advisories issued for lakes, rivers, or coastal waters increased substantially during 1993–2000 (Figure 16.4). In Sweden, an estimated 40,000 of the country’s 83,000 lakes contained 1-kg northern pike with mercury concentrations higher than the national guideline of 0.5 µg/g wet weight, and an

Figure 16.4 Recent trends in the issuance of consumption advisories in the United States caused by mercury in fish and wildlife. Shown are the total number of advisories for mercury (top panel), the number of states issuing advisories (center), and the total number of statewide advisories for surface waters of a given type (bottom), such as coastal waters, lakes, and rivers. Data reflect the status of advisories through the year 2000.⁴²¹ In 2001, the states of Pennsylvania and Maryland each issued a statewide advisory (not included above) for mercury in fish.

estimated 10,000 of these lakes contained 1-kg pike with mercury concentrations exceeding the “blacklisting” limit of 1.0 $\mu\text{g/g}$.⁴¹⁸ In Uppsala County, Sweden, pollution by toxic substances (specifically mercury and cesium-137) ranked as the second greatest anthropogenic threat to lakes.⁴²²

The economic losses caused by mercury contamination of fishery resources are largely unknown, having been estimated for only a few cases.⁴¹⁷ The adverse impacts of mercury pollution on some indigenous, or aboriginal, peoples who relied on aquatic ecosystems for subsistence via fishing and hunting are multidimensional, encompassing cultural, social, and health effects as well as economic consequences.^{419,420,423} For some of these peoples, the consequences of abandoning subsistence fishing and switching to alternative diets, combined with the social and cultural effects of a disrupted lifestyle, have presented a much more severe overall problem than the direct, clinical effects of exposure to methylmercury via consumption of contaminated fish or wildlife.^{419,420,423}

The presence of inorganic mercury on the landscape, whether from anthropogenic or natural sources, can devalue some of the services performed by aquatic ecosystems. Much of the inorganic Hg(II) present on vegetated terrestrial areas inundated to create reservoirs for hydropower development, for example, is methylated after flooding and enters the food chain, accumulating to high concentrations in fish in the reservoirs and riverine reaches downstream.^{84,85,100,240,242,424–427} In a new reservoir, the inundation of vegetated landscapes is rapidly followed by a rapid transition to anaerobic conditions caused by rapid decomposition of inundated organic matter and the associated depletion of dissolved oxygen near the soil-water interface. After this redox shift, anaerobic microbial communities (including sulfate reducers) proliferate, and the net rate of methylmercury production increases rapidly.⁹⁶ In the first 9 years after creation of the La Grande 2 reservoir (part of the La Grande hydroelectric complex in the Canadian province of Québec), concentrations of mercury increased from ~ 0.6 to $3.0 \mu\text{g/g}$ wet weight in 70-cm northern pike and from ~ 0.7 to

2.8 µg/g in 40-cm walleye.⁸⁴ In some cases, mercury levels in fish from recently flooded reservoirs have equaled or exceeded levels in fish from surface waters that were heavily contaminated by direct industrial discharges.^{242,428} Moreover, the mercury concentrations in the fishery resources of new impoundments may remain substantially elevated for decades after flooding.^{84,242,426,429}

The ecosystem services performed by natural and constructed wetlands can also be devalued by mercury. Freshwater wetlands improve water quality by retaining or partially removing many of the constituents from water passing through the wetland system, including suspended solids, bacteria, biological oxygen demand, chemical oxygen demand, certain heavy metals, phosphorus, and nitrogen.^{430–433} Constructed wetlands have been widely used for water treatment and are effective at improving water quality in a variety of situations.^{432,433} However, wetlands are also quantitatively important on the landscape as sites of methylmercury production, and they can be important sources of methylmercury for downstream surface waters.^{68,100,123–125,133,179,183,196,205,434}

The production and export of methylmercury, particularly in wetland systems where the abundance of mercury has been significantly increased by local anthropogenic sources or atmospheric deposition, can impair the water-treatment function and degrade the biological resources of wetlands and downstream waters. In riparian wetlands adjoining the Sudbury River in Massachusetts, for example, contaminated overbank sediments on the floodplain remained an active source of methylmercury for aquatic biota and downstream riverine reaches long after the primary anthropogenic source of mercury was controlled.^{60,67–69} In parts of the Florida Everglades, a nationally renowned wetland ecosystem receiving anthropogenic mercury in atmospheric deposition,^{435–437} the rates of methylmercury production are very rapid.⁹⁷ The fish and wildlife resources in areas of the Everglades having high methylation rates contain high levels of methylmercury,^{89,438–441} diminishing the value of the fishery and posing a threat to wildlife in upper trophic levels.^{438,442–444}

16.9 MERCURY POLLUTION — A CONTINUING SCIENTIFIC CHALLENGE

Environmental mercury research remains an area of substantive scientific progress and discovery. Virtually hundreds of studies have examined sources, environmental transport, biogeochemical transformations and cycling, bioaccumulation, and biological effects of the metal since global attention first focused on environmental mercury pollution. Amazingly, a variety of recent landmark discoveries indicate that environmental mercury research can be characterized as a relatively “young” field of scientific endeavor.

Examples of recent prominent advances in mercury research include, but certainly are not limited to, the following: (1) the discovery of mercury-sensitive ecosystems characterized by small inventories of total mercury, high rates of mercury methylation, and high concentrations of methylmercury in piscivorous fish and wildlife, (2) the observation that perturbations of the landscape by humans or natural processes (e.g., reservoir creation and prolonged flooding) can markedly increase methylmercury production and contamination of aquatic food webs, (3) the discovery of wetlands as important sites of mercury methylation and export on the landscape, (4) the observation of significant photodegradation of methylmercury in some surface waters, (5) the observation that selenium can worsen — rather than protect against — effects of methylmercury on avian reproduction and developing young, (6) the discovery of highly reactive, gaseous forms of Hg(II) that are rapidly removed from the atmosphere in wet and dry deposition, and (7) observation of the rapid conversion after polar sunrise of gaseous Hg⁰ in the polar atmospheres to reactive gaseous Hg(II).

Despite this impressive progress, many significant questions remain concerning the exposure and ecotoxicological effects of mercury in the environment. Our collective appraisal is that progress in assessing the biological and ecotoxicological *effects* of methylmercury exposure is lagging far behind progress in understanding biogeochemical processes and environmental factors that influ-

ence biological *exposure* to methylmercury. In particular, the following topics pertaining to the ecotoxicology of mercury in biota atop aquatic food webs merit intensive scientific study.

- *Critical examination of the reproductive effects of methylmercury on fish, birds, and mammals:* Which, if any, species and populations are being affected by dietary exposure to methylmercury? Is the vertebrate embryo the weak link in reproductive effects in exposed populations, or are other reproductive endpoints (such as territorial fidelity, courtship and other reproductive behaviors, gonadal development, and spawning success) more sensitive?
- *Variation among taxa of piscivorous fish, birds, and mammals in reproductive and early-life sensitivity to methylmercury:* Are fish-eating marine mammals and seabirds protected against the adverse effects of methylmercury exposure, given their apparent abilities to demethylate methylmercury and subsequently store or eliminate the resulting inorganic mercury? Are fish-eating mammals less vulnerable to methylmercury than fish-eating birds?
- *The combined effects of methylmercury and other co-occurring environmental stressors:* How does mercury interact, in an ecotoxicological sense, with other persistent toxic contaminants that bioaccumulate and biomagnify in food webs?

The modern environmental mercury problem, characterized by large geographic scale and enormous complexity, remains a serious challenge to environmental managers and scientists alike. In an ecotoxicological sense, the modern mercury problem can be viewed rather simply as *biotic exposure to methylmercury*. Given this view, the extraordinary challenge facing scientists and environmental managers is to identify approaches that can decrease biotic exposure to methylmercury. Clearly, a sustained, interdisciplinary effort will be needed to address critical questions concerning methylmercury exposure and the associated risks to wildlife and humans dependent on aquatic food webs.

16.10 SUMMARY

Growing awareness of the hazards of mercury exposure prompted widespread reductions in usage and discharges of the metal to many surface waters beginning in the late 1960s. Mercury concentrations in fish and other aquatic biota typically declined in the years and decades following reductions in discharges to industrially polluted waters, although contamination at some sites has decreased slowly and high concentrations persist in fish. Contaminated tailings and alluvium from mining operations are widespread and can remain a source of mercury emissions for decades or centuries. In some basins, contaminated sediment from historic mining sites has been transported to aquatic and floodplain habitats far downstream. Gold mining with the mercury-amalgamation process has resurged in South America, Southeast Asia, China, and Africa in widely dispersed operations that may contribute 10% of modern anthropogenic emissions worldwide.

Since the late 1970s, unexpectedly high concentrations of mercury have been observed in fish from waters lacking on-site anthropogenic or geologic sources of mercury, including low-alkalinity and humic lakes, wetlands, surface waters with adjoining wetlands, waters with adjoining or upstream areas subjected to inundation, and dark-water streams. We classify such systems as mercury-sensitive because seemingly small inputs or inventories of total mercury can cause significant methylmercury contamination in fish and wildlife in upper trophic levels. A common attribute of mercury-sensitive ecosystems is the efficient conversion of inorganic mercury to methylmercury. Concentrations of methylmercury in fish in mercury-sensitive ecosystems can equal or exceed those in fish from industrially contaminated waters.

The modern mercury problem is greatest in aquatic environments, where inorganic Hg(II) can be methylated to methylmercury, the highly toxic form that readily bioaccumulates in exposed organisms and biomagnifies to high concentrations in food webs. Methylation by sulfate-reducing bacteria at oxic-anoxic interfaces in sediments and wetlands is probably the dominant methylation pathway in the environment. Demethylation, or degradation of methylmercury, can occur via a

number of abiotic and biotic pathways in the environment, and photodemethylation can significantly affect methylmercury budgets of lakes.

Emissions from anthropogenic sources and long-range atmospheric transport of mercury have contaminated terrestrial and aquatic environments on a global scale. Analyses of sediment, peat, and glacial ice show that the rate of mercury accumulation at semiremote and remote sites has increased substantially (often by two- to fourfold) since the mid-1800s or early 1900s. It can be reasonably inferred that a significant fraction of the methylmercury in aquatic biota in remote or semiremote waters, including marine systems, is derived from anthropogenic mercury in deposition. In the North Atlantic, for example, concentrations of methylmercury in fish-eating seabirds (and their supporting food webs) increased substantially from 1885 through 1994.

Four compartments — atmospheric, terrestrial, aquatic, and biotic — are interconnected in the global mercury cycle. The atmosphere is dominated by gaseous elemental mercury (Hg^0), but the fluxes between the atmosphere and both aquatic and terrestrial compartments are dominated by $\text{Hg}(\text{II})$. The terrestrial compartment is dominated by $\text{Hg}(\text{II})$ in soils, the aquatic compartment by $\text{Hg}(\text{II})$ -ligand pairs in water and $\text{Hg}(\text{II})$ in sediments, and the biotic compartment by methylmercury. Mercury is reactive and moves readily between compartments. Atmospheric processes and pathways dominate global-scale transport from sources to receptors. The global cycle can be envisioned as a two-way exchange, in which sources emit Hg^0 and various species of $\text{Hg}(\text{II})$ to the atmosphere and the atmosphere loses mercury via oxidation of Hg^0 to $\text{Hg}(\text{II})$ and the rapid removal of gaseous and particulate species of $\text{Hg}(\text{II})$ in wet and dry deposition. Mercury deposited onto the land is sequestered in soils, largely as $\text{Hg}(\text{II})$ sorbed to organic matter in the humus layer. The global inventory of mercury in soils greatly exceeds that in the aquatic and atmospheric compartments. The $\text{Hg}(\text{II})$ in soils can be reduced and emitted to the atmosphere as Hg^0 or slowly transported down gradient; thus, soils are both a sink and a potential long-term source of mercury. Anthropogenic emissions, particularly since the industrial revolution, have greatly increased the size of cycling mercury pools and the importance of atmospheric pathways to a global pollution problem, increasing the abundance of mercury in the atmosphere, soil, sediment, and biota. Natural emissions of Hg^0 can be substantial in areas that are geologically enriched with mercury.

The aqueous abundances of methylmercury and total mercury vary widely. Total mercury in water (unfiltered) ranges 0.3 to 8 ng/L in aquatic systems lacking substantive, on-site anthropogenic or geologic sources, 10 to 40 ng/L in systems influenced by mercury mining or industrial pollution, and can exceed 100 or even 1000 ng/L in systems draining areas with substantive geologic sources or contaminated mine tailings. Methylmercury generally accounts for about 0.1 to 5% of the total mercury in oxic surface water, seldom exceeding 10%. In oxic waters, concentrations of methylmercury are typically in the range of 0.04 to 0.8 ng Hg/L, but can be 1 to 2 ng Hg/L in systems affected by industrial pollution or mercury mine drainage. Methylmercury can be the dominant species under anoxic conditions, and concentrations can exceed 5 ng Hg/L.

Methylmercury readily crosses biological membranes and accumulates in aquatic organisms to concentrations that vastly exceed those in water. Patterns of biomagnification of methylmercury in food webs are similar, even among aquatic systems that differ in ecosystem type, mercury source, and intensity of pollution. The entry of methylmercury into the food web and its concentrations in lower trophic levels are influenced strongly by the supply from methylating environments. Methylmercury concentration increases up the food web from water and lower trophic levels to fish and piscivores. The ratio of methylmercury to total mercury increases with ascending trophic level through fish and can vary greatly in trophic levels below fish. In pelagic food webs, the greatest increase in methylmercury concentration, relative to that in water, occurs between seston and water. Fish accumulate methylmercury mostly via the diet, to concentrations that commonly exceed those in water by 10^6 - to 10^7 -fold. Inorganic mercury, in contrast to methylmercury, is not readily transferred in food webs and does not biomagnify.

In fish, concentrations of methylmercury increase with increasing trophic position and with increasing age or size, because the rate of elimination is very slow relative to uptake. Much of the

methylmercury in fish is eventually stored in skeletal muscle, bound to sulfhydryl groups in protein; this may serve as a protective mechanism, given that sequestration in muscle reduces exposure of the central nervous system to methylmercury. In the laboratory, long-term dietary exposure of fish to methylmercury causes incoordination, diminished appetite or inability to feed, diminished responsiveness and swimming activity, starvation, and mortality. Fish inhabiting Minamata Bay (Japan) and Clay Lake (Ontario) — both extreme cases of industrial pollution — had very high mercury concentrations and exhibited multiple symptoms of methylmercury intoxication. In laboratory studies, sublethal exposure to waterborne methylmercury can impair the ability of test fish to locate, capture, and ingest prey and to avoid predators. Methylmercury can impair reproduction by affecting gonadal development or spawning success of adult fish, or by reducing the hatching success of eggs and the health and survival of embryolarval stages. Recent experiments have shown diminished foraging efficiency, reproductive success, health, and fitness in fish exposed to environmentally realistic concentrations of methylmercury, indicating that some fish populations may be adversely affected by existing exposure levels.

The sources of mercury responsible for reported deaths of wild birds and mammals (usage in seed grain and emissions from pulp and paper mills and chlor-alkali plants) have been greatly reduced or largely discontinued, yet methylmercury remains a threat to wildlife in upper trophic levels in many aquatic ecosystems. The present pathway of exposure to methylmercury is largely an aquatic one, and reptiles, birds, and mammals atop aquatic food webs often bioaccumulate high concentrations of methylmercury — even at semiremote or remote sites. The principal routes of elimination in birds and mammals are incorporation of methylmercury into growing feathers or hair and excretion in the feces. Some fish-eating birds (particularly seabirds) and mammals can demethylate methylmercury, and inorganic mercury can account for a significant fraction of the total mercury present in the liver, kidney, and brain in such species.

In laboratory experiments with birds and mammals, methylmercury adversely affects survival, reproduction, behavior, and cellular development and causes teratogenic effects. Animals dying from methylmercury intoxication exhibit characteristic neurological signs, including some combination of lethargy, weakness, ataxia, paralysis of limbs, tremors, convulsions, and impaired vision. In adult mink and otter, chronic exposure to dietary methylmercury of 1 $\mu\text{g/g}$ wet weight or greater causes neurotoxicity and mortality. Mortality and impaired reproduction, two endpoints observed in laboratory experiments, could affect populations of birds and mammals exposed to high levels of methylmercury. In field studies, exposure to high levels of methylmercury was a suspected cause of ill health, emaciation, and mortality in studies of wild white herons, grey herons, and common loons. In these cases, the observed mortality may have resulted from the combined effects of sublethal methylmercury exposure and other stressors. In field studies, it is often difficult to isolate the biological effects of methylmercury exposure from those of co-occurring toxic contaminants or other stressors.

In birds and mammals, early life stages are much more sensitive than the adult to methylmercury. Avian reproduction, for example, is significantly impaired at (maternal) dietary concentrations that are only one fifth of those that produce overt toxicity in the adult. In field studies, impaired reproduction has been associated with high mercury exposure in piscivorous birds, including wild merlins, common loons, wood storks, and common terns. In common loons, reductions in egg laying and territorial fidelity have been associated with mercury concentrations averaging 0.3–0.4 $\mu\text{g/g}$ wet weight in prey organisms, and many lakes in the breeding range of this species contain prey-size fish with concentrations equaling or exceeding this estimated threshold value. Reproductive experiments with fish-eating birds exposed to dietary methylmercury are urgently needed, given the uncertainties in extrapolating results from laboratory test species, such as the mallard, to wild piscivorous birds.

Few studies have examined subtle, sublethal effects of methylmercury in wild, piscivorous mammals. Yet medical studies with small mammals have shown that sublethal exposure to methylmercury can cause subtle visual, cognitive, or neurobehavioral deficits that could indirectly affect the survival and reproductive success of visual predators in the wild.

The antagonistic relation between mercury and selenium is well known in toxicology, but the biochemical mechanisms are poorly understood. In dolphins, there is an apparent threshold concentration in the liver above which the speciation of mercury is altered by *in vivo* demethylation followed by storage with selenium in insoluble, stable Hg-Se complexes. Dietary exposure of mallards to selenomethionine and methylmercuric chloride, separately and in combination, showed that selenium decreased methylmercury toxicity in adults. Yet in the same experiment, the adverse effects on the developing mallard embryo were much greater when selenomethionine and methylmercury were added jointly to the maternal diet than when only methylmercury was added.

Mercury contamination is adversely affecting a number of ecosystem goods and services. The most notable of these is the degradation of fishery resources that have substantial economic, nutritional, and cultural value. The economic losses caused by the widespread contamination of fishery resources have apparently not been estimated. For some aboriginal communities in Canada that once relied on subsistence fishing, the impacts of mercury pollution have encompassed adverse cultural, social, and health effects, as well as economic impacts. For some communities, abandonment of subsistence fishing and a change to less healthy diets, combined with the social and cultural effects of disrupted lifestyle, have presented a more severe overall problem than the direct, clinical effects of exposure to methylmercury via consumption of contaminated fish.

Mercury on the landscape can also devalue services performed by aquatic ecosystems. Much of the inorganic Hg(II) on land inundated to create reservoirs for hydropower is methylated after flooding to methylmercury, which rapidly enters the food web and substantively contaminates fish in the reservoirs and reaches downstream for decades. Mercury also devalues the ecosystem services performed by wetlands, which improve the quality of water passing through the wetland system by partial removal of nutrients and certain other constituents. Wetlands are also sites of mercury methylation, and the production and export of methylmercury can impair their water-treatment function and degrade the biological resources in wetlands and downstream waters.

Environmental mercury research is an area of substantive scientific discovery that can be characterized as a relatively young field of scientific endeavor. Our collective appraisal is that progress in assessing the biological and ecotoxicological *effects* of methylmercury exposure is lagging far behind the recent, impressive advances in our understanding of biogeochemical processes and environmental factors that influence biological *exposure* to methylmercury.

In particular, many questions concerning the ecotoxicology of mercury need to be addressed before the population-level effects of methylmercury exposure in fish and wildlife species atop aquatic food webs are fully understood. The modern environmental mercury problem, large in geographic scale and enormous in complexity, remains a daunting challenge for environmental scientists and managers alike.

17.1 INTRODUCTION

Selenium is a naturally occurring semimetallic (also referred to as a metalloid) trace element that is essential for animal nutrition in small quantities but becomes toxic at dietary concentrations that are not much higher than the required levels for good health. Thus, dietary selenium concentrations that are either below or above the optimal range are of concern. This chapter summarizes the ecotoxicology of excessive selenium exposure for animals, especially as reported during the last 15 years. It focuses primarily on freshwater fish and aquatic birds because fish and birds are the groups of animals for which most toxic effects have been reported in the wild. However, information related to bioaccumulation by plants and animals as well as effects in invertebrates, amphibians, reptiles, and mammals also are presented.

Selenium was recognized long ago as a cause of toxicity in domestic poultry and livestock (e.g., References 1–3), although a recent reevaluation of some of the historic samples and related information by O’Toole and Raisbeck⁴ indicates that the condition known as “blind staggers” in livestock is probably not caused by selenium. For fish and wildlife, selenium became much more of a concern in the 1970s and 1980s with the discovery of selenium bioaccumulation and severe impacts in fish and aquatic birds. These problems and other general information (such as environmental occurrence, general and biochemical properties, and other characteristics) are summarized in a number of recent reviews and books about selenium (see References 5–19) and are reviewed briefly in this chapter. Readers may wish to consult those references for additional information.

As a result of new information related to food-chain bioaccumulation and effects of selenium in freshwater fish, the ambient water quality criteria were revised in 1987,²⁰ and they are being reviewed again.^{21,22} Water quality criteria for freshwater systems are based on total recoverable selenium (as discussed later in this chapter), whereas the saltwater criteria are based on dissolved selenium. Because of differences in the toxicity of different chemical forms, the current acute criterion (criteria maximum concentration) for freshwater considers selenite and selenate as relative fractions of the total recoverable selenium concentration.

The environmental significance of selenium is a topic of ongoing discussion and debate. A recent issue of the journal *Aquatic Toxicology* (Vol. 57, No. 1) was devoted to papers on selenium. In December 1999, the journal *Human and Ecological Risk Assessment* devoted an issue (Vol. 5, No. 6) to debate and commentary on the topic, “Selenium — A potential time bomb or just another contaminant?” and published several papers on the topic. Needless to say, the debate continues, as not all the issues were resolved. In particular, there are differences of opinion concerning waterborne concentrations of selenium that are protective for fish and wildlife,^{23–28} the relative importance of sediment vs. waterborne selenium in affecting aquatic biota,^{29–31} and the specific thresholds of selenium in the diet or eggs of birds at which reproduction is adversely affected.^{32–34} These topics are discussed in later sections of this chapter.

Selenium concentrations typically are reported as micrograms per liter ($\mu\text{g/L}$) in fluids and milligrams per kilogram (mg/kg) or micrograms per gram ($\mu\text{g/g}$) in soil, sediment, plant or animal tissues, and diets. Concentrations in soil, sediment, tissues, and diets can be expressed either on a

wet-weight or fresh-weight basis (which are considered to be synonymous), or on dry-weight basis. Conversion from one basis to the other is a function of the moisture content in the sample (which should be reported regardless of which basis is used), as follows:

$$\text{Dry-weight conc.} = \text{Wet-weight conc.} \times \frac{100}{(100 - \text{Moisture percentage})}$$

For example, 10 mg/kg on a wet-weight basis in a sample having 80% moisture is equal to 50 mg/kg on a dry-weight basis. Selenium concentrations in soil, sediment, and tissue throughout this chapter are given on a dry-weight basis, unless otherwise noted.

17.2 ENVIRONMENTAL CHEMISTRY

From an ecotoxicological perspective, it is important to have an understanding of selenium's chemical characteristics, environmental sources and occurrence, and cycling in the environment. Those aspects of selenium chemistry can help define geographic areas and environmental settings in which selenium may be a chemical of ecological concern, and they are briefly summarized in this section.

17.2.1 Chemical Characteristics

Selenium chemistry is complex, and chemical forms vary in their environmental occurrence, biogeochemistry, and toxicity.^{7,15,17,19,35-38} In nature, selenium is generally recognized to occur in four oxidation states: selenide (Se^{2-}), elemental selenium (Se^0), selenite (Se^{4+}), and selenate (Se^{6+}), although a fifth form (selenium dioxide [Se^{2+}]) may occur as a product of combustion of elemental selenium present in fossil fuels or rubbish.¹⁹ Soluble selenates are the predominant form under oxidizing conditions in alkaline soils that are commonly found in arid areas. Selenates are readily available to plants, or they can be slowly reduced to selenites, which also can be taken up by plants and converted into organic forms. The common organic forms in plants include selenomethionine, selenocysteine, dimethylselenide, and dimethyldiselenide. Selenite is the more common soluble form of selenium under reducing conditions and in acidic soils, which occur more typically in higher-rainfall areas. Selenium occurs in various organic and inorganic forms in coal and other fossil fuels. In general, elemental selenium and metallic selenides are not readily bioavailable. However, under oxidizing conditions they can be transformed to bioavailable forms.

Selenium commonly occurs as a mixture of several different chemical forms in surface waters, but selenates and selenites are most common.^{10,17,25,38} Metal and organic selenides are common in bottom sediments. Waterborne selenium can be evaluated most reliably as total recoverable concentrations,¹⁷ and total recoverable concentrations are the basis of the ambient water quality criteria for freshwater ecosystems.^{20,22} This is because partitioning of selenium between the water column and other compartments of an aquatic ecosystem greatly affects the measurement of waterborne selenium. Low waterborne selenium concentrations can reflect low mass loading of the element, but they also may reflect high biotic uptake¹⁷ (see also Kesterson Reservoir example below). Total recoverable selenium includes suspended detrital particulate matter (a function of biotic uptake) and thus more accurately reflects the total mass load of selenium in the system. Differences between dissolved and total recoverable measurements increase with higher levels of eutrophication of the water body.

During the early and mid-1980s, subsurface agricultural drainage waters from the San Joaquin Valley, California, were disposed of by discharging them to Kesterson Reservoir, which was a series of 12 shallow ponds totaling about 500 ha.⁷ Selenium concentrations in water entering the reservoir during 1983 to 1985 averaged about 300 $\mu\text{g Se/L}$, and aquatic plants and invertebrates contained

greatly elevated concentrations of selenium (typically 10 to 100 times those found at a nearby reference site).^{7, 39-42} Almost all of the waterborne selenium was in the selenate form. Unlike boron and a number of other constituents, selenium concentrations *decreased* as the water flowed through the series of ponds and evaporated. Similarly, plants and animals as well as sediments in ponds nearer the inflow contained higher concentrations of selenium than those downstream. Thus, bioaccumulation by plants and animals removed substantial amounts of selenium from the water and deposited it into the sediments. Similar findings were reported for another site in Montana.⁴³

Selenium is essential for animals and for some plants.¹⁹ Biochemically, it is similar to sulfur; when selenium is present at elevated dietary levels, it replaces sulfur in some metabolic pathways and thereby causes problems^{23,36,37,44} (see also, later section on effects in fish). Selenium is an essential component of the enzyme glutathione peroxidase, which, along with vitamin E, serves as an antioxidant to prevent metabolic damage to tissues.

Selenium occurs in various chemical forms in plant and animal tissues, but bioavailability is greater from plant selenium than from animal foods.^{5,45} Selenomethionine has been found to be a good surrogate for natural food-chain selenium in experimental studies.¹⁷ In general, the diet is the most important exposure pathway for vertebrate animals and should be included when conducting or evaluating the effects observed in experimental studies.

17.2.2 Environmental Sources and Occurrence

Typical concentrations in the Earth's crust are < 0.5 mg Se/kg, but some geologic formations are greatly enriched in selenium.^{19,36,39,46-50} Especially when these formations are modified as a result of human activities (e.g., mining, agricultural irrigation), the selenium may be mobilized and become more available to plants and animals, which bioaccumulate selenium and incorporate it into the food chain for other organisms. Selenium tends to be present in large amounts in areas where soils were derived from Cretaceous and Tertiary marine sedimentary rocks, and selenium from these sources is highly mobile and biologically available in arid regions having alkaline soils.¹⁷

Industrial sources, such as coal and oil combustion, nonferrous metal production (primarily copper and nickel, but also lead, zinc, and cadmium), steel and iron manufacturing, municipal and sewage refuse incineration, and production of phosphate fertilizers, introduce much more selenium into the environment than do natural sources such as volcanic activity or weathering of seleniferous rocks.^{51,52} However, there are no ores from which selenium can be mined as a primary product.⁵³ It is found mainly in sulfide minerals of copper, iron, and lead and is most commonly produced by electrolytic separation from copper during the refining process. Average annual usage is estimated at 1850 metric tons. Selenium is used in a wide variety of industrial applications, with glass (35% of demand) and electrical (30%) applications representing most of the use. Other uses include pigments (10%), metallurgy (10%), agricultural/biological (5%), and miscellaneous applications (10%).

Fossil fuels (coal and oil), as well as associated formations from which they are extracted, may contain elevated concentrations of selenium.^{19,25} Concentrations vary considerably depending on the source. The selenium may be mobilized through mining of coal or disposal of fly ash from power plants where the coal was burned. In terrestrial environments, when fly ash is deposited in landfills, it may be taken up in significant amounts by plants growing on the landfill.¹⁸ One well-known example of effects associated with fly ash disposal into water bodies has been reported in a series of studies conducted at Belews Lake, North Carolina (see, for example, Reference 24). Similarly, selenium from crude oil may be discharged with process wastewater from the refinery, thereby contributing to bioaccumulation by organisms in the receiving waters.^{25,54}

Mass-loading of selenium into aquatic environments most typically results from disposal of coal fly ash, irrigation wastewater, or oil refinery wastewater.^{17,25,54} Mining or smelting of sulfide ores, uranium, phosphate, bentonite, and coal also contributes to mobilization of selenium because of its presence in the mined materials or the overburden that is moved during the mining process.^{17,19,47,55}

In freshwater systems, normal background levels of selenium in sediment are 0.2 to 2.0 mg/kg, and in water 0.1 to 0.4 µg/L.¹⁷

17.2.3 Cycling

Selenium reaches the earth's surface through volcanic activity, and some authors have proposed that oceans were enriched in selenium from volcanic activity during Cretaceous times.^{7,35,46,50,56} This early enrichment, along with bioaccumulation of selenium in the oceans and later deposition in the sediments,⁴⁸ would explain the high selenium concentrations found in many Cretaceous marine rocks. Tertiary marine sedimentary rocks contain selenium resulting from bioaccumulation and deposition of particulate matter derived by erosion of older (Cretaceous) seleniferous sedimentary deposits and also are generally seleniferous.

Irrigation of seleniferous soils can dissolve and mobilize selenium and then transport it in groundwater to irrigation drains.⁴⁸⁻⁵⁰ Geology, climate, and hydrology were found to be important factors affecting the mobilization and transport of selenium into habitats where biota are adversely affected in the western United States. Although selenium can be transported naturally as a result of rock weathering and drainage into water bodies, the process has been increased through irrigation of soils derived from seleniferous formations, especially Cretaceous and Tertiary marine sedimentary deposits.

Many biogeochemical processes affect the cycling of selenium through different components of the environment.^{7,10,35,52,57,58} In wetlands, selenium oxidation-reduction reactions are the most important processes controlling speciation, precipitation/dissolution, sorption/desorption, methylation, and volatilization of selenium. Selenate is stable in well-oxidized environments, but it is converted slowly to selenite or elemental selenium under less-oxidized conditions. It can be further reduced to metal selenides or volatile methylated forms (primarily dimethylselenide) through microbial processes. The metal selenides tend to be deposited in the wetland sediments, whereas volatile forms escape to the atmosphere. Selenides and elemental selenium tend to be very insoluble, although they can be converted to more soluble forms (selenite and selenate) under oxidizing conditions.

The changes described above can be important considerations in the wetting and drying cycles that occur in seasonal wetlands, as well as periodic draw-down of water levels in permanent wetlands. When submerged, especially where large amounts of organic material are present, selenium tends to be present in reduced (and less toxic) forms, and volatilization is favored.¹⁰ If the water level is lowered, the selenium becomes more oxidized and bioavailable. Thus, the selenium present in the wetland sediments and organic matter would become more likely to bioaccumulate into aquatic organisms soon after the wetland is reflooded than when it was previously flooded.

Although selenium in igneous and sedimentary rocks may be insoluble and unavailable to terrestrial plants, chemical weathering and plant and microbial action transform much of it into soluble (and bioavailable) forms.^{46,56} Oxidation of this selenium in alkaline soils produces selenate, making it readily available to plants. Selenium uptake by plants is affected by both the concentration and its bioavailability in soil. Selenium uptake by plants is greater in soils having higher pH and in areas of low rainfall. In areas with acidic soils and higher rainfall, selenium is generally less available to plants for uptake.

Selenium enters the atmosphere through volcanic activity, burning of fossil fuels (especially coal), and volatilization from terrestrial or aquatic environments.^{35,52} Although concentrations are low (typically around 1 ng/m³ air, but ranging up to 6000 times that level near a smelter⁵⁹), atmospheric dispersion and subsequent deposition of the selenium redistributes it in the environment. For example, deposition is estimated to have contributed to a 15% increase in soil selenium in the United Kingdom during the last century and to contribute between 33 and 82% of plant leaf selenium uptake. Deposition occurs either as "wet deposition" (with precipitation), which accounts for most of the deposition, or "dry deposition" (exchange of particulate and gaseous material between the atmosphere and the global surface).

Numerous studies of selenium transformations, cycling, and volatilization in aquatic and terrestrial ecosystems have been reported (or reviewed) in recent years.^{16,18,43,52,60-67} Not surprisingly, rates for these processes vary greatly, depending on temperature, moisture, organic carbon content of soil/sediment, selenium concentration and chemical form, and microbiological activity. Although details of some of the processes are not yet well known, it is clear that microbes are largely responsible for many of the changes that occur.

Plants vary widely in their ability to accumulate and volatilize selenium from contaminated wastewater, soils, and sediments.^{7,66,68} Under some circumstances, phytoremediation of these contaminated media may be a viable approach to reducing environmental exposures. However, waterborne selenium can be accumulated by plants and animals living in the wetlands to levels that are harmful to aquatic organisms as well as birds that feed upon them.^{7,19} As seleniferous waters enter a wetland, selenium is removed from the water through a combination of bioaccumulation by plants and animals, deposition in the sediments, and volatilization (as relatively low-toxicity dimethylselenide) to the atmosphere.^{40,42,69,70} Because of selenium bioaccumulation in the food chain and deposition to sediments, wetlands should not be used for phytoremediation of selenium-contaminated wastewater without conducting an ecological risk assessment to evaluate potential adverse effects to birds and other potentially exposed animals.

The biological half-life of selenium in animals is relatively short, varying from 10 days in pheasants to 64 days in earthworms.^{71,72} More detail concerning uptake and loss of selenium in birds is presented in the section on bioaccumulation in birds.

17.3 BIOACCUMULATION

Selenium bioaccumulates in aquatic and terrestrial food chains and in higher trophic-level animals that feed on those plants and animals. Bioaccumulation is defined as the combined net accumulation (taking into account any concurrent loss) of a chemical from abiotic media and ingestion of selenium-containing biota (i.e., the food chain). In aquatic systems, bioaccumulation may occur by direct absorption or partitioning from water or sediment or by ingestion. The greatest level of bioaccumulation is typically from water to aquatic plants or invertebrates (often a 1000-fold or greater increase occurs). In terrestrial systems, bioaccumulation is primarily from ingestion, because uptake from air is less than that from water, and airborne concentrations generally are lower than those in water. When concentrations in animals are considered on whole-body basis (which is the appropriate perspective), selenium does not biomagnify through the various trophic levels. (Biomagnification is defined as increasing concentrations through successive trophic levels.) Nevertheless, significant bioaccumulation does occur (as described in this section) and leads to adverse effects in sensitive organisms (especially fish and birds; see next section).

This section presents a general summary of selenium bioaccumulation by plants and animals. Selenium concentrations typically are higher in marine organisms than in those from freshwater ecosystems, and they are higher in areas having seleniferous soils or sediments and in areas receiving industrial, agricultural, or municipal wastes. Additional information, including more detailed tabulations of selenium concentrations in biota, are provided by Jenkins,⁷³ Wilber,⁷¹ and Eisler.¹⁹

17.3.1 Plants

17.3.1.1 Aquatic

Background concentrations in freshwater algae are 0.1 to 1.5 mg Se/kg, and in rooted plants they are 0.1 to 2.0 mg Se/kg.^{17,19} By comparison, algae and rooted aquatic plants accumulated 20 to 390 mg Se/kg in Kesterson Reservoir, California, which received agricultural drainage waters containing up to 330 $\mu\text{g Se/L}$.⁴⁰⁻⁴² Selenium bioaccumulated in aquatic plants 28 to 5100 (mean =

1105) times the concentration in water.⁴² Elevated concentrations of selenium also have been found in plants from ponds receiving coal fly ash.^{74, 75}

The bioaccumulation and volatilization of selenium by wetland plants (referred to as phytoremediation) can be used to treat waterborne selenium under certain conditions. There was at least a 50-fold variation in selenium accumulation and volatilization among 20 aquatic species tested with water containing selenite or selenate.⁶⁶ Several of the aquatic plant species showed selenium volatilization and accumulation rates that were similar to that of Indian mustard (*Brassica juncea*), the best-known terrestrial plant species for phytoremediation. However, the overall implications of using vegetated wetlands to remove selenium from agricultural or industrial wastewaters are not yet well studied. This technology may be appropriate for waters containing moderate levels of selenium (perhaps up to 25 or 30 µg/L), but only if it is designed and managed to limit access by aquatic birds that would feed on plants and invertebrates in the wetland. However, at higher waterborne concentrations of selenium, or with inadequate attention to design and management concerns, the wetland could present undesirable levels of exposure to birds.

Several laboratory microcosm studies (summarized below) have measured selenium bioconcentration (i.e., direct uptake) by algae from water and subsequent transfer of selenium to invertebrates or fish consuming the algae. These studies show that the chemical form of the waterborne selenium is an important factor in affecting uptake by aquatic biota and that sulfate content of the water can influence uptake. These and other similar laboratory studies of aquatic systems show that selenium bioaccumulation is a significant mechanism of concern for higher trophic-level organisms.

Bioconcentration factors (BCFs) from water to macrophytes (rooted plants and filamentous algae), periphyton (algae and associated material attached to the wall of the microcosm), and zooplankton (daphnids and their offspring) were significantly higher for selenomethionine than for selenite, which in turn had higher bioconcentration factors than selenate.⁷⁶ Volatilization of selenium from the microcosms followed the same pattern (i.e., highest for selenomethionine at 24% loss during the 28-day exposure). For all three forms of selenium, bioaccumulation was higher in zooplankton than in periphyton, which had greater accumulation than macrophytes.

Another study by Besser et al.⁷⁷ with algae (*Chlamydomonas reinhardtii*), daphnids (*Daphnia magna*), and fish (bluegill, *Lepomis macrochirus*) also showed higher bioaccumulation from waterborne selenomethionine than from either selenite or selenate. Algae and daphnids concentrated selenium more strongly from selenite (BCFs = 220 to 3600) than selenate (BCFs = 65 to 500), whereas bluegills concentrated selenium about equally from both inorganic forms (estimated BCFs = 13 to 106). Bioaccumulation of foodborne selenium by daphnids and bluegills was similar in food chains dosed with different forms of selenium, and they did not accumulate selenium concentrations greater than those in their diet (except at very low dietary selenium concentrations). In exposures based on selenite, bluegills accumulated greater selenium concentrations from food than from water, and aqueous and food-chain uptakes were approximately additive. The results indicate that most of the accumulation of inorganic waterborne selenium by bluegills in selenium-contaminated environments is via food uptake. However, organoselenium compounds, such as selenomethionine, may contribute significantly to selenium bioaccumulation by bluegills through both aqueous and food-chain uptake.

Corixids (*Trichocorixa reticulata*), which are common insects in wetlands receiving agricultural drainage waters and are important food-chain organisms for fish and birds, were exposed to waterborne and foodborne selenium.⁷⁸ Algae (*Oscillatoria* sp. filaments and a *Microcystis*-type colonial alga), the food for the corixids, were exposed to water containing sodium selenate at selenium concentrations ranging from 7.3 to 870 µg/L for 48-h exposures. Corixids exposed to waterborne selenate did not accumulate selenium above control concentrations. Corixids fed algae exposed to ≥87 µg Se/L selenate had significantly higher selenium concentrations than controls, suggesting that corixids may be isolated from the water and that selenium accumulation is solely through dietary exposure.

Transfer of selenium also was followed through a laboratory food chain (water-algae-rotifers-larval fish), and its effects on the larval fathead minnows (*Pimephales promelas*) were evaluated.⁷²

Selenium uptake was measured in rotifers (*Brachionus calyciflorus*) fed algae (*Chlorella pyrenoidosa*) that had been cultured in a selenate-containing medium. The rotifers were then fed to larval fathead minnows, and uptake and loss of selenium as well as effects in the fish were measured. Selenium concentrations in the fish (51.7 and 61.1 $\mu\text{g/g}$ in two experiments) were similar to those in their food (68 and 55 $\mu\text{g/g}$). Final weights of larvae fed selenium-contaminated rotifers were significantly lower than those of controls, although mortality did not occur. Biological half-life of food-derived selenium in the fish larvae was 28 days.

Selenium concentrations in field-collected widgeongrass (*Ruppia maritima*) varied among samples from four evaporation pond systems in the San Joaquin Valley, California.⁷⁹ These plants were used as a substrate to measure selenium bioaccumulation and effects in a laboratory benthic-detrital food chain with midge (*Chironomus decorus*) larvae. Following a 96-h exposure, selenium concentrations had increased significantly in the three groups of larvae exposed to plants having the highest selenium concentrations, but there was no consistent pattern of adverse effects on larvae weights. After a 14-day exposure, selenium bioaccumulation patterns in midge larvae were similar to that observed after 96 h. However, as midge selenium concentrations increased, mean weight decreased, indicating that selenium apparently had a significant effect on growth. The results of this study complement other findings that indicate sediment and the detrital pathway are important in the cycling of selenium in aquatic systems.⁸⁰⁻⁸²

Waterborne sulfate reduces the uptake of selenium by plants when waterborne selenium is in the selenate form. Increasing sulfate resulted in significantly reduced selenate uptake by algae (*Selenastrum capricornutum*) and increased algal growth.⁸³ Sulfate also reduced selenium uptake from waterborne selenate by widgeongrass, but selenite and selenomethionine uptake were not affected by sulfate.⁸⁴ As in other studies summarized above, uptake of selenomethionine (BCFs up to 21,800) by widgeongrass was much higher than for selenite or selenate, and the highest rates of uptake (i.e., BCFs) occur at the lowest waterborne concentrations. Results of this and other field and laboratory studies show that waterborne selenium occurs under field conditions in a mixture of chemical forms, and BCFs therefore vary depending on the environmental conditions and sources of selenium.

17.3.1.2 Terrestrial

Background selenium concentrations in terrestrial plants are 0.01 to 0.6 mg/kg .^{17,85} Bioaccumulation of selenium by plants depends on the species of plant, environmental conditions, age and phase of plant growth, and the chemical form of selenium present.^{3,36,46,85,86} Some plants, such as white clover (*Trifolium repens*), buffalograss (*Buchloe dactyloides*), and grama (*Bouteloua* spp.), growing on seleniferous soils accumulate surprisingly low levels of selenium. In contrast, high sulfur-containing plants like the *Brassica* species (mustard, cabbage, broccoli, and cauliflower) and other Brassicaceae are relatively good accumulators of selenium.

Three groups of plants are generally recognized on the basis of their tendency to accumulate selenium when grown on high-selenium soils (as originally described by Rosenfeld and Beath³). The first two groups of plants are referred to as *selenium accumulator* or *indicator* plants. These plants grow well on soils containing high levels of available selenium, and some have been used to locate seleniferous soils. Plants in Group 1 are called primary indicators or accumulators and normally accumulate selenium to very high concentrations (often several thousand mg/kg). Plants in Group 2 are referred to as secondary accumulators and may contain a few hundred mg Se/kg in their tissues. Those in Group 3 include grains, grasses, and many other plants that do not normally accumulate selenium in excess of 50 mg/kg when grown on seleniferous soils. Deep-rooted shrubs and other plants with long tap roots may act as pumps, bringing selenium from the deeper soil profiles to the surface and near-surface soils, where it is available to shallower-rooted plants such as grasses.⁸⁷

Selenium concentrations in plants usually decline with maturity, so the highest concentrations usually occur during the most active growth phase.^{3,85} Because selenium is associated with protein in the plant, leaves usually contain higher selenium concentrations than seeds (e.g., see also Schuler

et al.⁴²). Although plant selenium concentration can generally be used as an indicator of soil selenium status,⁸⁵ total selenium concentrations in soil do not necessarily determine whether the plants growing there will induce toxicity or nutritional deficiency in animals.⁸⁸

Following the discovery of significant effects of selenium in aquatic birds feeding at Kesterson Reservoir, California, inflow of agricultural drainage water was halted, the reservoir was dewatered, and lower-elevation portions of the site were filled with soil to prevent groundwater from rising to the ground surface.^{89,90} Loss of this wetland habitat was mitigated through wetland enhancement in nearby areas. These actions converted the site to a mosaic of three terrestrial habitats, including areas that were filled, those higher-elevation areas where existing vegetation (mainly cattail, *Typha* sp.) was disked, and other higher-elevation grassland areas where no action was taken. Further descriptions of the site and its early history are provided by Ohlendorf⁷ and Ohlendorf and Hothem.⁹¹

Biological monitoring of Kesterson Reservoir has been conducted annually since 1988 and has included extensive sampling and analyses of soil (for total and water-extractable selenium), plants, invertebrates, birds (mainly their blood or eggs), and mammals.^{89,90} The chemical behavior of selenium in the Kesterson environment has been characterized through studies of selenium speciation and fractionation in soils, long-term monitoring of the spatial and depth distribution of selenium in soil, field-measured volatilization rates from several experimental plots, laboratory measurements of selenium reoxidation rates under controlled conditions, modeling studies of the above-mentioned data to determine reoxidation and leaching rates, and bioaccumulation by plants and animals at the site. This information was integrated to conduct ecological risk assessments in 1993 with the limited data set available at that time and again with a much larger data set in 2000.^{89,90}

The key factor in the exposure model for the site is the water-extractable selenium concentration in soil, which influences bioaccumulation by plants that form the base of the food chain. Although there is a highly significant ($P < 0.001$) increase in plant selenium with increasing water-extractable soil selenium, the relation between the two matrices is highly variable.^{89,90} Selenium concentrations vary somewhat from year to year and among plant species. For example, in 1995, the selenium concentration ranged from 0.20 to 90 mg/kg in 286 samples, with a geometric mean of 3.4 mg/kg; in 1998, the range in 240 samples was 0.20 to 68 mg/kg, with a geometric mean of 3.8 mg/kg.

Uptake and accumulation of selenium by plants growing on fly-ash landfills has been studied extensively and reviewed recently.¹⁸ Concentrations of selenium in vegetation vary by plant species, with legumes typically accumulating more selenium than grasses. Although some other elements (such as boron and molybdenum) also bioaccumulate in these plants, this does not occur to elevated concentrations as consistently as the bioaccumulation of selenium. Application of sulfur in the form of gypsum reduced the bioaccumulation of selenium in several plant species. Plants growing on fly-ash landfills can transport selenium to the surface and make it available to the surrounding environment. Reported concentrations of selenium in plants growing on or near these landfills are typically less than 10 mg/kg, although concentrations exceeding that level have been found in grass (*Phalaris arundinacea*), trees (*Populus deltoides*, *Salix* spp.), and herbaceous vegetation growing at the margin of an ash-settling pond and in plants growing in fly ash without soil cover.

17.3.2 Invertebrates

17.3.2.1 Aquatic/Marine

Background concentrations in aquatic invertebrates are 0.4 to 4.5 mg Se/kg, although concentrations are typically less than 2 mg Se/kg.^{12,17,19} Elevated concentrations have been reported in freshwater and estuarine invertebrates from areas receiving subsurface agricultural drainage,^{40–42,82,92} urban/industrial discharges,⁹³ and in ponds or lakes that received selenium-containing fly ash.^{75,94–96}

Among the aquatic invertebrates sampled at Kesterson Reservoir, California, selenium concentrations were highest in benthic species, such as midge larvae (Chironomidae) and dragonfly and damselfly nymphs (Odonata), and lowest in water boatmen (Corixidae).^{40–42} Mean concentrations

in some of the invertebrates from Kesterson Reservoir exceeded 100 mg Se/kg. Selenium concentrations in adult damselflies were significantly higher than in nymphs.⁴¹ Selenium bioaccumulation factors for invertebrates ranged from 168 to 3700 (mean = 1090).⁴² Most aquatic insects contained lower concentrations than rooted aquatic plants but higher concentrations than water, sediment, algae, and diatoms.

Midge larvae show small-scale spatial variability in selenium accumulation,⁹⁷ which probably reflects variability in concentration and bioavailability of selenium in sediment and perhaps the ages of the larvae. Grain size and organic carbon content can influence sediment selenium concentration and bioavailability. Consequently, when sampling/monitoring is being conducted to characterize dietary exposure of fish and aquatic birds that feed on midge larvae, it is important to analyze randomly collected, composited samples taken throughout the potential feeding area.

Laboratory experiments have indicated that 96% of selenium in mussels (*Mytilus edulis*) was obtained from ingested food, with much less accumulation directly from water than for several other elements.⁹⁸ Several other laboratory studies of the relative bioaccumulation in freshwater aquatic organisms from waterborne selenite, selenate, and selenomethionine are discussed above in the section on plants. At selenate concentrations greater than 5 µg Se/L, selenium uptake by daphnids (*Daphnia magna*) was inversely related to waterborne sulfate concentration.⁹⁹ Similar effects were reported for aquatic plants, as described above.^{83,84}

17.3.2.2 Terrestrial

Background concentrations in terrestrial invertebrates are 0.1 to 2.5 mg/kg.¹⁷ Earthworms were found to bioaccumulate elevated concentrations of selenium from selenite-enriched soil (up to 7.5 mg Se/kg, fresh weight¹⁰⁰), and earthworms from soil amended with sewage and those from a control field contained 15 to 22 mg Se/kg (dry weight).¹⁰¹

Extensive sampling of terrestrial invertebrates (various kinds of insects as well as spiders) has been conducted at Kesterson Reservoir, California since its conversion to terrestrial habitats in 1988 (described above and in Ohlendorf and Santolo⁸⁹). From 1989 to 1995, samples were collected annually, and sampling was conducted again in 1998.⁹⁰ Generally, selenium concentrations in carnivorous invertebrates (such as ambush bugs, scarab beetles, and spiders) were significantly higher than those in noncarnivorous insects (such as herbivorous beetles, crickets, and grasshoppers). For example, the geometric mean for 35 samples of carnivorous invertebrates in 1995 was 18 mg Se/kg (range 4.5 to 48 mg Se/kg), and the geometric mean for 110 samples of noncarnivorous insects was 7.4 mg Se/kg (range 0.60 to 40 mg Se/kg). In 1998, the geometric mean for 35 samples of carnivorous invertebrates was 17.1 mg Se/kg (range 8.1 to 36 mg Se/kg), and the geometric mean for 104 samples of noncarnivorous insects was 12.8 mg Se/kg (range 1.8 to 61 mg Se/kg).

17.3.3 Fish

17.3.3.1 Freshwater

Background concentrations in livers of freshwater fish are 2 to 8 mg Se/kg, and in other tissues they are 1.0 to 4.0 mg Se/kg.¹⁷ In the National Contaminant Biomonitoring Program, sampling of freshwater fish was conducted five times throughout the United States during the period 1976 to 1986.¹⁰² Geometric means for whole-body fish were between 0.4 and 0.5 mg Se/kg wet weight (or about 1.6 to 2.0 mg/kg dry weight) in all years, with the highest mean in samples from 1976 to 77. The 85th percentile values were 0.66 to 0.82 mg Se/kg wet weight (about 2.6 to 3.3 mg/kg dry weight). These values were typically exceeded at several stations, most of which are in arid areas of the western United States in basins containing substantial amounts of irrigated agriculture. One exception to that pattern is the Waikele Stream site at Waipahu, Hawaii, where the 85th percentile values were regularly exceeded.

Elevated levels of selenium have been reported in fish primarily from seleniferous areas of the western United States and from reservoirs contaminated by fly ash from combustion of coal.^{14,19,25,40,41,96,103-108} Typical patterns found in these fish (and those sampled elsewhere) are that selenium concentrations in muscle tissue are considerably lower than in livers, gonads, or whole-body fish. Selenium concentrations in gonads (and especially the eggs) as well as whole-body fish provide the best basis for evaluating exposure of the fish to selenium and the potential for adverse effects in the fish or their reproduction (as discussed in a later section). However, it is possible, especially if the fish of concern is an endangered species, to evaluate exposure through nonlethal sampling of muscle plugs or eggs so the fish is not sacrificed for analysis.

Mosquitofish (*Gambusia affinis*) from the selenium-contaminated Kesterson Reservoir contained exceptionally high concentrations of selenium.^{7,40,41} Fish were analyzed as composite samples of many individuals taken from different portions of the site, and concentrations were compared to those in mosquitofish from a nearby reference site. Mosquitofish from Kesterson typically contained geometric mean concentrations greater than 100 mg Se/kg, in comparison to 1 to 2 mg Se/kg at the reference site. In 1984, one composite sample from Kesterson contained 430 mg Se/kg, and the means for fish from two of the ponds exceeded 300 mg/kg.

Laboratory bioaccumulation studies discussed above describe bioaccumulation of selenium by fish in relation to different waterborne forms of selenium and illustrate the importance of dietary exposure as a route of selenium uptake by fish. Studies report more frequently the rates of uptake of different forms of selenium than depuration after exposure to uncontaminated media (food and water). In one study,⁸⁰ cycling and fate of selenite and selenomethionine were compared in a 318-day experiment in which the selenium was introduced as an acute release into two experimental ponds. Biotic components sampled included periphyton, rooted plants (*Elodea canadensis*), snails (*Helisoma* sp.), and mosquitofish. Uptake rates for selenomethionine in the biota were at least an order of magnitude greater than for selenite, but elimination rates were similar (different by less than a factor of two). This study also demonstrated the importance of sediment and organic detritus in the recycling/remobilization of selenium within the ponds.

17.3.3.2 Marine

Estuarine and marine fish tend to have higher selenium concentrations than do freshwater species, but the differences for most species are generally less than an order of magnitude and sometimes are very similar.¹⁹ Higher concentrations were found in species such as tunas and marlins. Selenium has been shown to accumulate with age/length in several studies of marine fish, and a positive correlation between selenium and mercury has been demonstrated in several species.¹⁰⁹ A positive correlation of selenium with mercury in fish may be a significant factor influencing bioaccumulation. One study has shown that a lower portion of selenium is present as selenate in marine fish (24%) than in freshwater fish (36%).¹¹⁰

Kasegalik Lake (on the Belcher Islands, Hudson Bay, in the southern Canadian Arctic) is known to have both salt- and freshwater populations of Arctic char (*Salvelinus alpinus*).¹¹¹ Fish of both types were analyzed for mercury and selenium. There was an apparent difference in the two populations for mercury concentrations, but there was no difference between salt- and freshwater groups for selenium (which varied from 0.7 to 1.9 mg Se/kg, wet weight). Thus, some of the apparent differences in selenium levels between marine and freshwater fish may be attributed to species differences as well as relationships between selenium and mercury in larger, long-lived marine species.

17.3.4 Amphibians and Reptiles

Background concentrations in livers of amphibians and reptiles are 2.9 to 3.6 mg/kg and in other tissues 1 to 3 mg/kg.¹⁷ Many fewer studies of selenium bioaccumulation in amphibians and

reptiles have been conducted than those of other animals,^{7,17,19} but information on bioaccumulation is summarized below.

17.3.4.1 Amphibians

Selenium concentrations in adult southern toads (*Bufo terrestris*) from coal-ash-settling basins (17.4 mg/kg, whole-body analysis) were elevated by comparison to toads from a reference site (2.10 mg/kg).¹¹² When other toads were transferred from the reference site to the settling basin for a period of 7 weeks, their concentrations increased significantly — from 2.10 mg Se/kg to 5.46 mg/kg. Sediments in the ash basin contained 4.4 mg Se/kg, whereas those at the reference site had 0.10 mg Se/kg. Frog (*Rana clamitans*) tadpoles from a fly-ash-contaminated pond contained 4.7 mg Se/kg (wet weight), whereas those from a reference site had 1.5 mg/kg.⁷⁵ Red-spotted newts (*Notophthalmus viridescens*) from those same sites contained 4.2 and 1.8 mg Se/kg (wet weight), respectively. Similarly, bullfrog tadpoles (*Rana catesbeiana*) from an ash-waste site had elevated selenium (25.7 mg/kg) by comparison to a reference site (3.4 mg/kg).¹¹³

Because tadpoles apparently accumulate metals readily from sediments and vegetation they consume, some authors (e.g., References 114, 115) have suggested that they may be good indicators of contaminated environments. To evaluate the effects of gut contents (especially ingested sediment) on analyses of bullfrog tadpoles, wild-caught tadpoles were maintained in clean water and analyzed after 0, 24, 48, and 72 h and then analyzed for metals to test the effects of “clearing” of the gut contents.¹¹⁵ Metals concentrations in whole bodies and digestive tracts also were evaluated separately. Selenium concentrations in the bodies and tails of the tadpoles were unaffected by clearing, although selenium concentration was higher in the digestive tract than in the body without digestive tract, in the tail, or in the whole body. The tadpoles had higher selenium concentrations than those found in the sediment from the sampling location.

Bullfrogs collected from reference sites in the San Joaquin Valley, California contained 1.0 to 1.9 mg Se/kg when analyzed as whole-body samples.¹¹⁶ Livers of three bullfrogs from other reference sites in the San Joaquin Valley contained 3.6 to 9.3 mg Se/kg (mean 6.2 mg/kg).¹¹⁷ The lower end of that range is probably representative of background, whereas the upper value may reflect some elevation above background. Few frogs were observed in nearby Kesterson Reservoir, probably because of the highly saline water it contained. However, ten bullfrogs were collected from the San Luis Drain (which conveyed agricultural subsurface drainage waters to Kesterson); livers of these bullfrogs contained 25 to 88 mg Se/kg (mean 45 mg/kg). These liver concentrations were similar to the selenium concentrations in aquatic insects and mosquitofish in the Drain.

17.3.4.2 Reptiles

Livers of banded water snakes (*Nerodia fasciata*) from ash-settling basins associated with a coal-burning electric power plant were analyzed for selenium and several other elements that were found at elevated levels in sediment within the basins.¹¹⁸ Selenium concentrations in the livers of snakes from these basins averaged about 140 mg/kg, compared to 3.62 mg Se/kg in livers of snakes from a reference site. Water snakes were found to be feeding on small bullfrogs and bullfrog tadpoles, green treefrogs (*Hyla cinerea*), southern toads, bluegill sunfish (*Lepomis macrochirus*), mosquitofish, red-fin pickerel (*Esox americanus*), and largemouth bass (*Micropterus salmoides*). Samples of those potential prey items were collected at the polluted ash-basin site and at the reference site. Mean selenium concentrations in the amphibians and fish from the polluted site were about 10 to 27 mg/kg, whereas those in amphibians and fish from the reference site were typically less than 2 mg/kg. Thus, the water snakes from the ash-basin site bioaccumulated selenium in their livers to concentrations about tenfold the prey diet concentrations, and those at the reference site had selenium concentrations that were about equal to the prey item levels. Selenium concentrations in livers showed a significant linear relationship with snake body mass.

Water snakes (*Nerodia* sp.) from Florida contained 0.3 to 0.5 mg Se/kg (whole body, wet weight).¹¹⁹ Whole-body selenium concentrations in lizards and snakes from reference areas in the San Joaquin Valley averaged 0.7 to 2.0 mg/kg.¹¹⁶ Livers of gopher snakes (*Pituophis melanoleucus*) from other reference sites in the San Joaquin Valley contained mean selenium concentrations of 2.05 and 2.14 mg/kg.¹¹⁷ Livers of gopher snakes from the nearby Kesterson Reservoir had a mean selenium concentration of 11.1 mg/kg. Selenium bioaccumulation in these snakes at Kesterson and associated reference sites reflected selenium levels in prey species for the snakes at those sites.

Selenium levels in the plasma of wild and farm-reared American alligators (*Alligator mississippiensis*) reflected selenium concentrations in their diet.¹²⁰ Plasma selenium levels in captive alligators fed fish (*Micropogon undulatus*) were significantly higher (monthly means of 0.23 to 0.27 mg/kg) than in captive animals fed nutria (*Myocastor coypus*) (0.16 to 0.23 mg/kg) or in wild females (0.15 to 0.20 mg/kg); plasma selenium levels in the alligators fed nutria and in the wild females were not significantly different from each other. Fish contained 2.8 mg Se/kg (dry weight), compared to only 0.04 mg/kg (wet weight) in the nutria. Diet of the wild alligators was composed primarily (~70%) of nutria.

17.3.5 Birds

Background concentrations in whole-body birds are < 2 mg/kg.¹⁷ However, bioaccumulation in birds is more frequently (and appropriately) evaluated on the basis of various tissues, as discussed below.

17.3.5.1 Eggs

Mean background concentrations in eggs of freshwater and terrestrial species are < 3 mg Se/kg (typically 1.5 to 2.5 mg/kg), and maximums are < 5 mg Se/kg.^{17,19} In a wide variety of species, selenium concentrations (on a dry-weight basis) in bird eggs range from roughly equivalent to about three or four times the concentrations in the diet of the female at the time of egg-laying.^{7,121–127}

When birds feed on selenium-contaminated diets during the laying season, the exposure is quickly reflected by elevated levels of selenium in eggs.¹²⁸ Similarly, when the birds are switched to a clean diet, selenium concentrations in eggs decline quickly. When mallard (*Anas platyrhynchos*) hens were fed a diet containing 15 mg Se/kg (as selenomethionine), levels peaked in eggs (to about 13 to 20 mg Se/kg, wet weight) in about 2 weeks on the treated diet and leveled off at a relatively low level (<5 mg Se/kg, wet weight) after about 10 days back on the untreated diet. The findings of this study have important implications for evaluation of field exposures, such as how quickly and for what duration selenium exposure may adversely affect bird reproduction. Concentrations of selenium in eggs are especially important because they provide the best samples for evaluation of potential adverse reproductive effects (see also later section).¹²⁹

Selenium concentrations in the eggs of marine species are variable but may be higher, even in remote areas.⁷ For example, eggs of three species (wedge-tailed shearwater [*Puffinus pacificus*], red-footed booby [*Sula sula*], and sooty tern [*Sterna fuscata*]) were sampled at four locations throughout the Hawaiian archipelago, from Oahu to Midway.¹³⁰ Mean concentrations (converted from wet weight) varied only slightly by location — from 4.4 to 5.3 mg Se/kg for shearwaters, 5.0 to 6.1 mg Se/kg for boobies, and 4.1 to 5.1 mg Se/kg for terns — but all were higher than typical of freshwater species. Surprisingly low selenium concentrations were found in eggs of white-winged scoters (*Melanitta fusca*) when compared to the concentrations of selenium found in their livers.¹³¹

Elevated selenium concentrations have been found in eggs of birds nesting in areas affected by agricultural drainage, coal-fly-ash disposal, and discharge from an oil refinery.^{7,25,91,129,132,133} At Kesterson Reservoir, California, mean selenium concentrations in bird eggs during 1983 to 1985 were as high as 69.7 mg/kg (in eared grebes [*Podiceps nigricollis*]), with many of the species means exceeding 20 mg Se/kg.⁹¹ Some success in reducing selenium exposures of aquatic birds at evap-

oration ponds for agricultural drainage water was achieved by placing freshwater mitigation ponds near the contaminated ponds.¹³⁴

17.3.5.2 Livers

Background concentrations in bird livers are $< 10 \text{ mg Se/kg}$.¹⁷ In a manner similar to that for eggs, Heinz et al.¹³⁵ found that selenium concentrations in the liver respond quickly when birds are placed on or taken off a selenium-contaminated diet (see further description of this study below under Muscle). Thus, selenium concentrations measured in the livers of birds sampled outside the breeding season are not good predictors of potential reproductive effects. In laboratory studies of reproductive effects, livers of male mallards had higher concentrations of selenium than those of females, probably because females excreted part of the selenium they had accumulated through egg-laying.^{121,122} Nevertheless, analysis of livers of either male or female field-collected birds can provide a useful indication of the relative level of exposure experienced by the population.

In laboratory studies with birds fed diets containing selenomethionine, selenium concentrations in livers of mallards, black-crowned night-herons (*Nycticorax nycticorax*), and eastern screech-owls (*Otus asio*) ranged from roughly equal to the dietary concentration to about three times the dietary level.¹²¹⁻¹²⁶

At Kesterson Reservoir and a nearby reference site, several species of aquatic birds were sampled early and late in the nesting season as adults, and juveniles were sampled at about the same time as the late-season adults.¹³⁶ Selenium concentrations in livers of these birds were consistently much higher at Kesterson than at the reference site for both early and late samplings and seemed to reflect the period of exposure as well as the foraging range of the birds at the two sites. For example, adults of the more mobile species (such as dabbling ducks, *Anas* spp.) showed only three- to fivefold differences in mean selenium concentrations between sites, whereas more sedentary species (such as American coot [*Fulica americana*] and black-necked stilt [*Himantopus mexicanus*]) typically showed 10- to 20-fold differences. Selenium concentrations in juvenile birds were generally similar to those in late-season adults.

Selenium concentrations in the livers of aquatic birds from a number of other areas receiving subsurface agricultural drainage also were elevated and have reflected periods of residence in the contaminated areas.^{25,137-139} When use of subsurface agricultural drainage waters for wetland management was curtailed and replaced with better-quality water, selenium concentrations in aquatic birds declined.

Livers of diving ducks (such as scoters [*Melanitta* spp.] and scaups [*Aythya* spp.]) from estuarine habitats have been found to contain higher concentrations of selenium than other aquatic birds in the same habitats.¹⁴⁰⁻¹⁴³ The apparent reason for the higher concentrations of selenium in the diving ducks is that they forage on benthic organisms, which bioaccumulate selenium to a higher degree than foods of some of the other aquatic birds.

17.3.5.3 Kidneys

Selenium concentrations in kidneys of birds from selenium-normal areas were somewhat higher than those in the liver (liver/kidney ratios of less than L), but concentrations in the two tissues were similar in birds from selenium-contaminated Kesterson Reservoir and in the Imperial Valley of California.^{136,144,145} Selenium concentrations in American coots from Kesterson Reservoir and the reference site were significantly correlated ($r = 0.98$). Significant ratios and significant positive correlations also have been found in other field studies (e.g., Reference 146).

17.3.5.4 Muscle

Background selenium concentrations in muscle tissues of birds are 1 to 3 mg/kg.¹⁷ Concentrations increase and decrease in response to changes in dietary exposure, but the changes occur more

slowly than those in eggs or liver.¹³⁵ However, for muscle as well as other tissues, when tissue levels of selenium are made very high by elevated dietary exposures and the birds are then placed on a lower-selenium diet, the loss rate for all tissues is fast at first but then slows down.

Mallards were placed on a diet containing 10 mg Se/kg for 6 weeks; predicted equilibrium time for concentrations in the breast muscle of females (81 days) was more than ten times that for time to equilibrium in the liver (7.8 days).¹³⁵ The ducks were then provided an untreated diet for 6 weeks, and loss of selenium from liver and muscle was monitored; half-times were 18.7 days for liver and 30.1 days for muscle. Males reached similar levels of selenium in the liver and breast muscle as females and declined to similar levels when treatment ended. In another experiment with mallards, females were fed increasing levels of selenium until some died; survivors were then switched to an untreated diet and selenium was measured in blood, liver, and breast muscle over 64 days. Half-times were 9.8 days for blood and 23.9 days for muscle. Selenium initially decreased in liver by one-half in 3.3 days, with subsequent half-times of 3.9, 6.0, and 45.1 days.

Selenium concentrations in breast muscle from juvenile ducks (*Anas* sp.) at Kesterson Reservoir and a reference site were measured because of concern about human consumption of ducks harvested in the vicinity of Kesterson.¹³⁶ Mean selenium concentrations were higher at Kesterson than the reference site and were only slightly lower than those in livers of these birds. However, the relationships between muscle and liver ($r^2 = 0.69$) of the ducks were considerably more variable than those between kidneys and livers of American coots from the two sites ($r^2 = 0.97$).

17.3.5.5 Blood

Background concentrations in whole blood are 0.1 to 0.4 mg Se/kg on a wet-weight basis.¹⁷ In experimental studies, selenium concentrations in blood of mallards and American kestrels (*Falco sparverius*) reflected dietary exposure levels.^{127,135,147-149} In kestrels, maximal blood concentrations were about the same as those in the selenomethionine-supplemented diet. Mallards receiving selenium (as selenomethionine) at dietary concentrations of 10, 25, or 60 mg/kg had blood-selenium concentrations of 4.5, 8.9, or 16 mg/L (wet-weight basis).¹⁴⁸ The concentration of selenium in blood increased in a time- and dose-dependent manner and reached a plateau after 40 days. (The study by Heinz et al.¹³⁵ is described in the previous section.)

Selenium concentrations were measured in terrestrial birds of several species from Kesterson Reservoir, the area surrounding that site, and several reference areas in California from 1994 to 1998.¹⁵⁰ Except for loggerhead shrikes (*Lanius ludovicianus*), blood-selenium was higher in birds from within Kesterson than in birds from other areas. For shrikes, the mean concentrations for birds from Kesterson (13 mg Se/kg [dry weight]) were not significantly different than those from nearby surrounding areas (8.5 mg Se/kg), although the maximum selenium concentration at Kesterson (38 mg/kg) was more than twice the maximum for the surrounding area (16 mg/kg). Among species at Kesterson Reservoir, blood-selenium was higher in loggerhead shrikes and northern harriers (*Circus cyaneus*) than in the other species (hawks and owls) sampled.

17.3.5.6 Feathers

Background concentrations of selenium in feathers are 1 to 4 mg/kg and are typically less than 2 mg/kg.¹⁷ Selenium concentrations may be higher in the feathers of birds from areas with elevated levels of mercury because of the interactions between these two elements.

Analysis of feathers may provide useful information concerning exposures of birds to selenium if they are considered carefully. It is important to recognize that the selenium may have been deposited into the feathers at the time they were formed (which may have been months earlier and thousands of miles away from the sampling time and location), or the selenium may be the result of external contamination.¹⁵¹⁻¹⁵⁴ Concentrations also may have been reduced through leaching. Different kinds of feathers from the same bird may contain different concentrations, depending partly on when and where the feathers were grown during the moult cycle.

Feathers of five species of seabirds were sampled at Johnston Atoll (about 1300 km southwest of Hawaii) and three species at Manana Island, Oahu, Hawaii, and analyzed for selenium and several other elements.¹⁵⁵ Selenium concentrations were generally higher in brown noddies (*Anous stolidus*) than in other species at both locations, and noddies had significantly higher concentrations at Johnston Atoll (11.1 mg Se/kg) than Hawaii (7.59 mg Se/kg).

17.3.6 Mammals

Background whole-body selenium concentrations in terrestrial and freshwater mammals are < 1 to 4 mg/kg.¹⁷ In muscle, concentrations are typically < 1 mg Se/kg; in liver, they range from about 1 to 10 mg Se/kg and are typically ≤ 5 mg/kg; in hair, normal concentrations are < 3 mg/kg in individual samples, with population averages ranging from 0.5 to 1.5 mg Se/kg; selenium in whole blood is typically 0.1 to 0.5 mg/L, with concentrations below 0.1 mg/L indicating a deficiency in domestic livestock. Both hair and blood are considered good media for sampling/monitoring selenium status of live mammals.

17.3.6.1 Aquatic/Marine

Selenium concentrations in raccoons (*Procyon lotor*) collected at Kesterson Reservoir, California averaged 19.9 mg/kg in liver, 28.3 mg/kg in hair, 21.6 mg/kg in feces, and 2.61 mg/L in blood (wet weight in blood, others in dry weight).¹⁵⁶ These concentrations were 12, 30, 21, and 10 times higher, respectively, than those found in raccoons from a nearby reference site. Selenium concentrations in hair provided the strongest statistical separation between the two study areas. Selenium concentrations in raccoons and river otters (*Lontra canadensis*) at sites in Canada were similar to each other, but they were higher than those found in beavers (*Castor canadensis*).¹⁵⁷

Selenium concentrations in the tissues of marine mammals are highly variable, with some animals having concentrations in the liver or other tissues that are typical of mammals in freshwater or terrestrial environments and others (even of the same species in the same areas) having greatly elevated levels.^{19,109} Part of this variation may be due to interactions between selenium and mercury, with much greater bioaccumulation (especially as reflected by concentrations in the liver) when the animals are exposed to elevated levels of mercury.

Selenium concentrations greater than 100 mg/kg have been reported for livers of pilot whales (*Globicephala macrorhynchus*),¹⁵⁸ beluga whales (*Delphinapterus leucus*),¹⁵⁹ striped dolphins (*Stenella coeruleoalba*),¹⁶⁰ bottle-nosed dolphins (*Tursiops truncatus*),¹⁶¹ ringed seals (*Phoca hispida*),¹⁶² harbor seals (*P. vitulina*),¹⁶³ gray seals (*Halichoerus grypus*),¹⁶⁴ and California sea lions (*Zalophus californianus*).¹⁶⁵

17.3.6.2 Terrestrial

Mean selenium concentrations in several species of small mammals at Kesterson Reservoir, California, were greatly elevated by comparison to a nearby reference area.¹⁶⁶ For example, means for California voles (*Microtus californicus*) from Kesterson were as much as 522 times those from the reference area (means up to 119 mg Se/kg vs. 0.228 mg Se/kg in livers). There were species-to-species differences at Kesterson; higher selenium concentrations occurred in carnivorous species and species that fed on foods closely linked to the pond water. There were also pond-to-pond differences at Kesterson, with mammals reflecting a pattern similar to that for aquatic organisms (described above).

Following the conversion of Kesterson Reservoir to a terrestrial habitat in 1988 (as described above), selenium concentrations in small mammals have been monitored periodically.^{89,90} Mean whole-body selenium concentrations in mice on a site-wide basis are typically 5 to 7 mg Se/kg and tend to be lower in voles than in mice. However, the selenium levels tend to vary spatially

within the site, especially as related to habitat type and history of management activities that have altered the site since it served as a reservoir for agricultural drainage waters.

Elevated levels of selenium were found in woodchucks (*Marmota monax*) from the vicinity of a fly-ash landfill,¹⁶⁷ and in American bison (*Bison bison*), elk (*Cervus elaphus*), and mule deer (*Odocoileus hemionus*) that ate forage with elevated levels of selenium in Wyoming.¹⁶⁸ In contrast, analysis of blood from free-ranging mule deer sampled from a number of herds in California indicated the deer were selenium-deficient.^{169–173} Several methods of selenium supplementation to the deer were tested; some were more practical and effective than others and resulted in increased reproductive performance of the herds.

17.4 EFFECTS IN ANIMALS

17.4.1 Nutritional Requirements vs. Toxicity

Selenium is essential for animal nutrition at sub-mg/kg dietary concentrations, but it is toxic to sensitive species when concentrations are only a few mg/kg. For most animals, dietary requirements appear to fall in the range between about 0.05 and 0.5 mg/kg.^{5,19,46,56,174–179} Thresholds for toxicity are usually not much more than an order of magnitude higher than the concentrations that cause deficiency (as described below). Selenium deficiency is a more widespread problem for animal health than is excess selenium, so the issue of selenium ecotoxicology is one of balance between meeting the dietary requirements without exceeding toxicity thresholds. Signs of selenium deficiency have been reported in many domesticated species (including chickens, turkeys, pheasants, quail, ducks, cattle, horses, goats, sheep, and swine) as well as wild species (including species such as fish, bighorn sheep [*Ovis canadensis*], pronghorns [*Antilocapra americana*], elk, and deer). In poultry, selenium deficiency causes severe pancreatic atrophy as well as reduced egg production and hatchability; in mammals it causes poor health and reproduction. One of the more common myopathies resulting from selenium deficiency (referred to as “white muscle disease”) has been reported in at least 30 of the 50 U.S. states.

Selenium deficiency in some species can be ameliorated through a variety of means including addition of selenium to diets of domestic species, use of intraruminal boluses that release selenium slowly, and application of selenium-containing fertilizers to grazing lands.^{5,176–179} Selenium fertilization and use of intraruminal boluses have been tested for improvement of reproduction in free-ranging mule deer, sometimes with significant benefit.^{170,172,173} However, selenium deficiencies in other kinds of wildlife may not be corrected as easily as those in species such as deer.

17.4.2 Toxic Effects

Selenosis and selenium toxicosis are used interchangeably to refer to the pathological conditions resulting from ingestion of high-selenium diets. Those conditions include impaired health and reproduction, as discussed below in relation to vertebrate animals. When water is the only exposure route, selenium is not very toxic to fish or wildlife.^{17,20,57} Eggs and larvae of fish and amphibians may be the most sensitive life stages of vertebrate animals to direct effects of waterborne selenium. Eggs and larvae of fish and birds are very sensitive to the lethal or teratogenic effects of selenium transferred to the eggs by the female parent (as discussed below).

17.4.2.1 Invertebrates

Invertebrates are not particularly sensitive to the toxic effects of selenium, and there is limited information concerning adverse effects to invertebrates under field conditions.¹⁷ In laboratory studies, selenite was found to be more toxic than selenate, regardless of whether the effects were

measured as direct toxicity or impairment of reproduction.^{20,180,181} Duration of exposure is also an important factor, with toxicity increasing as exposure time increases, at least up to 14 days. For example, the 96-hour LC₅₀ for the scud (*Hyaella azteca*) was 340 µg Se/L or 760 µg Se/L in different studies,^{182,183} whereas the 14-day LC₅₀ was only 70 µg Se/L.¹⁸⁴ Similarly, for the *Daphnia magna* the 96-hour LC₅₀ was 710 µg Se/L and the 14-day LC₅₀ was 430 µg Se/L.¹⁸⁴

In a comparison involving the cladoceran *Daphnia magna* and larvae of the midge *Chironomus riparius*, the daphnids were more acutely sensitive than midges to the toxic effects of inorganic selenium.¹⁸⁵ An organic form of selenium (selenomethionine) was toxic to daphnids but relatively nontoxic to midges. Tissue concentrations of 14.7 and 31.7 mg Se/kg in daphnids were associated with reduced growth and reproduction, respectively. Nevertheless, these invertebrates were not adversely affected at waterborne concentrations that would affect fish or would bioaccumulate in the food chain to levels that are harmful to fish or aquatic birds.

In evaluating the potential for selenium to cause toxicity to aquatic invertebrates, it is important to note that other elements can affect the toxicity of selenium. For example, sulfate can reduce the bioavailability and toxicity of selenate selenium (the predominant form in many water bodies) to invertebrates.⁹⁹

Biologically incorporated selenium (presumably in organic forms) in widgeongrass from agricultural drainwater evaporation ponds in the San Joaquin Valley, California, caused significant reductions in growth of midge (*Chironomus decorus*) larvae that were cultured on detrital material from these plants.⁷⁹ Significant reductions in growth were observed in midges exposed to plant substrate having more than about 10 mg Se/kg, and relative bioaccumulation (as BAF) was inversely related to selenium concentrations in the plant material (i.e., a relatively smaller amount was taken up when concentrations were greater than 20 mg Se/kg).

17.4.2.2 Fish

Several recent publications provide reviews of the effects of selenium in fish and describe case studies of such effects.^{12,14,17,19,23,25,186,187} Those references provide more detailed descriptions of tissue or exposure media concentrations that are associated with no effects or with adverse effects in fish. Some also emphasize that a combination of biological (e.g., condition of larvae/fry, reproductive success, etc.) and chemical (e.g., analysis of ovaries/eggs, whole-body fish, or food-chain organisms) indicators should be used in evaluating risks to fish populations. The mortality of larvae/fry that is associated with excess selenium can have important effects on populations, resulting in lack of recruitment and subsequent declines or disappearance of affected species in a contaminated water body without evidence of “die-offs.” Given enough time, once the levels of selenium input are reduced, populations may recover; however, contaminated sediments will serve as a continuing source for selenium cycling.¹⁸⁸

Excess selenium in the diet of fish leads to substitution of selenium for sulfur during protein synthesis, among other effects.²³ Substitution of selenium for sulfur disrupts normal chemical bonding, resulting in improperly formed and dysfunctional proteins or enzymes. This causes a variety of toxic effects at subcellular, cellular, organ, and system levels.^{103,189} These effects are exhibited through effects on reproduction (especially in the form of teratogenesis) and reduced survival of young fish as well as effects on health, physiology, and survival of older fish.

There is general agreement that early life stages (i.e., eggs, larvae, and fry) are more sensitive to the adverse effects of excess selenium than are adult fish, and that some species of fish are more sensitive than others.^{14,17,23,186,190} Selenium concentrations in the ovary/eggs as well as those in whole-body fish and the diet are most useful in evaluating risks of adverse effects (i.e., more useful than selenium concentrations in water or sediment, or in livers or other tissues). However, there is no uniform agreement on the selenium concentrations that represent thresholds for adverse effects.

Selenium concentrations in ovaries/eggs are considered to represent a threat of adverse effects when they are greater than 10 mg/kg,^{14,23,190} 7 to 13 mg/kg,¹⁷ or 17 mg/kg.¹⁸⁶ At concentrations

exceeding the threshold, there is a large increase in the occurrence of teratogenic deformities and a concomitant reduction in survival of the larvae/fry. Although many of the larvae/fry die as a result of the deformities, some fish may survive and have noticeable deformities as adults. Selenium-related deformities observed in fish larvae and fry are due to their absorbing/using the yolk from the egg, which contains elevated levels of selenium deposited there by the female parent for their nourishment and development. Feeding excess but sublethal levels of selenium to fry, juvenile fish, or adult fish does not cause deformities such as those caused through maternal transfer of selenium to the egg.^{191–193}

Examples of the kinds of teratogenic deformities that are caused by selenium are provided by Lemly.²³ The typical deformities include lordosis (concave curvature of the lumbar region of the spine), scoliosis (lateral curvature of the spine), kyphosis (convex curvature of the thoracic region of the spine, resulting in a “humpback” condition), missing or deformed fins, missing or deformed gills and gill covers (opercle), abnormally shaped head, missing or deformed eyes, and deformed mouth.

Selenium concentrations in whole-body fish are considered to represent a threat of adverse effects to health or reproductive success when they are greater than 4 mg/kg^{14, 190} or greater than 4 to 6 mg/kg;¹⁷ however, DeForest et al.¹⁸⁶ evaluated results of available studies and considered the threshold to be 6 mg/kg for cold-water and anadromous species and 9 mg/kg for warm-water fish. These differences in values result from different interpretations of the available information from the various studies. Despite the differences, however, it is important to note that whole-body selenium concentrations in the range of 4 to 9 mg/kg are recognized to reflect risk of adverse effects in fish.

Threshold selenium concentrations in the diet of fish that are associated with adverse effects have been estimated as 3 mg/kg,^{14, 190} as 3–8 mg/kg,¹⁷ or separately as 11 mg/kg for cold-water and anadromous species and 10 mg/kg for warm-water fish.¹⁸⁶ As described in the previous section (Bioaccumulation), different forms of selenium bioaccumulate at very different rates in food-chain organisms, with selenomethionine > selenite > selenate. These differences in bioaccumulation can greatly affect the degree of risk associated with particular waterborne selenium concentrations. However, studies indicate that once the selenium is biologically incorporated in the food organisms, the risk to fish is similar at equivalent dietary concentrations.

In waterborne exposures, organic selenium (selenomethionine) also is much more toxic than selenite, which is more toxic than selenate. For example, the 96-hour LC₅₀ values for bluegill (13 µg Se/L) and striped bass (*Morone saxatilis*; 4 µg Se/L) based on selenomethionine were only a small fraction of the LC₅₀s for selenite (7800 to 13,000 and 1000 µg Se/L, respectively) and selenate (98,000 and 39,000 µg Se/L).¹⁸¹ However, as duration of exposure increases, the toxicity of selenium increases. For example, when selenium was introduced to outdoor experimental streams at 10 or 30 µg/L, all adult bluegill sunfish at the higher exposure level died in less than a year, and there also was significantly reduced survival of those at 10 µg Se/L when compared to controls.¹⁹⁴ Exposure of adults at both 10 and 30 µg Se/L for 40 weeks before spawning resulted in reduced embryo and larval survival and produced larvae with a high incidence of edema, lordosis, and internal hemorrhaging.

17.4.2.3 Amphibians and Reptiles

There is only limited information about the toxic effects of selenium in amphibians, and there is even less information about its effects in reptiles.^{17,19,195–198}

In laboratory exposures, amphibian embryos and tadpoles were about as sensitive as aquatic invertebrates and fish larvae/fry to the effects of waterborne inorganic selenium.^{199–201} In short-term toxicity tests (typically 96-h exposures, but up to 3 days) with the South African clawed frog (*Xenopus laevis*), LC₅₀ values for both selenite and selenate were 1500 µg Se/L or greater. Not surprisingly, the LC₅₀ values decrease as exposure duration increases. The 7-day LC₅₀ for this species was 456 µg Se/L, but in a 7-day exposure with narrow-mouthed toad (*Gastrophryne carolinensis*)

embryos, the LC_{50} values was only $90 \mu\text{g Se/L}$.^{202, 203} The low value for the narrow-mouthed toad apparently reflects species differences in sensitivity or perhaps differences in exposure conditions.

Adult and larval amphibians exposed to trace elements in coal combustion waste ponds showed physiological and morphological changes as well as bioaccumulation of some elements.^{112, 113} For example, tadpoles of the bullfrog collected in a coal-ash basin and a downstream drainage swamp had a reduced number of labial teeth and deformities of labial papillae when compared with tadpoles from reference areas. Tadpoles with deformities were less able to graze periphyton than were normal tadpoles, and they had lower growth rates. These tadpoles had significantly elevated concentrations of selenium (25.7 mg/kg) by comparison to a reference site (3.37 mg/kg). They also had significantly greater concentrations of arsenic, barium, cadmium, and chromium than those from the reference site, but they did not significantly bioaccumulate copper or lead in comparison to the reference site. Thus, it is not possible to determine which elements caused the effects.

Banded water snakes from a site contaminated by coal combustion wastes had high concentrations of trace elements, especially selenium and arsenic but also cadmium, chromium, and copper, by comparison to snakes from a nearby reference site.¹¹⁸ (Results of analyses of livers and potential prey items were summarized in a previous section.) Snakes from the ash-basin site exhibited mean standard metabolic rates 32% higher than snakes from the reference site. The authors concluded that snakes from the contaminated site probably allocate more of their energy to maintenance and theoretically should have less energy available for growth, reproduction, and storage.

17.4.2.4 Birds

Selenium has been identified as the agent responsible for mortality and reproductive failure in birds at a number of sites in the United States (see USDI¹⁷ and Skorupa²⁵ for a partial list). Much of the research evaluating the effects of selenium in birds has been related primarily to discharges of subsurface agricultural drainage water,^{7, 129} but effect levels in bird diets and eggs probably are similar once the selenium has been accumulated by food-chain organisms.

Selenium became recognized as a significant environmental contaminant for wildlife in 1983, with the discovery of developmental abnormalities and excessive embryonic and adult mortality in aquatic birds at Kesterson Reservoir, California.^{7, 91, 132, 144, 204, 205} Observations in the field were corroborated through a series of laboratory studies that documented the association between excessive dietary selenium and effects on reproduction and young birds as well as adult health, physiology, and survival. Those effects are described in several other reviews (e.g., References 4, 7, 8, 13, 17, 19, 25) and are summarized below.

17.4.2.4.1 Reproduction and Young Birds

Prior to the 1980s, most studies of avian reproductive effects in relation to selenium were conducted with domestic poultry.^{4, 7, 13} Studies of wild birds to determine the effects of selenium on reproduction and other aspects of avian biology have been conducted in the field and in the laboratory since 1983. Reproductive effects of selenium reported in wild aquatic birds and domestic poultry include embryo mortality and teratogenesis as well as the failure of adult birds to nest.

Excess selenium in the diet of female birds during the period just before egg-laying results in transfer of selenium to the eggs at harmful levels, although the sensitivity varies among species.^{7, 8, 13, 25, 128, 129, 206} Characteristic effects observed in the field and laboratory studies include reduced hatchability of eggs (due to embryo mortality) and high incidence of developmental abnormalities (due to teratogenesis). Selenium-induced abnormalities are often multiple and include defects of the eyes (microphthalmia and possible anophthalmia [i.e., abnormally small or missing eyes]), feet or legs (amelia and ectrodactylia [absence of legs or toes]), beak (incomplete development of the lower beak, spatulate narrowing of the upper beak), brain (hydrocephaly and exencephaly [fluid accumulation in the brain and exposure of the brain]), and abdomen (gastroschisis [an open fissure

of the abdomen]). Most of these abnormalities are illustrated through photographs that have been published elsewhere (e.g., References 4, 7, 8, 132, 144).

Reproductive effects have been produced in laboratory dietary studies using both organic and inorganic forms of selenium (e.g., in mallards and domestic chickens [*Gallus gallus*]).^{4,121,122,124,125,207–210} Selenomethionine, the most bioavailable and toxic of the different selenium compounds studied, is associated with reduced reproductive effects in mallards at dietary concentrations as low as 7 mg Se/kg.¹²⁵ This form of dietary selenium has been found to be the best surrogate for use in feeding studies to parallel the dose-effect levels found in field studies with birds.

Studies at Kesterson Reservoir showed there was poor hatching success of fertile eggs of a number of aquatic bird species^{7,204} and that there was also poor survival of those young that did hatch.^{7,211} This was attributed to high levels of selenium in the diet of the breeding females as well as the diet of newly hatched birds. Most aquatic insects at Kesterson had mean selenium concentrations greater than 100 mg/kg, and some composite samples exceeded 300 mg/kg.^{40–42} Mallard ducklings were fed diets containing either sodium selenite or selenomethionine at concentrations of 0, 10, 20, 40, or 80 mg Se/kg from hatching to 6 weeks of age.²¹² Among ducklings that received selenomethionine, 100% of the group receiving 80 mg Se/kg died in less than 6 weeks, and 12.5% of those that received 40 mg Se/kg died during the exposure period.

Predictive criteria for avian selenosis were developed through a broad-scale program that collected response data for avian teratogenesis at selenium-impacted and reference aquatic sites in the San Joaquin Valley, California.^{17,206} The largest cumulative sampling effort occurred within the Tulare Basin area in the southern San Joaquin Valley. In the Tulare Basin, evaporative disposal of subsurface irrigation drainage water was accomplished by letting it evaporate from 25 shallow impoundments. Even though the impoundments were not constructed to attract wildlife and were devoid of emergent vegetation (i.e., cattails, bulrush, etc.), large populations of nesting waterbirds used the sites. Two of the most abundant waterbirds that nested at the evaporation basins were American avocets (*Recurvirostra americana*) and black-necked stilts (*Himantopus mexicanus*). Water discharged to the evaporation basins contained from < 1 to > 1000 µg Se/L; consequently, selenium concentrations in eggs from this region spanned four orders of magnitude (< 1 to > 100 mg/kg egg selenium).

Using data on selenium in eggs from the Tulare Basin, combined with data from several other western sites where elevated selenium was found, a detailed exposure-response relationship was documented.^{17,25,206} Statistically distinct teratogenesis response functions were delineated for ducks, stilts, and avocets using the Tulare Basin data. The Tulare curves were used to estimate expected frequencies of teratogenesis for ducks, stilts, and avocets using other sites, and the predicted levels were tested against the observed frequencies from the sites. The predicted and observed frequencies of teratogenesis were not significantly different, and therefore the data were combined to generate final response curves. Using this data set, Skorupa²⁰⁶ developed species-specific response curves for stilts and avocets and a composite duck curve (using combined data from gadwalls [*Anas strepera*], mallards, pintails [*A. acuta*], and redheads [*Aythya americana*]).

Based on the response coefficients and their standard errors, the teratogenesis function for ducks, stilts, and avocets were significantly different.²⁰⁶ Within this data set, these responses represent “sensitive” (duck), “average” (stilt), and “tolerant” (avocet) species. The probability of overt teratogenesis in stilts increases markedly when selenium concentrations are greater than 40 mg/kg, with an EC₁₀ for teratogenic effects of 37 mg/kg. In contrast, the threshold for teratogenesis (expressed as an EC₁₀) in mallards is 23 mg/kg, and in avocets it is 74 mg/kg.

A more sensitive measure of avian selenosis is reduced egg hatchability due to embryo inviability.^{17,25,206} Egg selenium concentrations that cause embryo inviability are usually below the levels that cause embryo deformities. The threshold for mean egg selenium associated with impaired egg hatchability at the population level for black-necked stilts (and, therefore, the embryotoxicity threshold) was estimated to be 6 to 7 mg/kg. This threshold is approximately equivalent to the EC₁₀ on a clutchwise (or henwise) basis and the EC₀₃ on an eggwise basis.³³ Skorupa²⁰⁶ used more than

400 sample eggs from black-necked stilt nests monitored at Tulare Basin, Kesterson Reservoir, and Salton Sea, California to identify the background rate of inviable stilt eggs (8.9%) and developed the following equation to determine the number of clutches containing at least one inviable embryo:

$$Y = \exp(-2.327 + 0.0503X)/(1 + \exp(-2.327 + 0.0503X)); r^2 = 0.18 \quad (17.1)$$

where Y is the probability of ≥ 1 inviable egg in a sampled clutch based on selenium concentration in a random sample egg (X). In contrast to the stilt, with a threshold of 6 to 7 mg Se/kg for effects on egg hatchability, the avocet is much less sensitive, with no effects on hatchability at concentrations below 60 mg Se/kg.

In his review of the available information concerning reproductive effects of selenium in birds, Heinz¹³ suggested 10 mg Se/kg (converted from 3 mg Se/kg wet-weight basis he reported) in avian eggs as a threshold for effects on hatchability. Conclusions concerning egg-selenium threshold levels for effects in waterfowl depend on which data are included in the analyses, how the effects are expressed, and statistical approaches used in the analyses. For example, Fairbrother et al.^{32,34} used some of the data available from experimental studies with mallards and concluded that the threshold for reduced hatchability (EC₁₀) is 16 mg Se/kg in the egg. However, Skorupa³³ disagreed with this conclusion.

The data available from six studies in which mallards were fed selenomethionine^{121,122,124,125,207,208} are reanalyzed here using a two-parameter logistic regression model to calculate various effect levels for selenium, as follows: EC₁₀ = 12.5 mg/kg; EC₂₀ = 16.3 mg/kg; EC₅₀ = 25.7 mg/kg in the eggs; in the diet, EC₁₀ = 4.87 mg/kg; EC₂₀ = 5.86 mg/kg; and EC₅₀ = 8.05 mg/kg. Table 17.1 provides a brief summary of the relevant studies, including the dietary treatment level of selenium, reported egg hatchability, and mean selenium concentrations in the eggs. In addition, the table provides the egg hatchability results for the treatment groups as a proportion of the controls (to

take into account the variable hatching success for controls in the various studies). The results of these studies are illustrated graphically in Figures 17.1 and 17.2.

Fertility has been measured in only a small number of selenium studies. In American kestrels fed selenomethionine at 12 mg Se/kg, egg fertility was significantly reduced (by over 14%) compared to kestrels fed 6 mg/kg selenium.¹²⁷ Lack of reporting on fertility effects may be due in part to a general practice of simply including infertile eggs as inviable eggs in studies of selenium effects in birds (i.e., “infertility” effects may not be separated from “embryotoxic” effects in the overall measurement of hatchability). Failure to measure infertility as a separate endpoint may be due to the difficulty often associated with distinguishing infertile eggs from those containing embryos that have died very early in development. Nevertheless, decreased fertility is a distinct effect from embryotoxicity, particularly in that it indicates a mechanism acting on adult, rather than embryonic, physiology. Results obtained in kestrels suggest infertility may be a potentially important factor contributing to the overall reproductive impairment in some species. However, in mallards and black-crowned night-herons fed 10 mg Se/kg as selenomethionine, egg fertility was not reduced compared with controls.^{121,123,207,208} Similarly, fertility was not affected in mallards fed diets containing selenium at 7 mg/kg¹²⁵ or 16 mg/kg¹²² as selenomethionine, but hatchability of fertile eggs

Figure 17.2 Mallard egg hatchability vs. control as a function of selenium concentration in eggs.

was significantly reduced. Thus, effects on egg fertility in mallards and night-herons are not likely to be as ecologically significant as reduced hatchability.

17.4.2.4.2 *Adult Health, Physiology, and Survival*

O'Toole and Raisbeck⁴ have recently provided a comprehensive review of the various kinds of lesions associated with acute-subchronic and chronic selenosis in avian species. Other reviews of effects in adult birds also have been published recently.^{8,13,19}

Laboratory studies have been conducted with mallards to determine the kinds of lesions and other measurements that can be used for diagnosis of selenium toxicosis in birds.^{148,213,214} In general, ducks that received diets containing more than 20 mg Se/kg developed a number of lesions of the liver and integument. Those receiving 40 mg/kg or more selenium in their diets lost weight and had abnormal changes in the integument that involved structures containing hard keratin, such as feathers (alopecia/depterylation [i.e., feather loss]), beaks (necrosis), and nails (onychoptosis [soughed or broken]). When corroborated by elevated selenium concentrations in tissues (especially the liver), these integumentary and hepatic lesions, as well as weight loss, can serve for diagnosis of selenium toxicosis in birds. It should be noted, however, that some birds died without exhibiting any significant morphological lesions, even though they were emaciated.

Selenium toxicosis effects had been described previously in several species of aquatic birds found at Kesterson Reservoir from 1984 to 1986.^{7,136,144} Those birds exhibited many of the same signs of selenosis as those later found in mallards (as described above) including hepatic lesions, alopecia, necrosis of the beak, and weight loss. As described in a previous section, most kinds of aquatic invertebrates at Kesterson had mean selenium concentrations greater than 100 mg/kg. Thus, the laboratory studies with mallards provided strong evidence that selenosis was the main factor responsible for morbidities and mortalities among birds at Kesterson Reservoir.²¹⁴

In a 16-week exposure to evaluate susceptibility of mallards to over-winter mortality as a result of selenium exposure, ducks that received dietary concentrations of 20, 40, or 80 mg Se/kg (as selenomethionine) had higher mortality rates than ducks receiving the control or 10 mg Se/kg diets.¹⁴⁷ After 1 week of treatment, body weights were significantly depressed by the 20, 40, or 80 mg Se/kg diet. Ducks that survived for 16 weeks on the 20 mg/kg treatment were returned to a control diet; after 4 weeks, their body weight was similar to that of the control birds. Concentrations of selenium in blood were related to dietary treatment levels, but mortality was not clearly related to a threshold selenium concentration in the blood.

A number of studies (e.g., References 144, 215–218) have described physiological changes that are associated with selenium exposure in field-collected or laboratory-exposed birds. These generally involve changes in measurements associated with liver pathology and glutathione metabolism (e.g., glycogen, protein, total sulfhydryl and protein-bound sulfhydryl concentrations; glutathione peroxidase activity).

A few studies have suggested that effects of selenium on avian immune function are a sensitive endpoint and may affect birds at relatively low exposures.^{219–221} However, immunotoxicity of selenium has not been studied sufficiently to provide a threshold-effect level in wild birds.²⁰⁶

17.4.2.5 *Mammals*

Most studies of the effects of excess selenium have focused on livestock and laboratory animals, and there have been no well-documented cases of significant selenosis problems among wild mammals.¹⁷ The most common cause of chronic selenosis is consumption of forage containing more than 5 mg Se/kg. Sublethal effects were observed in dogs fed diets containing about 7 mg Se/kg.²

O'Toole and Raisbeck⁴ have recently provided a comprehensive review of the various kinds of lesions associated with acute-subchronic and chronic selenosis in mammalian species, and they stress the importance of using multiple lines of evidence (e.g., selenium concentrations in tissues,

presence and types of lesions) in diagnosing selenosis. Subchronic and chronic selenosis (sometimes called “alkali disease”) commonly involves changes in the integument, especially the hooves, horns, and hair. Loss of hair is a common sign of selenosis in a number of mammalian species and is similar to the bilateral loss of feathers observed in selenium-poisoned birds (described above).

Lesions of the liver occur in some species of mammals (sheep, dogs, cats, and rats), but they are not particularly significant in most livestock.⁴ Unlike birds, congenital abnormalities are not commonly associated with selenium toxicosis in mammals. When congenital abnormalities occur, the female parent usually was exposed to near-lethal dietary concentrations of selenium.

At Kesterson Reservoir, which contained seleniferous agricultural drainage waters,⁷ small mammals and raccoons were trapped and examined to determine whether selenium adversely affected the health of adult animals or their reproduction.^{156,166} Despite very high concentrations of selenium in livers or whole-body small mammals, or in livers, hair, feces, or blood of raccoons, there was no evidence of adverse effects in the mammals. Parameters evaluated for the small mammals included body size, body condition, liver size, and reproduction (including examination for malformations). Those measures as well as histopathology of selected tissues (liver, kidney, and spleen) and blood chemistry were evaluated in the raccoons.

17.4.3 Interactions

Many studies have shown interactions between selenium and other inorganic elements (especially arsenic, sulfur, and various metals), vitamins A, C, and E, as well as sulfur-containing amino acids.^{7,19,44,46,56,222} The interactions may be synergistic or antagonistic in terms of effects on uptake and metabolic effects, and the degree of interaction is affected by numerous factors. Thus, the topic of interactions is too complex to be addressed in detail in this review, and only a few examples of recent studies are discussed. Readers are encouraged to consult some of the references cited above for more details and a further introduction to this topic. Nevertheless, some of these interactions can be important factors in the design of field or laboratory studies and in the evaluation of results, and they should be taken into consideration.

Interactions between mercury and selenium have probably been studied more intensively in more kinds of animals than most of the others listed above. Mercury and selenium concentrations in the livers of various free-living carnivorous mammals often are highly correlated in a molar ratio of 1:1.^{19,109,223,224} However, there is no consistent pattern for such a correlation in the livers of birds. For example, hepatic mercury and selenium were correlated, with an overall mercury:selenium molar ratio of 1:6, in diving ducks (surf scoters [*Melanitta perspicillata*] and greater scaups [*Aythya marila*]) from San Francisco Bay, California, during 1982.¹⁴⁰ In a subsequent study of scoters sampled twice at six locations in the Bay during 1985, mercury and selenium in the livers were not correlated; mercury:selenium ratios were typically between 1:7 and 1:15 for most locations and collection times, but the mean ratio at one site was 1:45.²²⁵

Elsewhere, mercury and selenium concentrations were positively correlated in some bird livers, but not in others, or they were negatively correlated (see review by Ohlendorf²²⁶). These relationships may change as birds remain at the sampling location (due to differential accumulation and loss rates for mercury and selenium), they may vary because of differing relative concentrations of the two elements, and other factors (such as the chemical forms present) also may complicate the patterns of bioaccumulation.

In the selenium-mercury studies discussed above, concentrations were reported for total selenium and total mercury. However, recent studies by Henny et al.²²⁷ and Spalding et al.²²⁸ have shown high correlations of selenium with inorganic mercury on a molar basis in fish-eating birds. Those authors suggested that selenium may contribute to the sequestration of inorganic mercury, thereby reducing its toxicity. This conclusion would be consistent with the results of a selenium-mercury interaction study with mallards by Heinz and Hoffman²⁰⁸ discussed below.

Interactive effects of selenium with arsenic, boron, or mercury have been evaluated in reproductive studies with mallards.^{124,125,208} Each of the studies involved varying levels of dietary exposures of breeding mallards to selenium alone, one of the other elements alone, and also selenium in combination with the other chemical. In each study, selenium and the other chemical caused significant adverse effects on reproduction when present alone in the diet at higher treatment levels, but the interactions varied by chemical. Antagonistic interactions between arsenic and selenium occurred whereby arsenic reduced selenium accumulation in duck livers and eggs and alleviated the effects of selenium on hatching success and embryo deformities. There was little evidence of interaction between boron and selenium when ducks were fed the two chemicals in combination. Selenium provided a protective effect that reduced the toxicity of mercury to adult male ducks. However, when the diet contained 10 mg Se/kg plus 10 mg Hg/kg, the effects on reproduction were worse than for either selenium or mercury alone. The number of young produced per female and the frequency of teratogenic effects were significantly affected by the combination of mercury and selenium in the diet, and mercury also enhanced the storage of selenium in duck tissues.

17.5 SUMMARY AND CONCLUSIONS

Selenium is a naturally occurring trace element that is essential for animal nutrition, but it becomes toxic to sensitive species of fish or birds at dietary concentrations about two or three times the background levels found in many food-chain organisms. The biogeochemistry of selenium is complex, and it is essential to understand selenium chemistry to enable competent predictions of its ecotoxicology. Selenium concentrations generally are elevated in areas where soils were derived from Cretaceous and Tertiary marine sedimentary rocks in the western United States. Irrigation of such soils has led to contamination of wetlands receiving drainage from the agricultural lands. Industrial sources (such as coal and oil production or combustion and phosphate mining) have contributed selenium to habitats where fish and wildlife can be exposed. Once released to the surface environment, selenium cycling is affected by many biogeochemical processes, especially in aquatic habitats.

Selenium bioaccumulates in aquatic and terrestrial food chains and in higher trophic-level animals that feed on those plants and animals. The greatest level of bioaccumulation is typically from water to aquatic plants or invertebrates (often a 1000-fold or greater increase occurs). Background concentrations have been fairly well established for plants and animals in freshwater and terrestrial ecosystems, and these values can be used in evaluating the selenium status of an area if field-collected samples are analyzed and compared to background values. Such studies have been conducted in a number of areas. Multitrophic-level laboratory studies also have been conducted and help interpret the significance of bioaccumulation of selenium.

Studies of the effects of selenium have focused mainly on domestic livestock and on fish and aquatic birds because those animals have been found to be sensitive to the adverse effects of excess selenium. In fish and birds, the early life stages (fish larvae/fry, bird embryos) are most sensitive, although lethal and sublethal adverse effects also occur in adult animals under field conditions in some areas. Teratogenic effects in fish larvae/fry and in bird embryos may lead to death of young that hatch, but a significant amount of mortality also may occur without visible developmental abnormalities.

Many studies have shown interactions between selenium and other inorganic elements (especially arsenic, sulfur, and various metals), vitamins A, C, and E, as well as sulfur-containing amino acids. These interactions may be synergistic or antagonistic in terms of effects on uptake and metabolic effects. The interactions of selenium and mercury often are of particular interest, and there is no universal rule of thumb as to the net result of these interactions. For example, in mallards, selenium provided a protective effect that reduced the toxicity of mercury in adult ducks, but the

effects of mercury plus selenium in the diet caused greater impairment of reproduction than either chemical alone.

Overall, there is enough information to thoroughly evaluate the significance of selenium as an environmental contaminant if it is included among the chemicals of potential concern when ecological risk assessments are planned and conducted.²⁰⁴ The main difference between selenium and most other contaminants is that it is essential to have a good understanding of selenium's occurrence, complex biogeochemistry, and ecotoxicology to avoid serious errors.

ACKNOWLEDGMENTS

I appreciate the assistance of Gary M. Santolo in providing some of the material for the section on effects in birds and Bradley E. Sample in performing the statistical analyses of relationships between effects in mallards and the concentrations of selenium in the eggs or diet. Gary H. Heinz reviewed the manuscript and provided useful comments.

18.1 INTRODUCTION

Polychlorinated biphenyls (PCBs), dioxins (PCDDs), and dibenzofurans (PCDFs) all belong to a general class of pollutants labeled polyhalogenated organics. They all share the common distinction of having a benzene backbone that has chlorine substituted on it, and they all have several similarities in their modes of action, environmental pathways, and occurrence as direct products of commerce as opposed to agriculture. Bioconcentration and biomagnification are these compounds' prominent routes of exposure. The atmosphere plays an important role in the transport and fate of these compounds. Each grouping (PCBs and PCDDs/PCDFs) will be dealt with separately under each of the following major headings: Sources and Pathways in the Environment (Sections 18.2 and 18.3), Ambient Levels (Sections 18.4 and 18.5), and Effects (Section 18.6).

18.1.1 PCBs

Effective July 1979, the final PCB ban rule was implemented by the U.S. Environmental Protection Agency (EPA), which prohibited the manufacture, processing, distribution in commerce, and use of PCBs except in a totally enclosed system or unless specifically exempted by the EPA.¹ Essentially, the use of PCBs was unabated from their entry in the marketplace in the late 1920s until the early 1970s, when evidence became available that chronic exposure could result in hazard to humans and the environment. The Yusho incident² in Japan, in which over 1000 individuals were severely exposed to PCB-contaminated rice oil in 1968, provided a strong impetus to finalize this ban. The total worldwide production through 1976 is estimated to be about 6.1×10^{11} g³, of which about 5.7×10^{11} g (93%, 1.25 billion lbs) were produced by Monsanto in the United States. As concern continued to mount through the 1970s, the timing was right for PCBs to become a focus of the new U.S. Toxic Substances Control Act (TSCA), which was formulated in 1976 and pursuant to which all further manufacture of PCBs by U.S. companies was banned as of 1977.
